NEUROPSYCHOPHARMACOLOGY
The Fifth Generation of Progress

An Official Publication of the American College of Neuropsychopharmacology

5th Edition

2002

Lippincott Williams & Wilkins

Philadelphia

530 Walnut Street, Philadelphia, PA 19106 USA LWW.com

0-7817-2837-1

Printed in the USA

Library of Congress Cataloging-in-Publication Data

Neuropsychopharmacology: the fifth generation of progress: an official publication of the American College of Neuropsychopharmacology / editors, Kenneth L. Davis… [et al.].

p. ; cm.

Includes bibliographical references and index.

ISBN 0-7817-2837-1

1. Neuropsychopharmacology. 2. Neurobehavioral disorders. I. Davis, Kenneth L., 1947-II. American College of Neuropsychopharmacology.

[DNLM: 1. Psychopharmacology—methods. 2. Diagnostic Imaging—methods. 3. Drug Evaluation. 4. Neurotransmitters—physiology. QV 77 N4968 2002]

RM315 .N4825 2002

Editors

Kenneth L. Davis MD

Esther and Joseph Klingenstein Professor of Psychiatry and Chairman
Department of Psychiatry, Mount Sinai School of Medicine, New York, New York

Dennis Charney MD

Chief
Mood and Anxiety Disorder Research Program, National Institute of Mental Health Bethesda, Maryland

Joseph T. Coyle MD

Eben S. Draper Professor of Psychiatry and of Neuroscience; Chairman
Department of Psychiatry, Harvard Medical School, Boston, Massachusetts

Charles Nemeroff MD, PhD

Reunette W. Harris Professor and Chairman
Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia

SECTION EDITORS

Samuel H. Barondes MD

Jeanne and Sanford Robertson, MD, Director
Center for Neurobiology and Psychiatry, Department of Psychiatry, University of California, San Francisco, San Francisco, California

Dennis Charney MD

Chief
Mood and Anxiety Disorder Research Program, National Institute of Mental Health, Bethesda, Maryland

Joseph T. Coyle MD

Eben S. Draper Professor of Psychiatry and of Neuroscience; Chairman
Department of Psychiatry, Harvard Medical School, Boston, Massachusetts

Kenneth L. Davis MD

Esther and Joseph Klingenstein Professor of Psychiatry and Chairman
Department of Psychiatry, Mount Sinai School of Medicine, New York, New York

Robert Desimone PhD

Scientific Director
National Institute of Mental Health, Director, Intramural Research Program, National Institute of Mental Health, Bethesda, Maryland

Ronald Duman PhD
Departments of Psychiatry and Pharmacology, Laboratory of Molecular Psychiatry, Yale University School of Medicine, New Haven, Connecticut

Marian W. Fischman PhD

Professor of Behavioral Biology
Department of Psychiatry, College of Physicians and Surgeons of Columbia University and, The New York Psychiatric Institute, New York, New York

Eric Hollander MD

Professor of Psychiatry; Director of Clinical Psychopharmacology; Director of the Compulsive; Impulsive and Anxiety Disorders

Program Clinical Director
Seaver Autism Research Center, Department of Psychiatry, Mount Sinai School of Medicine, New York, New York

David Kupfer MD, PhD

Thomas Detre Professor and Chair
Department of Psychiatry, University of Pittsburgh Medical Center Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania

Herbert Meltzer MD

Bixler Professor of Psychiatry and Pharmacology
Vanderbilt University School of Medicine, Nashville, Tennessee

Charles Nemeroff MD, PhD

Reunette W. Harris Professor and Chairman

Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia

Eric Nestler MD, PhD

Lou and Ellen McGinley Distinguished Professor and Chairman Department of Psychiatry
The University of Texas Southwestern Medical Center at Dallas, Dallas, Texas

Charles P. O'Brien MD, PhD

Chief of Psychiatry; Philadelphia VA Medical Center Kenneth Appel Professor and, Vice Chair of Psychiatry
University of Pennsylvania, Philadelphia, Pennsylvania

Carol Tamminga MD

Professor of Psychiatry and Pharmacology
University of Maryland School of Medicine; Deputy Director, Maryland Psychiatric Research Center, Baltimore, Maryland

Daniel Weinberger MD

Chief
Clinical Brain Disorders Branch, National Institutes of Health, National Institute of Mental Health, Bethesda, Maryland

CONTRIBUTORS

Henry David Abraham M.D.

Lecturer
Department of Psychiatry, Harvard Medical School, Boston, Massachusetts

Paul D. Acton Ph.D

Research Assistant Professor
Radiology, University of Pennsylvania, Philadelphia, Pennsylvania

George K. Aghajanian M.D
Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut

Huda Akil Ph.D.
Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan

Meenakshi Alreja Ph.D.
Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut

James C. Anthony Ph.D

Professor
Johns Hopkins University, School of Hygeine and Public Health, Baltimore, Maryland

Paul S. Appelbaum M.D

Professor and Chair
Department of Psychiatry, University of Massachusetts Medical School, Worcester, Massachusetts

Jean-Michel Arrang Ph.D.

Research Director

Unité de Neurobiologie et Pharmacologie Moléculaire, INSERM, Paris, France

Gary Aston-Jones Ph.D.
Department of Psychiatry, University of Pennsylvania, VAMC, Philadelphia, Philadelphia

C. Bruce Baker M.D., J.D.

Assistant Professor
Department of Psychiatry, Yale University School of Medicine, Connecticut Mental Health Center, New Haven, Connecticut

Vaishali P. Bakshi Ph.D
Department of Psychiatry, University of Wisconsin at Madison, Madison, Wisconsin

Peter A. Bandettini Ph.D

Director
Functional Neuroimaging Facility, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland

Robert F. Barnes M.D
University of Washington School of Medicine, Department of Psychiatry and Behavioral Sciences, Seattle, Washington

Samuel H. Barondes M.D

Jeanne and Sanford Robertson M.D. Director
Center for Neurobiology and Psychiatry, Department of Psychiatry, University of California, San Francisco, San Francisco, California

Vincenzo S. Basile B.Sc., B.Ed.

Research Scientist
Psychiatric Neurogenetics, Centre for Addiction and Mental Health, Clarke Division, Toronto, Ontario, Canada

Russell Bauer Ph.D.
University of Florida, Health Science Center, Department of Clinical Psychology, Gainesville, Florida

Kevin L. Behar

Neal L. Benowitz M.D
Department of Psychiatry, University of California, San Francisco, San Francisco, California

Karen F. Berman M.D

Chief
Unit on Integrative Neuroimaging, Clinical Brain Disorders Branch, National Institute of Mental Health, National Institutes of Health, Intramural Research Program, Bethesda, Maryland

Wade Berrettini M.D., Ph.D.
University of Pennsylvania School of Medicine, Center for Neurobiology and Behavior, Philadelphia, Pennsylvania

Edward H. Bertram III M.D.

Associate Professor
Department of Neurology, University of Virginia, Charlottesville, Virginia

Joseph Biederman M.D.

Chief
Joint Program in Pediatric Psychopharmacology, Massachusetts General and McLean Hospitals; Professor, Department of Psychiatry, Massachusssets General Hospital, Boston, Massachusetts

Randy D. Blakely M.D., Ph.D
Department fo Pharmacology, Vanderbilt University, Nashville, Tennessee

Daryl E. Bohning Ph.D

Professor
Department of Radiology, Medical University of South Carolina, Charleston, South Carolina

Robert J. Boland M.D
Miriam Hospital, Department of Psychiatry, Providence, Rhode Island

David L. Braff M.D
Department of Psychiatry, University of California, San Diego, La Jolla, California

James Robert Brasic M.D., M.P.H.

Postdoctoral Fellow
Russell H. Morgan Department of Radiology and Radiological Science, Johns Hopkins University School of Medicine, Baltimore, Maryland

Monique Breteler M.D., Ph.D.
Department of Epidemiology and Biostatistics, Erasmus Medical Center, Rotterdam, Netherlands

Michael Brownstein M.D.
National Institutes of Health, National Institute of Mental Health, Bethesda, Maryland

Alastair Buchan FRCPC
Department of Clinical Neuroscience, Foothills Hospital, Calgary, Alberta, Canada

Christian Büchel M.D.
Department of Neurology, Hamburg University, Hamburg, Germany

Robert E. Burke M.D

Professor of Neurology and Pathology
Departments of Neurology and Pathology, Columbia University, New York, New York

David J. Burn F.R.C.P., M.D., M.A., M.B.B.S

Consultant and Service Lecturer in Neurology
Department of Neurology, Regional Neurosciences Centre, Newcastle upon Tyne, United Kingdom

Alistair Burns M.D.
Department of Old Age Psychiatry, Withington Hospital, West Disbury, Manchester, United Kingdom

Joseph D. Buxbaum Ph.D

Assistant Professor of Psychiatry
Department of Psychiatry, Mount Sinai School of Medicine, New York, New York

Daniel Buysee M.D.

Associate Professor of Psychiatry
University of Pittsburgh Health System, WPIC, Pittsburgh, Pennsylvania

William A. Carlezon Jr. Ph.D

Assistant Professor of Psychiatry
Harvard Medical School, McLean Hospital, Belmont, Massachusetts

James V. Cassella Ph.D
Neurogen Corporation, Branford, Connecticut

V. S. Caviness Jr. CMA
MGH-East, Charlestown, Massachusetts

Britton Chance M.D.
Department of Biophysics and Physical Biochemistry, University of Pennsylvania, Johnson Research Foundation, Philadelphia, Pennsylvania

Dennis Charney M.D.

Chief
Mood and Anxiety Disorder Research Program, National Institute of Mental health, Bethesda, Maryland

A. R. Childress
University of Pennsylvania School of Medicine, Department of Psychiatry, Addiction Treatment, Philadelphia, Pennsylvania

Emil F. Coccaro M.D
The University of Chicago, The Pritzker School of Medicine, Department of Psychiatry, Chicago, Illinois

C. Keith Conners M.D.
Behavioral Neurology Department, Durham, North Carolina

Jeremy D. Coplan M.D
Columbia University, New York Psychiatric Institute, New York, New York

Nancy H. Covell Ph.D

Project Director
Research Division, Connecticut Department of Mental Health and Addiction Services, Hartford, Connecticut, and, Research Associate, Department of Psychology, University of Connecticut, Storrs, Connecticut

Joseph T. Coyle M.D

Eben S. Draper Professor of Psychiatry and Neuroscience; Chairman

Department of Psychiatry, Harvard Medical School, Boston, Massachusetts

Merit E. Cudkowicz

Anders M. Dale M.D
NMR Center, Charlestown, Massachusetts

Richard Davidson M.D.
Department of Psychology, University of Wisconsin, Madison, Wisconsin

Michael Davidson
Sheba Medical Center, Tel Aviv, Israel

Linda Davies M.Sc.
Health Economics, Reader, Health Economics, School of Psychiatry and Behavioural Sciences, Univesity of Manchester, Manchester, United Kingdom

Kenneth L. Davis M.D

Esther and Joseph Klingenstein Professor of Psychiatry and, Chairman
Department of Psychiatry, Mount Sinai School of Medicine, New York, New York

Michael Davis Ph.D.
Department of Psychiatry, Emory University School of Medicine, Atlanta, Georgia

Mahlon R. DeLong M.D
Emory University, Department of Neurology, Atlanta, Georgia

Robert Desimone Ph.D.

Scientific Director
National Institute of Mental Health; Director, Intramural Research Program/National Institute of Mental Health, Bethesda, Maryland

Errol B. DeSouza Ph.D
Research and Development, Neurocrine Bioscience, Inc., San Diego, California

William L. Dewey
Virginia Commonwealth University, Department of Pharmacology and Toxicology, Richmond, Virginian

Vincenzo M. Di Marzo Ph.D.
Primo Richercatore, Istituto Chimica Biomoleculare, Consiglio Nazionale Ricerche, Pozzuoli (NA), Italy

David F. Dinges Ph.D

Professor of Psychology in Psychiatry
Department of Psychiatry, University of Pennsylvania, Philadelphia, Pennsylvania

Cynthia M. Dorsey Ph.D

Assistant Professor
Department of Psychiatry, Harvard Medical School, Boston, Massachusetts, and, Director, Sleep Research Laboratory, Behavioral Psychopharmacology Research Laboratory, McLean Hospital, Belmont, Massachusetts

Wayne C. Drevets M.D

Chief
Section on Mood and Anxiety Disorders Imaging, Molecular Imaging Branch, National Institute of Mental Health, Bethesda, Maryland

Karen Duff Ph.D.
Nathan Kline Institute, Dementia Research Program, Orangeburg, New York

Ronald S. Duman Ph.D

Professor of Psychiatry and Pharmacology, and, Director
Abraham Ribicoff Research Facilities, Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, Connecticut

Gary E. Duncan Ph.D

Research Associate Professor
Department of Psychiatry, University of North Carolina, Chapel Hill, North Carolina

Jane L. Eisen M.D

Assistant Professor
Department of Psychiatry and Human Behavior, Brown Medical School, Providence, Rhode Island

Mary-Anne Enoch M.D.

Visiting Associate
Laboratory of Neurogenetics, NIAAA, National Institutes of Health, Bethesda, Maryland

Charles M. Epstein M.D
Emory University, Department of Neurology, Atlanta, Georgia

Susan M. Essock Ph.D
Mount Sinai School of Medicine, Department of Psychiatry, New York, New York

Alan Evans M.D.
Department of Neurology, McGill University, Montreal Neurological Institute, Montreal, Quebec, Canada

Dwight L. Evans M.D
Department of Psychiatry, University of Pennsylvania, Philadelphia, Pennsylvania

StephenV. Faraone Ph.D.

Associate Professor
Department of Psychiatry, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts

Marian W. Fischman Ph.D

Professor of Behavioral Biology
Department of Psychiatry, College of Physicians and Surgeons of Columbia University and, The New York Psychiatric Institute, New York, New York

Joanna S. Fowler Ph.D

Senior Chemist
Chemistry Department, Brookhaven National Laboratory, Upton, New York

Teresa R. Franklin Ph.D

Substance Abuse Fellow
Department of Psychiatry, University of Pennsylvania, and, Philadelphia Veterans Affairs Medical Center, Philadelphia, Pennsylvania

Alan Frazer Ph.D.

Chair and Professor
Department of Pharmacology, University of Texas Health Science Center, San Antonio, Texas

Robert Freedman M.D.

Professor
Department of Psychiatry and Pharmacology, University of Colorado, Denver, Colorado

Nelson B. Freimer M.D
University of California, San Francisco, Department of Psychiatry, San Francisco, California

Linda K. Frisman Ph.D

Director of Research
Research Division, Connecticut Department of Mental Health and Addiction Services, Hartford, Connecticut, and, Research Professor, Department of Psychology, University of Connecticut, Storrs, Connecticut

Karl Friston
Wellcome, Department of Cognitive Neurology, London, United Kingdom

Paul J. Fudala Ph.D

Research Associate Professor of Pharmacology in Psychiatry
Department of Psychiatry, University of Pennsylvania, Philadelphia, Pennsylvania, and, Clinical Toxicologist, Department of Behavioral Health Service, Veterans Affairs Medical Center, Philadelphia, Pennsylvania

Masahiro Fujita M.D., Ph.D.

Assistant Professor
Department of Psychiatry, Yale University School of Medicine, West Haven, Connecticut

Fred H. Gage Ph.D

Professor
Laboratory of Genetics, The Salk Institute, La Jolla, California

Stephen J. Garlow M.D., Ph.D

Assistant Professor
Department of Psychiatry and Behavioral Science, Emory University, Atlanta, Georgia

L. Garrido
Massachusetts General Hospital-East, Charlestown, Massachusetts

Nori Geary Ph.D.

Research Professor
Department of Psychiatry, Weill Medical College of Cornell University, New York, New York

Mark S. George M.D
Departments of Psychiatry, Radiology and Neurology, Medical University of South Carolina, Charleston, South Carolina

Mark A. Geyer Ph.D

Professor
Department of Psychiatry, University of California, San Diego, La Jolla, California

Patricia S. Godman-Rakic Ph.D.
Department of Neurobiology, Yale University School of Medicine, New Haven, Connecticut

Donald C. Goff M.D

Director
Schizophrenia Program, Massachusetts General Hospital, Boston, Massachusetts, and, Associate Professor, Department of Psychiatry, Harvard Medical School, Boston, Massachusetts

Terry E. Goldberg Ph.D
National Institutes of Mental Health, Bethesda, Maryland

David Goldman M.D.

Chief
Laboratory of Neurogenetics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, Maryland

Patricia S. Goldman-Rakic Ph.D.
Department of Neurobiology, Yale University School of Medicine, New Haven, Connecticut

Jack M. Gorman M.D
Columbia University, Department of Psychiatry, New York, New York

Anthony A. Grace M.D
University of Pittsburgh, Department of Neuroscience and Psychiagtry, Pittsburgh, Pennsylvania

Jean-Michel Gracies M.D., Ph.D.

Assistant Professor
Department of Neurology, The Mount Sinai Medical Center, New York, New York

Steven H. Graham M.D., Ph.D

Associate Professor and Vice-Chair
Department of Neurology, University of Pittsburgh, Pittsburgh, Pennsylvania, and, Associate Director for Research, Department of Geriatric Research Education and Clinical Center, Veterans Affairs Pittsburgh Health System, Pittsburgh, Pennsylvania

Michael F. Green Ph.D

Professor
Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, California

Paul E. Greenberg M.A., M.S
Analysis Group, Inc., Cambridge, Massachusetts

David J. Greenblatt M.D
Dept of Pharmacology and Experimental Therapeutics, Tufts University School of Medicine, Boston, Massachusetts

Dimitri E. Grigoriadis Ph.D

Senior Director
Department of Pharmacology and Lead Discovery, Neurocrine Biosciences, Inc., San Diego, California

Amy Grogg PharM.D.

Associate Director
CNS Outcomes Research, Department of Outcomes Research, Janssen Pharmacetica, Titusville, New Jersey

Jerold S. Harmatz B.A

Assistant Professor of Medicine
Department of Pharmacology and Experimental Therapeutics, Tufts University School of Medicine, Boston, Masachusetts

Vahram Haroutunian Ph.D.

Associate Professor
Department of Psychiatry, Mount Sinai School of Medicine and, Bronx Veterans Affairs Medical Center, New York, New York

James C. Harris M.D

Director
Developmental Neuropsychiatry, Professor of Psychiatry and Behavioral Sciences and Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland

Philip D. Harvey Ph.D

Professor of Psychiatry
Mount Sinai School of Medicine, New York, New York

Robert W. Hickey M.D

Assistant Professor
Department of Pediatrics, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Makoto Higuchi Ph.D.
University of Pennsylvania, School of Medicine, Department of Pathology and Laboratory Medicine, Philadelphia, Pennsylvania

Steven A. Hillyard M.D
University of California, San Diego, Department of Neuroscience, La Jolla, California

Robert M. A. Hirschfeld M.D.

Titus H. Harris Chair; Professor and Chair
Department of Psychiatry and Behavioral Science, University of Texas Medical Branch, Galveston, Texas

J. Allan Hobson M.D.

Professor of Psychaitry
Massachusetts Mental Health Center, Boston, Massachusetts

Eric Hollander M.D.

Professor of Psychiatry; Director of Clinical Psychopharmacology; Director of the Compulsive, Impulsive and Anxiety Disorders

Program; Clinical Director Seaver Autism Research Center
Department of Psychiatry, Mount Sinai School of Medicine, New York, New York

Fahmeed Hyder
Department of Diagnostic Radiology, Yale University, School of Medicine, New Haven, Connecticut

Steven E. Hyman M.D
National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland

Robert B. Innis M.D

Professsor
Department of Psychiatry and Pharmacology, Yale University School of Medicine, West Haven, Connecticut

Bruce G. Jenkins Ph.D

Director
Neurochemical Imaging, MGH-NMR Center/Radiology, Massachusetts General Hospital, Charlestown, Massachusetts

J. David Jentsch Ph.D.
Department of Neuroscience, University of Pittsburgh, Pittsburgh, Pennsylvania

David S. Johnson M.D., Ph.D
Nina Ireland Laboratory of Developmental Neurobiology, Department of Psychiatry, Langley Porter Psychiatric Institute, University of California, San Francisco, San Francisco, California

Reese T. Jones M.D
Langely Porter Psychiatric Institute, University of California, San Francisco, San Francisco, California

Paramjit Joshi M.D.

Chair
Department of Psychiatry, Children's National Medical Center, Washington, DC

Ned H. Kalin M.D

Professor and Chair
Department of Psychiatry, University of Wisconsin Medical School, Madison, Wisconsin

Peter W. Kalivas Ph.D
Department of Physiology and Neuroscience, Medical University of South Carolina, Charleston, South Carolina

John Kane M.D.
Hillside Hospital, Glen Oaks, New York

Shatij Kapur M.D., Ph.D.
Department of Psychiatry, Clark Institute; University of Toronto, Ontario, Canada

Walter Kaye M.D.
Western Psychiatric Institute & Clinic, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Paul E. Keck Jr. M.D.
c/o Husseini K. Manji, M.D Department of Psychiatry, Wayne State University School of Medicine, Detroit, Michigan

John H. Kehne Ph.D

Executive Director
Department of Behavioral Biology, Neurogen Corporation, Branford, Connecticut

Martin B. Keller M.D

Professor and Chairman
Brown University School of Medicine, Butler Hospital, Providence, Rhode Island

David Kennedy M.D.
Morphometric Analysis Laboratory, Neuroscience Center, Charlestown, Massachusetts

James L. Kennedy M.D., FRCP(C)

Head
Neurogenetics Section, Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada

Justine M. Kent M.D
Columbia University, Department of Psychiatry, New York, New York

Matcheri S. Keshavan M.D

Professor of Psychiatry
Department of Psychiatry, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania

Ronald C. Kessler Ph.D
Harvard Medical School, Boston, Massachusetts

Clint Kilts M.D.
Emory University School of Medicine, Department of Psychiatry, Atlanta, Georgia

Joel E. Kleinman M.D., Ph.D
Clinical Brain Disorders Branch, National Institutes of Mental Health Neuroscience Center, Washington, DC

Violetta Klimek Ph.D.

Assistant Professor
Department of Psychiatry, University of Mississippi Medical Center, Jackson, Mississippi

Jacqueline D. Kloss Ph.D

Assistant Professor of Psychology
Department of Psychology, Sociology, Anthropology, Drexel University, and, Adjunct Assistant Professor of Psychology, Department of Psychiatry, University of Pennsylvania, Philadelphia, Pennsylvania

George F. Koob Ph.D
Department of Neuropharmacology, The Scripps Research Institute, La Jolla, California

Kathy L. Kopnisky
National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland

Thomas R. Kosten M.D

Professor of Psychiatry

Department of Psychiatry, Yale University School of Medicine, and, Chief, Department of Psychiatry, Veterans Affairs Connecticut Healthcare System, West Haven, Connecticut

Chris M. Kozma Ph.D

Senior Research Director
Strategic Outcomes Services of Care Science, Inc., Philadelphia, Pennsylvania

Mark S. Kramer M.D., Ph.D

Senior Director
Department of Clinical Neuroscience, Merck & Co., West Point, Pennsylvania, and, University of Pennsylvania, Philadelphia, Pennsylvania

Mary Jeanne Kreek M.D.
The Rockefeller University, Laboratory of the Biology of Addictive Diseases, New York, New York

Suchitra Krishnan-Sarin Ph.D.
Yale University School of Medicine, Department of Psychiatry, New Haven, Connecticut

John H. Krystal M.D

Psychiatry Service
Veterans Affairs Connecticut Healthcare System, West Haven, Connecticut

David Kupfer M.D.

Thomas Detre Professor and Chair
Department of Psychiatry, University of Pittsburgh Medical Center, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania

Marta Kutas Ph.D.

Professor of Cognitive Science and Neurosciences
Department of Cognitive Science, University of California, San Diego, La Jolla, California

Ariel J. Lang Ph.D

Assistant Professor in Residence
Department of Psychiatry, University of California, San Diego, San Diego, California, and, Psychologist, Veterans Affairs San Diego Health System, San Diego, California

Marc Laruelle M.D.
New York Psychiatric Institute, Department of Psychiatry, New York, New York

Paul Leber M.D.

Director
Neuro-Pharm Group, LLC, Potomac, Maryland

James F. Leckman M.D

Neison Harris Professor of Child Psychiatry and Pediatrics
Child Study Center, Yale University School of Medicine, New Haven, Connecticut

Virginia M.-Y. Lee Ph.D.

The John H. Ware 3rd Professor in Alzheimer's Research and Co-Director
Center for Neurodegenerative Disease Research, Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Robert H. Lenox M.D

Vice President
Head CNS Group, Aventis Pharmaceuticals, Bridgewater, New Jersey

Jane Leserman Ph.D.

Research Associate Professor
Department of Psychiatry, University of North Carolina School of Medicine, Chapel Hill, North Carolina

Michael L. Leski Ph.D

Instructor
Department of Psychiatry, McLean Hospital, Belmont, Massahusetts

David A. Lewis M.D

Professor
Department of Psychiatry and Neuroscience, University of Pittsburgh, Pittsburgh, Pennsylvania

Alfred J. Lewy M.D
Oregon Health Sciences University, Sleep & Mood Disorders Laboratory, Portland, Oregon

Jeffrey A. Lieberman M.D
Department of Psychiatry, University of North Carolina Chapel Hill, Chapel Hill, North Carolina

J. Listerud
University of Pennsylvania School of Medicine, Department of Psychiatry, Addiction Treatment, Philadelphia, Pennsylvania

Shauna N. MacMillan B.Sc.

Research Assistant
Department of Psychiatry and Behavioral Neurosciences, Wayne University School of Medicine, Detroit, Michigan

Pierre Magistretti M.D., Ph.D.
Inst de Physiologie, Univ Lausanne, Lausanne, Switzerland

Ramin Mahmoud M.D.

Director
Outcome Research, Janssen Research Foundation, Titusville, New Jersey

Nikos Makris M.D., Ph.D.

Instructor
Department of Neurology, Harvard Medical School, Boston, Massachusetts

Robert C. Malenka M.D., Ph.D
Department of Psychiatry and Behavioral Science, Stanford University School of Medicine, Palo Alto, California

Andrea Manca M.Sc.

Research Fellow
Centre for Health Economics, University of York, York, United Kingdom

Husseini K. Manji M.D
Department of Psychiatry, Wayne University School of Medicine, Detroit, Michigan

John D. Mann M.D
Department of Neurology, University of North Carolina, Chapel Hill, School of Medicine, Chapel Hill, North Carolina

J. John Mann M.D.

Chief of Neuroscience
Department of Psychiatry, Columbia University, New York, New York

Russell L. Margolis M.D

Associate Professor and Attending Psychiatrist
Department of Psychiatry, Johns Hopkins University School of Medicine and Hospital, Baltimore, Maryland

Athina Markou
The Scripps Research Institute, Department of Neuropharmacology, La Jolla, California

Billy R. Martin Ph.D
Department of Pharmacology and Toxicology, Virginia Commonwealth University, Richmond, Virginia

Mario Masellis B.Sc., M.Sc.

Research Scientist
Department of Psychiatric Neurogenetics, Clarke Division, Centre for Addiction and Mental Health, Toronto, Ontario, Canada

Karen I. Mason Ph.D

Neuropsychology Fellow
Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, School of Medicine, Los Angeles, California

Graeme F. Mason

Helen S. Mayberg M.D
Baycrest Center, Rotman Research Institute, Toronto, Ontario, Canada

W. Vaughn McCall M.D.

Professor
Department of Psychiatry and Behavioral Medicine, Wake Forest University School of Medicine, Winston-Salem, North Carolina

Una D. McCann M.D
Mt. Auburn Hospital, Department of Psychiatry and Behavioral Sciences, Lexington, Massachusetts

Robert W. McCarley M.D
Harvard Medical School, Department of Psychiatry, Brockton, Massachusetts

William M. McDonald M.D
Department of Psychiatry, Wesley Woods Health Center, Atlanta, Georgia

Christopher J. McDougle M.D

Raymond E. Houk Professor of Psychiatry; Professor of Pediatrics and Neurobiology
Department of Psychiatry, Indiana University School of Medicine, Indianapolis, Indiana

L. Alison McInnes M.D., M.S.

Assistant Adjunct Professor
Department of Psychiatry and Neurogenetics, University of California, San Francisco, San Francisco, California

Ian G. McKeith M.D
Department of Old Age Psychiatry, Wolfson Research Centre, Newcastle General Hospital, Newcastle upon Tyne, United Kingdom

Thomas McLellan Ph.D.
Philadelphia Veterans Affairs Medical Center, Philadelphia, Pennsylvania

Gavan P. McNally

Research Fellow
Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan

James H. Meador-Woodruff M.D.

Senior Associate Research Scientist
Mental Health Research Institute, and, Associate Professor, Department of Psychiatry, University of Michigan, Ann Arbor, Michigan

Brian Meissner PharM.D.

Janssen Outcomes Fellow
Department of Pharmacy, University of South Carolina, Columbia, South Carolina

Herbert Meltzer M.D.

Bixler Professor of Psychiatry and Pharmacology
Vanderbilt University School of Medicine, Nashville, Tennessee

Wallace B. Mendelson M.D

Professor
Departments of Psychiatry, Medicine, and Clinical Pharmacology, University of Chicago, Chicago, Illinois

Kathleen Merikangas Ph.D.

Professor of Epidemiology
Public Health and Psychiatry, Yale University School of Medicine, New Haven, Connecticut

Emmanuel Mignot M.D., Ph.D.

Associate Professor
Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California

Mark A. Mintun M.D
Washington University School of Medicine, Department of Radiology, St. Louis, Missouri

Seiya Miyamoto M.D., Ph.D.

Visiting Research Fellow
Department of Psychiatry, The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, and, Department of Neuropsychiatry, St. Marianna University School of Medicine, Kawasaki, Japan

Bita Moghaddam
Yale University School of Medicine, Department of Psychiatry, West Haven, Connecticut

Richard C. Mohs Ph.D
Research Service, Veterans Affairs Medical Center, Bronx, New York

Paul Morley M.D.
Receptors and Ion Channels Group, Institute of Biological Science, National Research Council of Canada, Ottawa, Ontario, Canada

John H. Morrison Ph.D
Mount Sinai Medical Center, New York, New York

Pierandrea Muglia M.D.

Postdoctoral Fellow
Neurogenetics Section, Centre for Addiction and Mental Health, Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada

Emanuela Mundo M.D.

Assistant Professor
Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada

Charles Nemeroff M.D., Ph.D.

Reunette W. Harris Professor and Chairman
Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia

Eric J. Nestler M.D., Ph.D

Lou and Ellen McGinley Distinguished Professor and Chairman
Department of Psychiatry, The University of Texas Southwestern Medical Center at Dallas, Dallas, Texas

Rachael Neve M.D.
McLean Hospital, Belmont, Massachusetts

Seiji Nishino M.D., Ph.D.

Senior Research Scientist
Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California

Ralph A. Nixon M.D., Ph.D
Nathan Kline Institute, Dementia Research Program, Orangeburg, New York

Eric Nofzinger M.D.
University of Pittsburgh Health System, Department of Psychiatry, Pittsburgh, Pennsylvania

Charles P. O'Brien M.D., Ph.D.

Chief of Psychiatry
Department of Behavioral Health, Philadelphia Veterans Affairs Medical Center, and, Kenneth Appel Professor and Vice Chair, Department of Psychiatry, University of Pennsylvania, Philadelphia, Pennsylvania

John T. O'Brien D.M.
Department of Old Age Psychiatry, Wolfson Research Centre, Newcastle General Hospital, Newcastle upon Tyne, United Kingdom

Stephanie S. O'Malley Ph.D.
Yale University School of Medicine, Department of Psychiatry, New Haven, Connecticut

C. Warren Olanow M.D., F.R.C.P.L.

Professor and Chairman
Department of Neurology, Mount Sinai Medical Center, New York, New York

Berend Olivier Ph.D.
Department of Psychopharmacology, Utrecht University, Utrecht, Netherlands, and, Department of Psychiatry, Yale University School of Medicine, Hawthorne, New York

Richard W. Olsen Ph.D

Professor of Neuroscience, Pharmacology, and Anesthesiology
Department of Molecular and Medical Pharmacology, University of California Los Angeles School of Medicine, Los Angeles, California

Gregory A. Ordway Ph.D

Division of Neurobiology and Behavior Research
Department of Psychiatry, University of Mississippi Medical Center, Jackson, Mississippi

Michael J. Owen Ph.D
University of Wales College of Medicine, Department of Psychological Medicine, Cardiff, United Kingdom

Vural Özdemir M.D., Ph.D.

Senior Scientist
Department of Pharmacogenetics, R. W. Johnson Pharmaceutical Research Institute, Raritan, New Jersey

Edward F. Pace-Schott M.S., M.A., L.M.H.C.

Instructor
Department of Psychiatry, Harvard Medical School, Boston, Massachusetts

Stefano Pallanti M.D.
Mount Sinai School of Medicine, Department of Psychiatry, New York, New York

G. M. Papadimitriou
Department of Neurology, Massachusetts General Hospital, Boston, Massachusetts

S. Parvathy Ph.D.

Postdoctoral Fellow
Department of Psychiatry, Mount Sinai School of Medicine, New York, New York

David L. Pauls Ph.D
Child Study Center, Yale University School of Medicine, New Haven, Connecticut

Robert H. Perry M.B., Ch.B.
Department of Neuropathology, Newcastle General Hospital, Newcastle upon Tyne, United Kingdom

Elaine Perry M.D.
MRC Neurochemical Pathology Unit, Newcastle General Hospital, Newcastle upon Tyne, United Kingdom

John Petitto M.D.
Department of Psychiatry, University of Florida, College of Medicine, Gainesville, Florida

Ognen A. C. Petroff

Michael Phelps M.D.
Department of Molecular and Medical Pharmacology, Center Health Services, University of California, Los Angeles, School of Medicine, Los Angeles, California

Marina Picciotto M.D.
Department of Psychiatry, Yale University School of Medicne, New Haven, Connecticut

Debra A. Pinals M.D

Director; Fellowship in Law and Psychiatry
Department of Psychiatry, University of Massachusetts Medical School, Worcester, Massachusetts

Daniel S. Pine M.D

Associate Professor of Clinical Psychiatry
Department of Psychiatry, Division of Child and Adolescent Psychiatry, Columbia University / New York State Psychiatric Institute, New York, New York

Joseph Piven M.D.
Department of Psychiatry, University of North Carolina, Chapel Hill, Chapel Hill, North Carolina

Mark Potenza M.D., Ph.D.

Director

PREFACE

Neuropsychopharmacology: The Fifth Generation of Progress appears at an important moment in the history of psychopharmacology. We have recently ended the decade of the brain, a decade that witnessed enormous progress in understanding fundamental physiology of the central nervous system. The fruits of these basic science discoveries have already resulted in important progress in the treatment of mental illness. The importance of these fundamental discoveries has recently been acknowledged by the awarding of the Nobel Prize in Psychology or Medicine to three members of the College, Arvid Carlsson, Paul Greengard and Eric Kandel for their discoveries on neuronal signaling. This edition in the *Generation of Progress* series details advances in both the basic science and clinical application of recent research in psychopharmacology. It also demonstrates the prospects for even greater advances in the future.

Section I
Neurotransmitters and Signal Transduction

Eric J. Nestler

Ronald S. Duman

Neurotransmitters and Signal Transduction - Introduction

Neuropsychopharmacology continues to be organized primarily according to the neurotransmitters that are utilized by various populations of neurons for synaptic transmission. This is because the vast majority of psychotropic drugs presently used clinically to treat neuropsychiatric disorders still have as their initial targets proteins that regulate the availability of a particular neurotransmitter (e.g., presynaptic reuptake transporters, synthetic or degradative enzymes) or that serve as ligands for particular neurotransmitter receptors. It is entirely appropriate then that this edition of *Neuropsychopharmacology: A Generation of Progress* begins with a section devoted to the major neurotransmitter systems in the brain. Rather than provide a comprehensive review of the now vast literature on neurotransmitter systems, the goal of this section is to highlight recent advances in the field.

Glutamate, as described in the chapter by Joseph Coyle, Michael Leski, and John Morrison, is the major excitatory neurotransmitter in the brain. During the past decade, numerous subtypes of glutamate transporters and glutamate receptors have been identified and characterized. Each of these represents a potentially exciting target for new pharmacotherapeutic agents. Richard Olsen focuses on γ-aminobutyric acid (GABA), which serves as the major inhibitory neurotransmitter in the brain. GABA receptors and GABA transporters are important targets for commonly used antianxiety, anticonvulsant, and antimanic medications. Agents with improved specificity toward subtypes of these proteins may offer substantial benefit as future treatments.

The next several chapters focus on other small-molecule neurotransmitters, which are used by relatively small fractions of neurons and generally serve to modulate the efficacy of glutamatergic and GABAergic synapses through diffuse projections throughout the neuraxis. Such neurotransmitters include the catecholamines, norepinephrine, and dopamine. Norepinephrine, covered in a chapter by Gary Aston-Jones, regulates mood, attention, and alertness and is a substrate for many commonly used antidepressants. Dopamine, discussed in a chapter by Anthony Grace, plays a critical role in movement and reward. Accordingly, it is involved in movement disorders such as Parkinson's disease and is a common target for most drugs of abuse. The catecholamines, along with serotonin and histamine, are often referred to as *monoamine neurotransmitters* because they contain a single amine group. Serotonin is critically involved in many brain functions and is the target for many commonly used antidepressants. George Aghajanian and Elaine Sanders-Bush focus on new findings about serotonin, including the discovery and characterization of 14 distinct serotonin receptors and their physiologic functions. Histamine is discussed by Jean-Charles Schwartz and Jean-Michel Arrang. Although it has been known for some time that histamine regulates alertness and sleep, new advances in histamine pharmacology have been made possible by the cloning of three distinct histamine receptors. Finally, acetylcholine is often categorized along with the monoamines because it too is concentrated in discrete regions of the brain, many of which project diffusely to other parts of the brain. A major goal of neuropsychopharmacology research, as discussed by Marina Picciotto, Meenakashi Alreja, and J. David Jentsch, continues to be the development of drugs that are selective for the many subtypes of cholinergic receptors expressed in the central nervous system.

Many other types of molecules serve neurotransmitter functions. Michael Williams covers the so-called purinergic neurotransmitters, which include adenosine and adenosine triphosphate. The last few years have seen the cloning and characterization of a vast number of purinergic receptors,

with very different transmitter selectivities and functional properties. It is believed that selective ligands at these various receptors may serve as novel drugs in the treatment of Parkinson's disease, insomnia, anxiety, and pain, to name a few. Many types of polypeptides serve as neurotransmitters; these molecules are often termed *neuropeptides*. Significant recent progress has been made in understanding the physiologic role and pharmacology of certain neuropeptides, which are discussed in several chapters in this section. Gavan McNally and Huda Akil cover the opioid peptides, including a newly discovered opioid-like peptide, termed *orphanin-FQ* or *nociceptin*, that promotes nociception. Errol De Souza and Dimitri Grigoriadis review recent advances in the understanding of corticotropin-releasing factor, including the identification of two main types of receptors for corticotropin-releasing factor and other peptides (e.g., urocortin) that serve as endogenous ligands for the receptors. Nadia Rupniak and Mark Kramer focus on substance P and related neurokinins. Long known to be involved in the regulation of pain perception, recent evidence suggests that antagonists at certain neurokinin receptors may be effective antidepressants.

Despite the importance of neurotransmitter systems in neuropsychopharmacology, it must be emphasized that all the proteins that account for neurotransmitter synthesis and degradation, reuptake, and receptors, and for neuropeptide transmitters themselves, represent a small fraction of the perhaps hundreds of thousands of proteins expressed in the adult brain. A central promise of neuropsychopharmacology as we enter a new century is to evaluate these vast arrays of other proteins as targets for entirely new families of pharmacotherapeutic agents. Robert Malenka reviews what we know about synaptic plasticity, the processes by which the efficacy of transmission at particular synapses is altered as a consequence of synaptic activity. Mark von Zastrow covers the molecular and cellular mechanisms underlying receptor internalization, a process in which the numbers of many and perhaps most types of neurotransmitter receptors on the plasma membrane are regulated by synaptic activity. David Russell and Ronald Duman offer an overview of neurotrophic factors and their signaling pathways. Neurotrophic factors have long been recognized for their role in neural growth and differentiation during development, and we now know they are also important for regulating the survival and plasticity of adult neurons. Eric Nestler and Steven Hyman review the intracellular signaling pathways by which neurotransmitters, acting on plasma membrane receptors, regulate gene expression. Such regulation represents a prominent mechanism of long-term plasticity in the nervous system, including the actions of repeated exposure to psychotropic drugs (e.g., antidepressant action and drug addiction). Pierre Magistretti and Bruce Ransom discuss the role of glial cells in the central nervous system—in particular, their control of the energy metabolism in the brain. Finally, Fred Gage and Henriette van Praag summarize new knowledge of neurogenesis in the adult brain. The recent discovery that new neurons are born in certain regions of the brain each day, and may be incorporated into the existing circuitry within those regions, raises new hope for the treatment of neurodegenerative and other neuropsychiatric disorders. The subject matter of these last several chapters has not yet been exploited pharmacologically, but it is believed that the next generation of progress will see new pharmacologic agents directed at these nontraditional mechanisms.

Acetylcholine

Marina R. Picciotto

Meenakshi Alreja

J. David Jentsch

Marina R. Picciotto and Meenakshi Alreja: Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.

J. David Jentsch: Department of Neuroscience, University of Pittsburgh, Pittsburgh, Pennsylvania.

Acetylcholine (ACh) is critical for communication between neurons and muscle at the neuromuscular junction, is involved in direct neurotransmission in autonomic ganglia, and has been implicated in cognitive processing, arousal, and attention in the brain (1). Cholinergic transmission can occur through muscarinic (G protein-coupled) or nicotinic (ionotropic) receptors and is terminated by the action of cholinesterases. Seventeen different subunits of the nicotinic ACh receptor (nAChR) (2) and five different subtypes of the muscarinic receptor (3) have been cloned to date, and a majority of those are known to be expressed in the brain. Although the anatomic locations of cholinergic cell bodies and their projections have been known for some time (Fig. 1.1), recent studies using specific cholinotoxins, electrophysiology, or molecular genetics have altered our view of the functional role of the cholinergic system in the brain. The anatomic, pharmacologic, and biochemical complexity of the cholinergic system indicates an intricate involvement in nervous system function, and new advances in this field are discussed here.

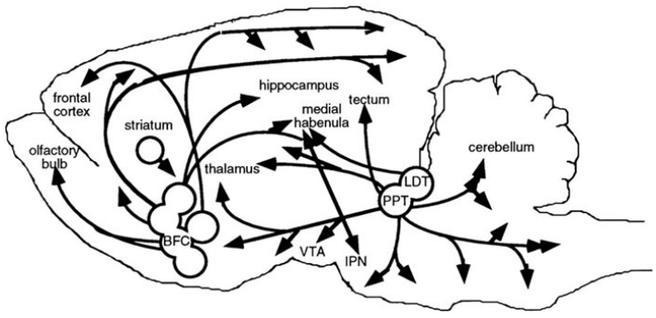

FIGURE 1.1. Anatomy of major cholinergic pathways in the brain. The principal source of cholinergic input to the cortex and hippocampus is the basal forebrain complex, whereas the pedunculopontine and laterodorsal tegmental areas innervate brain stem and midbrain targets preferentially. Cholinergic interneurons are found in the olfactory tubercle, striatum, nucleus accumbens, and islands of Calleja. BFC, basal forebrain complex; VTA, ventral tegmental area; IPN, interpeduncular nucleus; PPT, pedunculopontine tegmental nucleus; LDT, laterodorsal tegmental nucleus.

KNOCKOUT OF MUSCARINIC- AND NICOTINIC-RECEPTOR SUBUNITS

Part of "1 - Acetylcholine "

A particularly useful tool in identifying the role of individual molecules in the physiologic and behavioral functions of the cholinergic system are transgenic animals that lack specific subunits or subtypes of muscarinic receptors or nAChRs. These animals, termed *"knockout" mice*, can be generated by means of genetic engineering techniques and have been extremely useful in determining the functional role of many proteins that have been identified through molecular cloning (see refs. 4 and 5 for a review of this technology). Mice lacking the α3 (6), α4 (7), α5 (8), α7 (9), α9 (10), β2 (11), β3 (12), or β4 (13) subunit of the nAChR have been reported. In addition, mice lacking the M1 (14), M2 (15), and M4 (16) subtypes of the muscarinic receptor have been generated. These mice have already been used to demonstrate the role of particular receptor subtypes in the physiologic effects of ACh in muscle, the peripheral ganglia, and the central nervous system (Table 1.1).

TABLE 1.1. KNOCKOUTS OF MUSCARINIC AND NICOTINIC SUBUNITS

Subunit	Knockout	Knockout Phenotype	References
Muscarinic receptors			
M1	Viable	Disruption of M current and muscarinic seizures	(14,21)
M2	Viable	Disruption of muscarinic receptor-dependent movement and temperature control and antinociception	(15,21)
M4	Viable	Enhancement of D1 receptor-mediated locomotor stimulation	(16,21)
Nicotinic subunits			
α3	High mortality rate before and after weaning	Impaired growth, megalocystis (inflamed urinary bladder) and mydriasis (widely dilated ocular pupils)	(6)
α4	Viable	Reduced antinociception	(7)
α5	Viable	Not yet reported	(8)
α7	Viable	Largely normal; lack MLA-sensitive nicotine response in hippocampal interneurons; may have slightly decreased anxiety response	(9,22)
α9	Viable	Involved in cochlear efferent innervation development and function	(10)
β2	Viable	Lack nicotine-induced increases in passive avoidance, reinforcement, antinociception; show increased neurodegeneration during aging	(7,11,24,31,32)
β3	Viable	Altered locomotor activity	(12)
β4	Viable	Viable, but lethal when combined with β2 subunit knockout	(13)

MLA, methyl-lyaconitine, a β7 antagonist.

The function of ACh has been best studied at the neuromuscular junction, where signaling occurs through the muscle form of the nAChR. In the embryo, the nAChR at the neuromuscular junction is a pentamer made up of two α, one β, one γ, and one δ subunit. After birth, the γ subunit is replaced by the ε subunit, so that the physiologic properties of the receptor are altered. In mice in which the ε subunit has been knocked out, the neuromuscular junction nAChRs remain in the embryonic form; the consequence is survival past birth with progressive muscle degeneration and lethality by 2 to 3 months of age (17). These experiments demonstrate that maturation of the neuromuscular junction nAChR is necessary for muscle cell function and survival and imply that the kinetics of ACh neurotransmission are critical for the health of muscle fibers in adulthood.

Cholinergic neurotransmission within the sympathetic ganglia occurs through several receptor subtypes. In the peripheral nervous system, the issue of which ACh-receptor subtypes are involved in cholinergic neurotransmission has been addressed both by knocking out muscarinic and nicotinic subunits and by treating sympathetic neurons from isolated chick sympathetic ganglia with antisense oligonucleotides (short stretches of DNA that can inhibit the translation of a particular protein of interest) to decrease the expression of α3, α4, and α7 nAChR subunits. Antisense experiments have indicated that the α3 nAChR subunit plays a primary role in nicotinic transmission in sympathetic ganglia and that the α7 subunit also contributes to the observed currents (18 ,19). These data are in agreement with electrophysiologic and immunoprecipitation studies of nAChR subunits from ganglionic neurons (20). Although the results of studies using this powerful technique are compelling,

some problems have been noted with antisense approaches, including issues of specificity, so that it is useful to complement these studies with other techniques that can be used to manipulate levels of nAChR subunits.

In studies of knockout mice, disruptions of two nicotinic-receptor subunits expressed in sympathetic ganglia, α7 (9) and ß2 (11), do not grossly alter ganglionic function. In contrast, if the ß2 and the ß4 nAChR-subunit mutations are combined (13), or if the α3 nAChR subunit is knocked out (6), mutant mice die perinatally of severe autonomic failure. These experiments suggest that a nicotinic cholinergic receptor composed of the α3/ß4 or ß2 subunit, or both, is responsible for mediating direct neurotransmission by ACh between ganglionic neurons.

Muscarinic function has also been studied in the autonomic ganglia with knockout technology. Mutation of the M1 muscarinic receptor is sufficient to abolish the M current, a muscarine-mediated potassium current, in the sympathetic ganglia, but M1 mutation does not significantly perturb ganglionic function (14). In contrast, mice lacking

the M2 muscarinic-receptor subtype do not show carbachol-induced bradycardia, confirming that the effect of ACh on sympathetic control of heart rate is mediated through the M2 receptor (15). In addition, knockout animals have been very useful in determining which subtypes of muscarinic receptors are responsible for the effects of ACh on modulation of calcium channels in sympathetic neurons (21). A slow, voltage-independent modulation is mediated by M1 receptors, whereas a fast, voltage-dependent modulation is mediated through M2, and neither is affected in M4 knockout mice.

The function of ACh in the brain has also been examined in electrophysiologic experiments with mice lacking cholinergic-receptor subtypes. For example, a rapidly desensitizing nicotinic current in the hippocampus is mediated through an α7-containing receptor (9). Mice lacking the α7 subunit appear grossly normal in behavioral experiments (22), but future experiments should determine whether these currents contribute to nicotine-induced improvements in cognitive function or to nicotine-induced seizure activity. Antisense experiments have also demonstrated that the α5 nAChR subunit can alter the electrophysiologic properties of nAChRs containing the α4 and ß2 subunits *in vivo* (23). Mice lacking the ß2 subunit have been used to characterize four classes of nAChR in the brain by means of pharmacologic and electrophysiologic techniques (24) and to extend the existing pharmacologic characterization of nicotinic-receptor subtypes (Fig. 1.2). Future experiments using mice lacking individual nAChR α subunits should allow a finer definition of these receptor classes.

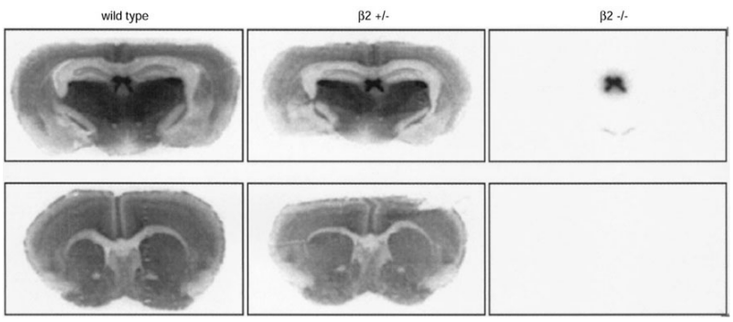

FIGURE 1.2. Nicotinic ligand binding in brain slices from wild-type and ß2-subunit knockout mice. Mice lacking individual subunits of the nicotinic acetylcholine receptor (nAChR) can be used to distinguish between subclasses of receptors. For example, although ß2-subunit knockout mice lack the highest-affinity subclass of nicotine binding sites, the frog toxin epibatidine, shown here, still reveals ß4 subunit-containing nAChRs in the medial habenula (remaining binding shown in panel at *top, far right*). Binding of epibatidine in brain slices through thalamus *(top)* or striatum *(bottom)* is shown in wild-type heterozygous (ß2 +/-) and homozygous (ß2 -/-) ß2-subunit knockout mice.

A significant development in thinking about nicotinic-receptor function has been the idea that nicotine exerts many of its functions in brain through the regulation of neurotransmitter release, at least partly through terminal and preterminal nAChRs (25 ,26). Experiments on synaptosomes (nerve terminals) isolated from mice lacking the ß2 subunit of the nAChR have shown that presynaptic regulation of GABA release by nicotine is mediated through ß2 subunit-containing receptors in most brain areas (27). This is also likely to be the case for other neurotransmitters because the efflux of rubidium, a radioactive tracer that serves as a marker of neurotransmitter vesicle fusion, is mediated through ß2 subunit-containing receptors in most brain areas (28). More recently, dopamine release from striatal synaptosomes has been shown to be disrupted in ß2-subunit knockout mice, while ACh release in the interpeduncular nucleus is preserved (29). This suggests that a distinct nAChR subtype, most likely containing the ß4 subunit, mediates nicotine-elicited ACh release in the interpeduncular nucleus.

Systems-level function and behavioral effects of ACh have also been examined in knockout mice. Muscarinic agonist-induced seizures are dependent on the presence of the M1 receptor because M1 knockout mice are resistant to pilocarpine-induced seizure activity (14). Interestingly, although the M1 receptor has been implicated in the modulation

of potassium channels in the hippocampus in pharmacologic experiments, muscarinic modulation of potassium channels is unchanged in the hippocampus of M1 knockout mice (30). In contrast, the pharmacologic effects of muscarinic agonists on movement, temperature control, and antinociception appear to be mediated through the M2 receptor because these responses are absent in M2 knockout mice (15). M4 receptors are also involved in locomotion; these knockout animals exhibit increased basal locomotor activity and a potentiated locomotor response to D1-selective dopaminergic agonists (16).

Like the M2 receptors, the α4/ß2 subtype of nAChR is implicated in antinociceptive cholinergic pathways. Mice lacking either of these subunits show decreased nicotine-induced analgesia (7). In behavioral experiments, the ß2 nicotinic subunit mediates the ability of nicotine to improve avoidance learning and may also be involved in the circuitry underlying this form of associative learning in wild-type mice (11). In addition, this subunit appears to be necessary for the mouse to experience the reinforcing properties of nicotine because animals without the ß2 subunit will not self-administer nicotine (31). Extensions of these experiments to mice lacking other subunits of the nicotinic receptor should allow identification of the receptor subtypes that are activated by smoking in humans and result in tobacco addiction. An interesting effect of ACh on neuronal survival was demonstrated in mice lacking the ß2 nAChR subunit (32). Mice that lack this cholinergic-receptor subtype show progressive neuronal loss with age in cortical and hippocampal brain areas, which appears to lead to age-related impairments in spatial learning. These experiments demonstrate that the effects of ACh on cognition, antinociception, locomotion, and overall neuronal activity are differentially mediated through the various subtypes of muscarinic and nicotinic receptors, and that the various roles of ACh may be separated pharmacologically, suggesting new targets for rational drug design.

ROLE FOR CHOLINERGIC NEURONS IN AROUSAL AND SLEEP

Part of "1 - Acetylcholine "

Traditionally, the basal forebrain complex, the primary source of cholinergic innervation to the telencephalon (Fig. 1.1), was thought to be involved in arousal or sleep regulation. Either lesions or electric stimulation of subregions of the basal forebrain can facilitate sleep and synchronize the EEG, and cholinergic drugs regulate EEG synchrony (33). Moreover, a correlation between cortical ACh release and the state of behavioral activation or sleep has been observed in rodents. Thus, it was hypothesized that cholinergic input to the neocortex from the basal forebrain is critical for regulating arousal (see ref. 34 for review).

The pontomesencephalic tegmentum is also critical for the sleep–wake cycle. These neurons largely do not innervate the neocortex but project to the diencephalon (thalamus) and the basal forebrain complex. Stimulation of tegmental brainstem cholinergic neurons can evoke cortical ACh release and EEG desynchrony, and these effects are blocked by reversibly decreasing the activity of the basal forebrain (35). Moreover, application of cholinergic agonists to the basal forebrain produces behavioral activation and EEG desynchrony (33). Although the brainstem cholinergic projections to the thalamus undoubtedly also contribute to EEG regulation (36), these findings suggest that cholinergic projections to the basal forebrain from the pontomesencephalic tegmentum regulate behavioral arousal.

It was subsequently noted that cholinergic tegmental projections largely formed connections with noncholinergic neurons within the basal forebrain (37). This finding is critical because it could explain why stimulation of the horizontal diagonal band, preoptic area, and substantia innominata, but not of the septal nucleus and nucleus basalis, produces sleep in the cat (33). The ratio of cholinergic to noncholinergic neurons in the horizontal diagonal band, preoptic area, and substantia innominata is significantly lower than in the septum and nucleus basalis. This observation has led to the hypothesis that activation of primarily noncholinergic neurons is responsible for producing sleep after basal forebrain stimulation (33). These noncholinergic neurons are believed to be GABAergic and achieve their effects through inhibition of cholinergic basal forebrain neurons and neurons within the brainstem reticular formation. In contrast, stimulation of the nucleus basalis or septal nucleus produces behavioral activation and cortical ACh release, and this is consistent with the notion that basal forebrain cholinergic neurons are involved in behavioral arousal (activation), whereas noncholinergic basal forebrain neurons are involved in regulating the sleep state. These two effects are related (sleep vs. arousal), but the qualitative contributions of the GABA and cholinergic systems to sleep and arousal are opposed.

ROLE FOR CHOLINERGIC NEURONS IN MOTIVATION AND REWARD

Part of "1 - Acetylcholine "

Cholinergic neurons have also been implicated in motivation and reward. The strongest evidence for the hypothesis that nAChRs are involved in motivation and reward is that nicotine is abused by humans and is reinforcing in animals (see ref. 38 for review). The effects of nicotine on tests of reinforcement and behavioral sensitization are primarily mediated through the mesolimbic dopamine system (39). Indeed, the ventral tegmental area (VTA) may be sufficient to mediate the reinforcing properties of nicotine, as local injection of nicotine or nicotinic agonists into the VTA can result in increased locomotion (40) or conditioned place preference (41).

Basal forebrain cholinergic neurons may also be involved in modulating cortical processing of stimuli with conditioned or unconditioned rewarding properties because these neurons are more responsive to stimuli with a high incentive value. Novel stimuli that typically elicit orienting responses and attention in animals increase cortical ACh release, but this effect is diminished with repeated exposure if the stimulus has no contingent incentive valence. In contrast, if the stimulus is repeatedly paired with an incentive stimulus (e.g., food or foot shock), the (now-conditioned) stimulus can evoke ACh release even after multiple exposures (42). These sorts of changes are reflected in the firing of “reinforcement-related” neurons within the primate basal forebrain (43). Pontomesencephalic cholinergic neurons are also involved in motivation and reward, although these effects are likely mediated, in part, by projections to the dopamine neurons within the VTA (44 ,45).

Stimulation of the VTA by the pedunculopontine tegmental nucleus (PPT) enhances mesostriatal dopamine transmission (45 ,46). While a significant proportion of the PPT neurons that project to the tegmental dopamine neurons are noncholinergic (44), the cholinergic input *per se* appears to stimulate dopamine neurons (47). Thus, ascending projections from the PPT to the dopamine cells may regulate the ability of mesostriatal dopamine neurons to affect incentive/motivational processes.

This innervation of dopamine cells by cholinergic neurons may explain the finding that lesions of the PPT can modulate the rewarding qualities of addictive drugs. Lesions of the PPT reduce the self-administration of nicotine (48) and opiates (49). Moreover, conditioned place preference for food, opiates (50), morphine (51), and amphetamine (52) is blocked or reduced by PPT lesions, whereas cocaine-induced reward is unaffected (53). Although the mesolimbic dopamine pathway is known to be involved in drug reward (see ref. 54 for review), it is not yet known whether the influence of the PPT on drug reinforcement is through cholinergic projections. It is also not known whether the effect of PPT lesions on these processes is mediated through projections to areas other than the dopamine cell groups within the VTA.

The PPT may have another, more critical, role in motivation and reward via afferent inputs from the striatum (55). Excitotoxic lesions of the PPT (that equivalently destroy both cholinergic and noncholinergic neurons) disrupt responding for conditioned reinforcement and augment stimulant-induced orofacial stereotypy, yet no difference is observed in stimulant-induced locomotion or other measures of food consumption (42 ,56). These data may implicate the PPT (and its innervation from the striatum) in response selection when discrimination is involved because the disruption of responding for conditioned reinforcement resulted from decreased discrimination of response between a lever associated with reinforcement and an inactive lever (56). However, a recent study found that although PPT lesions increased sucrose consumption, similar lesions did not affect discrimination or contrast effects (57). Nevertheless, the hypothesis of Winn (58) is that lesions of the PPT affect responding for rewarding stimuli similarly to lesions of the frontal cortex, so that the role of the PPT, like that of the basal forebrain, is expanded into higher-order cognitive processes.

ROLE FOR CHOLINERGIC NEURONS IN COGNITIVE PROCESSES

Part of "1 - Acetylcholine "

Lesion Studies

The hypothesis of cholinergic involvement in learning and memory processes arose from several findings. Both destruction of the basal forebrain complex and the administration of cholinergic antagonists produce profound deficits in a variety of forms of cognition, including learning and memory (59 ,60).

The original finding that lesions of the basal forebrain could produce deficits in a variety of cognitive tasks suggested a role for ACh in cognitive function. Electrolytic, radiofrequency, or nonspecific excitotoxic lesions of cholinergic subnuclei within the basal forebrain (particularly the medial septum/diagonal band) profoundly impair performance on a variety of tests of learning, memory, and attention, particularly the Morris water maze and passive avoidance learning (see ref. 59 for review). These deficits appeared to be reversed following regeneration of cholinergic projections across a bridging graft (61) or after grafting of ACh-producing cells in the hippocampus (62). These findings have been interpreted as support for the hypothesis of cholinergic involvement in cognitive functions; however (as with arousal and sleep), noncholinergic neurons within the basal forebrain may likewise be involved in these effects, and more specific approaches must be employed to address these issues.

Novel approaches for selectively destroying cholinergic neurons depend on the differential sensitivity of basal forebrain neurons to excitotoxins and new types of immunotoxins. Systematic studies have demonstrated that cholinergic and noncholinergic neurons within the basal forebrain are differentially sensitive to excitotoxic amino acids such as quisqualate, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) (Fig. 1.3), kainate, and *N*-methyl-D-aspartate (NMDA) (59). Based on the results of these studies, new methods for preferentially destroying cholinergic neurons have been described (63). Moreover, an IgG–saporin toxin has been developed that takes advantage of the fact that basal forebrain cholinergic neurons are particularly enriched with low-affinity receptors for nerve growth factor (64). The toxin selectively binds to the receptor for nerve growth factor and then kills the neuron expressing the receptor. More excitingly, recent studies suggest that IgG–saporin can be used to destroy the cholinergic innervation of

terminal regions into which the toxin is injected (65). These methods have been applied to studies of learning and memory in an attempt to qualify earlier findings.

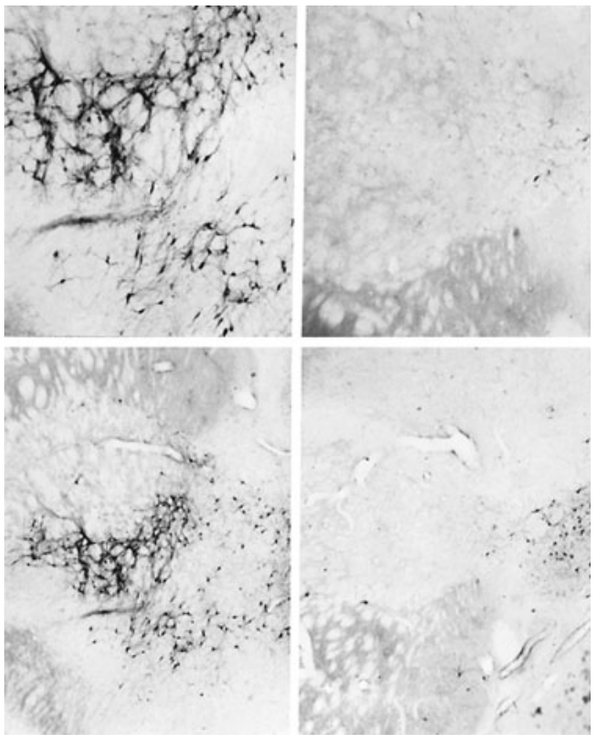

FIGURE 1.3. Acetylcholinesterase staining of the nucleus basalis magnocellularis after infusion of saline solution or AMPA to destroy cholinergic neurons preferentially. Low concentrations of the glutamatergic agonist AMPA selectively destroy cholinergic neurons (measured by acetylcholinesterase staining) and spare γ-aminobutyric acid (GABA) neurons *(left)*. In contrast, control sections show robust acetylcholinesterase staining after infusion of saline solution *(right)*. This process allows more specific cholinergic lesions to be generated, so that the function of the neurons in behavioral processes can be clarified. (Courtesy of Professor Barry J. Everitt, University of Cambridge.)

Based on either excitotoxic or saporin lesions of the basal forebrain, the hypothesis for cholinergic function has been revised considerably. Essentially, selective damage to cholinergic neurons of the basal forebrain has failed to produce the retrograde or anterograde amnesia or deficits in learning that have been reported to result from nonspecific lesions of the basal forebrain (59 ,66). Previously, the medial septal/diagonal band nuclei and their projections to posterior cortical regions were thought to be critical for spatial learning and contextual conditioning (59). By means of saporin lesions, however, cholinergic depletion within the hippocampus or posterior parietal cortex has been shown to result in impairments in latent inhibition or unblocking (65), with sparing of spatial learning (67) and spatial working memory (68). Moreover, selective excitotoxic lesions of the medial septum/diagonal band produce enhancements in contextual conditioning but impairments in discrete cue (trace) conditioning (69). Both sets of data may suggest that the attentional processing of discrete stimuli is disrupted following cholinergic depletion from posterior cortical regions. It is possible, however, that the depletion of ACh from caudal or rostral cortical regions alone may be insufficient to impair performance of some tasks, whereas combined depletions may have more than additive effects (70).

Other investigators have further argued that the cholinergic innervation of rostral (e.g., frontal) cortex from the nucleus basalis is also involved in attentional functions, such as vigilance or sustained, divided attention (59 ,71). Direct pharmacologic manipulation of basal forebrain neurons has been used to alter activated cholinergic efflux in the frontal cortex and performance of tasks related to stimulus processing or detection (72). Selective excitotoxic lesions or pharmacologic manipulation of the nucleus basalis has also been reported to impair performance in a five-choice serial reaction task that requires animals to detect and respond to brief visual stimuli (73). Interestingly, the observation that appetitive pavlovian learning for a discrete cue is enhanced after nucleus basalis lesions (74) suggests that attentional processing of discrete cues may not be affected by depletion of ACh from the rostral neocortex except when divided attention is required. The findings of these latter studies are also bolstered by advances in the measurement of ACh transmission *in vivo*, which allows investigators to quantify directly the extent of the lesions produced by the toxins for the first time (75). Taken together, the available data seem to suggest that basal forebrain cholinergic neurons are capable of regulating the cortical processing of sensory stimuli within a variety of domains, which may be explained by a role for basal forebrain ACh in the regulation of cortical processing.

Tegmental cholinergic neurons have also been implicated in cognitive processes (58 ,76). Although some of the effects of PPT lesions on learning and memory may be related to generalized anxiety (76), PPT lesions also produce a set of behavioral deficits that are consistent with executive dysfunction and impairments in frontal lobe functioning (58). In particular, PPT lesions result in deficits of behavioral inhibition and motor perseveration. Notably, working memory performance does not seem to be affected by destruction of the PPT (77). The position of the PPT as a modulator of dopaminergic systems (which affect frontal cortex function), in addition to the influence of the frontal cortex on the PPT (mediated through the striatum), suggests that this nucleus is in an excellent position to affect the functions of the frontostriatal system. Further research that attempts to control for the extent and selectivity of PPT lesions is necessary.

Muscarinic Mechanisms

Although lesions of cholinergic nuclei have implicated ACh in various behavioral processes, it is also of interest to determine

which cholinergic-receptor subtypes mediate these responses to ACh. Systemic infusions of the muscarinic-receptor antagonists atropine and scopolamine produce an amnesic syndrome in humans (78), monkeys (79), and rats (80). Several lines of evidence suggest that multiple central nervous system structures, including the medial septum/diagonal band region, are critical in mediating the effects of muscarinic drugs on mnemonic functions (80). Infusions of muscarinic-receptor antagonists into a variety of cortical regions, including the hippocampus, prefrontal cortex, and amygdala, can impair the cognitive functions associated with these respective regions (81). Similarly, the effects of systemic muscarinic antagonists are attenuated by intraseptal injections of muscarinic agonists, and intraseptal applications of muscarinic antagonists mimic the amnesic effects of systemic treatment with muscarinic antagonists in experimental animals (82). These results suggest that activation of muscarinic receptors by ACh at multiple forebrain sites, including within the somatodendritic regions of the cholinergic neurons, may be involved in the behavioral dysfunction produced by muscarinic cholinergic antagonists.

Figure 1.4 presents the results of an experiment aimed at determining the relationship between *in vivo* cortical cholinergic transmission and the cognitive effects of muscarinic-receptor antagonists. Scopolamine was administered systemically to rats performing a test of working memory, the spatial delayed alternation task, both alone and in combination with FG7142, an anxiogenic ß-carboline that acts as an inverse agonist of the benzodiazepine site of the $GABA_A$ receptor. Consistent with previous findings, scopolamine produced dose-dependent performance impairments when administered 45 minutes before testing on the delayed alternation task, suggesting that decrements in cholinergic stimulation of muscarinic receptors result in cognitive dysfunction. FG7142 (20 mg/kg) significantly elevated prefrontal cortical ACh release *in vivo* (measured in parallel studies), and FG7142 on its own impaired delayed alternation performance. Interestingly, the fact that coadministration of FG7142 and scopolamine did not affect the slope of the dose–response curve for scopolamine suggests that these two drugs act on different mechanisms to impair delayed alternation performance. The additivity of these effects indicates that supranormal ACh transmission produced by FG7142 likely does not contribute to the working memory deficits produced by this drug; moreover, the data indicate that the impairments produced by scopolamine are independent of the level of ongoing cortical cholinergic transmission. Thus, it is possible that the cognitive effects of muscarinic antagonists may not be solely the consequence of changes in cortical cholinergic transmission.

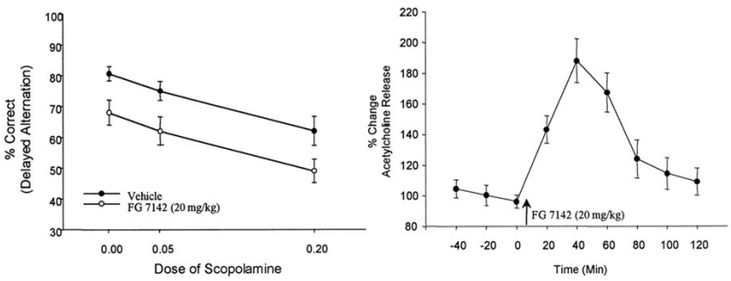

FIGURE 1.4. The cognitive effects of scopolamine administration are insensitive to phasic changes in cortical acetylcholine (ACh) release. Scopolamine dose-dependently impairs performance on a test of spatial working memory, the delayed alternation task, in control rats and rats treated with FG7142, an inverse agonist of the benzodiazepine site of the γ-aminobutyric acid subtype A ($GABA_A$) receptor *(left)*. Although FG7142 increases prefrontal cortical ACh release *in vivo (right)* and produces performance deficits on its own *(left)*, it does not alter the slope of the dose– response curve for scopolamine.

The septohippocampal pathway was first believed to convey only cholinergic fibers to the hippocampus (83); the noncholinergic, GABAergic component was discovered almost two decades later (84). Work focusing on the GABA limb of the septohippocampal GABA pathway has suggested that the septohippocampal GABA and cholinergic pathways may both be critical for the effects of septal efferents on cognitive functioning (85). In support of this hypothesis, agents that increase impulse flow in the septohippocampal GABA pathway, including muscarinic agonists, augment

learning and memory (86), whereas agents that impair learning and memory decrease impulse flow in the GABA pathway (87). Interestingly, impulse flow in the septohippocampal GABA pathway is maintained by ACh released via the *tonic* firing activity of septohippocampal cholinergic neurons. This release occurs via local axon collaterals of septohippocampal neurons, which then synapse on septohippocampal GABA neurons within the medial septum/diagonal band (Fig. 1.5). Thus, interaction between the septohippocampal GABA pathway and muscarinic mechanisms within the medial septum/diagonal band may be crucial for learning and memory (86).

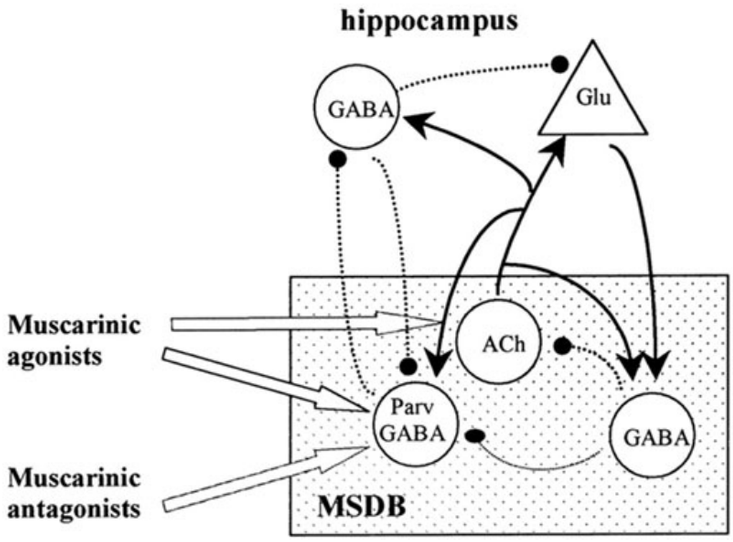

FIGURE 1.5. Schematic representation of the septohippocampal pathway. The medial/septum diagonal band region is composed primarily of cholinergic and GABAergic neurons, and the activity of both neuronal populations is regulated by locally released γ-aminobutyric acid (GABA). The cholinergic neurons and a subpopulation of GABA neurons, containing the calcium-binding protein parvalbumin (parv), project to the hippocampus via the fimbria/fornix. Muscarinic agonists may not increase hippocampal acetylcholine release directly, but rather activate septohippocampal GABA neurons via M3 (and possibly M5) receptors. Similarly, muscarinic antagonists disrupt impulse flow in the septohippocampal GABA pathway.

Cholinergic neurons, the primary source of ACh input to the hippocampus, innervate both the hippocampal pyramidal neurons and subpopulations of GABAergic interneurons (88). In contrast, septohippocampal GABA neurons are very selective in their innervation pattern, do not innervate the pyramidal cells at all, but innervate almost every type of hippocampal interneuron (89). Septohippocampal GABA neurons are able to produce a powerful disinhibitory effect on pyramidal cells via this connectivity and so enhance their excitability (90). Loss of cholinergic neurons severely disables the septohippocampal pathway by reducing both the direct excitatory cholinergic drive and the indirect disinhibitory GABA drive to the hippocampus via locally released ACh. A restoration of cholinergic function within the medial septum/diagonal band, not just in the hippocampus, could therefore be critical for the treatment of cognitive deficits associated with the septohippocampal pathway.

At a molecular level, the excitatory effects of ACh on hippocampal pyramidal cells were at first thought to be mediated via the M1 subtype of muscarinic receptor, partly as a result of closing of M-type potassium channels, so that specific M1-receptor agonists were developed. However, M1-receptor agonists were found to be of limited use in improving cognition. This might not be surprising because studies of knockout mice lacking M1 receptors show no change in muscarinic enhancement of potassium currents in the hippocampus (30). The finding that non-M1 receptors (M3 and possibly M5) mediate the effects of ACh in the medial septum/diagonal band may further explain the limited effectiveness of M1 agonists in improving learning and memory functions and supports the need for M3-selective agonists (85).

Nicotinic Mechanisms

Nicotinic systems are also involved in several important aspects of cognitive function, including attention, learning, and memory (60). Nicotinic ACh receptors are expressed throughout the brain, including areas involved in cognitive function, such as the hippocampus and frontal cortex (91). Nicotinic agonists improve performance on a variety of memory tasks, particularly following lesions or aging, whereas nicotinic antagonists such as mecamylamine impair working memory function (60). The nAChR subtypes involved in cognitive function are under investigation, and different subtypes may be involved in the performance of different cognitive tasks. As mentioned above, experiments on knockout mice have implicated nAChRs containing the β2 subunit in both passive avoidance learning (11) and maintenance of spatial learning during aging (32). Although the cellular basis for the effects of nicotine are likely to be diverse, one site of action for nicotine, excitation of hippocampal GABAergic interneurons through both α7 and non-α7 subtypes of the nAChR, has been demonstrated by several groups (see ref. 92 for review). Further, although theta rhythm in the hippocampus, a mechanism that appears to facilitate the induction of synaptic plasticity, is abolished by atropine (93), it is converted to burst-mode activity by nicotinic antagonists (94).

Another major contributor to the cholinergic hypothesis of cognitive functioning was the discovery in the early 1980s that cholinergic neurons in the basal forebrain degenerate in Alzheimer's disease (95). Since then, loss/atrophy of cholinergic neurons has been reported not only in Alzheimer's disease but also in Parkinson's disease, Lewy body dementia, progressive supranuclear palsy, and several other disorders (96), although not all studies have reported losses in cholinergic neurons (97). In those that have reported losses, the greatest reduction in numbers, of the order of 50% to 65%, has been observed in cholinergic neurons of the nucleus basalis and the medial septal/diagonal band regions of patients pathologically verified as having Alzheimer's disease (96). Loss of high-affinity nAChRs has also been seen in the brains of patients with Alzheimer's disease (98), and

nicotinic agonists have been proposed as potential therapeutic agents to treat the disease (60).

ROLE FOR CHOLINERGIC NEURONS IN STIMULUS PROCESSING

Part of "1 - Acetylcholine "

Several lines of evidence suggest that cholinergic neurotransmission through nAChRs can affect stimulus processing. In support of this notion, nicotine has been reported to alleviate some sensory gating deficits in schizophrenic patients (99), and animal studies also suggest that nicotine may act to facilitate sensory inhibition, such as prepulse inhibition of startle in mice (100) and rats (101). In another animal model of sensory processing, latent inhibition, nicotine can either enhance or disrupt sensory habituation, depending on the preexposure parameters (102). Lesions of the nucleus accumbens or the pedunculopontine nucleus have been shown to block prepulse inhibition (103), whereas lesions of the hippocampus, septum, medial raphe, and nucleus accumbens disrupt latent inhibition (104), observations suggesting that nicotine may act in one or more of these brain areas to affect sensory processing. Another brain area that is likely to mediate the effect of nicotine on sensory gating in schizophrenia is the hippocampus. Postmortem studies have shown a reduced number of α-bungarotoxin-sensitive nAChRs (α7-containing nAChRs) in the hippocampus in schizophrenic patients (105). Further, pharmacologic (106) and genetic (107) studies have suggested a role for the α7 nAChR in prepulse inhibition in rodents.

A series of physiologic studies also supports the concept that ACh, acting on muscarinic receptors within the cerebral cortex, promotes cortical responses to exogenous stimuli. ACh can produce a biphasic effect on membrane polarization in cortical neurons: a rapid hyperpolarization followed by a prolonged depolarization (108). The inhibitory component was mediated through ACh-induced activation of GABAergic interneurons that inhibited the pyramidal cells in a feed-forward manner. In contrast, the long-lasting depolarization was mediated through direct effects of ACh on the cortical neuron. Subsequent studies suggested that this effect is mediated by blockade of I_m, a voltage-sensitive rectifying K^+ channel (14). In addition, ACh reduced spike frequency adaptation by blocking the after-hyperpolarization effect.

The net physiologic effect of these changes in cortical cell physiology may be to render pyramidal cells more responsive to afferent input. Because the membrane is more depolarized, neurons are more likely to fire in response to a given excitatory stimulus; also, the response to that stimulus may be prolonged because the after-hyperpolarization has been blocked. Thus, it seems plausible that muscarinic cholinergic effects on cortical pyramidal cells may indeed promote stimulus access to the cortical circuit. Inasmuch as attentional processing may represent the ability of stimuli to be processed actively within the neocortex, these physiologic actions of ACh may be consistent with the reported behavioral effects of cholinergic lesions.

CONCLUSIONS

Part of "1 - Acetylcholine "

Recent studies using new physiologic techniques, cholinergic-selective toxins, and molecular genetic techniques have refined our ideas about the role of ACh in the brain. In particular, it is clear that cholinergic and GABAergic pathways are intimately connected in the hippocampus and basal forebrain complex and may combine to exert their effects on cognition, attention, and arousal. Further, the subtypes of cholinergic receptors that mediate these effects of ACh are beginning to be elucidated with the use of knockout mice that lack specific receptor subunits. These techniques have contributed to a minirevolution in our views of how ACh contributes to cognitive processes. Research in this area is moving very quickly, and it is likely that these ideas will continue to be refined as the new techniques are applied to previously described behavioral paradigms. Improvements in existing techniques—for example, through the development of inducible and site-specific mutations in cholinergic-receptor subtypes—will also contribute to further refinements in our view of cholinergic functions in the brain.

SUMMARY

Part of "1 - Acetylcholine "

Acetylcholine is critical for communication between neurons and muscle at the neuromuscular junction, is involved in direct neurotransmission in autonomic ganglia, and has been implicated in cognitive processing, arousal, and attention in the brain. The results of recent studies in which specific cholinotoxins, electrophysiology, or molecular genetic techniques were used have altered our view of the functional role of the cholinergic system in the brain. Mice that lack specific subunits or subtypes of muscarinic or nAChRs have recently been generated and used to demonstrate the role of particular receptor subtypes in physiologic effects of ACh in muscle, peripheral ganglia, and the central nervous system. Roles for cholinergic neurons have been found in arousal and sleep, motivation and reward, cognitive processes, and stimulus processing. The evaluation of these functions by means of novel cholinotoxins and new electrophysiologic techniques have refined our ideas about the role of ACh in the brain. The evidence that cholinergic and GABAergic pathways are intimately connected in the hippocampus and basal forebrain complex and may combine to affect cognition, attention, and arousal is reviewed. In addition, the subtypes of cholinergic receptors that mediate these effects of ACh are discussed based on studies of knockout mice that lack specific receptor subunits. Improvements in existing techniques—for example, through the development of inducible and site-specific mutations in

cholinergic-receptor subtypes—will contribute to further refinements in our view of cholinergic functions in the brain.

Serotonin, or 5-hydroxytryptamine (5-HT), has been implicated in almost every conceivable physiologic or behavioral function—affect, aggression, appetite, cognition, emesis, endocrine function, gastrointestinal function, motor function, neurotrophism, perception, sensory function, sex, sleep, and vascular function (1). Moreover, most drugs that are currently used for the treatment of psychiatric disorders (e.g., depression, mania, schizophrenia, autism, obsessive-compulsive disorder, anxiety disorders) are thought to act, at least partially, through serotoninergic mechanisms (see elsewhere, *this volume*). How is it possible for 5-HT to be involved in so many different processes? One answer lies in the anatomy of the serotoninergic system, in which 5-HT cell bodies clustered in the brainstem raphe nuclei are positioned through their vast projections to influence all regions of the neuraxis. Another answer lies in the molecular diversity and differential cellular distribution of the many 5-HT receptor subtypes that are expressed in brain and other tissues.

During the past decade, molecular cloning techniques have confirmed that putative 5-HT receptor subtypes, predicted from radioligand binding and functional studies (e.g., 5-HT_1, 5-HT_2, 5-HT_3, 5-HT_4), represent separate and distinct gene products. This knowledge has revolutionized contemporary research on the serotoninergic system. Through the use of *in situ* messenger RNA (mRNA) hybridization and immunocytochemical maps, studies of previously recognized 5-HT receptors could be directed more precisely toward neurons and model cell lines that express these specific 5-HT receptor subtypes. Moreover, by the use of cloning techniques, investigations could be initiated to determine the functional role of previously unrecognized 5-HT receptors (e.g., 5-HT_5, 5-HT_6, 5-HT_7). Concurrently, much progress has been made in delineating the signal transduction pathways of the various 5-HT-receptor subtypes. The focus of this review is on the molecular and cellular aspects of individual 5-HT receptor subtypes and their transduction mechanism, in addition to interactions between different receptor subtypes within a single neuron or region. The implications of this work in understanding the global functions of the 5-HT system are discussed.

5-HT RECEPTOR SUBTYPES: MOLECULAR AND CELLULAR ASPECTS

Part of "2 - Serotonin "

Molecular Biology

In the first half of the last decade, the cloning of the major known families of 5-HT receptors was accomplished. More recently, attention has turned to issues of transcriptional and post-transcriptional regulation.

RNA Processing

The 5′-flanking region of several 5-HT-receptor genes has been cloned, and consensus sequences for transcription factors have been identified in the promoter region (2 ,3 and 4). The identification of these potential regulatory sites sets the stage for investigations on possible functionally significant regulation of gene transcription *in vivo* (5). A prominent form of post-transcriptional regulation is alternative RNA splicing, in which the splicing out of intronic sequence varies. Alternative splicing is common and occurs for a number of 5-HT receptors, including the 5-HT_{2C}, 5-HT_4, and 5-HT_7 receptors. The two splice variants of the 5-HT_{2C} receptor described in the literature encode severely truncated proteins with no obvious function (6 ,7 and 8). In contrast, the splice variants of the 5-HT_4 receptor (5-$HT_{4(a)}$-5-$HT_{4(f)}$) and 5-HT_7 receptor (5-$HT_{7(a)}$-5-$HT_{7(d)}$) differ in length and composition in the carboxyl terminus (see refs. 9 and 10 for review). Marked species differences and perhaps regional differences lead to different patterns of splicing. Recently, Claeysen et al. (11) showed that the shortest 5-HT_4 receptor variants have the highest degree of constitutive activity, suggesting that the long tail provides structural stability to the molecule. Splice variants of the 5-HT_7 receptor have no known functional differences. In contrast, a second form of post-transcriptional regulation, RNA editing, tends to

have marked effects on the functional properties of proteins. For example, RNA editing changes a single amino acid in the ß subunit of the AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) receptor, which dictates the gating properties of this ligand-gated ion channel (see ref. 12 for review).

RNA editing in mammalian systems was discovered about a decade ago and is defined as any modification, other than alternative splicing, that occurs at the level of mRNA. Several mechanisms of RNA editing exist, but mammalian editing generally involves the conversion of adenosine residues to inosines by the action of a family of adenosine deaminases (13). Such editing events have the potential to alter the genetic code at the level of RNA; the resulting is the formation of multiple protein isoforms with altered function. The discovery of RNA editing of the 5-HT_{2C} receptor provided the first, and so far only, example of editing of a G protein-coupled receptor (14). Editing of the human 5-HT_{2C} receptor mRNA involves five sites, *A* through *E*, where adenosine is converted to inosine; inosine substitutes for guanosine in the genetic code, thus generating different protein isoforms. Multiple RNA isoforms have been found for the 5-HT_{2C} receptor in human brain, predicting the formation of protein isoforms with up to three amino acids changed in the second intracellular loop of the receptor (15 ,16). Editing at the *A, B, C*, and *D* adenosine residues of human 5-HT_{2C}-receptor mRNA leads to predicted changes in all three amino acids to yield valine, serine, valine (VSV) at positions 156, 158, and 160 rather than isoleucine, asparagine, isoleucine (INI) at these positions in the unedited receptor isoform (Fig. 2.1). Editing at all five sites predicts the formation of the valine, glycine, valine (VGV) isoform. Because the second intracellular loop has been implicated in receptor–G protein coupling, initial functional studies have focused on the intracellular signaling properties of 5-HT_{2C}-receptor isoforms. These studies have shown that edited receptor isoforms couple less efficiently to G_q proteins, evidenced by lowered agonist potencies to activate phospholipase C (7 ,14 ,15) and reduced receptor constitutive activity (16 ,17). The discovery that the 5-HT_{2C} receptor is regulated by RNA editing presents a challenge for pharmacologists because multiple isoforms with potentially different pharmacologic properties and functions are predicted to exist in brain. It is not clear, for example, which receptor isoform should be used for *in vitro* modeling of the receptor and to characterize newly developed drugs. The unedited INI isoform is predicted to represent less than 10% of the total population of receptors in human brain; the principal isoform is VSV (15 ,16). To date, all studies of function have involved recombinant cells expressing a single receptor isoform. Evaluation of the *in vivo* functional consequences of RNA editing of the 5-HT_{2C} receptor awaits the development of experimental methods for isolating the function of a single, specific isoform in brain. Strategies such as the generation of blocking antibodies that target specific amino acid combinations in the second intracellular loop or the development of transgenic mice that express a single isoform may be successful, although they are experimentally challenging and time-consuming. It is not known whether other 5-HT receptors, or for that matter other G protein-coupled receptors, are subject to RNA editing. It seems likely that the 5-HT_{2C} receptor would not be unique. However, screening methods for reliably detecting RNA editing are not available; instead, the discovery of edited substrates depends on comparing genomic and cyclic DNA sequences. Consequently, new edited substrates are slow to emerge.

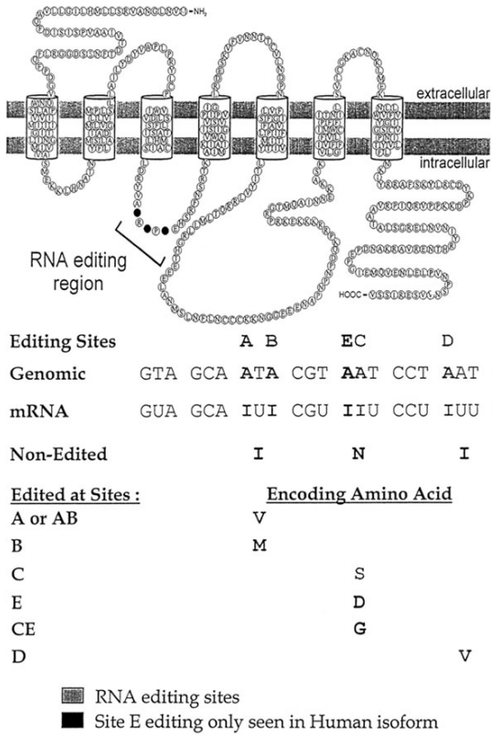

FIGURE 2.1. RNA editing of the 5-hydroxytryptamine subtype 2C (5-HT_{2C}) receptor. Editing of the 5-HT_{2C}-receptor messenger RNA transcript generates multiple receptor isoforms that differ in one to three amino acids in the second intracellular loop.

Post-translational Regulation

Receptor desensitization and down-regulation are common adaptive responses to sustained agonist exposure. The most widely accepted model of desensitization of G protein-coupled receptors is based on extensive studies of the ß-adrenergic receptor, a G_s-linked receptor. In a simplified rendition of the model, agonist binding to a cell surface receptor leads to receptor phosphorylation, arrestin binding, receptor internalization into endosomes, dephosphorylation of the receptor, and recycling back to the cell surface. Receptor phosphorylation is thought to mediate desensitization by uncoupling the receptor from G protein. For many receptors, this phosphorylation event is promoted by a family of G protein-coupled receptor kinases (GRKs). However, second messenger-dependent kinases and protein kinases C and A, in addition to GRKs, have all been implicated in the desensitization of 5-HT_{1A} receptor (18). Abundant *in vivo* studies have documented a blunting of 5-HT_{1A} receptor-mediated behavioral responses after long-term treatment with agonists or serotonin uptake inhibitors that indirectly promote receptor activation. Indeed, desensitization of raphe 5-HT_{1A} autoreceptors has been proposed to play a role in the delayed therapeutic onset of antidepressant drugs (see ref. 19 for review).

Protein kinase C has also been implicated in 5-HT_{2A}-receptor desensitization (20). Subsequent steps in the desensitization-resensitization cycle have been demonstrated for the 5-HT_{2A} receptor, including arrestin binding to the third intracellular loop of the receptor (21) and internalization into endocytotic vesicles (22). Surprisingly, 5-HT_{2A}-receptor antagonists also cause receptor internalization, which may be related to the earlier findings of antagonist down-regulation of 5-HT_{2A} receptors (see ref. 23 for review). Importantly, antagonist-mediated 5-HT_{2A}-receptor internalization has been confirmed in cortical pyramidal cells and is accompanied by an apparent redistribution from dendrites to cell bodies (24). The fact that atypical antipsychotic drugs such as clozapine and olanzapine, but not haloperidol, promote 5-HT_{2A}-receptor internalization has led to speculation that this novel antagonist property may be related to therapeutic action in schizophrenia.

Receptor Constitutive Activity and Inverse Agonism

In *Psychopharmacology: The Fourth Generation of Progress*, the concept of inverse agonist properties of serotonin-receptor antagonists was novel and unique to the 5-HT_{2C} receptor (25). *Inverse agonism* is the ability of certain antagonists to block the spontaneous (also referred to as *constitutive*) activity of a G protein-coupled receptor, in addition to blocking the binding of an agonist. These antagonists are referred to as *inverse agonists* because their effects are opposite to those of agonists. In contrast, other antagonists, referred to as *neutral antagonists*, have no apparent activity when added alone, even though they block the action of an agonist. To explain receptor constitutive activity and inverse agonism of antagonists, the model of receptor–G protein coupling was modified to propose spontaneous receptor isomerization to an active form (*R**) in the absence of an agonist (26). Antagonists with inverse agonist activity bind to and stabilize the inactive receptor conformation (*R*), whereas neutral antagonists were proposed to bind equally well to the active and inactive forms of the receptor. Since 1995, 5-HT_{1A} receptors (27, 28), 5-HT_{1B} receptors (29), 5-HT_{1D} receptors (30), mutant 5-HT_{2A} receptors (31), 5-HT_4 receptors (11 ,32), and 5-HT_7 receptors (33) have been shown to exhibit constitutive activity; both inverse agonists and neutral antagonists have been described for these receptors.

All these studies demonstrating inverse agonist properties of 5-HT antagonists have been performed *in vitro* in cells expressing recombinant receptors. It is not known whether inverse agonism is relevant to the *in vivo* actions of receptor antagonists, including their therapeutic properties. Recent *in vivo* studies of a simple motor reflex have produced convincing evidence for constitutive activity of the 5-$HT_{2A/2C}$ receptor and differential effects of inverse agonists versus neutral antagonists (34 ,35). However, Millan et al. (36) were unable to show differential effects of inverse agonists versus neutral antagonists at the 5-HT_{1B} receptor and concluded that *in vitro* demonstrations of inverse agonist activity cannot be extrapolated to the *in vivo* situation. Recent studies by Berg et al. (37) suggest that even in the absence of measurable effects on basal activity, prolonged treatment with inverse agonists at the 5-HT_{2C} receptor produces enhanced phospholipase C activation, likely because of increased expression of G_q proteins.

Electrophysiology

Although the electrophysiologic actions of 5-HT may seem quite varied, considerable uniformity is found within each of the major receptor families. For example, all members of the 5-HT_1 family tend to have inhibitory actions either presynaptically or postsynaptically. Similarly, all members of the 5-HT_2 family tend to have excitatory actions. Therefore, the discussion of 5-HT electrophysiology is organized according to receptor family subtypes.

5-HT_1 Receptors

Dense concentrations of 5-HT_{1A} binding sites and high levels of 5-HT_{1A} mRNA expression are found in a number of regions, including the dorsal raphe nucleus, hippocampal pyramidal cell layer, and cerebral cortex (38 ,39 and 40). Studies in these regions have been useful in delineating the physiologic role of this receptor.

Raphe Nuclei

Serotoninergic neurons of the raphe nuclei are inhibited by the local (microiontophoretic) application of 5-HT to their cell body region. Thus, the receptor mediating this effect has been termed a *somatodendritic autoreceptor* (as opposed to the prejunctional autoreceptor). Early studies in the dorsal raphe nucleus showed that lysergic acid diethylamide (LSD) and other indolamine hallucinogens are powerful agonists at the somatodendritic 5-HT autoreceptor (41 ,42). Functionally, the somatodendritic 5-HT autoreceptor has been shown to mediate collateral inhibition (43). The ionic basis for the autoreceptor-mediated inhibition, either by 5-HT or LSD, is an opening of K^+ channels to produce a hyperpolarization (44); these channels are characterized by their inwardly rectifying properties (45). As in the dorsal raphe nucleus, serotoninergic neurons of the lower brainstem are also hyperpolarized by 5-HT via the opening of inwardly rectifying K^+ channels (46 ,47). Similar findings in acutely isolated (48) and individually microcultured (49) dorsal raphe neurons underscore the fact that autoreceptor inhibition is independent of any inputs to the raphe nucleus. Patch-clamp recordings in the cell-attached and outside-out configuration from such acutely isolated dorsal raphe neurons show that the increase in K^+ current results from a greater probability of opening of unitary K^+ channel activity (50).

The somatodendritic autoreceptors of serotoninergic neurons in both the dorsal raphe nucleus and the nucleus raphe magnus appear to be predominantly of the 5-HT_{1A} subtype; a variety of drugs with 5-HT_{1A} selectivity (e.g., 8-OH-DPAT and the anxiolytic drugs buspirone and ipsapirone) share the ability to inhibit raphe cell firing potently in a dose-dependent manner (47 ,50a ,50b). Recently, a highly selective 5-HT_{1A} antagonist (WAY 100635) has been found that potently blocks the direct inhibition of dorsal raphe serotoninergic neurons both by 5-HT and selective 5-HT_{1A} agonists (51 ,52). WAY 100635 also blocks the indirect inhibition of dorsal raphe neurons induced by selective 5-HT reuptake inhibitors (53). Complementing this autoinhibitory role of local 5-HT_{1A} receptors is a long-loop negative-feedback system activated by postsynaptic 5-HT_{1A} receptors in the medial prefrontal cortex (54 ,55).

In addition to long-loop feedback systems, short-loop regulatory circuits are found within the dorsal raphe nucleus and the adjacent periaqueductal gray (PAG). These short-loop circuits involve interactions between 5-HT and local inhibitory GABAergic (γ-aminobutyric acid) and excitatory glutamatergic neurons (56). Interestingly, both the local excitatory and inhibitory inputs to 5-HT cells are negatively modulated by μ opiate receptors. Local GABAergic neurons are activated by 5-HT via 5-$HT_{2A/2C}$ receptors in a local, negative feedback loop that complements 5-HT_{1A}-mediated autoinhibition (57). Neurokinins such as substance P and neurokinin B, via NK_1 and NK_3 receptors, respectively, activate mostly local glutamatergic excitatory inputs to 5-HT cells (58). Some of these local circuits are depicted schematically in Fig. 2.2 .

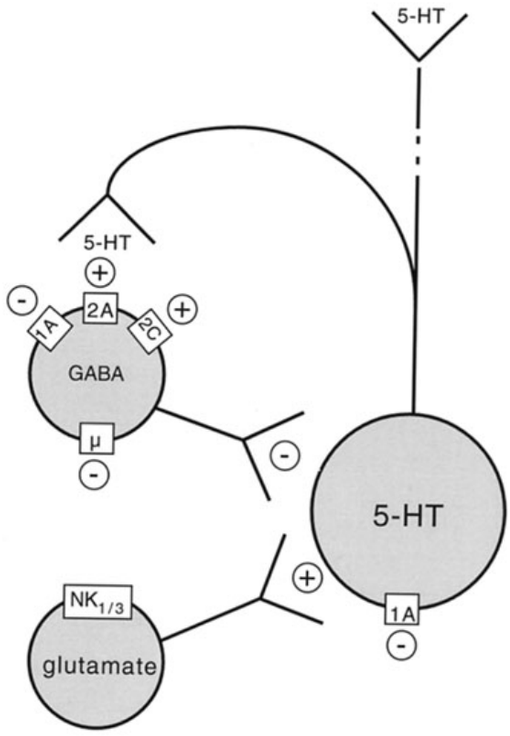

FIGURE 2.2. Schematic representation of local regulatory circuitry within the dorsal raphe nucleus (DRN). In addition to somatodendritic 5-hydroxytryptamine subtype 1A (5-HT_{1A}) autoreceptors on the 5-HT neurons *per se*, local GABAergic (γ-aminobutyric acid) and glutamatergic neurons in the DRN/ventral periaqueductal gray (PAG) region modulate the activity of serotoninergic neurons. Note the location of inhibitory μ opiate receptors on both categories of local neurons. Also depicted are excitatory 5-$HT_{2A/2C}$ and inhibitory 5-HT_{1A} receptors on GABAergic neurons and excitatory NK_1 (substance P) and NK_3 (neurokinin B) receptors on glutamate neurons in the DRN/PAG.

Other Subcortical Regions

Inhibitory or hyperpolarizing responses to 5-HT have been reported in a wide variety of neurons in the spinal cord, brainstem, and diencephalon. In general, such responses have been attributed to mediation by 5-HT_1 receptors. In sensory neurons of dorsal root ganglia, a 5-HT_1-like receptor has been reported to reduce the calcium component of action potentials and to produce hyperpolarizations that can be mimicked by 5-HT_{1A} agonists such as 8-OH-DPAT (59). In cerebellar Purkinje cells, 5-HT-induced inhibition, but not excitation, is mediated through 5-HT_{1A} receptors (60). In brain slices of the nucleus prepositus hypoglossi, focal electric stimulation evokes inhibitory postsynaptic potentials (IPSPs) that are mediated by 5-HT_{1A} receptors to activate an inwardly rectifying K^+ conductance (61) and a novel outwardly rectifying K^+ conductance (62). In the midbrain PAG, a region known to be involved in pain modulation and fear responses, approximately half the cells are inhibited/hyperpolarized by 8-OH-DPAT, suggesting mediation by 5-HT_{1A} receptors (63). In the ventromedial hypothalamus (64) and lateral septum (65 ,66), 5-HT and 5-HT_{1A} agonists produce inhibitory effects, also by activating a K^+ conductance. In addition to these postsynaptic effects, 5-HT has been shown to suppress glutamatergic synaptic transmission via presynaptic 5-HT_{1B} receptors in various regions, including the hypoglossal nucleus (67) and the nucleus accumbens (68).

In the rat laterodorsal tegmental nucleus, bursting cholinergic neurons are hyperpolarized by 5-HT via 5-HT_1 receptors (69). In freely behaving rats, the direct injection of 5-HT into the laterodorsal tegmental nucleus has been found to suppress rapid-eye-movement (REM) sleep (70). In unanesthetized cats, a corresponding population of neurons that are active selectively during REM states (REM-on neurons) in the laterodorsal tegmental nucleus has been shown to be inhibited by direct application of the 5-HT_{1A} agonist 8-OH-DPAT (71). It has been proposed that during REM sleep, the removal of a tonic inhibitory 5-HT influence from these cholinergic neurons may be responsible for the emergence of an activated EEG during this behavioral state.

Hippocampus

Pyramidal cells of the CA1 region express high levels of 5-HT_{1A}-receptor mRNA and 5-HT_{1A}-receptor binding (72). Early on, intracellular recordings in brain slices showed that the 5-HT-induced inhibition was caused by hyperpolarization resulting from an opening of K^+ channels (73). Subsequent work, in which various pharmacologic approaches have been used in brain slices, has shown that the 5-HT-induced inhibition in both CA1 and CA3 pyramidal cells is mediated by the activation of receptors of the 5-HT_{1A} subtype (74 ,75 ,76 and 77). After long-term but not short-term administration of various antidepressant treatments (selective 5-HT reuptake inhibitors, monoamine oxidase inhibitors,

tricyclic drugs, electroconvulsive therapy), disinhibitory responses are seen with the selective 5-HT_{1A} antagonist WAY 100635, which suggests increased 5-HT_{1A}-mediated inhibitory tone on CA3 hippocampal pyramidal cells (78). Interestingly, this increase in 5-HT_{1A} tone after long-term antidepressant treatment is potentiated by short-term treatment with lithium (79).

In addition to the above-mentioned direct effects on pyramidal cells, 5-HT has been shown to depress both excitatory and inhibitory synaptic potentials in the hippocampus. Relatively high concentrations of 5-HT cause a reduction in electrically evoked excitatory postsynaptic potentials (EPSPs) in CA1 pyramidal cells (80), an effect that is mimicked by 8-OH-DPAT, which suggests mediation by 5-HT_{1A} receptors. Indirect measures indicate that 5-HT acts presynaptically to reduce Ca^{2+} entry and thereby glutamatergic synaptic transmission. In addition, a 5-HT_{1A}-mediated inhibitory effect on putative inhibitory interneurons of the hippocampus has been observed (81 ,82). Consistent with an opening of K^+ channels, the inhibitory effects of 5-HT on interneurons result from a hyperpolarization associated with a reduction in input resistance. Functionally, the 5-HT_{1A}-mediated inhibition of GABAergic interneurons in the hippocampus leads to a disinhibition of pyramidal cells in CA1. Clearly, the effects of 5-HT in the hippocampus are highly complex, involving both presynaptic and postsynaptic actions that may, to varying degrees, be inhibitory or disinhibitory, facilitative or disfacilitative.

Cerebral Cortex

Hyperpolarizing/inhibitory responses in pyramidal cells of the cerebral cortex induced by 5-HT_{1A} have been described in a number of studies. In entorhinal cortex, where the density of 5-HT_{1A} receptors is especially high (and the density of 5-HT_{2A} receptors low), unopposed 5-HT_{1A} receptor-mediated hyperpolarizing responses are seen (83). However, cortical neurons in most other regions typically display mixed inhibitory and excitatory responses to 5-HT because of expression by the same pyramidal cells of multiple 5-HT receptor subtypes (e.g., 5-HT_{1A} and 5-$HT_{2/2C}$) (84 ,85 ,86 and 87). Hyperpolarizing responses mediated by 5-HT_{1A} receptors are often unmasked or enhanced in the presence of 5-HT_2 antagonists, consistent with the idea that an interaction occurs between 5-HT_{1A} and 5-HT_{2A} receptors at an individual neuronal level (84 ,88 ,89). A similar suggestion of a shift in the balance between 5-HT-mediated excitation and inhibition comes from another *in vivo* study, in which both systemic and local application of 5-HT_2 antagonists was shown to prevent an enhancement of the unit activity (and cortical desynchronization) that normally occurs in response to noxious stimuli (tail compression) in anesthetized rats (90).

In addition to the above-mentioned postsynaptic effects, various presynaptic effects are mediated by 5-HT_1 receptors in the cerebral cortex. In cingulate cortex, 5-HT, acting on presynaptic 5-HT_{1B} receptors, reduces the amplitude of electrically evoked EPSPs, including both *N*-methyl-D-aspartate (NMDA) and non-NMDA components (87). Similar modulations of EPSPs, mediated by 5-HT_{1A} or 5-HT_{1B} receptors, have been reported for several cortical regions, including medial prefrontal (91) and entorhinal cortex (92).

5-HT_2 Receptors

Quantitative autoradiographic studies show high concentrations of 5-HT_2 binding sites and mRNA expression in certain regions of the forebrain, such as the neocortex (layers IV/V), piriform cortex, claustrum, and olfactory tubercle (93). With few notable exceptions (e.g., motor nuclei and the nucleus tractus solitarius), relatively low concentrations of 5-HT_2 receptors or mRNA expression are found in the brainstem and spinal cord. Studies aimed at examining the physiologic role of 5-HT_2 receptors in several of these regions are discussed in the following sections.

Motoneurons

In the facial and other cranial motor nuclei, motoneurons have a high density of 5-HT_2-receptor binding sites. Early studies *in vivo* showed that 5-HT applied microiontophoretically does not by itself induce firing in the normally quiescent facial motoneurons, but does facilitate the subthreshold and threshold excitatory effects of glutamate (94). Intracellular recordings from facial motoneurons *in vivo* or in brain slices *in vitro* (95 ,96) show that 5-HT induces a slow, subthreshold depolarization associated with an increase in input resistance, indicating a decrease in resting K^+ conductance. Ritanserin and other 5-HT_2 antagonists are able to block the excitatory effects of 5-HT in facial motoneurons selectively (97). Indolamine (e.g., LSD and psilocin) and phenethylamine (e.g., mescaline and DOI) hallucinogens act as 5-HT_2 agonists at facial motoneurons. Iontophoretically administered LSD, mescaline, and psilocin, although having relatively little effect by themselves, produce a prolonged facilitation of facial motoneuron excitability (98). Intracellular studies in brain slices show that the enhancement is in part caused by a small but persistent depolarizing effect of the hallucinogens (97 ,99).

Other Subcortical Regions

In brain slices of the medial pontine reticular formation, 5-HT induces a hyperpolarization in some cells and a depolarization in other cells (100). The hyperpolarizing responses are associated with an increase in membrane conductance and have a 5-HT_1 pharmacologic profile. The depolarizing responses have a 5-HT_2 pharmacology and are associated with a decrease in membrane conductance resulting from a decrease in an outward K^+ current. These two actions of 5-HT do not appear to coexist in the same neurons because none of the cells display dual responses to selective agonists.

In brain slices of the substantia nigra pars reticulata, a majority of neurons are excited by 5-HT via 5-HT_2 receptors (101), possibly of the 5-HT_{2C} rather than 5-HT_{2A} subtype (102). Neurons in the inferior olivary nucleus are excited by 5-HT via 5-HT_{2A} receptors, so that the oscillatory frequency of input to cerebellar Purkinje cells is altered (103). In the nucleus accumbens, the great majority of neurons are depolarized by 5-HT, and they are induced to fire (104). This depolarization is associated with an increase in input resistance secondary to a reduction in an inward rectifier K^+ conductance. Pharmacologic analysis shows that the depolarization is mediated by a 5-HT_2- rather than a 5-HT_1- or 5-HT_3-type receptor.

GABAergic neurons of the nucleus reticularis thalami show marked depolarizing responses to 5-HT, associated with a decrease in a resting or "leak" K^+ conductance; these excitatory responses are blocked by the 5-HT_2 antagonists ketanserin and ritanserin (105). The 5-HT-induced slow depolarization potently inhibits burst firing in these cells and promotes single-spike activity. It has been suggested that the 5-HT-induced switch in firing mode from rhythmic oscillation to single-spike activity, which occurs during states of arousal and attentiveness, contributes to the enhancement of information transfer through the thalamus during these states. GABAergic neurons within the medial septal nucleus are also excited by 5-HT via 5-HT_2 receptors (106). In the dentate gyrus of the hippocampus, a subpopulation of GABAergic neurons is activated via 5-HT_{2A} receptors, evidenced by an increase in IPSP frequency in granule cells in the dentate gyrus (107). Recently, similar activation of GABAergic neurons via 5-HT_{2A} receptors has been reported in the CA1 region of the hippocampus (108). These observations closely resemble findings in the piriform cortex, where a subpopulation of GABAergic interneurons is excited by 5-HT via 5-HT_{2A} receptors (see below). Also, indirect evidence suggests that 5-HT-induced inhibition of dentate/interpositus neurons of the deep cerebellar nuclei is mediated indirectly by the activation of GABAergic interneurons through 5-HT_2 receptors (109). Taken together, these findings suggest that in multiple locations within the central nervous system, excitation of subpopulations of interneurons by 5-HT via 5-HT_2 receptors gives rise to indirect inhibitory effects.

Cerebral Cortex

The electrophysiologic effects of 5-HT have been studied in several cortical regions. *In vitro* studies in brain slice preparations have shown that pyramidal cells in various cortical regions respond to 5-HT by either a small hyperpolarization, depolarization, or no change in potential (84 ,85 and 86 ,110). Depending on the region of cortex under study, as described below, the depolarizations appear to be mediated by 5-HT_{2A} or 5-HT_{2C} receptors.

In addition to these postsynaptic effects, 5-HT induces an increase in "spontaneous" (not electrically evoked) postsynaptic potentials or currents (PSPs/PSCs) in brain slices from various cortical regions. Originally, recordings were made from pyramidal cells in a paleocortical region, the piriform cortex. In that region, as in the hippocampus (see above), 5-HT, acting through 5-HT_{2A} receptors, induces an increase in spontaneous IPSPs (86 ,111 ,112 ,113 ,114 and 115). *In vivo* studies have also provided evidence for a 5-HT_{2A} receptor-mediated activation of GABAergic neurons in piriform cortex (116). As in piriform cortex, 5-HT can increase IPSCs in pyramidal cells in various layers of the neocortex (117 ,118). The IPSCs result from the activation of cortical interneurons via 5-$HT_{2A/2C}$ or 5-HT_3 receptors (117). Immunocytochemical evidence has been found in primate cerebral cortex for a segregation of 5-HT_{2A}- and 5-HT_3-expressing interneurons; the former project to somatobasilar and the latter to distal apical dendritic regions of pyramidal cells (119).

Quantitatively, in layer V pyramidal cells, synaptic events induced by 5-HT consist largely of EPSPs/EPSCs (118). Thus, approximately 85% of all PSCs are blocked by AMPA/kainate glutamate-receptor antagonists (e.g., LY293558) but not by the $GABA_A$ antagonist bicuculline (118). The 5-HT-induced increase in EPSCs is most pronounced in frontal regions, including the medial prefrontal cortex (118). In that region, 5-HT_{2A} receptors are denser than in more posterior regions (40 ,120). Recent studies, in which intracellular labeling with biocytin was used, have confirmed that 5-HT-induced increases in EPSCs occur predominantly in layer V pyramidal cells, whereas responses are minimal in layer II/III cells and lacking in layer VI cells (121).

The 5-HT-induced EPSCs are antagonized competitively by low concentrations of the highly selective 5-HT_{2A} antagonist MDL 100,907 (pA_2, 8.8), which indicates mediation by 5-HT_{2A} receptors (118 ,122). Norepinephrine, via α_1 adrenoceptors, also induces an increase in EPSPs in layer V pyramidal cells, but (at least in the rat) the increase is only a fraction of that produced by 5-HT (122). Changes in the frequency of synaptic currents or potentials are generally regarded as indicative of a modulation of presynaptic function. Accordingly, the nonspecific group II/III metabotropic glutamate receptor agonist (1*S*,3*S*)-ACPD (118) and the selective mGlu II/III metabotropic agonist LY354740 (123), which act at inhibitory autoreceptors and are located on glutamatergic nerve terminals, suppress the 5-HT-induced increase in the frequency of EPSCs. In addition, the activation of μ receptors, located presynaptically on thalamocortical inputs, also suppresses 5-HT-induced EPSCs, particularly in the medial prefrontal cortex (124). These results are consistent with the idea that activation of 5-HT_{2A} receptors increases the release of glutamate onto layer V pyramidal cells through a presynaptic mechanism. 5-HT also produces a small but significant increase in the *amplitude* of spontaneous EPSCs, an effect that may involve postsynaptic amplification mechanisms (118). Such postsynaptic

effects are consistent with the finding of a high level of 5-HT_{2A}-receptor immunoreactivity in the apical dendrites of cortical pyramidal cells (125 ,126 and 127).

The 5-HT-induced EPSCs are blocked by bath application of the slice with the fast sodium channel blocker tetrodotoxin or perfusion with a solution containing no added calcium (“zero” calcium) (118). Ordinarily, tetrodotoxin sensitivity and Ca^{2+} dependence would suggest that activation of glutamatergic cells within the slice by 5-HT had led to an impulse flow-dependent release of glutamate. However, several lines of evidence argue against this conventional interpretation. First, rarely were neurons within the confines of the brain slice induced to fire by bath application of 5-HT. Second, none of the pyramidal cells (a potential source of intracortical excitatory inputs) was depolarized sufficiently by 5-HT as recorded under our conditions to reach the threshold for firing. Third, EPSCs can be induced by the microiontophoresis of 5-HT onto “hot spots” along the trajectory of apical dendrites of layer V pyramidal cells (118). Together, these experiments suggest that the increase in spontaneous EPSCs induced by 5-HT in neocortical pyramidal cells occurs through a focal action involving a Ca^{2+}-dependent mechanism that is not based on an increase in impulse flow in excitatory afferents.

As an alternative to a conventional impulse flow-related mechanism, it has been hypothesized that the 5-HT-induced EPSCs result from an activation of the “asynchronous” release pathway (128). One of several distinguishing characteristics of this alternative mechanism of transmitter release is that Sr^{2+} can substitute for Ca^{2+} in the asynchronous, but not synchronous, release (129). This feature appears to be the result of the differential involvement of two isoforms of the calcium-sensing protein synaptotagmin in the two alternative release mechanisms (130). Consistent with this idea, Sr^{2+} is highly effective in enabling 5-HT to induce an increase in the frequency of EPSCs in the absence of Ca^{2+} (128).

Recently, it has been found that LSD and other hallucinogenic drugs, acting as partial agonists at 5-HT_{2A} receptors, promote a late component of electrically evoked EPSPs (131). It is possible that this late component, rather than representing conventional polysynaptic transmission, is mediated through the mechanism of asynchronous transmitter release, possibly involving a release of intraterminal Ca^{2+} stores via the phospholipase C, inositol triphosphate (IP_3) pathway. An enhancement of asynchronous evoked EPSPs via 5-HT_{2A} receptors would provide a possible synaptic mechanism for the hallucinogenic effects of these drugs. In contrast, 5-HT itself does not promote the late component of *electrically evoked* release except during the washout phase, presumably because of opposing actions at 5-HT_1 or other non-5-HT_{2A} receptors (132). Figure 2.3 depicts the proposed location of various 5-HT-receptor subtypes and their interactions with other neurotransmitter receptors within cortical circuitry.

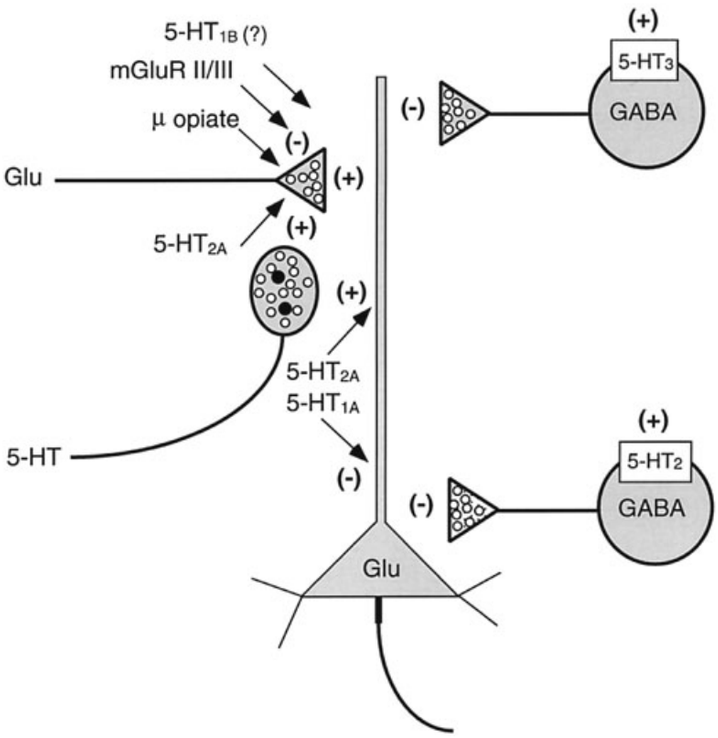

FIGURE 2.3. Modulation of excitatory and inhibitory transmission by multiple 5-hydroxytryptamine (5-HT) receptors in the cerebral cortex. 5-HT_{2A} receptors are depicted as enhancing glutamate release from a glutamatergic terminal onto a layer V pyramidal cell; the same terminal is seen to be negatively modulated by various G_i/G_o-coupled receptors (e.g., μ-opiate, 5-HT_{1B}, and mGluR II/III). In addition, 5-HT_{2A} receptors are shown to have a direct postsynaptic excitatory effect that is opposed by postsynaptic 5-HT_{1A} receptors. Finally, 5-HT_2 and 5-HT_3 receptors are shown on anatomically distinct GABAergic inputs to the somatobasilar and apical regions, respectively, of the pyramidal cell.

5-HT_3 Receptors

Excitatory responses to 5-HT have been found in various central neurons that have many of the characteristics of peripheral 5-HT_3 responses, including rapid onset and rapid desensitization, features typical of ligand-gated ion channels rather than G protein-coupled receptor responses (133 ,134). In cultured NG108-15 cells, the permeation properties of the 5-HT_3 channel are indicative of a cation channel with relatively high permeability to Na^+ and K^+ and low permeability to Ca^{2+} (134). A 5-HT-gated ion channel has been cloned that has physiologic and pharmacologic properties appropriate for a 5-HT_3 receptor (135). In the oocyte expression system, this receptor shows rapid desensitization and is blocked by 5-HT_3 antagonists (e.g., ICS 205–930 and MDL 72222). Its sequence homology with the nicotinic acetylcholine receptor (27%) and the $ß_1$ subunit of the $GABA_A$ receptor (22%) indicates that this 5-HT_3-receptor clone is a member of the ligand-gated ion channel superfamily. Typically, members of this superfamily are comprised of multiple subunits; however, only one 5-HT_3-receptor subunit and an alternatively spliced variant have been cloned to date (136).

In hippocampus slices, 5-HT has been reported to increase spontaneous GABAergic IPSPs, most likely through a 5-HT_3 receptor-mediated excitation of inhibitory interneurons; these responses also show fading with time (137 ,138). A similar 5-HT_3 receptor-mediated induction of IPSCs has been reported in the neocortex (117). Whole-cell patch-clamp recordings have confirmed a direct 5-HT_3 receptor-mediated excitatory effect on hippocampal interneurons independent of G-protein activation (139). Although fast, rapidly inactivating excitation has generally become accepted as characteristic of 5-HT_3 receptors, nondesensitizing responses have also been reported. In dorsal root ganglion cells, a relatively rapid but noninactivating depolarizing response has been described that has a 5-HT_3 pharmacologic profile (140). In neurons of nucleus tractus solitarius brain slices, a postsynaptic depolarizing response to 5-HT_3 agonists has been observed that is not rapidly desensitizing (141). In addition to these postsynaptic effects, a 5-HT_3 receptor-mediated increase in Ca^{2+} influx has been described in a subpopulation of striatal nerve terminals (142).

5-HT_4, 5-HT_6, and 5-HT_7 Receptors

The first known protein G_s-coupled 5-HT receptor, the 5-HT_4 receptor, was identified on the basis of pharmacologic and biochemical criteria (e.g., positive coupling of 5-HT responses to adenylyl cyclase) (9). Subsequently, a receptor with matching pharmacologic and other properties was cloned and found to be expressed in various regions of the brain (143). Two other 5-HT receptors positively coupled to adenylyl cyclase have been cloned. Because their pharmacology differed from that of the previously described 5-HT_4 site, they were designated as 5-HT_6 and 5-HT_7 receptors (144 ,145 and 146). At this time, electrophysiologic studies are available only for the 5-HT_4 and 5-HT_7 receptors and are described below.

5-HT_4 Receptors

Binding studies using a selective 5-HT_4 ligand indicate that 5-HT_4 receptors are present in several discrete regions of the mammalian brain, including the striatum, substantia nigra, olfactory tubercle, and hippocampus (147). Because these regions also express 5-HT_4-receptor mRNA, it appears likely that the receptors function postsynaptically to mediate certain actions of 5-HT. The best studied of these regions is the hippocampus, in which both biochemical and electrophysiologic studies have provided a detailed picture of the actions of 5-HT at 5-HT_4 receptors. Electrophysiologic studies show that 5-HT_4 receptors mediate an inhibition of a calcium-activated potassium current that is responsible for the generation of a slow after-hyperpolarization in hippocampal pyramidal cells of the CA1 region (74 ,148 ,149). A suppression of the after-hyperpolarization would enhance the ability of these cells to respond to excitatory inputs with robust spike activity.

5-HT_7 Receptors

The circadian rhythm in mammals is set by a pacemaker located primarily in the suprachiasmatic nucleus of the hypothalamus. This pacemaker activity can be maintained in hypothalamic slices, in which suprachiasmatic neurons display diurnal changes in neuronal firing rate. Administration of 5-HT appears to produce a phase shift in this activity (150) by acting on a receptor that may be of the 5-HT_7 subtype (144). This shift is mediated by stimulation of adenylate cyclase because it is mimicked by increasing intracellular cyclic adenosine monophosphate (cAMP) and blocked by inhibiting protein kinase A (151). However, the precise mechanism by which 5-HT_7 receptors act is not presently known because it is unclear whether suprachiasmatic neurons themselves express the 5-HT_7 receptors (144). Furthermore, the effect of 5-HT on the membrane properties of these cells has not been examined. 5-HT_7 receptor activation has been reported to inhibit $GABA_A$ currents on suprachiasmatic neurons in culture (152), but the relationship, if any, between these observations and 5-HT changes in circadian activity remains to be determined.

Another electrophysiologic effect that may be mediated through 5-HT receptors that are positively coupled to adenylate cyclase is the enhancement of the hyperpolarizing-activated nonselective cationic current I_h. The I_h channels, which are homologous to cyclic nucleotide-gated channels in specialized sensory neurons, are positively modulated by cAMP (153 ,154). An increase in I_h tends to prevent excessive hyperpolarization and increase neuronal excitability. In a number of regions of the brain, including the thalamus (155), prepositus hypoglossi (156), substantia nigra zona compacta (157), and hippocampus (158), 5-HT has been shown to enhance I_h through a cAMP-dependent mechanism. Results of a pharmacologic analysis with multiple nonselective drugs suggested that the increase in I_h induced by 5-HT in dorsal root ganglion cells is mediated by 5-HT_7 receptors (159). Recently, the first drug with selectivity toward the 5-HT_7 receptor was shown to block activation of adenylyl cyclase by 5-HT agonists in guinea pig hippocampus (33). The increasing availability of such selective drugs should greatly enhance the electrophysiologic evaluation of G_s-coupled 5-HT receptors.

INTRACELLULAR SIGNAL TRANSDUCTION PATHWAYS

Part of "2 - Serotonin "

Multiple Signaling Pathways: G Proteins and Second Messengers

Multiple intracellular signaling pathways constitute a common theme for G protein-coupled receptors, and the 5-HT receptor family is not unique. Inhibition of adenylate cyclase

was the first intracellular pathway to be described for $G_{i/o}$ protein-coupled receptors, such as the 5-HT_{1A} receptor. However, it is now clear that these receptors regulate multiple signaling pathways and effector molecules (Fig. 2.2), including activation of G protein-gated inwardly rectifying K^+ (GIRK) channels, inhibition of voltage-sensitive Ca^{2+} channels, activation of phospholipase Cß, and activation of mitogen-activated protein kinase (see ref. 18 for review). Although all these signals are sensitive to pertussis toxin, so that $G_{i/o}$ proteins are implicated, they may be mediated by distinct G protein complexes. For example, coupling to GIRK channels is mediated by ßγ subunits released from G_i (and possibly G_o) proteins, whereas inhibition of Ca^{2+} channels is mediated by ßγ subunits released from G_o proteins. The profile of signaling molecules varies from cell to cell, offering diverse signaling possibilities and contributing additional complexity. For example, 5-HT_{1A} receptor activation of phospholipase C is cell-type dependent; this signal is mediated by G protein ßγ subunits and thus requires the presence of a ßγ-regulated phospholipase C isoform. The ßγ subunits, generated by dissociation of the heterotrimeric G_i protein, also activate the type 2 isoform of adenylate cyclase. This activation is conditional, dependent on the coactivation by $G_{\alpha s}$ (i.e., $G_{\alpha i}$ potentiates the action of $G_{\alpha s}$). The obvious question is why the opposing actions of $G_{\alpha i}$ and $G_{\beta\gamma}$ do not offset each other. The answer may lie in the details. In addition to the large family of G proteins (21 α subunits, 5 ß subunits, and 11 γ subunits), the adenylate cyclase family comprises at least nine members, each regulated by distinct inputs. Most of these molecules are found in the central nervous system. The G protein that contributes ßγ activation of type 2 adenylate cyclase is $G_{\alpha i1}$ or $G_{\alpha i2}$ heterotrimer (160), whereas all three $G_{\alpha i}$ subunits ($\alpha_{i3} > \alpha_{i2} > \alpha_{i1}$) have the ability to inhibit adenylate cyclase types 5 and 6 (161). Thus, in cells in the brain in which $G_{\alpha i1}$ or $G_{\alpha i2}$ heterotrimer is coexpressed with type 2 adenylate cyclase, 5-HT_{1A}-receptor activation may potentiate G_s-mediated increases in cAMP. This type of interaction has been shown to occur in brain, in which G_i-linked receptors enhance ß-adrenergic responses (162); a similar interaction may take place in cells that coexpress a 5-HT_{1A} receptor family member with one of the 5-HT receptors (5-HT_4, 5-HT_6, or 5-HT_7) linked to activation of adenylate cyclase.

Although a 5-HT receptor-mediated increase in cAMP formation in superior colliculus was one of the earliest second messenger pathways defined in brain, the 5-HT_4 receptor was one of the last 5-HT receptors to be cloned (143). This receptor and the 5-HT_6 and 5-HT_7 receptors have in common the ability to activate adenylate cyclase via $G_{\alpha s}$ (Fig. 2.2). In transfected cells, the 5-HT_6 receptor couples to adenylate cyclase type 5, the typical $G_{\alpha s}$-sensitive isoform (163). In contrast, the 5-HT_7 receptor increases intracellular calcium, which activates calmodulin-stimulated adenylate cyclase type 1 or 8. A recent characterization of rat hippocampal homogenates suggests that both the 5-HT_4 and 5-HT_7 receptors are involved in cAMP formation (adenylate cyclase isoform unknown) in the hippocampus (164). Interestingly, the 5-HT_{1A} receptor produces a slight increase in cAMP formation, perhaps reflecting $G_{\beta\gamma}$ potentiation of G_s activation of adenylate cyclase type 2 mediated by the 5-HT_4 or 5-HT_7 receptor.

Receptors that couple to the G_q family members (G_q, G_{11}, G_{14}, and $G_{15/16}$) activate phospholipase C in a pertussis toxin-insensitive manner. Activation of phospholipase C was the first signal transduction mechanism identified for the 5-HT_2-receptor family and is essentially universal. This probably reflects the wide distribution of $G_{q/11}$ and the functional redundancy of these two G proteins. The 5-HT_{2C} receptor has been shown to couple in a pertussis toxin-sensitive manner to $G_{i/o}$ in *Xenopus* oocytes (e.g., see ref. 165) and in some transfected cell lines (166). In contrast, recent evidence suggests that phospholipase C activation in a native setting (choroid plexus) is mediated entirely by $G_{q/11}$ coupling (167). Coupling of the 5-HT_{2C} receptor to G_{13} with subsequent cytoskeletal rearrangement has been recently described in a transfected cell line (168). Extensive evidence suggests that 5-HT_{2A} and 5-HT_{2C} receptors couple to other effector pathways, in addition to phospholipase C (Fig. 2.4). Phospholipase A_2 is a well-characterized independent signal transduction pathway that leads to arachidonic acid, with subsequent prostaglandin and leukotriene formation (169). 5-HT_{2A}-receptor activation of mitogen-activated protein kinase has been extensively characterized in vascular smooth muscle and is also thought to be independent of phospholipase C activation (170 ,171). The 5-HT_{2A} receptor increases phospholipase D activity via a small G-protein ARF (adenosine diphosphate ribosylation factor) pathway, with protein kinase C activation being the principal consequence (172). 5-HT_{2A} receptors differentially regulate brain-derived neurotrophic factor in hippocampus and cortex and play a role in stress-induced down-regulation of brain-derived neurotrophic factor expression in hippocampus (173 ,174). In addition, a 5-HT_{2A} receptor-mediated increase in transforming growth factor-α_1, secondary to protein kinase C activation, has been described (175). The 5-HT_{2A} and 5-HT_{2C} receptors elicit region-specific increases in immediate early genes c-*fos* and *Arc* in rat brain (176), which are likely downstream of phospholipase C activation. Extensive, complex cross-talk between the 5-HT_{2A} and 5-HT_{2B} receptor and the 5-$HT_{1B/D}$ receptor has been demonstrated in immortalized serotoninergic cells, in which the 5-HT_{2B} receptor, via a phospholipase A_2 product, attenuates 5-$HT_{1B/D}$ receptor-mediated adenylate cyclase inhibition (177). Coactivation of the 5-HT_{2A} receptor blocks this interaction by an unknown mechanism. These examples of parallel, interacting, and converging intracellular signaling pathways illustrate the complexity of receptor signaling, even within a single receptor subclass.

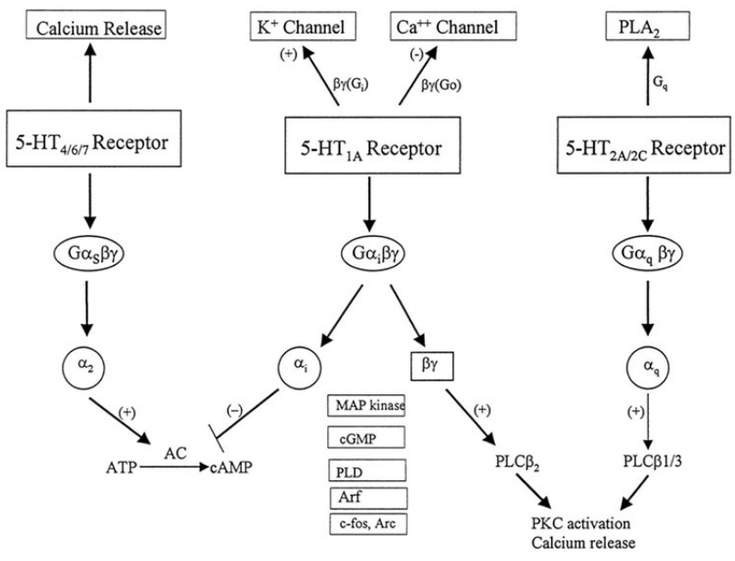

FIGURE 2.4. Examples of potential converging and interacting signaling pathways for 5-hydroxytryptamine-receptor subtypes. This figure illustrates only a few of the nearly unlimited possibilities, depending on the cell phenotype. Also listed are additional effectors activated by one or another of these receptors with pathways of activation that have not yet been determined.

Physiologic Correlates

In general, the electrophysiologic effects of 5-HT correspond well to the G-protein and second messenger coupling of the various receptor subtypes. The G_i/G_o-coupled 5-HT_1 receptors generally mediate inhibitory effects on neuronal firing through an opening of inwardly rectifying K^+ channels or a closing of voltage-gated Ca^{2+} channels. Inhibitions mediated by 5-HT_1 receptors have been observed in neurons located in diverse regions of the central nervous system, ranging from pyramidal cells of the cerebral cortex and hippocampus to serotoninergic neurons of the brainstem raphe nuclei. The $G_{q/11}$-coupled 5-HT_2 family of receptors generally mediates slow excitatory effects through a decrease in K^+ conductance or an increase in nonselective cation conductance. Slow excitatory effects mediated by 5-HT_2 receptors have been observed in a number of regions, including the spinal cord and brainstem (e.g., motoneurons), subcortical regions (e.g., nucleus accumbens), and cerebral cortex, where these receptors are most concentrated. The 5-HT_3 receptors, which are ligand-gated channels with structural homology to nicotinic cholinergic receptors, mediate fast excitatory effects of 5-HT. Specific examples are given below for 5-HT_1, 5-HT_2, and 5-HT_4 receptors, for which intracellular transduction pathways have been studied most intensively.

5-HT_1 Receptors

The opening of K^+ channels via 5-HT_{1A} receptors in dorsal raphe neurons is mediated by pertussis toxin-sensitive G proteins (178 ,179). The molecular mechanisms underlying the opening of K^+ channels are most likely common to all neurotransmitter receptors that couple through the G_i/G_o family of G proteins. As in the dorsal raphe, these receptors activate a pertussis toxin-sensitive G protein that couples to the opening of inwardly rectifying K^+ channels through a membrane-delimited pathway (74 ,180). It is widely accepted that the βγ rather than α subunits regulate the channels (181 ,182 and 183). The effector mechanism that ultimately mediates the inhibitory effect signaled by 5-HT_{1A} receptors is the inwardly rectifying K^+ channel. Interestingly, at least one of the potassium K^+ subunits identified in heart, GIRK-1, is expressed at high levels in hippocampus (184), which suggests that it might be involved in mediating the 5-HT_{1A} receptor-induced hyperpolarization in this region.

Consistent with this possibility, the K^+ current activated by 5-HT_{1A} receptors in the CA1 region does show the characteristic signature of this potassium channel family-namely, inward rectification (74).

5-HT_2 Receptors

The role of G proteins in mediating the 5-HT_2-induced slow inward current that results from K^+ channel closure has been evaluated in facial motoneurons by using the hydrolysis-resistant guanine nucleotide analogues GTPγS and GDPβS (185). The 5-HT-induced inward current becomes largely irreversible in the presence of intracellular GTPγS. Mediation by G proteins is also suggested by the fact that the inward current is reduced by intracellular GDPβS, which prevents G-protein activation. Although the identity of the G protein(s) mediating the electrophysiologic responses has not yet been determined directly, the 5-HT_2 family of receptors is known to be coupled to phospholipase C. Thus, a member of the $G_{q/11}$ family may be involved because the latter can directly activate phospholipase C (186).

5-HT_4 Receptors

Initially, it was shown that 5-HT suppresses a calcium-activated potassium current that is responsible for the generation of a slow after-hyperpolarization in hippocampus pyramidal cells of the CA1 region (see above). Subsequent studies have implicated 5-HT_4 receptors, acting via cAMP and protein kinase A, in mediating this action (187). A similar activation of a cAMP-dependent protein kinase has been implicated in the suppression of a voltage-activated K^+ current in cultured neurons from the superior colliculus (188). More recently, it has been shown that 5-HT_4 receptors reduce after-hyperpolarization in hippocampus pyramidal cells by inhibiting calcium-induced calcium release from intracellular stores (189).

Pharmacologic Significance

The pharmacologic significance of a single receptor regulating multiple signaling pathways is only just beginning to be defined. The most explicit studies of promiscuous coupling of receptors to multiple G-protein signaling pathways have involved transfection of a recombinant receptor into various cell models that do not normally express the receptor. Powerful genetic strategies involving antisense techniques, overexpression of signaling molecules, and expression of constitutively active and dominant negative mutants have exposed a multitude of fascinating possibilities for a single receptor to sculpt multiple signals depending on the properties of the cell. In addition, theoretical arguments (190) and experimental evidence (191 ,192 and 193) have appeared in support of the novel concept of agonist-directed trafficking of the intracellular signal. This model proposes that when a single receptor interacts with multiple signaling pathways, the pattern of intracellular signaling may differ depending on the agonist. Although the mechanism of agonist-specified signaling is not known, one possibility is that different agonists promote distinct receptor conformations, thereby exposing interfacial domains with altered protein–protein interaction properties. All these studies in artificial conditions tell us only what can occur, not what does occur *in vivo*. Techniques for studying the role of multiple signaling pathways in native preparations are needed to tease out the significance of the various signaling molecules in normal physiology and in pathologic states. Transgenic and knockout strategies have some utility; however, targeting signaling molecules will have a multitude of unwanted consequences because of their universal role in cell physiology. Another strategy was recently described that has significant potential for teasing out signaling pathways downstream of receptor activation (167). Synthetic blocking peptides targeting specific protein–protein interactions in a signaling pathway are rendered membrane-permeable by a novel conjugation reaction, so that the function of a particular signaling step in native systems can be defined.

BEHAVIORAL CORRELATES

Part of "2 - Serotonin "

5-HT Neuronal Activity and Behavioral State

In a variety of mammalian species, serotoninergic neurons of the raphe nuclei have been found to have a slow, tonic pattern of firing (approximately one to two spikes per second). The maintenance of rhythmic firing under a wide variety of conditions has suggested that serotoninergic neurons possess intrinsic tonic pacemaker mechanisms. Intracellular recordings from dorsal raphe neurons show that spikes arise from gradual depolarizing ramps (pacemaker potentials) rather than synaptic potentials. The pacemaker rhythm of serotoninergic neurons results from a complex interplay of intrinsic ionic currents (e.g., a voltage-dependent transient outward potassium current, a low-threshold inward calcium current, and a calcium-activated outward potassium current) (194). Also modulating the activity of serotoninergic neurons are various neurotransmitters, including norepinephrine and 5-HT itself. Norepinephrine, acting via α_1 adrenoceptors, accelerates pacemaker activity of serotoninergic neurons by closing potassium channels. Conversely, 5-HT itself, acting on 5-HT_{1A} autoreceptors, opposes excessive activity of serotoninergic neurons.

The highly regulated pacemaker activity of serotoninergic neurons suggests that the 5-HT system serves an important homeostatic function. Through its effects on neuronal excitability in diverse regions of the brain and spinal cord, the serotoninergic system is in a strategic position to coordinate complex sensory and motor patterns during different

behavioral states. Recordings from serotoninergic neurons in unanesthetized animals have shown that activity is highest during periods of waking arousal, reduced in quiet waking, reduced further in slow-wave sleep, and absent during REM (dream) sleep (195). It can be hypothesized that the function of the 5-HT system, by its coordinated fluctuations in activity, is to promote a given behavioral state. This concept is illustrated in the following scenario. When serotoninergic neurons are in a tonic firing mode, the following conditions would prevail: (a) Motoneurons would be in a relatively depolarized, excitable state (via 5-HT_2 receptors) and thus receptive to the initiation of movement; (b) neurons of the nucleus reticularis thalami would be in a depolarized, single-spike mode (via 5-HT_2 receptors) and thus conducive to thalamocortical sensory information transfer (105 ,155); (c) GABAergic neurons of the septohippocampal pathway would be activated (in part via 5-HT_{2A} receptors), potentially enhancing long-term potentiation by inhibiting GABAergic neurons of the hippocampus (106 ,196); (d) neurons of the laterodorsal tegmental nucleus would be hyperpolarized (via 5-HT_1 receptors) and therefore not able to generate the bursting activity of REM sleep (69 ,70 and 71). Conversely, with a reduction in serotoninergic activity during various stages of sleep, the above conditions would switch such that motoneurons would become less excitable, thalamocortical sensory information transfer would be diminished, hippocampal function would be reduced, and sleep spindles and pontogeniculo–occipital (PGO) waves would emerge.

Molecular Genetics (Including Genetic Polymorphisms)

5-HT-Receptor/Transporter Knockouts

New drugs are beginning to appear that show considerable selectivity for a particular serotonin receptor subtype; however, many are not yet readily available to the general scientific community. Genetically modified mice that fail to express a specific receptor provide a powerful means to complement pharmacologic tools for evaluating the behavioral consequences of a particular serotonin-receptor protein (see ref. 197 for review). The first 5-HT-receptor knockout mouse was described in 1994 (198), in which the 5-HT_{1B} receptor was eliminated by homologous recombination technique. These original studies showed markedly enhanced aggression in 5-HT_{1B}-receptor knockout mice. Since then, altered responses to drugs of abuse, including enhanced alcohol consumption (199) and sensitization to cocaine (200), in addition to impaired paired-pulse inhibition (201) and paradoxical sleep (202), have been shown to be prominent phenotypic traits. In 1995, a “knockout” mouse line expressing a mutant, nonfunctional 5-HT_{2C} receptor was described (203). Subsequently, enhanced seizure susceptibility (204), obesity and late-onset diabetes (205), and a specific deficit in dentate gyrus long-term potentiation (206) have been reported. Mouse lines have recently been generated that are null for other important 5-HT-related molecules; these including the 5-HT_{1A} receptor, which is associated with enhanced anxiety (207 ,208 and 209), the serotonin transporter, with enhanced cocaine sensitivity (210 ,211), and the 5-HT_{5A} receptor, with reduced sensitivity to LSD (212). Although monoamine oxidase A-null mice have general alterations in biogenic amine dynamics, evidence suggests that the enhanced levels of 5-HT found in these mice are associated with neurodevelopmental abnormalities (213 ,214). Innovative technologies such as inducible, conditional knockouts, which have the potential for temporally and spatially controlling gene manipulation, hold great promise for the future. This is illustrated in a recent study in which localized rescue of knocked-out genes was used to study the differential sorting of the 5-HT_{1A} and 5-HT_{1B} receptor in striatal neurons (215). In these transgenic mice, but not transfected neurons in culture, reproduction of the normal targeting of the 5-HT_{1B} receptor to axon terminals set the stage for mutagenesis studies of molecular determinants of receptor targeting to axon terminals *in vivo*.

Genetic Polymorphisms

Molecules involved in brain 5-HT pathways have been favorite targets for candidate gene studies, and the number of publications dealing with genetic variations in 5-HT systems has increased dramatically during the past few years. Recent population studies have probed for single nucleotide polymorphisms in synthetic enzymes, inactivation molecules, and receptors for 5-HT. The list of human diseases studied is extensive and includes obsessive-compulsive disorder, major depression, bipolar depression, schizophrenia, Alzheimer’s disease, eating disorders, anxiety, neuroticism, fibromyalgia, alcoholism, suicide, homicide, substance abuse, pathologic gambling, and responses to psychotherapeutic agents. Despite the abundance of publications, no definitive, reproducible links between allelic variants of 5-HT-related molecules have been found in human populations with behavioral disorders or brain diseases. More often than not, results are not reproducible from study to study, in large part because of the heterogeneous nature of psychiatric diseases, the absence of a specific diagnostic laboratory test, and the modest numbers of patients in many studies. The most extensively studied genetic polymorphism in a 5-HT-related molecule is the insertion/deletion polymorphism in the promoter region of the 5-HT transporter gene (216). These variable-length polymorphisms are biologically significant because *in vitro* studies have shown that the short form reduces the expression of transporter mRNA, with subsequently reduced uptake capacity (217). Although many studies suggest that the short form is associated with affective disorders, others have failed to replicate these findings (218).

Some commonly studied polymorphisms, such as the C103T variant in the 5-HT_{2A} receptor, are silent (i.e., do not change the genetic code), whereas other polymorphisms, such as the 5-HT_{2C} receptor Cys23Ser allele (219), produce mutant proteins with no apparent alterations in functional properties. The clinical importance of such a subtle genetic variant may require analysis of other related genes in tandem. Methods for detecting genetic polymorphisms are advancing rapidly and now allow simultaneous genotyping of several nucleotide polymorphisms; for example, a method was recently described to detect multiple single-nucleotide polymorphisms of 5-HT-related genes (220).

OVERVIEW AND CONCLUSIONS

Part of "2 - Serotonin "

This review has emphasized recent developments in molecular, transductional, and cellular aspects of the 5-HT system. Molecular topics that were hardly mentioned in the previous edition of this book include RNA editing, post-translational processing, genetic polymorphisms, and the use of selective 5-HT-receptor and transporter gene knockouts. Notable developments in cellular physiology since the previous edition include growing numbers of studies on the more recently cloned 5-HT-receptor subtypes (e.g., 5-HT_{3-7}) and refinements in the analysis of 5-HT_1- and 5-HT_2-receptor function. Examples of the latter include the following: (a) the recognition that the well-known 5-HT_{1A} autoreceptor feedback regulation of 5-HT neurons occurs within the context of a complex set of local and long-loop regulatory circuits; (b) the finding that 5-HT_2 receptors have a dramatic influence on cortical information processing, which has allowed new insights into the mechanism of action of hallucinogenic and atypical antipsychotic drugs. In turn, advances in molecular and cellular research on individual receptor subtypes have provided new experimental tools for the behavioral analysis of the 5-HT system (e.g., pharmacologic agents with more precisely defined actions and gene knockouts). The question remains of whether the diverse cellular and molecular actions of 5-HT mediated by the various receptor subtypes can be incorporated into a holistic scheme that can define the overall function of the 5-HT system. Selected examples have been given of how the 5-HT system can be seen as modulating, in a complex but coordinated fashion, a number of motor, sensory, and other systems to promote a given behavioral state or function. The recent molecular and cellular advances, by enabling a more comprehensive analysis of the elementary actions of individual 5-HT-receptor subtypes, have set the stage for a more precise analysis of overall function.

Opioid Peptides and Their Receptors: Overview and Function in Pain Modulation

Gavan P. McNally

Huda Akil

Gavan P. McNally and Huda Akil: Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan.

Few neurotransmitter systems have fascinated the general public as much as the endorphins, otherwise known as the *endogenous opioid peptides*. They have been termed the “heroin within” and endowed with the power to relieve pain and allow one to experience “runner’s high” or enjoy the taste of chocolate. Although these powers may or may not withstand close scientific scrutiny, there is little question that endogenous opioid systems play a critical role in modulating a large number of sensory, motivational, emotional, and cognitive functions. As inhibitory neuropeptide transmitters, they fine-tune neurotransmission across a wide range of neuronal circuits, setting thresholds or upper limits. In addition, they have served as prototypes for understanding many structural and functional features of peptidergic systems. Thus, the first neuronal receptor binding assays were conducted on opioid receptors. The first peptides to be discovered and identified after the hypothalamic neurohormones (oxytocin and vasopressin) were the endogenous opioids. The first mammalian cyclic DNA (cDNA) to be cloned was an opioid precursor (proopiomelanocortin), which also served as the prototype for genes that encode multiple active substances and process them in a tissue-specific and situation-specific manner.

Scientific studies of these systems during the last 30 years have uncovered a complex and subtle system that exhibits impressive diversity in terms of the number of endogenous ligands (more than a dozen) yet amazing convergence at the level of receptors (only three major types). Based on the results of these studies, the endogenous opioids have been implicated in circuits involved in the control of sensation, emotion, and affect, and a role has been ascribed to them in addiction—not only to opiate drugs, such as morphine and heroin, but also to other highly abused drugs, such as alcohol. This chapter cannot do justice to the rich body of information we possess on the endogenous opioid system. However, we attempt to give the reader key information about the biochemical nature of the system, along with an update on our understanding of the recently cloned receptors and their functions. Finally, we describe the regulation of pain responsiveness as one example of a function mediated by opioids to illustrate the complexity of their role.

OPIOID PEPTIDES AND THEIR RECEPTORS

Part of "3 - Opioid Peptides and Their Receptors: Overview and Function in Pain Modulation "

Genes and Proteins

The opioid peptide precursors are encoded by three genes: pre-proopiomelanocortin, pre-proenkephalin, and pre-prodynorphin. Each precursor is subject to complex post-translational modifications that result in the synthesis of multiple active peptides. These peptides share the common N-terminal sequence of Tyr-Gly-Gly-Phe-(Met or Leu), which has been termed the *opioid motif*; this is followed by various C-terminal extensions yielding peptides ranging from 5 to 31 residues in length. The major opioid peptide encoded by pre-proopiomelanocortin is ß-endorphin. In addition to ß-endorphin, the proopiomelanocortin precursor encodes the nonopioid peptides adrenocorticotropic hormone (ACTH), α-melanocyte-stimulating hormone (α-MSH), and ß-lipotropic pituitary hormone (ß-LPH). Pre-proenkephalin encodes multiple copies of Met-enkephalin, including two extended forms of Met-enkephalin (a heptapeptide and an octapeptide), and a single copy of Leu-enkephalin. Pre-prodynorphin encodes three opioid peptides of various lengths that all begin with the Leu-enkephalin sequence: dynorphin A, dynorphin B, and neoendorphin (Fig. 3.1).

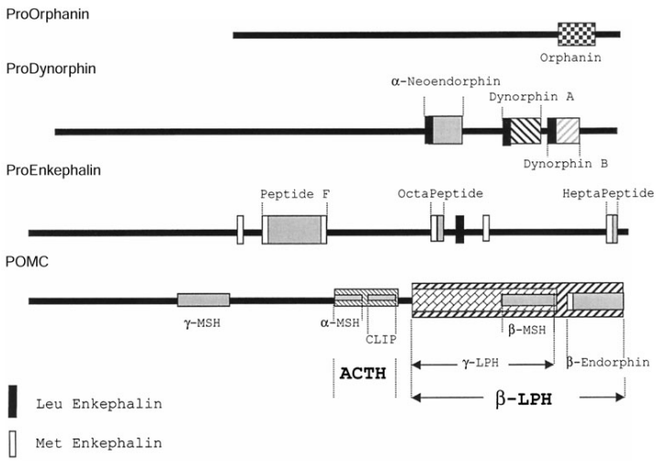

FIGURE 3.1. The opioid-peptide precursors. (From Akil H, Owens C, Gutstein H, et al. Endogenous opioids: overview and current issues. *Drug Alcohol Depend* 1998;51:127–140, with permission.)

The μ-opioid receptors (MORs), δ-opioid receptors (DORs), and κ-opioid receptors (KORs) have been isolated and cloned. The mouse DOR receptor was the first opioid receptor cloned (1 ,2), and this initial cloning facilitated the rapid cloning of MOR and KOR from various rodent species (3 ,4 ,5 ,6 ,7 ,8 and 9). The coding regions of human genes for these

receptors were subsequently isolated and chromosomally assigned (10 ,11 and 12). These studies confirmed earlier pharmacologic data indicating that all three receptors belong to the superfamily of seven transmembrane-spanning G protein-coupled receptors. A high degree of structural similarity exists between the three opioid receptors, which is highest in transmembrane domains 2, 3, and 7 and the first and second intracellular loops. The extracellular loops diverge considerably among the three receptor classes, and this divergence may explain differences in ligand selectivity among the opioid receptors (Fig. 3.2).

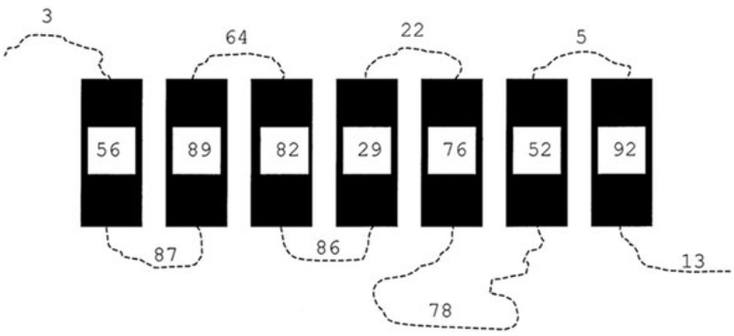

FIGURE 3.2. The opioid receptors display a high degree of structural similarity. Numbers refer to the percentages of amino acid identity between the cloned μ-, δ-, and κ-opioid receptors.

The relationship between the opioid peptides and their receptors is complex. This has been reviewed in detail elsewhere (13), and we will note only some salient features. It is clear from studies of the cloned receptors that high-affinity interactions between each of the precursor and receptor families are possible (14). For example, the proenkephalin peptide Tyr-Gly-Gly-Phe-Met-Arg-Phe binds with subnanomolar affinity to each of the cloned receptors. Similarly, although binding with greater affinity to the KOR, several of the shorter prodynorphin peptides bind with reasonable affinity to the MOR and DOR. By contrast, the binding of shorter proenkephalin peptides Leu-Enk (Tyr-Gly-Gly-Phe-Leu) and Met-Enk (Tyr-Gly-Gly-Phe-Met) readily discriminates between the three receptor families. Overall, the KOR displays the greatest selectivity across the endogenous ligands, with an approximately 1000-fold difference in affinity between the most preferred (Dyn A 1–7) and least preferred (Leu-Enk) ligand, whereas the MOR and DOR differ only across a 10-fold range (14). These differences in selectivity could indicate the existence of distinct mechanisms for ligand recognition, such that MOR and DOR recognize the common Tyr-Gly-Gly-Phe core, whereas the KOR discriminates among the larger variation in C-terminal regions. Indeed, elegant studies in which receptor chimeras were used have identified the critical domains in the three opioid receptors that help discriminate among the endogenous ligands (13).

Further attempts to detect novel opioid receptors resulted in the isolation of a clone with high structural homology to the opioid clones but little or no binding affinity for the opioid ligands (15 ,16). The structural similarity between this orphan (or opioid receptor-like) opioid receptor

(ORL-1) and the opioid receptors is highest in the transmembrane regions and cytoplasmic domain and lowest in the extracellular domains critical for ligand selectivity (see below). A ligand for the receptor was subsequently identified by two groups using chromatographic fractionation techniques coupled to ORL-1-mediated inhibition of adenylyl cyclase (17 ,18). This 17-amino acid peptide is identical in length and C-terminal sequence to dynorphin A. Curiously, the N-terminal is slightly modified (*Phe*-Gly-Gly-Phe) from the opioid core described above. It has been termed *orphanin-FQ* or *nociceptin* because of its putative ability to lower pain thresholds. The orphanin-FQ/nociceptin (OFQ/N) precursor has been cloned from mouse, rat, and human and has been localized on the short arm of human chromosome 8 (19 ,20). In addition to OFQ/N, evidence suggests that this precursor may encode other biologically active peptides. Immediately downstream to OFQ/N is a 17-amino acid peptide (OFQ-2) that also starts with phenylalanine and ends with glutamine but is otherwise distinct from OFQ/N, and a putative peptide upstream from OFQ/N may be liberated on post-translational processing (nocistatin). The OFQ/N system is a distinct neuropeptide system with a high degree of sequence identity to the opioids. This slight change in structure results in a profound alteration in function. Thus, OFQ/N is motivationally neutral, as indexed by conditioned place preference (21), and has pain modulators distinct from those of the opioid peptides (see below). However, changes in as few as four amino acids endow the ORL-1 receptor with the ability to recognize prodynorphin products while still retaining recognition of OFQ/N (22). These findings suggest that unique mechanisms may have evolved to ensure selectivity against the opioids versus selectivity for OFQ/N.

Issues and Complexities Revealed by Multiple Pharmacologic Forms, Splice Variants, and Receptor Dimers

The molecular cloning studies described above identified only a single gene encoding each of the opioid receptors. These findings contrast with results of pharmacologic studies indicating the existence of two subtypes of MOR and DOR and up to four subtypes of KOR, and suggesting additional receptor families (23 ,24 ,25 and 26). For example, the DOR_1 subtype is held to display greater affinity for the agonist DPDPE, whereas the DOR_2 subtype displays greater affinity for the agonist deltorphin 2 (26). These two subtypes may also make independent contributions to DOR antinociception (27). It is possible that further molecular cloning will identify unique genes encoding these receptor subtypes. However, several authors have suggested that if multiple opioid-receptor subtypes exist, they could be derived from a single gene, and multiple mechanisms might exist to achieve these distinct pharmacologic profiles. In this section, we consider two such pathways to opioid-receptor diversity: alternative splicing of receptor RNA and dimerization of receptor proteins.

Alternative splicing of receptor heteronuclear RNA (e.g., exon skipping and intron retention) has been accorded an important role in producing *in vivo* diversity within many members of the superfamily of seven transmembrane-spanning receptors (28). For example, alternative splicing of the coding region for the N-terminus of the corticotropin-releasing hormone CRH-2 receptor results in α, β, and γ variants, each with a unique tissue distribution (see ref. 28 for review). It follows that splice variants may exist within each of the three opioid-receptor families and that this alternative splicing of receptor transcripts may be critical for the diversity of opioid receptors. A technique used extensively to identify potential sites of alternative splicing is antisense oligodeoxynucleotide (ODN) mapping. The ability of antisense ODNs to target specific regions of cDNA allows systematic evaluation of the contribution of individual exons to the observed properties of a receptor. Antisense ODN targeting of exon 1 of the cloned rat and mouse MOR prevents morphine analgesia in these species (29 ,30 and 31). By contrast, administration of antisense ODNs targeting exon 2, which are inactive against morphine analgesia, prevents the analgesia produced by heroin, fentanyl, and the morphine metabolite morphine-6-β-glucuronide (M6G) (29 ,30 and 31). A similar disruption of M6G but not morphine analgesia is observed following administration of antisense ODNs targeting exon 3 (29). These results suggest that unique MOR mechanisms may mediate the analgesic effects of a variety of opiate alkaloids, and are consistent with the claim that these unique receptor mechanisms could be achieved via alternative splicing. The use of antisense ODNs has also resulted in the identification of potential sites for splice variation in the KOR and DOR (32). Central to the claim that these results reflect the existence of opioid-receptor splice variants is the *in vivo* isolation of such variants. A splice variant of the MOR has been identified that differs considerably within its C-terminus (33). As might be expected on the basis of the location of the alternative splicing, this variant exhibits a binding profile similar to that of the cloned MOR but does not readily undergo the desensitization frequently observed following agonist exposure. Thus, although it differs in composition, the existence of this splice variant cannot explain the results described above. However, just such a variant was detected in mice subjected to targeted disruption of exon 1 (34). Thus, transcripts of the MOR that contained exons 2 and 3 were identified in exon 1-deficient mice. Moreover, whereas morphine analgesia was abolished, heroin and M6G analgesia was retained in these mice (see below).

The physical interaction of receptors to form a unique structure (dimerization) has also been accorded an important role in regulating receptor function. For example, dimerization of $GABA_BR1$ (γ-aminobutyric acid subtype B receptor 1) and $GABA_BR2$ subunits is required for the formation

of a functional $GABA_B$ receptor (35). Both the cloned KORs and DORs have been found to exist *in vitro* as homodimers (36). However, the most important demonstrations of this kind are those showing dimerization between different functional opioid-receptor types. Jordan and Devi (37) coexpressed tagged KOR and DOR or tagged KOR and MOR and used coprecipitation techniques to show that KOR and DOR can exist as heterodimers *in vitro*. Dimerization of these receptors profoundly altered their properties. The affinity of the heterodimers for highly selective KOR and DOR agonists and antagonists was greatly reduced. Instead, the heterodimers showed greatest affinity for partially selective agonists such as bremazocine. This pharmacologic profile is similar to that claimed for the KOR_2-receptor subtype, which suggests that receptor dimerization may explain at least part of the discrepancy between the molecular and pharmacologic properties of opioid receptors. Heterodimerization thus offers a mechanism for the formation of novel receptor forms and a possible explanation for the *in vivo* diversity of opioid receptors. It will be of particular interest to identify those factors governing formation of opioid-receptor heterodimers, to determine if and how frequently opioid receptors dimerize *in vivo*, and to generate ligands that selectively recognize the dimerized form of the receptors.

Signal Transduction Mechanisms and Their Adaptation after Chronic Stimulation

The opioid receptors couple to G proteins inhibiting adenylyl cyclase, activating inwardly rectifying K^+ channels and decreasing the conductance of voltage-gated Ca^{2+} channels (38). These mechanisms of signal transduction have been verified by studies of the cloned receptors expressed in a variety of host cells (see ref. 39 for review). Studies with the cloned receptors have also indicated that the opioid receptors may couple to an array of other second messenger systems, which include activation of the mitogen-activated protein (MAP) kinases and the phospholipase C-mediated cascade leading to the formation of IP_3 (inositol-1,4,5-triphosphate) and diacyl glycerol (see ref. 40 for review). Prolonged exposure to opiates results in adaptations at multiple levels within these signaling cascades. The significance of these adaptations rests, at least in part, in the causal relationship that may exist between them and those seen at the organismic level following iterated exposure to opiates, such as tolerance, sensitization, and withdrawal. We consider two such adaptations: those related to cyclic adenosine monophosphate (cAMP) signaling and those related to receptor densensitization and internalization.

In an elegant series of experiments using rat locus ceruleus (LC) neurons, Nester and co-workers identified increased levels of protein $G_{i\alpha}$ and protein $G_{o\alpha}$, adenylyl cyclase, and protein kinase A following prolonged *in vivo* exposure to morphine (41 ,42 and 43). This up-regulation of the cAMP signaling pathway mediates the increased excitability of LC neurons observed after prolonged exposure to morphine and has been invoked as a causal mechanism for the increased or “rebound” activity of LC neurons frequently observed when the drug is withdrawn (44 ,45). It follows that these compensatory adaptations in cAMP signaling could be causal to the opiate withdrawal syndrome observed at the organismic level. Consistent with this possibility, infusions of a protein kinase A inhibitor into the LC reduced the severity of the antagonist-precipitated withdrawal syndrome in rats (46 ,47). Importantly, these adaptations are not unique to opioid receptors in the LC. Increased levels of adenylyl cyclase and protein kinase A in response to chronic morphine exposure have also been detected in the nucleus accumbens and amygdala (48). However, the changes in levels of G-protein subunits induced by this treatment are more complex, with decreased levels of $G_{i\alpha}$ detected in the nucleus accumbens and increased levels of $G_{i\alpha}$ and G_{io} in the amygdala. These widespread changes are also of significance at the organismic level. For example, infusions of a protein kinase A inhibitor into the periacqueductal gray (PAG) reduced the severity of the antagonist-precipitated withdrawal syndrome (47), and inactivation of G_i and G_o proteins in the nucleus accumbens reduced heroin self-administration in rats (49).

The desensitization, internalization, and sequestration of opioid receptors following their activation may also constitute mechanisms for adaptation in signaling relevant for understanding alterations in the physiologic impact of opiates. For example, phosphorylation of MOR and DOR via protein kinase C results in a transient desensitization that could subserve acute tolerance to opiates (50 ,51 ,52 and 53). Similarly, the internalization of opioid receptors via a classic endocytic pathway may have important implications for the physiologic impact of opiates. The internalization of opioid receptors occurs in a ligand-specific manner. For example, DAMGO and methadone promote internalization of the MOR, but morphine does not (53 ,54). This ligand-specific internalization is determined, at least in part, by differences in the conformational changes induced by the ligand and is independent of its ability to stimulate G-protein signaling (55). These findings may offer a novel explanation of differences in the efficacy and abuse potential of various opiates. However, at the time of this writing, few attempts have been made to study the relevance of these alterations in signaling to the adaptations seen in response to opiate exposure *in vivo*. Perhaps the most interesting are demonstrations that acute morphine analgesia is enhanced in mice in which the gene encoding ß-arrestin 2 was disrupted (56). Opioid-receptor internalization is mediated, at least in part, by the actions of the G protein-receptor kinases (GRKs). The GRKs selectively phosphorylate the agonist-bound receptor promoting interactions with ß-arrestins, which interfere with G-protein coupling and promote receptor internalization (56).

Demonstrations that acute morphine analgesia is enhanced in mice lacking ß-arrestin 2 are consistent with a role for the GRKs and arrestins in regulating alterations in responsivity to opiates *in vivo*. This finding is even more intriguing given the inability of morphine to support arrestin translocation and receptor internalization *in vitro* (57).

RECEPTOR AND LIGAND KNOCKOUTS: INSIGHTS, ISSUES, AND COMPLEXITIES

Part of "3 - Opioid Peptides and Their Receptors: Overview and Function in Pain Modulation "

Advances in understanding the molecular biology of the opioid family, coupled with developments in recombinant technology, have resulted in the generation of mice with targeted disruptions of various opioid genes. The study of these animals offers unique insights into opioid-receptor function. The initial study of these mice has allowed evaluation of the critical receptor subtypes mediating the effects of a variety of opiate alkaloids and the selective peptide agonists. In addition, they have identified potential interactions between receptor subtypes and suggested novel functions for opioids (e.g., reproductive function).

MOR Knockouts

The *MOR* gene has been disrupted via targeted deletion of exon 1 (34 ,58 ,59), exon 2 (34), or exons 2 and 3 (60). Disruption of exons 2 and 3 had no detectable effect on development, health, and fertility (60), whereas disruptions of exon 1 impaired sexual function in male mice, manifested by reduced mating activity, decreased sperm count and motility, and smaller litter size (59). Evidence was also found for alterations in hematopoiesis—specifically, increased proliferation of granulocyte-macrophages and erythroid and multipotential progenitor cells—in exon 1 knockout mice (59). Assessment of these mice has revealed that the MOR is absolutely necessary for the analgesic effects of morphine. Thus, systemic, intracerebal ventricular, and intrathecal administration of morphine failed to produce analgesia as assayed by tail flick, hot plate, and paw withdrawal tests across a wide dose range. For example, doses of morphine as high as 56 mg/kg failed to produce analgesia in exon 1 knockout mice (58), and the median effective dose (ED_{50}) for morphine analgesia in exon 2 knockout mice exceeded 100 mg/kg (a potency shift of two orders of magnitude) (34). The MOR is also required for the rewarding (indexed by levels of conditioned place preference) and immunosuppressive effects of injections of morphine, and for the physical dependence induced by such injections (indexed by somatic signs of morphine withdrawal) (60 ,61). By contrast, the analgesic efficacy of heroin and the major morphine metabolite M6G remains intact in exon 1-deficient mice (34). This result is consistent with the antisense mapping studies described above. Although successfully identifying the critical receptor substrate for the therapeutic and recreational uses of morphine, these experiments have failed to address the involvement of MOR in basal pain sensitivity convincingly. For example, considerable controversy has surrounded the ability of an injection of naloxone to produce hyperalgesia in otherwise intact animals, and this has not been resolved by studies of the MOR knockout mice. Sora et al. (58) reported that MOR knockout mice displayed increased sensitivity to noxious stimulation, but this hyperalgesia was not readily detected by others (60). This difference could be related to differences in the impact of specific exon deletion, as in measurements of reproductive function. Alternatively, a stress-induced analgesia, such as that provoked by exposure to novel handling procedures or contextual cues, may have decreased basal pain sensitivity among control animals.

In addition to providing insight into the mechanisms of actions of the opiate alkaloids, studies of MOR knockout mice have allowed systematic investigation into the potential interactions between the three opioid-receptor families *in vivo*. Studies of DOR function in MOR knockout mice have failed to detect compensatory changes in either the number or localization of DORs (62). Similarly, no significant alteration in DOR signal transduction, as indexed by G-protein and adenylyl cyclase activity, has been observed (63). By contrast, the analgesic efficacy of DOR agonists in these mice may be slightly reduced. Specifically, a reduction in DPDPE analgesia appears most robust, whereas the analgesic effects deltorphin 2 have been found intact or slightly attenuated (63 ,64). This evidence for MOR-mediated effects of DOR agonists is intriguing and consistent, at least in part, with the possibility of interactions between MOR and DOR *in vivo*. However, it is worth bearing in mind that these studies uniformly indicate the preservation of a large component of DOR function in MOR knockout mice. Studies of KOR function in MOR knockout mice have also failed to detect significant alterations in receptor number, distribution, and signal transduction (62 ,63). However, no evidence has been found of a reduction in the analgesic efficacy of KOR agonists, unlike that of DOR agonists, in MOR knockout mice (64).

DOR Knockouts

The *DOR* gene has been disrupted in mice via targeted disruption of exon 2 (65). This deletion had no detectable effects on the health or reproductive function of the mice. Deletion of exon 2 completely abolished [^{3}H]DPDPE and [^{3}H]deltorphin 2 binding in the brain, which indicates that the putative subtypes of the DOR are encoded by the same gene product. Studies of pain sensitivity in these mice indicate that basal pain sensitivity is unaffected by disruption of the *DOR* gene. Spinal DPDPE and deltorphin 2 analgesia is significantly reduced in the DOR knockout mice. By contrast, the analgesic efficacy of intracerebral ventricular infusions of DPDPE and deltorphin 2 remains intact. The

retention of supraspinal but not spinal DOR analgesia in DOR knockout mice is surprising. This could be evidence for a novel receptor mechanism because this residual supraspinal analgesia is reduced by naltrexone but not by selective MOR or KOR antagonists. Disruption of the *DOR* gene has no significant effect on the levels and distribution of either MOR or KOR, nor is any effect noted on the levels and distribution of proenkephalin, prodynorphin, and proopiomelanocortin. Similarly, no significant alterations occur in the analgesic effectiveness of morphine, M6G, and the κ agonist U50,488H.

KOR Knockouts

The *KOR* gene has been disrupted in mice via targeted deletion of the initiation codon and N-terminal coding region (66). This disruption had no detectable effects on the health of the mice but increased litter size. The deletion completely abolished [^{3}H]CI-977 binding in the brain. Studies of pain sensitivity revealed that KOR knockout mice are hyperalgesic when assayed by the acetic acid writhing test but not the formalin, tail pressure, tail flick, and hot plate tests. This finding is consistent with the important role accorded KOR in the regulation of visceral nociception. Systemic injection of the KOR agonist U50,488H failed to produce an analgesic response as assayed by the tail flick and hot plate tests. Similarly, the locomotor depressive effects and aversive motivational effects of the injection (indexed by conditioned place aversion learning) were abolished. These results indicate that the analgesic and motivational effects of the prototypical KOR agonist are mediated via actions at the receptor(s) encoded by the *KOR* gene and are consistent with results of antisense mapping studies indicating that ODNs directed against each of the three exons of the *KOR* gene disrupt the analgesic efficacy of U50,488H. The effects of disruption of the *KOR* gene on the activity of dynorphin B and α-neodynorphin, whose selectivity in antisense mapping studies differs considerably from that of U50,488H (67), remains unclear. Disruption of the *KOR* gene had no significant effect on the levels and distribution of either MOR or DOR (68), nor was any effect noted on the level and distribution of proenkephalin, prodynorphin, and proopiomelanocortin (67). Interestingly, the analgesic efficacy of morphine was retained, but the aversive motivational effects of the dependence induced by iterated exposures to morphine were reduced. This finding supports demonstrations of a role for dynorphin and the KOR in opiate withdrawal (69).

Pre-proenkephalin Knockouts

Mice with targeted deletions of exon 3 of the pre-proenkephalin gene have been created (70). Although this disruption had little effect on levels of prodynorphin- and proopiomelanocortin-derived peptides, a large up-regulation of MOR binding in the striatum was observed (71). Neither fertility nor gross abnormalities developed in the enkephalin knockout animals. These mice displayed increased anxiety and fear-related behaviors (indexed by freezing, hiding, and performance in an open field and elevated O maze). These results suggest that enkephalins are important in the negative feedback control of anxiety and aversive motivation. Enkephalin knockout mice appeared hyperalgesic when tested with the hot plate, but not the tail flick, test. However, because the procedure for this test involved repeated exposure to the hot plate apparatus, it is again unclear whether the experimental mice were hyperalgesic or whether the control mice were hypoalgesic as a consequence of repeated testing in the hot plate apparatus. The enkephalin knockout mice also showed altered sensitivity when assayed by the formalin test. Specifically, a decrease in recuperative behaviors (lifting and licking the injected paw) could be mimicked by injection of naloxone (10 mg/kg) in wild-type control mice, which suggests that the proenkephalin-derived peptides may regulate responding in the formalin test. This result is also difficult to interpret because naloxone does not modulate formalin pain in rats under resting conditions. In short, across three measures of pain sensitivity, three different influences of the deletion of the pre-proenkephalin gene were detected: no effect in the tail flick test, increased sensitivity (hyperalgesia) in the hot plate test, and decreased sensitivity (indexed by recuperative responding) in the formalin test. Although dissociations between these measures are not uncommon, the pattern of responding across the three measures is difficult to interpret and underscores the complexity of pain modulation by aversive motivational states such as anxiety and fear. Indeed, these mice displayed intact analgesic responses to stressors (swim stress) that produce naloxone-reversible analgesia. This result is consistent with the binding studies reviewed above, indicating the potential for high-affinity interactions between peptides derived from the proopiomelanocortin and prodynorphin precursors and each receptor class.

Orphanin-FQ-Receptor and Ligand Knockouts

The gene encoding the ORL-1 receptor has been disrupted via targeted deletion of exon 1 (72), and the OFQ/N precursor has been disrupted via targeted deletion of exon 2 (73). Studies of these mice have proved particularly interesting. First, they have confirmed that the role of OFQ/N in pain modulation is quite distinct from that of the other opioids. Thus, disruption of the ORL-1 receptor had no effect on basal pain sensitivity in the tail flick test but prevented the development of tolerance to morphine analgesia (72), whereas disruption of the OFQ/N precursor consistently decreased pain sensitivity on the same measure. This discrepancy between the effects of receptor and precursor disruption could be interpreted to mean that post-translational

processing of the OFQ/N precursor may result in the presence of multiple active peptides that interact with unique receptors to produce different physiologic effects (see above). However, these studies uniformly indicate that if OFQ/N and the ORL-1 receptor have any role in pain modulation, it is facilitative (or pronociceptive) rather than inhibitory (or antinociceptive). Second, these studies have confirmed that OFQ/N serves an important role in the regulation of emotional responsiveness. Specifically, OFQ/N knockout mice display increased anxiety (indexed by performance in the elevated plus maze, open field, and light–dark box) and enhanced basal and post-stress glucocorticoid levels. Interestingly, these findings contrast with the effects of administration in rats. Devine et al. (74) have shown that infusions of OFQ/N increase plasma ACTH and glucocorticoid levels in the unstressed animal and prolong the stress response in the stressed rat. The reasons for this discrepancy are unclear. Finally, these studies have suggested an important role for the OFQ/N system in learning and memory processes. Thus, OFQ/N-receptor knockout mice show enhanced hippocampal long-term potentiation and a moderately enhanced performance in tests of spatial learning (75). However, the OFQ/N-precursor knockout mice do not show enhanced performance in the same test of spatial learning (73). Regardless of the reason for the discrepancy between the OFQ/N and ORL-1 knockout mice, the interpretation of these effects on learning and memory is difficult. For example, the spatial task used in these experiments can be mediated by several learning strategies. Clearly, a more sophisticated characterization of the nature of the potential learning and memory deficits in these mice is required, and the results described above provide an important starting point.

Summary

Studies of mice with targeted disruptions of opioid-receptor and peptide genes have enabled important insights into the function of the opioid family. Chiefly, they have made possible the identification of the critical receptor substrates for a variety of opiate alkaloids and opioid peptides. These studies have also provided insights into the functional diversity of each receptor class. For example, it is clear that the two subtypes of DOR identified in pharmacologic studies are encoded by the single cloned *DOR* gene. Furthermore, the retention of MOR- and KOR-independent supraspinal DPDPE analgesia in these mice raises the possibility that further, unidentified opioid-receptor variants may exist. A similar possibility is raised by the retention of heroin and M6G analgesia in mice with targeted deletions of the MOR. These results suggest that complex post-transcriptional modifications play an important role in producing the *in vivo* diversity of opioid-receptor pharmacology. At the time of this writing, only OFQ/N-receptor and OFQ/N-precursor knockout mice have been studied in more complex behavioral tasks. However, the widespread distribution of opioid peptides and their receptors in the central nervous system, in addition to their critical role in controlling an animal's interaction with its environment, ensure that it is only a matter of time before mice are studied with more behaviorally sophisticated and ecologically relevant measures of attention, learning, memory, and motivation. Finally, it is worth noting that this first generation of genetic manipulations are neither tissue-specific nor conditional. Compensatory adaptation within the opioid-peptide and receptor family following the targeted disruption of one of its members appears to be minimal. Indeed, in the studies reviewed above, the only evidence for such compensation has been obtained for measures of receptor binding in pre-proenkephalin knockout animals. Nonetheless, the possibility of widespread adaptation in nonopioid systems cannot be discounted. Thus, the application of tissue-specific and inducible knockout techniques to the opioid receptors and their peptides remains an exciting area of research.

AN EXAMPLE OF OPIOID FUNCTION AND ITS CLINICAL IMPLICATIONS: OPIOIDS AND PAIN CONTROL

Part of "3 - Opioid Peptides and Their Receptors: Overview and Function in Pain Modulation "

Understanding the role of opioids in pain modulation is not only of clinical importance but also of historical interest. Demonstrations that microinjections of morphine into various brainstem regions are analgesic (76), and that injections of naloxone partially reverse the analgesia produced by focal electric stimulation in these regions (77 ,78), provided the first physiologic evidence for an endogenous opioid system. In this section, we briefly review the neural circuits subserving opioid analgesia and discuss recent findings relevant to these actions. Many excellent reviews of this topic are available (79 ,80).

Functional Anatomy of Opioids in Descending Pain Control Circuits

It is well established that the analgesic effects of opioids arise from their ability to inhibit directly the ascending transmission of nociceptive information from the spinal cord dorsal horn, and from their ability to activate pain control circuits that descend from the midbrain, via the rostral ventromedial medulla (RVM), to the spinal cord dorsal horn. Opioid peptides and their receptors are distributed throughout these descending pain control circuits (81 ,82). MOR messenger RNA (mRNA) or binding has been detected throughout the PAG, pontine reticular formation, median raphe, nucleus raphe magnus and adjacent gigantocellular reticular nucleus in the RVM, and spinal cord. Inspection of the discrepancies between levels of receptor binding and mRNA expression provide important insights into the mechanisms of MOR analgesia. For example, the

presence of significant MOR binding in the superficial dorsal horn but scarcity of mRNA expression suggests that the majority of these spinal MOR binding sites are located presynaptically on the terminals of primary afferent nociceptors. This conclusion is consistent with the high levels of MOR mRNA expression in dorsal root ganglia (DRG). A similar mismatch between MOR binding and mRNA expression can be found in the dorsolateral PAG (strong binding vs. sparse mRNA). DOR mRNA and binding have been detected in the ventral and ventrolateral quadrants of the PAG, pontine reticular formation, and gigantocellular reticular nucleus, but only at low levels in the median raphe and nucleus raphe magnus. Like MOR binding sites, DOR binding sites are present in significant numbers in the dorsal horn without detectable mRNA expression, which suggests an important role for presynaptic actions of DOR in spinal analgesia. Finally, KOR mRNA and binding are widely distributed throughout the PAG, pontine reticular formation, median raphe, and nucleus raphe magnus and adjacent gigantocellular reticular nucleus. Again, significant levels of KOR binding but sparse levels of mRNA have been found in the dorsal horn. Although all three receptor mRNAs are found in the DRG, they are localized on different classes of primary afferent nociceptors. Thus, MOR mRNA has been detected in medium- and large-diameter DRG cells, DOR mRNA in large-diameter cells, and KOR mRNA in small- and medium-diameter cells. This differential localization could be linked to functional differences in pain modulation.

The distribution of opioid receptors in descending pain control circuits indicates substantial overlap between MOR and KOR. The largest differentiation between these two receptors and DOR is in the PAG, median raphe, and nucleus raphe magnus (82). A similar differentiation of MOR and KOR from DOR is observed in the thalamus, which suggests that interactions between KOR and MOR may be important for modulating nociceptive transmission from the dorsal horn as well as in higher nociceptive centres. The actions of MOR agonists are invariably antinociceptive, whereas those of KOR agonists can be either antinociceptive or pronociceptive. Consistent with the anatomic overlap between the MOR and KOR, the pronociceptive actions of the KOR appear to be mediated by a functional antagonism of the actions of the MOR. The MOR produces antinociception within descending pain control circuits, at least in part, via the removal of GABAergic inhibition of RVM projecting neurons in the PAG and spinally projecting neurons in the RVM (79). Pan et al. (83) have presented evidence from both *in vitro* slice preparations and *in vivo* pain responding that the pain modulatory effects of the KOR in the brainstem oppose those of the MOR. Thus, activation of the KOR hyperpolarized the same RVM neurons hypopolarized by the MOR, and microinjections of a κ agonist into the RVM antagonized the analgesia produced by microinjections of DAMGO into this region. These data are among the strongest that opioids can have pronociceptive in addition to antinociceptive effects and could explain behavioral evidence for a reduction in hyperalgesia following injections of naloxone.

As described above, significant opioid-receptor binding, little detectable expression of receptor mRNA in the spinal cord dorsal horn, but large levels of this mRNA in DRG have been observed. The anatomy of spinal opioid receptors suggests that their actions relevant to analgesia at this level are predominantly presynaptic. At least one presynaptic mechanism viewed as having clinical significance is the inhibition of spinal tachykinin signaling. Indeed, it is well established that opioids decrease the noxious stimulant-evoked release of tachykinins from primary afferent nociceptors (84 ,85). Recently, the significance of this action has been questioned. Measuring the internalization of neurokinin receptors following noxious stimulation, Trafton et al. (86) demonstrated that at least 80% of tachykinin signaling remains intact after the intrathecal administration of large doses of opioids. These results indicate that although opioid administration may reduce tachykinin release from primary afferent nociceptors, the reduction has little functional impact on the actions of tachykinins on postsynaptic nociceptive neurons. The obvious implication of this finding is that either tachykinin signaling is not central to nociception and/or opioid antinociception at the spinal level, or that, contrary to the conclusions suggested by anatomic studies, the presynaptic actions of opioids are of little analgesic significance.

Just as important insights have been made into brainstem and spinal mechanisms for opioid analgesia, so too have insights been made into forebrain mechanisms for such analgesia. It is well established that the actions of opioids in bulbospinal pathways are critical to their analgesic efficacy. It has been less clear what role should be accorded forebrain actions and whether these actions are independent of those in bulbospinal pathways. There can be little doubt that opioid actions in the forebrain contribute to analgesia because decerebration prevents analgesia when rats are tested for pain sensitivity with the formalin test (87), and microinjections of opioids into the several forebrain regions are analgesic in this test (88). However, because these manipulations frequently leave intact the analgesic efficacy of opioids in measures of phasic nociception, such as the tail flick test, a distinction has been drawn between forebrain-dependent mechanisms for morphine analgesia in the presence of tissue injury and bulbospinal mechanisms for this analgesia in the absence of tissue injury. In an important series of experiments, Manning and Mayer (89 ,90) have shown that this distinction is not absolute and that opioid actions in the forebrain are also important to analgesia, both in measures of tissue damage and in acute, phasic nociception. Thus, systemic morphine analgesia in both the tail flick and formalin tests was disrupted by either lesioning or reversible inactivation of the central nucleus of the amygdala. The involvement

of the amygdala in morphine analgesia is particularly interesting because this structure has been implicated in the environmental activation of pain control circuits, and it projects extensively to those brainstem regions involved in descending pain control (80).

Role of OFQ/N and ORL-1 in Pain Modulation

OFQ/N mRNA and peptide are present throughout the descending pain control circuits described above. For example, OFQ/N-containing neurons are present in the PAG, the median raphe, throughout the RVM, and the superficial dorsal horn (91) This distribution overlaps with that of the opioid peptides, but the degree of colocalization remains unclear. ORL-1 binding and mRNA can be detected in the PAG, median raphe, and RVM (92). In the spinal cord, ORL-1 mRNA expression is stronger in the ventral than in the dorsal horn, but levels of binding are higher in the dorsal horn. High levels of ORL-1 mRNA are also found in the DRG. Despite this clear anatomic evidence for a role of the orphanin system in pain modulation, its function remains unclear. As reviewed above, targeted disruption of the ORL-1 receptor had little effect on basal pain sensitivity according to several measures, whereas targeted disruption of the OFQ/N precursor consistently elevated pain sensitivity in the tail flick test, findings that suggest an important role for OFQ/N in regulating basal pain sensitivity. Intrathecal injections of OFQ/N have been reported to be analgesic as assayed by the tail flick and formalin tests (93 ,94). Similarly, these injections attenuated the hyperalgesia produced by constriction injury of sciatic nerve (95). However, the profound motor effects of these injections render interpretation of changes in response latency difficult. The effects of supraspinally administered OFQ/N are also difficult to interpret; hyperalgesia has been detected across a variety of measures, but failures to detect hyperalgesia have also been reported.

Three interesting results may explain at least part of the variations noted in the effects of the orphanin opioid system in modulating pain. First, Rossi et al. (95 ,96) reported a biphasic effect of OFQ/N administration, characterized initially by hyperalgesia and later by analgesia. Second, Grisel et al. (97) reported that OFQ/N does not affect basal pain sensitivity but does reduce analgesia according to the site of administration. Finally, Heinricher et al. (98) reported that OFQ/N exerts an inhibitory effect on several classes of RVM neurons whose activity has been implicated in producing analgesia and hyperalgesia at the spinal level. These results suggest that the effects on pain modulation observed following administration of OFQ/N in the intact animal are influenced by route, time since administration, the presence of stressors that provoke analgesia (e.g., novel handling or test procedures), and the current balance of activity in pain modulatory neurons in the RVM. The development of specific ORL-1-receptor antagonists will undoubtedly enable a rapid clarification of the role of the orphanin opioid system in pain modulation.

CONCLUSIONS AND FUTURE DIRECTIONS

Part of "3 - Opioid Peptides and Their Receptors: Overview and Function in Pain Modulation "

The interplay between the orphanin system and the endogenous opioids represents a prime example of evolutionary changes that have led to subtle diversity in structure and significant alteration in function. Indeed, this entire peptidergic family exemplifies the way in which an increase in genetic diversity can lead from simple on/off signaling to a complex pattern of signaling wherein multiple, coordinately secreted peptides interact with multiple receptors to effect a complex regulation of functions as diverse as pain responsiveness, stress regulation, control of feeding, and modulation of development, learning, and memory. Many questions remain to be answered in the context of the opioid family. At the most basic level is the question of whether additional members of the family exist. The completion of sequencing of the human genome and the rat or mouse genome should help answer this question. We should be able to lay to rest the questions of whether additional opioid-receptor types or subtypes exist, and whether other endogenous ligands that are uniquely selective for a particular receptor type exist. In particular, endomorphin 1 (Tyr-Pro-Trp-Phe) and endomorphin 2 (Tyr-Pro-Phe-Phe) have been proposed by Zadina et al. (99) to be endogenous, highly selective μ ligands. However, their precursor remains uncloned, although the genome project should help clarify the matter. Further, as we obtain full sequences of the genomes of other species, we should be able to track the fascinating evolutionary history of this peptide family.

At functional levels, many questions remain, especially concerning the exact role of endogenous opioids in addictive and emotional behavior and psychiatric disorders. Because these disorders are typically of a complex genetic nature, involving the interaction of multiple genes with one another and with the environment, it is likely that the endogenous opioid genes are involved in vulnerability to certain brain-related illnesses. Here again, progress in genomics and complex genetics should open new avenues for investigating the likely role of the opioid molecules in a range of psychiatric disorders.

Norepinephrine

Gary Aston-Jones

G. Aston-Jones: Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.

This chapter reviews findings from basic research concerning brain norepinephrine (NE) systems. The focus is on work that is relevant to the mechanisms of psychiatric disorders, or the actions of drugs used to treat such disorders. The locus ceruleus (LC) system receives most of the attention here, but recent findings concerning the role of the A2/A1 medullary cell groups in drug abuse are also reviewed. Emphasis is placed on studies published since the last version of this volume. Space limitations prevent a thorough review of the involvement of any brain NE system in mental function and dysfunction, so that only a fraction of the relevant research can be covered. Apologies are offered to those whose work could not be included.

MOLECULAR–GENETIC STUDIES

Part of "4 - Norepinephrine "

Previous studies have revealed molecular properties of NE neurons and their effector systems that have extended our understanding of the function and pharmacology of this system. For example, Duman et al. (1) have shown that acute opiate administration decreases cyclic adenosine monophosphate (cAMP) and adenylate cyclase activity in LC neurons, whereas long-term use of opiates or opiate withdrawal results in elevated activity in this second messenger mechanism. Continuing studies in this vein have resulted in a more complete picture of molecular events and properties within LC neurons that help regulate their discharge activity. Thus, the adenylate cyclase/cAMP system is up-regulated with chronic stress but down-regulated with long-term antidepressant treatment (2). Additional studies indicate that impulse activity of LC neurons may be regulated in part by a nonspecific cation current that is activated by this second messenger system (2). These findings suggest a molecular mechanism whereby the overall excitability of LC neurons may be modulated in accordance with long-term environmental or pharmacologic conditions and may be involved in the mechanisms of action of antidepressant and other psychopharmacologic agents.

Recent genetic studies have also revealed important aspects of NE systems relevant to their role in psychopharmacology. Xu et al. (3) studied the brains of mice with a knockout of the NE transporter (3). These mice exhibited characteristics of animals treated with antidepressants (i.e., prolonged clearance of NE and elevated extracellular levels of this catecholamine). In a test for antidepressant drugs, the NE transporter knockouts behaved like antidepressant-treated wild-type mice, being hyperresponsive to locomotor stimulation by cocaine or amphetamine. Importantly, these animals also exhibited dopamine D2/D3-receptor supersensitivity. Thus, NE transporter function can alter midbrain dopaminergic systems, an effect that may be an important mechanism of action of antidepressants and psychostimulants.

NEUROANATOMY

Part of "4 - Norepinephrine "

Chemoanatomy of the LC

The neuroanatomy of the major brain NE systems has been recently reviewed in detail (4), and only the most salient features are described here. In the rat and primate (but not cat, guinea pig, and most other species), virtually all neurons located within the compact LC nucleus are noradrenergic. It is notable that LC neurons also often contain other possible neurotransmitters (e.g., neuropeptides), and subsets of rat NE neurons can be distinguished by neurotransmitter molecules that they co-localize (see ref. 4 for review). Additional work is needed to determine the functional significance of co-localization of other transmitter molecules within LC neurons.

Peri-LC Dendritic Shell

A prominent feature of LC neurons in all species is that their dendrites typically extend hundreds of micra from the parent cell body. Our recent studies have revealed that these dendrites in rat are organized into two prominent collections that project outside the nuclear core in the caudodorsal

and rostroventromedial directions (5). This work has also demonstrated that these dendrites receive numerous synaptic contacts, indicating that the extranuclear peri-LC processes serve as a substantial receptive surface for LC neurons.

Afferents to the LC

Prior studies indicated that prominent afferents to the LC include the nucleus paragigantocellularis (PGi) and the ventromedial aspect of the prepositus hypoglossi (PrH) in the rostroventrolateral and dorsomedial medulla, respectively (6 ,7). These nuclei provide strong excitatory and inhibitory influences on LC neurons, respectively, and are also sources of several neurotransmitter inputs to the LC nucleus (see below) (4 ,8). However, as previously stated, LC dendrites that extend outside the LC nucleus proper provide a prominent receptive surface for inputs to LC neurons (5). Studies of inputs to these peri-LC dendritic zones indicate several additional possible strong inputs to LC neurons, including the periaqueductal gray, medial preoptic nucleus, prefrontal cortex, and hypothalamus (4 ,8). Recent work has confirmed some of the proposed inputs, showing direct contacts onto peri-LC dendrites from amygdala (9) and nucleus tractus solitarius (NTS) (10). Additional work is needed to test some of the other possible inputs to LC distal dendrites. These dendritic inputs are important in revealing additional functional circuitry linked to the LC system (e.g., limbic, autonomic, and cognitive functions).

A host of immunohistochemically defined fibers have been found in LC afferents (see ref. 4 for review). The sources of some of these inputs have been determined. Strong glutamate (11) and epinephrine inputs (12) originate in the PGi, γ-aminobutyric acid (GABA) inputs arise from the PrH (13), and strong enkephalin projections to the LC originate in both the PGi and the PrH (14). Histamine fibers innervate the LC, presumably originating in the tuberomammillary nucleus (15). A particularly dense innervation by serotonin fibers also exists; the origin of this projection has not been determined. Ultrastructural analyses have shown that several of these inputs directly innervate LC neurons (16 ,17 ,18 ,19 and 20).

Most recently, the novel neuropeptide hypocretin (synonymous with orexin) has been shown to innervate the LC densely in rats and monkeys (21 ,22 ,23 and 24) (Fig. 4.1). This projection presumably originates in the hypothalamus (the sole location of hypocretin-producing cells) and is mirrored by dense projections to other nuclei associated with sleep and arousal functions (e.g., the raphe serotonin neurons, tuberomammillary histamine cells, and cholinergic neurons of the brainstem). Initial studies of this peptide suggested a role in feeding (24 ,25). However, more recent work has stimulated considerable interest in this neurotransmitter by closely linking its function to sleep regulation. Specifically, mutations of the gene that makes a hypocretin receptor (26), or of another gene that makes hypocretin itself (27), produced narcolepsy symptoms in animals. This finding supports the long-standing belief that the LC system is important in sleep–waking processes (28) and indicates that sleep disorders may involve anomalies in this hypocretin projection to the LC. These findings also offer a novel target for pharmacologic manipulation of the LC and other systems involved in sleep function.

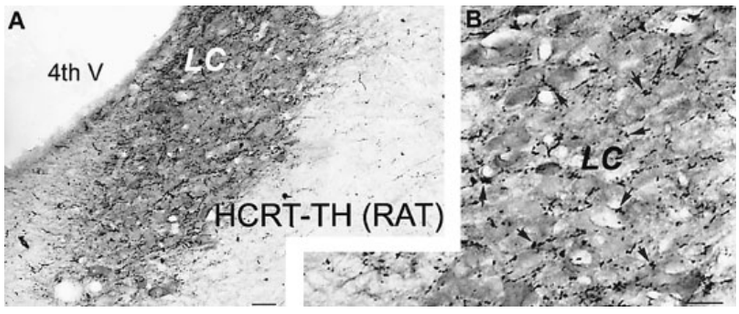

FIGURE 4.1. Photomicrograph showing dense innervation of the locus ceruleus (LC) by hypocretin/orexin Fibers. Low-power **(A)** and high-power **(B)** photographs of frontal sections through the rat LC after staining with antibodies for hypocretin and tyrosine hydroxylase (TH). Note the proximity of numerous black, punctate hypocretin fibers and brown TH-positive NE somata and dendrites. (From Horvath TL, Peyron C, Sabrina D, et al. Strong hypocretin (orexin) innervation of the locus coeruleus activates noradrenergic cells. *J Comp Neurol* 1999;415:145–159, with permission.) See color version of figure.

The functions of the different inputs to LC neurons or their dendrites are being revealed in behavioral and neurophysiologic studies. Stimulation of the PGi strongly excites LC neurons (11). The PGi has strong autonomic functions, an observation consistent with the marked parallel found between LC and sympathetic activities (29). These findings, together with the strong cortical projections of LC neurons, suggest that the LC acts as a cognitive component of a global sympathetic system (8). In contrast, strong inhibition is produced by PrH stimulation (13); the functional significance of this input is unclear. That inhibitory adrenergic input also arises from the PGi is revealed when the strong glutamate input is antagonized pharmacologically (30). Inputs to distal LC dendrites from the amygdala (9) or NTS (10) may convey limbic/emotional or autonomic information to the LC, respectively, although an influence of activity in these afferents on LC activity has not yet been found (8 ,31). Our unpublished studies in monkey indicate that the anterior cingulate cortex strongly innervates the LC (32). Some of our other recent results suggest that this input may modulate the mode of LC activity and thereby its influence on cognitive performance (described below) (33). Finally, our recent studies using transsynaptic retrograde tracing reveal that the suprachiasmatic nucleus is a prominent indirect afferent to the LC (34 ,35 and 36). This is the first demonstration of a circuit that links the circadian suprachiasmatic nucleus mechanism with the arousal/alerting LC system. Inasmuch as other studies have linked circadian disturbances with

depression (37), and the LC system is also associated with depression and other mood disorders (38), this pathway may also be important for affective function.

Topography of LC Efferents

It is well-known that LC axons are highly branched and have extensive efferents that ramify throughout the central nervous system, providing NE innervation at all levels of the neuraxis (see ref. 4 for review). Previous studies have found topography among these efferent projections (39), but the degree of specificity for projections of different LC neurons appears to be quite limited. Recent studies by Simpson et al. (40) have revealed topography of a novel type. They report that LC neurons selectively collateralize to different nuclei of the somatosensory system, so that individual neurons are more likely to send branches to thalamic and cortical areas within the somatosensory system than to, e.g., a somatosensory thalamic nucleus and a visual cortical area. This "functional topography" for projections of individual LC neurons provides a new dimension for the anatomic organization of this ubiquitous brain system and may indicate a means for coordination or synchronization of NE release along relays in serial functional pathways.

A2 NE Neurons of the Caudal Medulla

Norepinephrine neurons in the A2 group (caudal NTS) have recently been implicated in behavioral functions of psychiatric importance. Previously relegated solely to autonomic and visceral control (e.g., see ref. 41), the strong ascending projections of these NE cells to forebrain areas such as the hypothalamus (42), bed nucleus of the stria terminalis (BNST) (43), nucleus accumbens (44), and amygdala (45 ,46) have now been shown also to be important in affective and cognitive processes (43 ,47). As described below, these findings identify new circuits for understanding affective and mnemonic functions.

NEUROPHYSIOLOGY

Part of "4 - Norepinephrine "

Several recent findings regarding the neurophysiology of LC neurons have extended our understanding of this system. Notably, integration of studies at the cellular and behavioral levels indicates a potentially important role of coupling among LC neurons.

Electrotonic Coupling

Experiments by Christie and Williams and colleagues (48 ,49 and 50) showed that LC neurons may be regulated by electrotonic coupling, not only during development but also in adults. Additional studies by these workers indicate that such coupling may be modulated by inputs to LC neurons that alter cAMP (51). This is significant because electrotonic coupling allows rapid, powerful cell-to-cell communication (electrically and biochemically) via large transmembrane channels between neurons (called *gap junctions*). Once relegated to the domain of the esoteric but unimportant, electrotonic coupling is now being demonstrated in an increasing number of central neurons. Of great interest is the fact that such coupling is readily modulated by other inputs to coupled cells—for example, in the retina, coupling is strongly attenuated by dopamine inputs in a cAMP/protein kinase A manner. This line of work is very promising in neuropsychopharmacology because it suggests a novel set of targets (receptors that regulate electrotonic coupling) that could be used to develop new drugs to modulate the function of systems important in mental function and dysfunction (such as the LC). Our recent work (described below) shows how modulation of such coupling can have profound influences on behavior and cognitive performance (33). It is noteworthy that electrotonic coupling has been reported among striatal neurons in a dopamine-modulated manner (see Chapter 9 , *this volume*), as well as among interneurons in the cerebral cortex (52 ,53).

LC Activity, Electrotonic Coupling, and Cognitive Performance in Behaving Monkeys

A possible role for electrotonic coupling among LC neurons in cognitive performance was revealed by combining our recordings of LC neurons in monkeys performing a signal detection task with neural network modeling (33). In these recordings, LC neurons exhibited two modes of activity during task performance: a phasic mode, in which LC cells responded phasically to target stimuli, and a tonic mode, in which the tonic baseline activity of LC neurons was high but responses to target cues were absent. Moreover, the phasic mode corresponded closely to focused attention and good task performance, whereas the tonic mode was associated with scanning attentiveness and poor performance in this task, which requires focused attention. Task performance could be improved by systemic or local (intra-LC) injection of clonidine during poor performance, which indicates a causal influence of these patterns of LC activity on performance. A neural network model was constructed to investigate mechanisms involved in generating these modes of LC activity and the corresponding task performance. Space limitations prohibit a full discussion of the findings, which are reported and reviewed in recent publications (33 ,54). In brief, the model showed that modulated electrotonic coupling among LC neurons could produce the patterns of LC firing observed in the monkeys, and that known modulatory effects of NE could then translate these modes of LC activity into corresponding levels of task performance, also observed in the monkeys (Fig. 4.2 and Fig. 4.3). These findings have a number of implications for neuropsychopharmacology.

First, they support the view that the LC has an important role in attentional processes, and that pathology in LC function could contribute to mental disorders with attentional components [e.g., attention-deficit/hyperactivity disorder (ADHD), stress disorders, schizophrenia]. These results also indicate that alterations in coupling among widely projecting neurons can have profound mental and behavioral consequences, offering a new dimension for analyzing the function of highly divergent modulatory brain systems. Finally, these results, in view of other findings that electrotonic coupling can be rapidly modulated by neurotransmitter inputs (55), indicate that coupling may be a valuable new target for pharmaceutical development in neuropsychopharmacology.

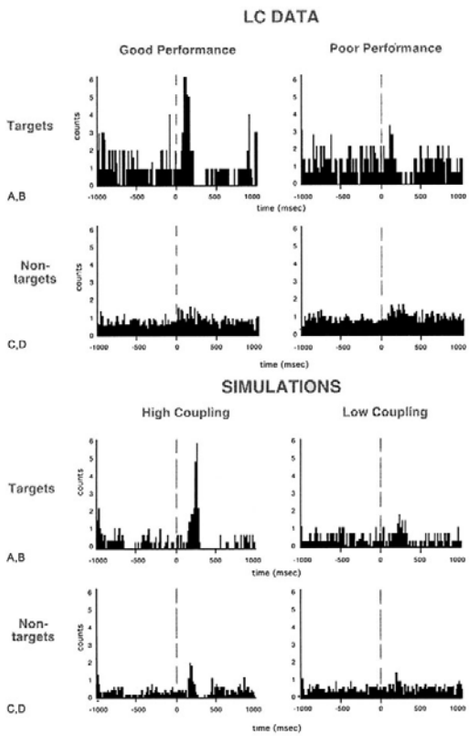

FIGURE 4.2. Simulation of locus ceruleus (LC) activity by modulated electrotonic coupling. **Upper:** Post-stimulus time histograms (PSTHs) for LC activity during the visual discrimination task. **A,B:** Response for targets. **C,D:** Response for distractors. **A,C:** Periods of good performance (phasic LC mode). **B,D:** Poor behavioral performance (false alarm rate typically > 7%; tonic LC mode). Stimuli occur at time zero. All histograms are normalized to a standard of 100 trials. Note that the phasic LC mode is found during periods of good performance, and that the tonic mode corresponds to poor performance on this task. Bin width, 10 ms. **Lower:** Simulation of LC responses. **A,B:** Response to targets. **C,D:** Response to distractors. **A,C:** Coupling among LC neurons. **B,D:** No coupling among LC neurons. These simulation PSTHs are normalized for 100 trials, as for the empiric data. Note that coupling reduces tonic (baseline) LC activity but increases phasic (transient) response to target stimuli, capturing the phasic mode of LC neurons in our recordings. See Fig. 4.3 for corresponding behavioral simulation results. (From Usher M, Cohen JD, Rajkowski J, et al. The role of locus coeruleus in the regulation of cognitive performance. *Science* 1999;283:549–554, with permission.)

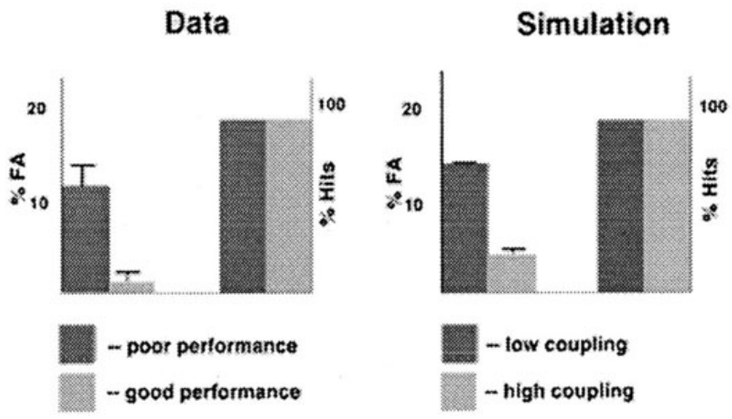

FIGURE 4.3. Simulation of behavioral performance by modulated coupling among locus ceruleus (LC) neurons. **Left:** Graphs showing higher rate of false alarm errors (% FA) during epochs of poor versus good performance by monkeys in the visual discrimination task (33). No differences were noted in the percentage of hit responses during the various levels of performance, as misses were rare. **Right:** Graphs showing higher % FA in the simulated data from our model (33) during epochs of low versus high coupling among LC neurons. Note similarity to empiric data at left. See Fig. 4.2 and ref. 33 for further details.

Opiate Withdrawal

A long series of studies has implicated the LC system in opiate withdrawal (see ref. 56 for review). Recent work has

shed light on molecular and cellular changes that occur in LC neurons during long-term opiate exposure that may underlie their strong activation during withdrawal (reviewed above). It is generally acknowledged that the bulk of this hyperactive LC response is mediated by glutamate inputs from the PGi (11 ,57 ,58). However, a possible intrinsic source of withdrawal-induced hyperactivity in LC neurons has been somewhat controversial. Although some studies find no evidence for withdrawal-induced activation of LC neurons in slices taken from morphine-dependent rats (59 ,60), others have presented evidence for such intrinsically mediated withdrawal responses in LC (61 ,62 ,63 and 64). Our study of local intra-LC microinfusion of opiate antagonists in morphine-dependent rats has confirmed the likelihood that intrinsic changes with dependence contribute to the hyperactivity of these neurons during withdrawal (65). Different studies have suggested different mechanisms for this locally mediated withdrawal effect. Lane-Ladd et al. (62) and Nestler and Aghajanian (66) have presented evidence from slice experiments consistent with the possibility that long-term morphine exposure causes a sustained increase in a tetrodotoxin-insensitive Na^+ current, linked to the increase in cAMP, adenylate cyclase activity, and cAMP response element-binding protein (CREB) that occurs in the LC during withdrawal. In their view, this inward current causes LC hyperactivity when the inhibitory influence of morphine is removed during withdrawal. Our recent *in vitro* studies suggest a different mechanism. These results indicate that long-term opiate administration produces a decrease in K^+ conductance in LC cells that leads to a state of increased excitability when the inhibitory influence of morphine is removed during withdrawal (63 ,64). The decreased K^+ conductance during long-term morphine administration may be a direct compensatory response to the increased K^+ conductance evoked by acute opiates (49). In either case, it seems clear that the local component of withdrawal-induced activation of LC neurons is small compared with the strong excitation evoked by the increased glutamate input from the PGi (see above).

Hypocretin/Orexin

As discussed above, the hypothalamic neuropeptide hypocretin, which is strongly implicated in sleep regulation, densely innervates the LC in rat and monkey (21). Recent studies have revealed that this peptide activates LC neurons both *in vitro* (21 ,67) and *in vivo* (68). The activation is associated with a mild depolarization but is independent of tetrodotoxin and Ca^{2+} (67). The results have led to the tentative conclusion that hypocretin activates LC neurons by decreasing a resting potassium conductance (67). Overall, the results are important because they indicate a possible pathway and transmitter mechanism by which the LC becomes activated during arousal from sleep, which may in turn help to drive a sleep-to-waking transition. This pathway could be involved also in the psychiatric disorders associated with sleep dysfunction (e.g., depression, stress disorders, ADHD).

Cortical Influences on LC Activity

Tract-tracing studies have revealed that the prefrontal cortex may directly innervate LC neurons. Our retrograde and anterograde studies in rat find a projection from the medial prefrontal cortex to the extranuclear peri-LC dendritic zone (69). Another of our studies confirms a projection from the cingulate cortex to the LC in the monkey (32). In line with these findings, additional experiments have revealed prominent effects of cortical stimulation on LC activity. As shown in Fig. 4.4 , we found that electric stimulation of the medial prefrontal cortex in rats activates LC neurons; similar results were obtained with chemical stimulation (70). We also found this activation to be mediated by glutamate release within the LC, as would be expected for a direct cortical (presumably glutamatergic) input (71). In contrast, Sara and Herve-Minvielle (72) reported that medial prefrontal stimulation in rats results in inhibition of LC activity. Procedural differences may underlie the different results. In particular, the study by Sara and Herve-Minvielle used ketamine anesthesia, a potent glutamate antagonist. Thus, the results may indicate an underlying inhibitory effect of prefrontal activation on LC activity when the more potent glutamate-mediated excitation is antagonized. In any case, the results reveal that the prefrontal cortex can strongly influence activity of LC neurons.

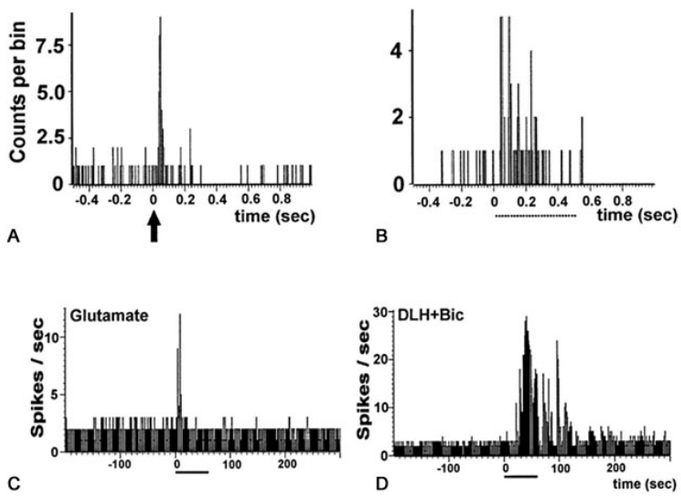

FIGURE 4.4. Activation of locus ceruleus (LC) neuron by stimulation of medial prefrontal cortex (PFC) in rat. **A:** Cumulative post-stimulus time histogram (PSTH) for single-pulse electric stimulation of the PFC. Stimulation presented at *arrow*. **B:** PSTH for train stimulation (20 Hz for 0.5 s) given during the epoch designated by *small dots*. Bin width in each PSTH, 5 ms. **C:** Response of an LC cell to stimulation of PFC with 100-mM glutamate (at *bar* below). **D:** Response of an LC neuron to stimulation of PFC with 10-mM D,L-homocysteic acid plus 50-µM bicuculline (DLH + bic; 60-nL injection). (From Jodo E, Chiang C, Aston-Jones G. Potent excitatory influence of prefrontal cortex activity on noradrenergic locus coeruleus neurons. *Neuroscience* 1998;83:63–80, with permission.)

Postsynaptic Actions of NE

The proposed role of the NE–LC system in arousal was confirmed by Berridge and Foote (73), who showed that local activation of LC neurons by microinjection of bethanechol produces EEG activation in the halothane-anesthetized rat. Similar studies demonstrated that LC inactivation by local microinfusion of clonidine decreases EEG arousal (74). Additional experiments revealed that the arousing effects of LC stimulation are mimicked by stimulation of ß adrenoceptors within the medial septum and are blocked by ß-receptor antagonists infused into this area (75). Continuing studies along these lines confirmed that local LC stimulation in waking animals increases EEG and behavioral indices of arousal (76). Additional studies found, however, that septal infusion of ß antagonists in unanesthetized animals does not decrease arousal (77). Thus, in the waking rat, actions at other NE or non-NE receptors may also be necessary for arousal. Together, these studies indicate that LC activity is an important regulator of EEG arousal, and that these effects are mediated, at least in part, by ß receptors in the medial septum area. Additional studies are needed to determine the precise location of these actions and what other systems and receptors may be important for maintaining the alert state.

Studies in intact animals have shown that ß-receptor activation from the LC can induce plasticity in hippocampal responses. Chaulk and Harley (78) found that *in vivo* or *in vitro* administration of ß- or α-receptor agonists significantly potentiates the population spike amplitude recorded in the dentate gyrus in response to perforant path stimulation. Because the LC is the sole source of NE in the hippocampus, these findings confirm previous results that LC stimulation also potentiates such dentate gyrus responses (79 ,80). These results indicate a role for NE from the LC in plasticity in hippocampal activity, and may provide evidence for a role of this system in memory consolidation (described below).

BEHAVIOR

Part of "4 - Norepinephrine "

Opiate Withdrawal and the LC

Several recent studies in which behavioral pharmacologic techniques were used have reexamined the role of the LC system in opiate withdrawal and abuse. The results of lesion studies by Chieng and Christie (81), Caille et al. (82), and Delfs et al. (43), in which different methods and approaches were used, all agree that the LC system is not necessary for physical signs of morphine withdrawal (Fig. 4.4). This finding contrasts with previous ideas and represents a significantly changed view of the role of the LC system in withdrawal. Although some studies involving microinjection of agents that alter LC activity (83) or molecular events within LC neurons (62 ,84) implicate the LC in withdrawal responses, their results must be viewed with caution because diffusion of injected substances from the small LC nucleus to adjacent areas that have been implicated in withdrawal, such as the periacqueductal gray (85), difficult to rule out. Further studies are needed to determine the behavioral consequences of LC hyperactivity during opiate withdrawal.

Critical Role of A2 NE Neurons Innervating the BNST in Aversion Induced by Opiate Withdrawal

Our recent work has demonstrated that NE innervation of the BNST from A2 noradrenergic neurons is critical for affective responses to opiate withdrawal (43 ,86). We demonstrated that antagonists of ß receptors injected into the BNST, or lesions of the ventral NE bundle that carries fibers from the A2 group to the BNST, eliminate aversive responses to withdrawal (Fig. 4.5). Interestingly, these same manipulations had almost no effect on the physical withdrawal response. These findings, and other results showing that aversive responses to withdrawal can occur in the absence of somatic responses (87 ,88), indicate that withdrawal aversion is not simply a consequence of physical symptoms, and that separate pathways are involved in physical and affective withdrawal responses (Fig. 4.5 and Fig. 4.6). This is important for neuropsychopharmacology because the affective response during withdrawal is the most potent motivator of further drug seeking (89). Thus, studies to develop pharmacotherapies for opiate abuse should focus on aversive withdrawal responses specifically, rather than examining only physical signs. Lesions of the LC system had no effect on aversive or physical signs of withdrawal, findings that corresponded to other recent results (discussed above).

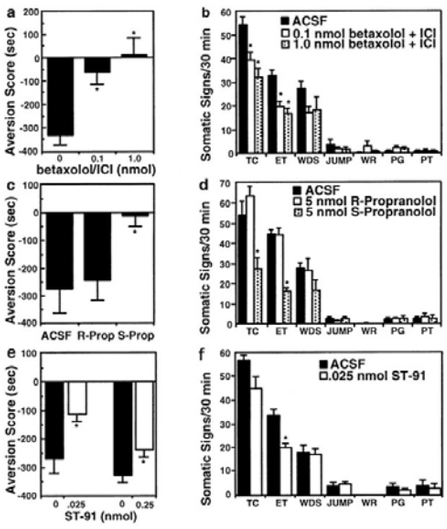

FIGURE 4.5. Effects of intra-BNST (bed nucleus of the stria terminalis) injection of noradrenergic drugs on conditioned place aversion and somatic signs of opiate withdrawal. **A–D:** Effects of the ß-antagonist cocktail betaxolol/ICI 118,551 (A,B) or propranolol isomers (C,D) on place aversion and somatic signs. **E,F:** Effects of ST-91 on place aversion and somatic signs. TC, teeth chatter; ET, eye twitch; WDS, wet dog shakes; JUMP, jumping; WR, writhing; PG, penile grooming; PT, paw tremor. All data are expressed as mean ± standard error of the mean (n = 6 to 8 animals per dose). For A–D, $p < .05$, analysis of variance followed by Fisher's PLSD test for multiple comparisons. For E,F, $p < .05$, Student's t-test. (From Delfs J, Zhu Y, Druhan J, et al. Noradrenaline in the ventral forebrain is critical for opiate withdrawal-induced aversion. *Nature* 2000;403:430–434, with permission.)

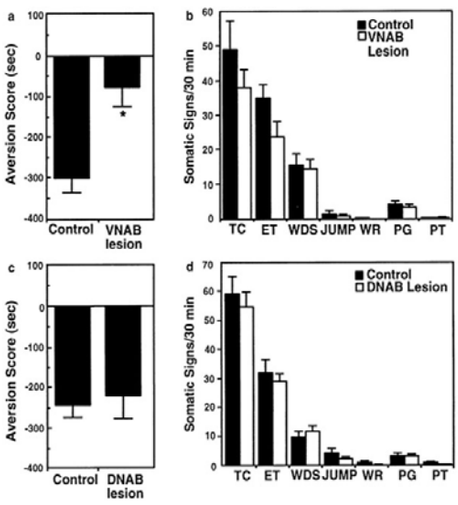

FIGURE 4.6. Effects of dorsal (DNAB) and ventral (VNAB) noradrenergic bundle lesions on aversive and somatic signs of opiate withdrawal. **A,C:** Aversion scores. Aversion score equals time in the naltrexone-paired side on the test day minus the preconditioning day. **B,D:** Number of somatic counts in 30 minutes. See Fig. 4.5 legend for details and abbreviations. Nondependent lesioned animals exhibited neither aversion nor somatic signs following naltrexone (data not shown). All data are mean ± standard error of the mean (n = 6 to 8 control, 10 to 11 lesioned animals per group). $p < .05$, analysis of variance followed by Fisher's PLSD test for multiple comparisons. (From Delfs J, Zhu Y, Druhan J, et al. Noradrenaline in the ventral forebrain is critical for opiate withdrawal-induced aversion. *Nature* 2000;403:430–434, with permission.)

Memory and the LC

Recent studies by Clayton and Williams (90) have indicated new evidence for involvement of the NE–LC system in memory. Inactivation of the PGi (a major input to the LC, described above) with either lidocaine or the GABA agonist muscimol immediately after acquisition in a one-trial inhibitory avoidance task produced marked deficits on a retention test given 48 hours later. Conversely, chemical stimulation

of the PGi with glutamate following training in either an inhibitory avoidance or spatial delayed matching to sample radial maze task enhanced retention performance when assessed 48 or 18 hours later, respectively (91). Given the excitatory connections between PGi and LC, these findings suggest that pharmacologic manipulation of PGi neuronal activity may affect memory formation via influences on LC and subsequent NE release in brain systems involved in the encoding of new information.

Recent studies by Przybyslawski et al. (92) have also indicated a role for the LC–NE system in memory. These experiments indicate that memories are normally reconsolidated each time they are reactivated by relevant cues. They found that blockade of ß adrenoceptors after memory reactivation, during the consolidation process, produced impairment on future tests of the same memory. These results indicate that reactivation of memory produces a ß receptor-dependent intracellular cascade that reenacts the consolidation process responsible for the initial memory acquisition. This NE-dependent lability of active memory traces indicates a novel mechanism to target in pharmacologic manipulation of memory-related disorders, such as posttraumatic stress disorder and Alzheimer's disease.

Studies by Mao et al. (93) have found a role for α_1 and α_2 NE receptors in the dorsolateral prefrontal cortex in memory. Infusion of α_1 agonists into the monkey prefrontal cortex produced deficits in working memory (93), whereas similar treatments with α_2 agonists improved memory performance (94).

Memory and the A2 NE System

Studies by McGaugh (95) during the last several years have established a role for NE stimulation of ß receptors in the amygdala in the strong memories that are established for emotionally salient events. Recently, this line of work has shown that the NTS is involved in this process, as lidocaine anesthesia of the NTS prevents the memory-enhancing effects of peripheral epinephrine (47). Because the A2 neurons of

the NTS strongly innervate the amygdala, this finding indicates that the A2 neurons may be importantly involved in memory modulation. These studies suggest that a “central nervous system–periphery–central nervous system long-loop” circuit may be involved, in which descending activity in response to emotional events produces a peripheral response (e.g., epinephrine release); this response in turn stimulates receptors on vagal afferents that then stimulate the NTS to release NE in its hypothalamic and forebrain targets. This possible route for enhancement of emotional memories and other cognitive processes has received little attention previously. Such a loop may also be involved in the activation of A2 neurons during opiate withdrawal that leads to the corresponding aversive response (described above) (43). This is potentially important clinically and psychopharmacologically because peripheral receptors on visceral afferent fibers that may be involved in mental disorders represent a novel mechanism and target for new pharmacotherapies.

PSYCHOPATHOLOGY

Part of "4 - Norepinephrine "

Depression

Recent work by Miller et al. (96) has increased our understanding of the role of NE systems in depression. In their studies, reduction of NE metabolites (presumably reflecting decreased NE turnover) after treatment with α-methyl-*p*-tyrosine (AMPT) caused no change in scores on the Hamilton Depression Rating Scale in normal human subjects. In contrast, AMPT administration and reductions in NE turnover in patients in remission from depression after treatment with desipramine or mazindol significantly increased the Hamilton Depression Rating Scale measures of depressive symptoms (97). This change was not seen in patients under treatment with serotonin antidepressants (fluoxetine or sertraline). The results indicate that monoamine deficiency alone may not produce depressive symptoms, but that different types of depression exist that respond to manipulations of different monoamine systems.

Advances in understanding the actions of antidepressant drugs have highlighted the possible role of NE systems in depression. New drugs such as venlafaxine, which inhibits reuptake of both serotonin and NE, have been found to be effective, particularly in refractory depression (98). In addition, the highly effective antidepressant paroxetine, which was previously thought to act selectively to block serotonin reuptake, has recently been found also to inhibit NE reuptake (99 ,100). These findings confirm long-held beliefs that NE is importantly involved in depression, and indicate that blockers of NE uptake, including drugs that selectively act at the NE transporter, such as reboxetine (101 ,102), may be effective in treating at least certain types of affective illness (103).

Anxiety

Brain NE has long been implicated in anxiety disorders (104). Our studies with cocaine- and morphine-dependent animals have provided new evidence for a role of central NE systems in anxiety. By means of a place-conditioning paradigm, we found that withdrawal from long-term administration of morphine or cocaine is associated with strong anxiety, measured by the conditioned burying paradigm (105). Importantly, the anxiogenic response to drug withdrawal is strongly attenuated by administration of the ß-receptor antagonist propranolol, and by similar doses of the lipophobic $ß_1$ antagonist atenolol, which is believed to act primarily peripherally. These findings indicate that at least some types of anxiety involve stimulation of peripheral ß adrenoceptors.

ADHD

The firing patterns of LC neurons in behaving monkeys indicate that this system plays an important role in attention and performance (reviewed above) (33 ,54 ,106). In particular, one mode of LC activity, characterized by elevated tonic discharge, corresponds to poor performance on a continuous performance task that requires focused attention, with a high rate of false alarm errors. These and other results have led us to propose that this tonic mode of LC activity promotes high behavioral flexibility and disables focused or selective attention (33 ,54). This view also implies that attentional disorders may be associated with LC dysregulation in which the proper mode of activity is not engaged adaptively for the context at hand. Specifically, several parallels have been noted between behaviors in monkeys during the tonic mode of LC activity and symptoms of ADHD, including hypervigilance, irritability, poor focused attentiveness, and a high false alarm rate in continuous performance tasks. These findings indicate that the LC may play an important role in ADHD, and that drugs that modulate LC mode, or switching between modes, may be helpful in treating this disorder. In fact, many of the stimulants that are effective in treating ADHD decrease tonic LC activity.

A role for the LC–NE system in attentional disorders is also indicated by behavioral pharmacology experiments by Arnsten and colleagues (107). These investigators have found that overstimulation of $α_1$ receptors in the prefrontal cortex produces deficits in behaviors that depend on prefrontal function (107). Because ADHD includes symptoms of prefrontal dysfunction, these findings raise the possibility that an overactive LC system may contribute to ADHD by overstimulation of $α_1$ receptors in prefrontal areas (108).

CONCLUSIONS

Part of "4 - Norepinephrine "

An impressive amount of research on NE systems has been performed since the previous edition of this volume was

published. This work is revealing an increasingly important role for brain NE in mental function and dysfunction. Mechanisms by which NE systems are involved in cognitive, addictive, stress-related, and other behavioral functions are being elucidated. This progress not only reinforces the importance of this system for neuropsychopharmacology, but also indicates that NE systems represent a promising area for discovering new and fruitful approaches to developing treatments for psychiatric disorders.

Regulation of G Protein-Coupled Receptors by Phosphorylation and Endocytosis

Mark Von Zastrow

Mark von Zastrow: Department of Psychiatry, Department of Cellular and Molecular Pharmacology, and Program in Cell Biology, University of California, San Francisco, California.

G protein-coupled receptors (GPCRs) comprise a large superfamily of heptahelical integral membrane proteins that mediate transmembrane signal transduction in response to a wide variety of hormones, neurotransmitters, and neuromodulators. GPCRs are extremely important targets for neuropsychopharmacology. Indeed, the vast majority of clinically relevant neuropsychiatric drugs either bind directly to specific GPCRs (e.g., many antipsychotic drugs) or function indirectly via GPCRs by influencing the amount of available native agonist (e.g., many antidepressant drugs).

A general feature of GPCRs is that they are extensively regulated in cells (1 ,2 ,3 and 4). Regulation of GPCRs is thought to play a fundamental role in maintaining physiologic homeostasis in the face of fluctuating internal and external stimuli. A number of pathologic states are associated with disturbances in the number or functional activity of certain GPCRs (5). In addition, many clinically important drugs influence the physiologic regulation of GPCRs (6). Together, these observations suggest that mechanisms of GPCR regulation may be of fundamental importance to neuropsychiatric disorders and to the actions of clinically relevant drugs.

The physiologic and biomedical importance of GPCR regulation has motivated an enormous amount of study into underlying molecular mechanisms of regulation. Progress in this area has been facilitated enormously by molecular and cell biological approaches applied to a variety of experimental model systems. Our understanding remains at an early stage and is limited, in most cases, to studies of a small number of GPCRs. Nevertheless, great progress has been made in elucidating certain mechanisms of GPCR regulation, to the extent that it is possible to begin to discern fundamental principles that control the number and functional activity of GPCRs in individual cells.

The present chapter discusses some of this progress, with an emphasis on developing a unified view of GPCR regulation. We have restricted our scope to a limited number of regulatory mechanisms that have been elucidated by detailed study of the some of the most extensively characterized GPCRs. First, we survey classic studies describing the general properties of the physiologic and pharmacologic regulation of receptor-mediated signaling; these have established a terminology and conceptual framework for our later focus on specific mechanisms of receptor regulation. Second, we discuss pioneering studies of “prototypic” GPCRs that have established paradigms for understanding the role of receptor phosphorylation in mediating rapid desensitization of GPCRs. Third, we focus on a specific mechanism mediating regulated endocytosis of certain GPCRs, and discuss how this endocytic mechanism can promote rapid desensitization and resensitization of receptor-mediated signal transduction. In this section, we also highlight the close interdependence between mechanisms of GPCR phosphorylation and membrane trafficking in mediating rapid regulation of receptor function. Finally, we discuss the functions of both phosphorylation and endocytic membrane trafficking in mediating longer-term regulation of the number of GPCRs present in cells, focusing on recent studies into mechanisms that control down-regulation of receptors via proteolytic degradation in lysosomes.

GENERAL PROCESSES OF GPCR REGULATION

Part of "5 - Regulation of G Protein-Coupled Receptors by Phosphorylation and Endocytosis "

Rapid Desensitization and Resensitization

It has been known for many years that multiple mechanisms can contribute to GPCR regulation (1 ,7). Early studies,

which preceded the elucidation of any of the biochemical machinery involved, distinguished general processes of receptor regulation according to differences in kinetics and reversibility. This is well illustrated by classic studies of the β_2-adrenergic receptor (B2AR), reviewed in detail elsewhere (2 ,3 and 4). Agonist-induced activation of the B2AR stimulates adenylyl cyclase via coupling to the G_s heterotrimeric G protein (Fig. 1A). Receptor-mediated signaling via this pathway occurs within seconds after agonist binding. However, after more prolonged activation, the ability of receptors to activate adenylyl cyclase via G_s diminishes greatly. This diminution of signal transduction is generally called *desensitization* and is mediated, at least in part, by regulation of the receptor itself. A process of *rapid desensitization* was so named because it occurs within seconds to minutes after agonist-induced activation. Rapid desensitization of the B2AR can be reversed within several minutes after removal of agonist in a process called *resensitization*. Rapid desensitization of the B2AR is not associated with a decrease in the total number of receptors present in cells or tissues, and resensitization does not require biosynthesis of new receptor protein. Therefore, rapid desensitization is thought to reflect a change in the *functional activity*, rather than absolute number, of receptors (Fig. 5.1B).

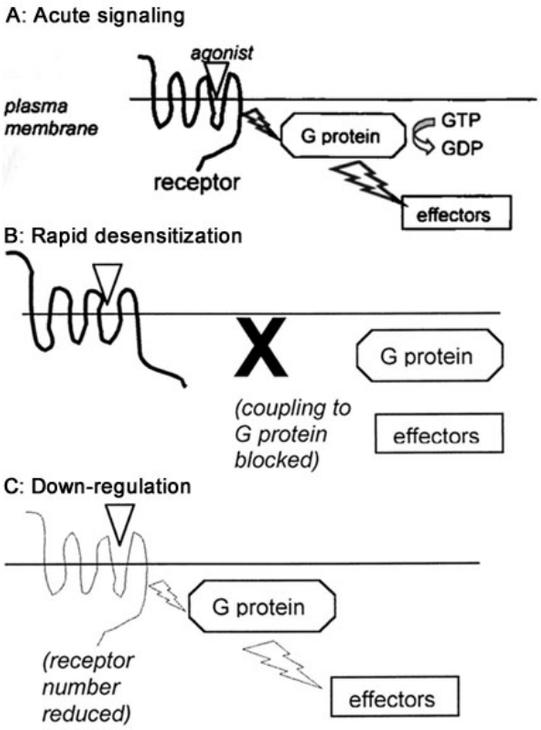

FIGURE 5.1. Desensitization and down-regulation of G protein-coupled receptors. **Panel A:** Within milliseconds to seconds after agonist binding, receptors present in the plasma membrane mediate signal transduction to effectors by functionally coupling (promoting guanine nucleotide exchange on) a heterotrimeric G protein. **Panel B:** Within several minutes after agonist binding, rapid desensitization occurs by functional uncoupling of the receptor from G protein. This represents a change in the functional activity of receptors, which inhibits signal transduction to the effector without changing the number of receptors in the cell. **Panel C:** After more prolonged agonist-induced activation of receptors (typically several hours to days), the number of receptors present in cells is greatly reduced, so signal transduction via G proteins to effectors is strongly attenuated. This process is called *receptor down-regulation* because it is thought to represent primarily a reduction in the number, rather than functional activity, of receptors.

Down-regulation and Up-regulation of Receptors

The kinetics of rapid desensitization and resensitization may be relevant to the physiologic action of catecholamines (endogenous agonist ligands for the B2AR), as these molecules can be released intermittently by vesicular exocytosis and are rapidly removed from the extracellular milieu by membrane transport, enzymatic degradation, or both. However, many clinically important drugs that activate GPCRs have a more prolonged duration of action. Studies of these drugs established the existence of a distinct process of receptor regulation that occurs much more slowly, typically within several hours to days after prolonged or repeated exposure of tissues to ligand. This process is called *down-regulation* because (in contrast to rapid desensitization) it is associated with a pronounced decrease in the total number of receptors present in cells or tissues, as typically detected by means of radioligand binding techniques. Further distinguishing the process of down-regulation from rapid desensitization, recovery of signaling activity after down-regulation is generally a slow process that requires biosynthesis of new receptor protein (8). Therefore, down-regulation is thought to reflect primarily a change in the *number*, rather than functional activity, of receptors present in cells or tissues (Fig. 5.1C). In most cases, down-regulation of GPCRs (like rapid desensitization) is induced by *agonists*, but not by antagonists. Moreover, certain antagonists can induce an opposite process of increased receptor number called *up-regulation* (9 ,10). These observations are consistent with a fundamental role of down-regulation and up-regulation as a negative feedback mechanism that seeks to maintain physiologic homeostasis of receptor signaling. However, in some cases, processes associated with GPCR down-regulation may be induced by antagonists (11 ,12). In other cases, up-regulation of receptors can be induced by drugs with partial agonist activity (10). These observations suggest that certain clinically relevant drugs may not simply mimic or block the effects of endogenous agonists. Indeed, it is proposed that such “paradoxical” regulatory effects may contribute to the pathologic or therapeutic actions of certain clinically relevant

neuropsychiatric drugs, including opiate analgesics and atypical antipsychotic agents (10 ,13 ,14 ,15 and 16).

Distinguishable Processes of Homologous and Heterologous Desensitization

Another important observation leading to our present view of GPCR regulatory mechanisms has come from studies investigating the pharmacologic specificity of receptor regulation (1 ,17). Many cell types express multiple types of GPCR (Fig. 5.2A). It has been observed that in some cases, prolonged activation of one type of GPCR causes attenuated signal transduction only by that receptor, without any detectable effect on signaling by other types of GPCR present in the same cell. In this case, the regulation of receptors is said to be *homologous* (Fig. 5.2B). The existence of homologous processes of regulation provided early evidence, before specific regulatory mechanisms were elucidated, that signal transduction can be modulated by modification of the receptor itself. In other cases, activation of one type of GPCR attenuates signaling not only by that receptor but also by other type(s) of GPCR present in the same cell. Regulation of this kind is said to be *heterologous* (Fig. 5.2C). Heterologous regulation of receptor signaling is consistent with modification of a "downstream" component in the signal transduction pathway that is involved in signaling by more than one type of GPCR. However, as discussed below, important examples of heterologous regulation mediated by modification of the receptor protein itself also exist. Homologous processes of receptor regulation are capable of modulating signal transduction in a highly specific manner, whereas heterologous processes of regulation may play an important role in facilitating functional "cross-talk" between pharmacologically distinct signaling pathways (18).

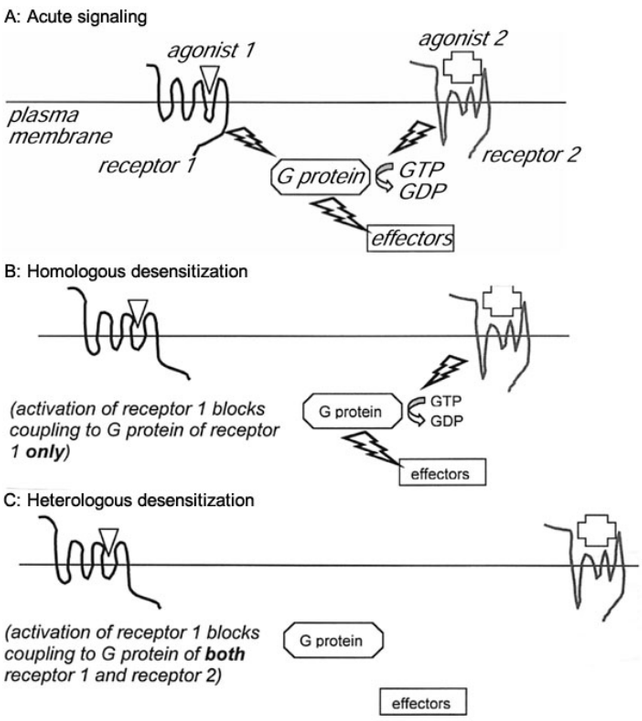

FIGURE 5.2. Homologous and heterologous desensitization. **Panel A:** Receptors 1 and 2 can signal via the same G protein-mediated pathway. **Panel B:** Agonist 1 causes uncoupling only of receptor 1; signaling induced by agonist 2 binding to receptor 2 is not affected. This is homologous desensitization of receptor 1. **Panel C:** Agonist 1 causes functional uncoupling of both receptor 1 and receptor 2, so that signaling induced by both agonists is blocked. This is heterologous desensitization.

SPECIFIC MECHANISMS OF GPCR REGULATION

Part of "5 - Regulation of G Protein-Coupled Receptors by Phosphorylation and Endocytosis "

Rapid Desensitization Mediated by Phosphorylation-Dependent Uncoupling of Receptor from Heterotrimeric G Protein

It is well established that many GPCRs are regulated by phosphorylation. Classic studies of rhodopsin (a light-activated GPCR) and the B2AR (a ligand-activated GPCR) provide examples of illustrating distinct molecular mechanisms that mediate homologous and heterologous desensitization of receptors. Because the principles behind these mechanisms have proven to be widely applicable to other GPCRs, rhodopsin, and the B2AR are often considered "prototypic" GPCRs that have established general paradigms for understanding phosphorylation-dependent regulation of GPCRs (19).

Phosphorylation of Rhodopsin: a Model for Functional Inactivation of GPCRs

Elegant studies of the vertebrate visual system identified a critical role of phosphorylation in inactivating rhodopsin following light-induced activation (20). Light-activated rhodopsin is a good substrate for phosphorylation by a cytoplasmic enzyme called *rhodopsin kinase*, whereas rhodopsin that has not been activated by light is a poor substrate (20). Phosphorylation of the carboxyl-terminal cytoplasmic domain of rhodopsin is sufficient to attenuate the ability of light-activated rhodopsin to couple functionally to its cognate heterotrimeric G protein (transducin). Studies of rhodopsin function in isolated membrane fractions indicated that rhodopsin kinase-mediated phosphorylation can strongly attenuate rhodopsin signaling, but it does so to a lesser extent than observed in the intact rod cell. A second cytoplasmic protein was identified that, when added to membrane preparations in combination with rhodopsin kinase, greatly accelerates the attenuation of rhodopsin signaling (21). This protein was proposed to act as a protein

cofactor that “arrests” signal transduction by phosphorylated rhodopsin and was therefore called *arrestin* (Fig. 5.3A).

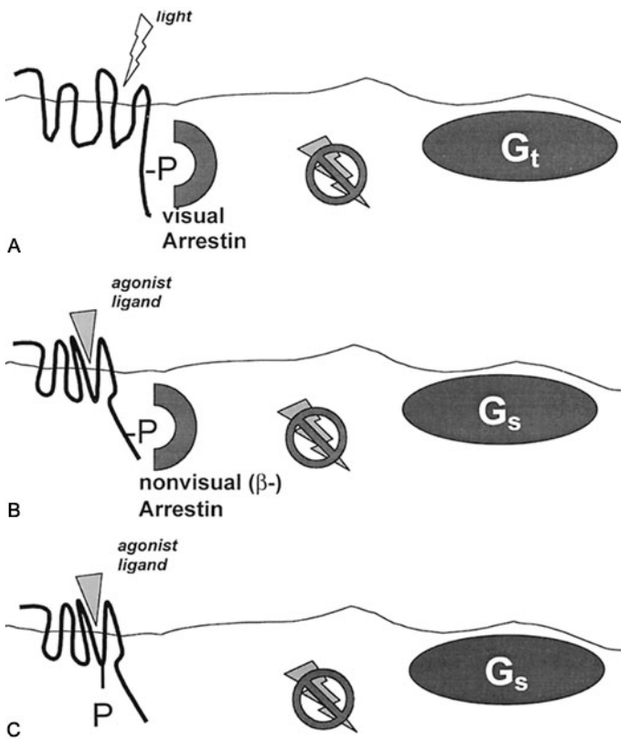

FIGURE 5.3. Paradigms for phosphorylation-dependent desensitization. **A:** GRK1-mediated inactivation of rhodopsin. **B:** GRK2-mediated desensitization of the B2AR. **C:** PKA-mediated desensitization of the B2AR.

GRK-Mediated Phosphorylation of the B2AR: a Model for Homologous Desensitization

Studies of functional reconstitution of B2AR-mediated activation of adenylyl cyclase provided compelling evidence for a role of phosphorylation in mediating rapid desensitization of a ligand-activated GPCR (22). Biochemical purification of the cytoplasmic activity responsible for this phosphorylation identified a kinase called *β-adrenergic receptor kinase* (BARK), and it was noted that this kinase preferentially phosphorylates agonist-occupied receptors (23). Protein sequencing and cyclic DNA (cDNA) cloning later indicated that this kinase is closely similar in structure to rhodopsin kinase (24). Furthermore, cDNA-cloning experiments in which reduced stringency hybridization was used identified additional kinases homologous to rhodopsin kinase and BARK (19). Collectively, these observations led to the discovery of the family of *G protein-coupled receptor kinases* (GRKs). According to this nomenclature, rhodopsin is denoted GRK-1, the originally identified BARK enzyme is denoted GRK-2, and other members of this family of protein kinases are numbered sequentially thereafter. Six members of the GRK family of receptor kinases have been identified to date.

Biochemical reconstitution studies indicated that increasingly purified fractions of BARK exhibit a reduced ability to attenuate B2AR-mediated signal transduction. Further analysis of this effect led to the identification of a distinct protein component that copurifies with BARK in initial stages of purification but is resolved from BARK in more highly purified fractions. This protein component reconstitutes strong attenuation of B2AR-mediated activation of adenylyl cyclase when added back to highly purified fractions of BARK (25 ,26). The protein cofactor involved in desensitization of the B2AR turned out to be a protein similar to visual arrestin and was therefore named *β-arrestin* or *barrestin*. cDNA cloning has identified additional proteins with similar structure, thus defining a family of protein cofactors for phosphorylation-dependent regulation of GPCR function (4). Two nomenclatures are currently in common use for these molecules. In one, the originally identified ß-arrestin is denoted barrestin 1, and additional homologues are named sequentially barrestin 2, and so on. In another nomenclature, all members of this protein family are referred to as *arrestins*, with visual arrestin denoted arrestin 1, ß-arrestin as arrestin 2, and subsequently identified family members numbered sequentially thereafter. Four members of the arrestin family of protein cofactors have been identified to date.

As noted above, an important feature of many GRKs is that their kinase activity is highly sensitive to the conformation of the receptor that they phosphorylate. This property of GRKs facilitates specific phosphorylation of only those receptors that are activated by ligand, whereas other receptors present in the same cells (but not activated by agonist) are not phosphorylated. Thus, GRK-mediated phosphorylation is generally considered to be a paradigm for *homologous* desensitization (Fig. 5.3B).

Protein Kinase A-Mediated Phosphorylation of the B2AR: a Model of Heterologous Desensitization

Other kinases, such as the so-called second messenger-regulated kinases, are also implicated in mediating desensitization of GPCRs. For example, the B2AR can be phosphorylated by cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA). PKA-mediated phosphorylation of a single residue located in the third intracellular loop of the B2AR impairs the ability of the receptor to couple to G_s and subsequently activate adenylyl cyclase (27 ,28 and 29). Phosphorylation of this residue is thought to impair receptor–G protein coupling directly, without a requirement for any known protein cofactor such as an arrestin. An important feature of PKA is that this kinase can phosphorylate B2ARs whether or not they have been activated

by ligand, in contrast to the preferential phosphorylation of agonist-activated receptors by GRK-2. Because PKA is activated by cAMP, a signaling intermediate produced as a result of B2AR activation, PKA-mediated phosphorylation of the B2AR can be viewed as an example of feedback inhibition by a second messenger. In addition, because activation of any other receptor that stimulates adenylyl cyclase can also activate PKA, phosphorylation of the B2AR by PKA is generally considered to be a paradigm for *heterologous* desensitization (Fig. 5.3C).

Rapid Desensitization and Resensitization Mediated by Regulated Endocytosis of Receptors

Endocytosis of GPCRs by Clathrin-Coated Pits

Studies conducted in cultured cells indicate that many GPCRs can be regulated by ligand-induced endocytosis. The B2AR is perhaps the most extensively studied GPCR with respect to endocytic membrane trafficking. Early evidence for agonist-induced endocytosis of the B2AR was suggested by observations from subcellular fractionation and radioligand binding assays conducted with membrane-impermeant antagonists (30 ,31). These studies indicated that the number of B2AR binding sites detected in the plasma membrane can be reduced within several minutes after agonist-induced activation, a process called *sequestration*.

The development of receptor-specific antibodies allowed the application of immunocytochemical methods to visualize the subcellular localization of the B2AR and directly demonstrate agonist-induced internalization of the receptor protein. Internalization of the B2AR was observed to represent a steady state of a highly dynamic process involving continuous endocytosis and recycling of receptors through an endocytic pathway similar to that mediating constitutive (ligand-independent) endocytosis of nutrient receptors (32). This dynamic cycling of the B2AR was also suggested by elegant studies in which subcellular fractionation and radioligand binding techniques were used (33).

Regulation of B2AR endocytosis was shown to be mediated by a ligand-dependent lateral redistribution of receptors in the plasma membrane, from a relatively diffuse distribution throughout the plasma membrane to a pronounced concentration of agonist-activated receptors in structures resembling clathrin-coated pits when examined by immunoelectron microscopy. Furthermore, this process of ligand-regulated concentration of B2ARs in coated pits of the plasma membrane was shown to be mechanistically distinct from the subsequent endocytosis of receptors by membrane fission, which can occur even in the absence of continued ligand-induced activation of receptors (34). A protein that is required for this latter step of endocytic membrane fission is the cytoplasmic guanosine triphosphatase *dynamin* (35 ,36). Consistent with this, agonist-induced endocytosis of the B2AR is inhibited by overexpression of certain “dominant-negative” mutant forms of dynamin (37 ,38). Subsequent studies have demonstrated that regulated endocytosis of several other GPCRs is also mediated by a dynamin-dependent mechanism, which suggests a conserved role of clathrin-coated pits in the endocytosis of many GPCRs (Fig. 5.4).

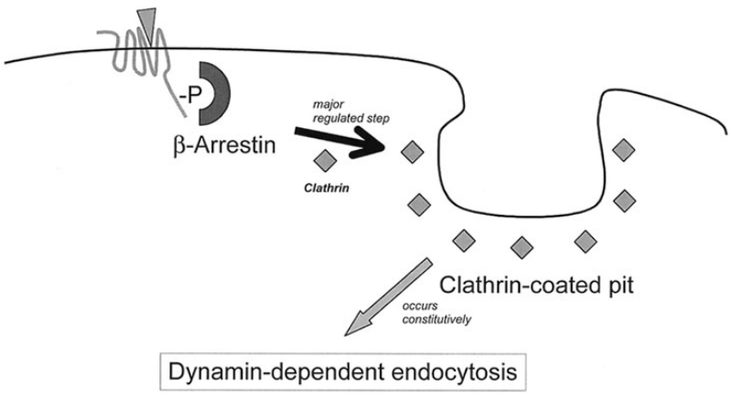

FIGURE 5.4. Regulated endocytosis of the β_2-adrenergic receptor (B2AR) by clathrin-coated pits. G protein-coupled receptor kinase-mediated phosphorylation of the B2AR promotes receptor interaction with nonvisual arrestins, which cause uncoupling of heterotrimeric G proteins and also promote interaction of arrestin–receptor complexes with clathrin coats. Once concentrated in clathrin-coated pits by this mechanism, receptors undergo endocytosis rapidly (even if agonist is removed from the receptor in the coated pit) via a constitutive (ligand-independent) mechanism of endocytic membrane fission that requires the cytoplasmic guanosine triphosphatase dynamin.

Role of GPCR Phosphorylation in Promoting Endocytosis by Clathrin-Coated Pits

Studies elucidating the mechanism mediating the key step of regulated concentration of GPCRs in clathrin-coated pits were initiated by the observation that GRK-mediated phosphorylation of the M2 muscarinic acetylcholine receptor can promote agonist-induced endocytosis of the receptor, whereas a kinase-defective mutant form of GRK inhibits this process (39). Similar observations were made for other GPCRs, including the B2AR (37 ,40). In an elegant series of

experiments, it was shown that certain arrestins can directly promote B2AR concentration in clathrin-coated pits by physically linking phosphorylated receptors with clathrin (40). This endocytic “adapter” function of arrestins can be distinguished from the function of arrestins as cofactors for functional uncoupling of receptor from G protein because the latter process can occur in the absence of endocytosis. Further distinguishing these functions, visual arrestin (arrestin 1) was shown to be unable to serve as an adapter for B2AR endocytosis even though it can serve as a cofactor for desensitization mediated by functional uncoupling of G protein (41). This distinction between visual and nonvisual arrestins led to the identification of a carboxyl-terminal clathrin-binding domain, present specifically in nonvisual arrestins, that is necessary for endocytosis of GPCRs but not for phosphorylation-dependent uncoupling of receptors from heterotrimeric G proteins (42 ,43).

Functional Role of Endocytosis in the Processes of Rapid Desensitization and Resensitization of GPCRs

Physiologic ligands are generally thought to bind to GPCRs in the plasma membrane. Biochemical and immunocytochemical studies suggest that certain GPCRs, such as the B2AR, interact with heterotrimeric G proteins primarily in the plasma membrane but not in intracellular membranes after endocytosis (44 ,45). Together, these observations suggest that endocytosis may, by itself, mediate *desensitization* of GPCR-mediated signal transduction by directly reducing the number of receptors present in the plasma membrane. Indeed, in some cases, endocytosis may be a principal mechanism of rapid desensitization (46). However, as discussed above, rapid desensitization by phosphorylation-dependent uncoupling of receptor from G protein does not require endocytosis of the receptor. This is consistent with the ability of certain GPCRs, such as the α_{2A}-adrenergic receptor, to desensitize in the absence of detectable endocytosis (47 ,48). Studies of μ-opioid receptors expressed in transfected cells suggest that the effectiveness of endocytosis as a means of attenuating signal transduction is inversely proportional to the number of “spare receptors” present in cells (46). Thus, the precise role of endocytosis in contributing to desensitization of GPCR-mediated signal transduction probably varies among systems and may be particularly important in cells expressing relatively low numbers of receptors.

Strong evidence is available to indicate that endocytosis of certain GPCRs serves a distinct function in promoting *resensitization*, rather than desensitization, of signal transduction. The most thoroughly studied example of this mechanism derives from elegant studies of the B2AR (2 ,49 ,50). As discussed above, agonist-induced phosphorylation of the B2AR by GRKs causes rapid desensitization by promoting receptor interaction with arrestins and functional uncoupling from heterotrimeric G proteins (Fig. 5.5 , step 1). This initial desensitization of receptors occurs in the plasma membrane and does not require endocytosis of the receptor protein. Within several minutes after this initial uncoupling of receptor from heterotrimeric G protein, arrestins promote the concentration of receptors in clathrin-coated pits and subsequent endocytosis (Fig. 5.5 , steps 2 and 3). Endocytic membranes containing internalized

B2ARs are associated with activity of a protein phosphatase (PP2A) that can catalyze dephosphorylation of receptors (51). Based on these observations, it is proposed that endocytosis of receptors promotes dephosphorylation of receptors, after which receptors can be recycled back to the plasma membrane in a dephosphorylated, fully active state (Fig. 5.5 , steps 4 and 5). Supporting this hypothesis, inhibitors of B2AR endocytosis do not block agonist-induced desensitization but strongly inhibit resensitization of receptor-mediated signal transduction following removal of agonist from the culture medium (52). Thus, agonist-induced regulation of the B2AR appears to involve two linked regulatory cycles: a biochemical cycle mediating phosphorylation and dephosphorylation of receptors, and a membrane trafficking cycle mediating endocytosis and recycling of receptors.

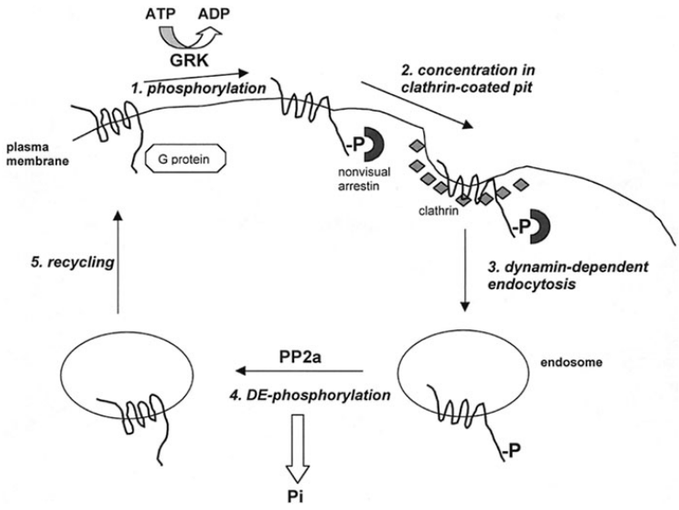

FIGURE 5.5. Linked cycles of G protein-coupled receptor phosphorylation and endocytosis mediating rapid desensitization and resensitization of the β_2-adrenergic receptor (B2AR). Agonist-induced activation of the B2AR causes G protein-coupled receptor kinase-mediated phosphorylation, which promotes receptor interaction with nonvisual arrestins and uncoupling of heterotrimeric G protein (step 1). Arrestin binding to the phosphorylated receptor also promotes receptor concentration in clathrin-coated pits (step 2), promoting rapid endocytosis of receptors by dynamin-dependent fission of coated pits from the plasma membrane and subsequent formation of endocytic vesicles (step 3). Together, these steps cause profound functional desenstization of signal transduction. Endocytic membranes containing internalized B2ARs are associated with a protein phosphatase (PP2A) that can catalyze dephosphorylation of receptors (step 4). Dephosphorylation of receptors followed by recycling to the plasma membrane (step 5) mediates the return of receptors to the plasma membrane in a fully functional state, promoting functional resensitization of the signal transduction system.

Down-regulation of GPCRs by Regulated Proteolysis

Evidence for Regulated Proteolysis of GPCRs

Down-regulation of GPCRs is defined from saturation binding analysis by a decrease in total specific binding sites (*B*max) without a change in apparent affinity (*K*d), which suggests that down-regulation reflects a decreased number of total receptors present cells or tissues (1 ,53). In principle, this process could be mediated by modulation of receptor biosynthesis or degradation. In practice, evidence suggests that both classes of mechanism contribute to the GPCR down-regulation observed physiologically. The role of transcriptional regulatory mechanisms in controlling biosynthesis have been characterized in some detail (see Chapter 17). As discussed in greater detail below, there is also considerable evidence supporting the importance of proteolysis of the receptor itself in mediating down regulation of a number of GPCRs (8).

Mechanisms of GPCR Proteolysis

Multiple mechanisms can mediate GPCR proteolysis. Proteolysis of endocytosed receptors in lysosomes is perhaps the best-established mechanism contributing to GPCR down-regulation in mammalian cells, including certain neurally derived cell types (54 ,55). However, it is apparent that other mechanisms of GPCR proteolysis also exist, some of which may not involve membrane trafficking of receptors at all. For example, the V2 vasopressin receptor can undergo ligand-induced proteolysis at the cell surface by a nonendocytic mechanism mediated by a plasma membrane-associated metalloprotease (56). Recent studies of B2AR down-regulation support the idea that regulated proteolysis of GPCRs can occur without endocytosis in some cell types (57).

In mammalian cells, ubiquitination is well established to promote degradation of various cytoplasmic proteins by a nonlysosomal mechanism mediated by proteasomes (58). Emerging evidence also suggests a role of ubiquitination in promoting endocytosis and proteolytic degradation of certain membrane proteins, including GPCRs in yeast (59 ,60). The role of such a mechanism in mediating down-regulation of mammalian signaling receptors comes from studies of receptor tyrosine kinases (61). Alternate mechanisms of GPCR proteolysis in mammalian cells have been reported to be mediated by a distinct, nonproteasomal mechanism (56) or have been shown to be insensitive to inhibitors of proteasome-mediated proteolysis (57). Thus, to our knowledge, it is not yet clear to what extent ubiquitination or proteasomes may contribute to down-regulation of GPCRs in mammalian cells.

Membrane Pathway Mediating Receptor Delivery to Lysosomes

The delivery of membrane proteins from the plasma membrane to lysosomes is a multiple-step process that is mediated by endocytosis of receptors from the plasma membrane followed by shuttling to lysosomes via a specific series of membrane transport reactions (62 ,63). It is well-known that many GPCRs undergo ligand-induced endocytosis. However, specific mechanisms and pathways mediating subsequent stages of receptor trafficking to lysosomes are poorly understood.

Early studies demonstrated that ligand-induced sequestration and down-regulation of the B2AR can be differentially affected by pharmacologic manipulations and receptor mutation, which suggests that these processes may be mediated by distinct mechanisms (64 ,65 ,66 and 67). Furthermore, naturally occurring subtypes of α_2-adrenergic receptor down-regulate with similar rates (68) despite significant differences in their ability to undergo rapid endocytosis (47 ,48). Analogous processes of rapid sequestration and more gradual down-regulation have also been observed in studies of opioid receptors, where pharmacologic differences between the effects of individual agonists are very pronounced (69 ,70 and 71) and appear to be relevant to the physiologic effects of opiate drugs in native neurons (14 ,72). Compelling evidence for the existence of distinguishable membrane trafficking mechanisms comes from recent studies of mutant thrombin and substance P receptors, in which divergent residues in the carboxyl-terminal cytoplasmic domain specify differences in receptor trafficking between lysosomal and recycling pathways (73). Analyses based on kinetic modeling techniques are consistent either with completely separate pathways mediating rapid endocytosis and proteolytic degradation of GPCRs or with the operation of partially overlapping pathways that differ in their rate-limiting step (53). These models differ in whether sorting of GPCRs is proposed to occur before or after endocytosis (Fig. 5.6).

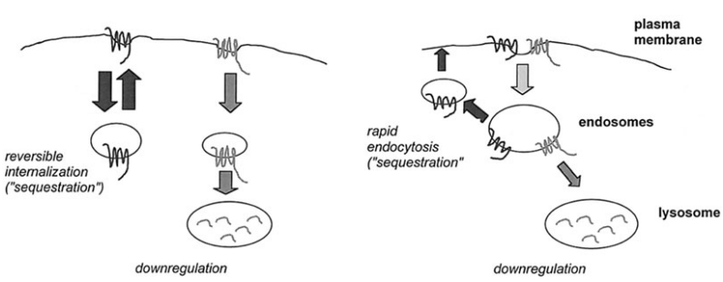

FIGURE 5.6. Models for sorting of G protein-coupled receptors (GPCRs) between pathways mediating reversible internalization ("sequestration") and proteolytic down-regulation of GPCRs. **Panel A:** This model proposes that distinct GPCRs are segregated in the plasma membrane and are subsequently endocytosed by different membrane vesicles that either mediate reversible internalization or deliver receptors to lysosomes. **Panel B:** This model proposes that receptors can be endocytosed by the same membrane mechanism and delivered to the same early endocytic vesicles. Receptors are sorted after endocytosis between distinct pathways that mediate either recycling or lysosomal delivery of receptors.

Molecular Sorting of GPCRs after Endocytosis

Extensive previous studies of receptor-mediated uptake of extracellular ligands indicate that sorting of receptors between recycling and lysosomal pathways can occur after endocytosis (74). Recent studies of adrenergic and opioid receptors suggest that this is also true for certain GPCRs. For example, it has been shown recently that both agonist-induced sequestration and down-regulation of the B2AR are specifically inhibited by a dominant-negative mutant form of dynamin, which suggests that endocytosis of receptors by clathrin-coated pits is an obligate first step common to membrane pathways leading to recycling of endosomes and lysosomes (75). Recent studies of membrane trafficking of opioid receptors, which are also endocytosed by a dynamin-dependent mechanism involving clathrin-coated pits (76), support this conclusion. These studies demonstrate that distinct GPCRs can be sorted in a type-specific manner between recycling and degradative pathways after endocytosis by the same mechanism (Fig. 5.6B). These studies also suggest that the machinery that sorts GPCRs can function very rapidly (within several minutes) after the initial endocytosis of receptors (77).

Insight into a Mechanism Controlling Endocytic Sorting of the B2AR

The membrane machinery controlling postendocytic sorting of internalized GPCRs to lysosomes remains poorly understood. A recent study of B2AR trafficking has provided initial insight into a specialized mechanism that controls sorting of a specific GPCR between recycling and lysosomal pathways. As noted above, the B2AR is capable of recycling rapidly to the plasma membrane following endocytosis in cultured cells. It was observed that a series of mutations in the distal part of the carboxyl-terminal cytoplasmic tail strongly inhibit recycling of receptors and cause receptors to be “mistargeted” to lysosomes (78). All the receptor mutations that cause this phenotype disrupt a specific interaction of the B2AR with NHERF/EBP50/E3KARP-family proteins (78 ,79 and 80), a previously described

family of proteins that interact with the B2AR via PDZ (PSD95/Discs large/ZO-1-homologous) domains and also associate with the cortical actin cytoskeleton (81). Overexpression of a mutant form of EBP50/NHERF that cannot interact with the cortical actin cytoskeleton, or chemical disruption of the actin cytoskeleton itself, also inhibits recycling of internalized B2ARs. These observations suggest that sorting of internalized B2ARs between a distinct recycling and degradative pathway can be mediated by a protein complex associated with the cortical actin cytoskeleton. Moreover, these studies suggest that phosphorylation of a specific serine residue (Ser411), a potential substrate for a subset of GRKs (82), can modulate the sorting of receptors by this mechanism (78). Thus, sorting of receptors after endocytosis, like the initial endocytosis of receptors from the plasma membrane, may be closely linked to the cycle of receptor phosphorylation and dephosphorylation involved in mediating desensitization and resensitization of signal transduction. A proposed model summarizing our current understanding of distinct stages of B2AR endocytosis and sorting is summarized in Fig. 5.7 .

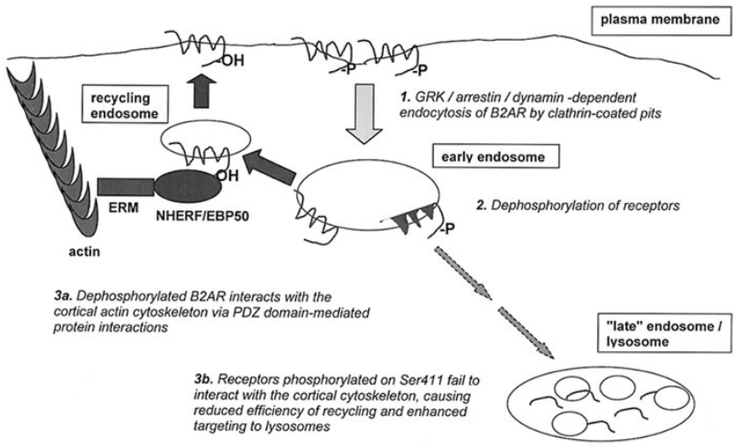

FIGURE 5.7. Model for endocytic sorting of the $ß_2$-adrenergic receptor (B2AR) by phosphorylation-regulated association of receptors with the cortical actin cytoskeleton. B2ARs undergo rapid desensitization and endocytosis (step 1). If receptors are dephosphorylated (step 2), they are able to interact with a cytoskeleton-associated protein complex via a PDZ domain-mediated protein interaction with the carboxyl-terminal cytoplasmic domain of the receptor, which promotes rapid recycling of receptors to the plasma membrane (step 3a). If serine 411 in the receptor tail remains phosphorylated, this protein interaction does not occur, and recycling of receptors is inhibited. Receptors that fail to recycle can later be delivered to lysosomes, with down-regulation of receptors accomplished by proteolysis (step 3b).

CONCLUSIONS AND FUTURE PERSPECTIVES

Part of "5 - Regulation of G Protein-Coupled Receptors by Phosphorylation and Endocytosis "

In this chapter, we have surveyed general processes of GPCR regulation and focused on selected mechanisms that are understood in molecular detail. A general principle emerging from this approach is that phosphorylation and membrane trafficking mechanisms are of fundamental importance to multiple processes of GPCR regulation. A second important principle is that distinct mechanisms of regulatory phosphorylation and membrane trafficking are closely interdependent, which leads to an appreciation of linked cycles coordinating the functional activation and regulation of receptors. An interesting corollary of this principle, suggested by certain recent studies of atypical antipsychotics and opiate analgesics (15), is that the linkage between specific mechanisms of receptor activation and regulation may be modified or disrupted by certain drugs. Therefore, it may be possible to target specific mechanisms of GPCR regulation, or the biochemical linkages between these mechanisms, to develop novel therapeutics that may influence the regulation of GPCRs in a manner quite different from that of classic agonists or antagonists.

We have restricted our focus to a subset of mechanisms that are, arguably, among the best established experimentally. It is important to note that these studies are in large part limited to model cell systems rather than native tissues. Nevertheless, the available data derived from transgenic and homologous recombination methodologies, and studies based on immunocytochemical localization of endogenously expressed GPCRs, suggest that phosphorylation (83 ,84) and endocytosis of receptors do occur in native tissues in response to physiologic stimulation (85 ,86) and certain drugs (14 ,72). Thus, it is reasonable to propose that mechanisms elucidated with model cell systems may indeed be relevant to receptor regulation *in vivo*. However, it is not yet possible to predict precisely how specific mechanism(s) of regulation modulate the central nervous system under physiologic or pathophysiologic conditions, or how specific mechanisms of regulation may contribute to the *in vivo* effects of clinically important drugs. Thus, an important future goal is to examine the regulation of GPCRs in native cell types and tissues, and to determine how specific mechanisms of regulation contribute to physiologic and pathophysiologic states.

Finally, it is important to note that by restricting our scope to a limited subset of GPCR regulatory mechanisms, we have underrepresented the diversity of GPCR regulation and the high degree of specificity with which individual receptors are regulated in various cell types. For example, although we have discussed only endocytosis of GPCRs by clathrin-coated pits, substantial evidence indicates that other mechanism(s) also can mediate regulated endocytosis of receptors (37 ,87 ,88 and 89). Moreover, it is increasingly apparent that mechanisms of GPCR phosphorylation and endocytosis discussed in this chapter serve additional important functions in signal transduction, such as controlling the interaction of “classic” GPCR signaling pathways with mitogenic kinase cascades (see also Chapter 16 and Chapter 22) (90 ,91 and 92). Indeed, we anticipate that our present understanding of the array of GPCR signaling and regulatory mechanisms is at a relatively early stage of rapid development, a view consistent with the results of recent studies identifying an unexpected diversity of cellular proteins that interact with specific GPCRs (93). Future studies of these unexplored mechanisms of GPCR regulation may lead to important new insights relevant to neuropsychiatric disease and may identify exciting new targets for the development of novel therapeutic drugs.

L-Glutamic acid (Glu) is accepted as the major excitatory neurotransmitter in the nervous system, although other acidic amino acids such as L-aspartic acid and L-homocysteic acid may also participate (1). Nevertheless, ongoing research reveals that the functions of Glu are much more diverse and complex than simply generating excitatory postsynaptic currents (EPSCs). It plays a major role in brain development, affecting neuronal migration, neuronal differentiation, axon genesis, and neuronal survival (2, 3 and 4). In the mature nervous system, Glu is central to neuroplasticity, in which there are use-dependent alterations in synaptic efficacy as well as changes in synaptic structure. These latter actions are intimately implicated in memory and related cognitive functions. Finally, persistent or overwhelming activation of glutamate-gated ion channels can cause neuronal degeneration (5) depending on the circumstances, this occurs by means of necrosis or apoptosis (6). Known as “excitotoxicity,” this phenomenon has been linked to the final common pathway of neuronal death in a range of disorders including Huntington’s disease, Alzheimer’s disease, amyotrophic lateral sclerosis (ALS), and stroke (7, 8).

This chapter provides an overview of the physiology and pharmacology of brain glutamatergic systems. There is a special emphasis on glutamate receptors because their rich diversity confers physiologic and pharmacologic specificity for this single neurotransmitter, which is used by up to 40% of all brain synapses. Finally, the potential role of glutamatergic system dysfunction in the pathophysiology of neuropsychiatric disorders is addressed.

AMPA-KAINATE RECEPTORS

Part of "6 - The Diverse Roles of L-Glutamic Acid in Brain Signal Transduction "

Glutamate receptors mediating fast EPSCs have been distinguished from the voltage-dependent NMDA receptors through the effects of conformationally restricted agonists. The former glutamate-gated ion channels (iGluRs) have been segregated into two types: the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors and KA receptors; however, cloning of the genes that encode the proteins comprising these iGluRs and the analysis of their pharmacology and biophysics in various expression systems indicate that each family of receptors represents complex heteromeric proteins consisting of multiple subunits with differential representation resulting in diverse functional attributes (9).

The AMPA receptor family consists of four genes that encode proteins of approximately 900 amino acids with 70% homology among themselves (GluR1-4) (1); however, cell-specific exon splice variants and posttranscriptional editing result in a complex range of physiologic responses. Two exon splice variants of GluR1-4 known as “flip” and “flop” affect desensitization, with the flip form associated with larger, more sustained currents (10). Splice variants truncated at the carboxy terminus have been described for GluR2 and GluR4 as well as the kainate subunits, GluR5–7 (9). Furthermore, nuclear editing of the mRNA encoding GluR2 transforms this receptor channel from one permeable to Ca^{2+} to one impermeable to the cation. Double-stranded RNA adenosine deaminase converts the adenosine in a CAG codon for glutamine (Q) to an inosine, thereby creating a CIG codon for arginine (R) (11, 12). The regulatory site for the editing process is located downstream in an intron that aligns with the exon to form the secondary structure recognized by the enzyme. Although the other AMPA receptor subunits are generally Ca^{2+} permeable, the presence of edited GluR2 dominates a heteromeric receptor

complex in that the multisubunit AMPA receptor behaves like GluR2 (i.e., has low calcium permeability). In the mature brain, the vast majority of GluR2 is edited and the majority of AMPA receptors have low calcium permeability, suggesting that GluR2 is reasonably ubiquitous (see the following). Mice in which the GluR2 editing process has been inactivated by a null mutation exhibit increased Ca^{2+} permeability with AMPA receptor activation, epilepsy, and early death (13). Stroke is associated with the suppression of GluR2 expression in the penumbra, resulting in increased Ca^{2+} permeability through the remaining AMPA receptors, thereby causing delayed neuronal degeneration (14).

Five separate genes encode the components of the kainate receptor: GluR5–GluR7 and KA1–KA2 (1). Homomeric complexes of GluR5, GluR6, and GluR7 form ion channels in the Xenopus expression system that are activated by KA but not by AMPA. However, homomeric complexes of KA1 or KA2 do not generate functional ion channels, although they exhibit high-affinity binding for kainic acid. It appears that KA1 or KA2 in conjunction with GluR5, GluR6, or GluR7 form functional KA receptors. GluR5 and GluR6 possess the Q/R editing site in their second transmembrane (M2) domain, which modulates Ca^{2+} permeability as for GluR2. Additional editing sites on GluR5–7 have complex effects on the receptor-channel function (15, 16). GluR5–7 are also widely represented in the brain, particularly in neocortex and hippocampus.

A number of modulators of AMPA/KA receptors have been identified that act by attenuating their rapid and profound desensitization. Cyclothiazide selectively inhibits desensitization of AMPA receptors, whereas the lectin, concanavalin A, blocks desensitization at KA receptors (17). “Ampakines” also enhance AMPA receptor activity by attenuating desensitization and have been shown to facilitate glutamatergic neurotransmission *in vivo*, thereby improving performance in several cognitive tasks (18). Polyamines, first noted for their effects on NMDA receptors, mediate rectification of Ca^{2+}-permeable AMPA and KA receptors by inducing a voltage-dependent channel blockade (19).

A number of conformationally restricted analogues have assisted in characterizing the activity of subsets of AMPA/KA receptors. Prior to development of AMPA, quisqualic acid was used as a non–NMDA receptor agonist; however, its specificity for AMPA receptors is poor as it also activates mGluR 1 and 5 metabotropic receptors and inhibits glutamate carboxypeptidase II (GCP II) (20, 21). The conformational rigidity of AMPA provides good specificity for AMPA receptors, whereas the more flexible kainic acid interacts with KA receptors as well as other types of iGluRs. The orientation, length, and saturation of the side chain of kainic acid and its analogues play a critical role in their binding to the receptor site with domoic acid exhibiting higher affinity and dihydrokainic acid having much lower affinity than kainate (22). The first potent selective antagonists at AMPA/KA receptors with negligible effects at NMDA receptors to be developed were the dihydroxyquinoxalines: CNQX, DNQX, and NBQX. With the exception of NBQX, which has a somewhat higher selectivity for AMPA receptors, they do not distinguish between AMPA and KA receptors. More recently 2,3-benzodiazepines have been demonstrated to act as selective noncompetitive AMPA receptor antagonists. The most potent in this family, GYKI53655, blocks AMPA receptors with an IC_{50} of 1 μM and has a 200-fold lower affinity for KA receptors (23). The recently developed LY294486 has tenfold specificity for inhibiting GluR5, indicating that iGluR subtype specific ligands can be developed.

Most of our initial knowledge concerning the regional brain expression of KA/AMPA receptors was based on autoradiographic studies. Specific binding of [^{3}H]-KA is relatively enriched in the hippocampal CA 3, striatum, deep layers of the neocortex, the reticular nucleus of the thalamus, and the cerebellar granular cell layer. When considered in aggregate, immunohistochemical staining for the five KA receptor subunits shares this ligand binding distribution (26).

Audioradiographic studies of the distribution of [^{3}H]-AMPA binding show high density in the CA 1 stratum radiatum, the dentate gyrus, superficial layers of the neocortex, and the molecular layer of the cerebellum (25). Consistent with its role in mediating EPSCs, moderate levels of binding are observed throughout the rest of the central nervous system (CNS). The distribution of [^{3}H]-AMPA binding corresponds with the regional expression of GluR1 and GluR2, because levels of GluR3 and GluR4 are much lower in the adult rat brain and have a more restricted distribution (27).

Although the autoradiographic approaches have been very informative with respect to general distribution of the KA/AMPA receptors, they have been less informative with respect to cellular and synaptic distribution and differential subunit distribution. It has recently become possible to overcome these limitations on both spatial and biochemical resolution, and begin the arduous process of delineating the GluR subunit profile of identified neurons and circuits in specific brain structures such as the neocortex and hippocampus. This capacity is a direct result of molecular neurobiological analyses that have fostered a detailed understanding of the subunit protein constituents of the three classes of inotropic GluRs, and thus allowed for *in situ* hybridization to be used to localize specific mRNAs (28) and with the use of class and subunit-specific antibodies for immunocytochemistry, it is now feasible to analyze GluR distribution at the highest levels of cellular and synaptic resolution (29, 30).

AMPA receptor subunit distribution in the hippocampus and neocortex offer an instructive example of such an approach. Although early studies demonstrated a wide distribution of AMPA subunits GluRs 2/3 in the brain and spinal cord (31, 32, 33 and 34), it became clear early on that the relationship

between GluRs and specific circuits needed to be analyzed at a high level of resolution; colocalization studies directed at subsets of neurons (29, 35, 36, 37 and 38) and ultrastructural dissection of the synapse (39, 40, 41, 42, 43 and 44). A key theme that emerges from these studies is that regional distribution and cellular colocalization patterns should not be extended to a synaptic interpretation: Such interpretations must be founded on ultrastructural data as seen in the following examples.

The cellular distribution of GluR2 has been linked to heterogeneity in calcium permeability of AMPA receptors (45, 46). For example, electrophysiological analyses have demonstrated that pyramidal cells have AMPA receptors with low calcium permeability, and interneurons have AMPA receptors with relatively high calcium influx (47, 48), and these properties are linked to the relative abundance of GluR1 versus GluR2 mRNAs (45, 46). In addition, early reports using polyclonal antisera that did not differentiate among GluR2, 3, and 4c, obtained results implying that GABAergic interneurons might not contain GluR2, 3, and 4C (49, 50 and 51).

Definitive conclusions regarding selective distribution of GluR2-specific protein were not possible until 1996, when an exclusively GluR2-specific monoclonal antibody (52), followed by a rabbit polyclonal (53) were developed. The GluR2 antibodies showed that virtually all pyramidal cells and the majority of GABAergic interneurons in the neocortex (e.g., S1) contain GluR2. A similar pattern was found in hippocampus, suggesting that the majority of the GABAergic interneurons in hippocampus are GluR2-positive, although a subset of GABAergic neurons lacks any detectable GluR2 (52, 53), as in neocortex. These results are in excellent accord with the GluR2 mRNA results obtained by single cell RT-PCR studies (45, 46), and suggest that a minority of the GABAergic interneurons lack GluR2 mRNA/protein. Thus, the differences in calcium permeability between GABAergic interneurons and pyramidal cells could not be the result of a widespread lack of GluR2 in GABAergic interneurons.

A double label GABA/GluR2 analysis that was extended to the ultrastructural level further clarified the issue of GluR2 representation in GABAergic interneurons (54). It was hypothesized that if the difference in calcium permeability between pyramidal and GABAergic neurons was related to differences in GluR2 expression, then it would likely be more apparent on the synaptic than the cellular level (54). Ultrastructural analysis revealed that there is a consistently lower number of immunogold particles at the labeled asymmetric synapses on GABAergic dendrites than those on pyramidal cell dendrites or spines, suggesting that a cell class-specific difference in synaptic abundance of GluR2 is the substrate for the observed differences in calcium permeability across these two cell classes revealed electrophysiologically (45, 46).

As demonstrated in the GluR2 studies discussed in the preceding, cellular colocalization may not adequately reflect the localization patterns at the synaptic level. This was reinforced in studies of GluR2/NR1 colocalization in hippocampus and neocortex, designed to delineate the degree of synaptic colocalization of NMDA and AMPA receptors in asymmetrical synapses (39, 40, 41, 42 and 43). Although NR1 and GluR2 are broadly colocalized on a cellular level, extensive synaptic heterogeneity exists in their representation. NR1 and GluR2 are often colocalized at the same synapse; however, there are also a large group of NR1-containing synapses that lack GluR2 labeling (33% in [39]), many of which were on spines. These may be candidates for the “silent synapses” that have been described electrophysiologically (55, 56) that might be activated by insertion of AMPA subunits (40, 42, 55, 56 and 57).

It has been generally recognized that AMPA receptors play a dominant role in mediating EPSCs. A physiologic role for KA receptors has been elucidated only recently with the development of more selective agonists and antagonists. In the hippocampal slice in which the AMPA, NMDA, and GABA receptors have been blocked pharmacologically, stimulation of the mossy fibers generates a slow excitatory synaptic current system with the biophysical properties of the KA receptor (58). This current is absent in mice homozygous for null mutation of the GluR6 subunit and less vulnerable to the epileptogenic effects of systemic KA (59). The presynaptic inhibitory effect on GABA release in the CA 1 region of the hippocampus is mediated by the GluR5 subunit (60).

Although KA subunits have not been localized as extensively at the ultrastructural level as have AMPA or NMDA receptors, immunocytochemical studies have demonstrated their broad distribution in the hippocampus and neocortex and broad colocalization with AMPA and NMDA receptor subunits (38, 61) in both pyramidal and GABAergic interneurons (35, 36).

NMDA RECEPTORS

Part of "6 - The Diverse Roles of L-Glutamic Acid in Brain Signal Transduction "

The NMDA receptor, as its name indicates, was identified by the selective excitatory effects of the synthetic analogue of glutamate, N-methyl-D-aspartic acid (1). A number of properties distinguishes the NMDA receptor from the non-NMDA iGluRs. First, its activity is voltage dependent. At resting membrane potential, the channel is blocked by Mg^{2+}, which is relieved by membrane depolarization. Second, the receptor requires occupancy of another ligand binding site, the so-called glycine modulatory site, in order for glutamate to gate channel opening. Recent evidence indicates that not only glycine but also D-serine, which is synthesized in astrocytes by serine racemase, is a potent endogenous agonist at the glycine site (62). Third, the NMDA receptor possesses a number of modulatory sites of physiologic significance. Zn^{2+} is a potent inhibitor of NMDA receptor conductance, especially those containing the NR2A subunit (24). Zn^{2+} is concentrated in some glutamatergic

terminals (e.g., the mossy fibers) and released with glutamate (63). A binding site for polyamines, when occupied, enhances conductance in part through increasing the affinity of the glycine modulatory site on the NMDA receptor (64). Receptor function is also modulated by redox status (65). Within the channel, there is a binding site for the dissociative anesthetics such as phencyclidine (PCP), MK-801, and ketamine, which serve as noncompetitive inhibitors (66). The effects of the dissociative anesthetics occur only with open channels, thereby causing a use-dependent inhibition. Finally, the NMDA channel provides ready passage of Ca^{2+}, a cation involved in a number of intracellular signaling processes.

Molecular cloning has disclosed at least six genes that comprise a family of polypeptides that form the various subtypes of the NMDA receptor (1). NR1 was the first component cloned and, when expressed in Xenopus oocytes, was shown to possess the primary electrophysiologic and pharmacologic features of the NMDA receptor–channel complex. Seven splice variants of NR1 have been described, which reflect the exclusion or inclusion of three exons, two in the C terminal and one in the N terminal portion (1). These splice variants significantly impact the biophysical characteristics of the receptor. The NR2 subunits, NR2A-D and the recently identified NMDARL or NR3A, do not form channels (67); however, when coexpressed with NR1, the heteromeric channels exhibit a markedly increased current as compared to the homomeric NR1 channels. Each of the NR2 subunits, when complexed with the NR1 subunit, exhibits different biophysical and pharmacologic properties. The NR2A and NR2B subunits, more highly expressed in adult cortex in contrast to NR2C/D receptors, appear to be less sensitive to NMDA receptor antagonists, not as vulnerable to Mg^{2+} blockade, and have lower Ca^{2+} conductance (1).

NR1 is expressed in most neurons, whereas the NR2 mRNAs exhibit different regional and developmental patterns of expression (68, 69). The NR2A subunit is highly expressed in the neocortex, hippocampus, cerebellum, and several thalamic nuclei. The NR2B subunit is found in the neocortex, hippocampus, striatum, septum, and thalamic nuclei of the adult rat brain. The expression of the NR2C subunit is much more restricted in the adult brain, being enriched in the olfactory bulb, thalamic nuclei, and cerebellum. Finally, the NR2D subunit is enriched in brainstem nuclei, midline thalamic nuclei, and bipolar cells of the retina. The NR2B and NR2D subunits appear early in brain development, followed by a decline in NR2D expression in the third week after birth of the rat, whereas the acquisition of NR2A and NR2C subunits appears primarily postnatally in the rat (1).

With respect to NMDA receptor localization, as in the case of AMPA/kainate receptors, the early *in situ* hybridization studies discussed in the preceding offered important information as to the regional distribution of NMDA receptors in the brain. These studies have been followed with very extensive immunocytochemical analyses, particularly of the obligatory subunit NR1. With respect to hippocampus and neocortex, NR1 is very broadly distributed and present in virtually all pyramidal neurons and nonpyramidal GABAergic interneurons (29, 38), and in fact, appears to be present in over 90% of asymmetric synapses (30, 41). NR1 distribution has also been shown to be modifiable on both the cellular and synaptic level with respect to plasticity. For example, deafferentation causes rearrangements of NR1 distribution at the cellular and synaptic level in a matter of days (70, 71). In addition, although NMDA receptors have a very broad distribution on a cellular level, they can display a high degree of specificity on a synaptic basis. The most dramatic example of this is in CA3 of the hippocampus, where NMDA receptors are present postsynaptically in the distal dendrites (i.e., stratum moleculare), yet are absent in the stratum lucidum terminal zone, which is noted for LPT being NMDA receptor-independent (37, 56, 72). This suggests that there are intracellular trafficking mechanisms or local synthesis that can position NMDA receptors in a subset of synapses receiving a particular input to a given cell while not mediating other inputs.

The data on the distribution of other subunits are less well developed, and this is partly owing to the fact that it has been very difficult to develop antibodies that differentiate NR2A from NR2B, the two dominant subunits in the NR2 group in the hippocampus and neocortex. In general, it appears that NR2A and NR2B overlap in their distribution with NR1 to a large degree (73, 74 and 75); however, there are regions such as CA3 where they differ in their distribution with NR1 (75, 76), but this has yet to be worked out at the synaptic level. The detailed delineation of the synaptic distribution of NR2A and NR2B is an important task for the future given that the presence of these subunits confer different functional attributes on the receptor, and the analysis of genetically manipulated mice have suggested that up- or down-regulation of one of these subunits can profoundly impact their function. For example, NR2B overexpression in mouse enhances learning and memory (77). Thus, as is the case for AMPA and kainate receptors, delineating the subunit representation and potential stoichiometry at specific circuits and synapses for the NMDA receptor is of paramount importance if this receptor is to be definitively linked to circuits that mediate specific behaviors and suffer under certain pathologic conditions.

Several endogenous amino acids, aside from glutamate, are selective agonists at the NMDA receptor, including L-homocysteic acid, L-aspartic acid, L-cysteine sulfate, L-serine-O-sulfate, L-cysteic acid, and quinolinic acid in order of decreasing potency (78). Given the multiple modulatory sites and agonist binding sites for the NMDA receptor, it is not surprising that the antagonist pharmacology for this receptor is complex. Several phosphonate analogues of glutamate, including D-aminophosphonovaleric acid (APV),

D-aminophosphonoheptanoic (APH) acid, D-aminoadipic acid, and the cyclic analogue of AHP, (2-carboxypiperazin-4-yl)-propyl-1-phosphonate (CPP), are competitive inhibitors to glutamate. As described, the NMDA receptor channel has a binding site for dissociative anesthetics, which shares pharmacologic features with the σ receptor. The glycine modulatory site, which must be occupied for glutamate gating of the ion channel, is subject to inhibition by the endogenous metabolite of tryptophan, kynurenic acid as well as synthetic analogues such as 7-chlorokynurenate (79). For greater selectivity, attention is now directed at developing subtype specific antagonists such as ifenprodil, which inhibits NMDA receptors bearing the NR2B subunit (80).

METABOTROPIC GLUTAMATE RECEPTORS

Part of "6 - The Diverse Roles of L-Glutamic Acid in Brain Signal Transduction "

It was generally believed that the neurophysiologic effects of glutamate were mediated exclusively by iGluR, until Sladeczek and colleagues (81) reported that glutamate catalyzed phosphoinositide hydrolysis through a receptor coupled to a G-protein. Since then, research has disclosed the existence of a family of glutamate receptors whose effects are largely mediated by G-proteins, the so-called metabotropic glutamate receptors (mGluRs). The mGluRs appear to play an important role modulating both presynaptically and postsynaptically the effects of glutamate at glutamatergic synapses where iGluRs are also engaged (82).

Cloning of mGluR 1 indicated that the predicted amino acid sequence shared negligible homology with any of the other G-protein coupled receptor (GPCR) families except the parathyroid Ca^{2+}-sensing receptor (83) and the GABA-B receptor (84). On the basis of pharmacology, physiologic effects, and sequence homology, the eight mGluRs have been subdivided into three groups (85). Group I includes mGluR 1 and mGluR 5, which act via phospholipase C; group II includes mGluR 2 and mGluR 3, which are negatively coupled to adenylyl cyclase; and group III, which includes mGluR 4, 6, 7, and 8, and are also negatively coupled to adenylyl cyclase. Adding to this complexity, mGluR 1 has four splice variants, whereas mGluR 4 and 5 each have two. The mGluRs within a group exhibit greater than 70% sequence homology, whereas the homology falls to approximately 45% between groups (82).

Like other GPCRs, the mGluRs have seven putative transmembrane domains separated by short intracellular and extracellular loops and an unusually large extracellular domain that contains nearly a score of cysteine residues (86). In further contradistinction to other GPCRs, the agonist binding sites for the mGluRs are located in the extracellular domain. As a family, mGluRs are broadly expressed in the nervous system, with group I having primarily a postsynaptic localization, whereas groups II and III primarily have a presynaptic localization where they serve as autoreceptors and heteroreceptors that negatively regulate neurotransmission (82). mGluR 1 is prominently expressed in the hippocampal granule and pyramidal cells, the Purkinje cells of the cerebellum, the thalamus, and the lateral septum (87). mGluR 5 exhibits somewhat of a complementary distribution with high levels expressed in the neocortex, the pyramidal cells in CA1 sector of the hippocampus, lateral septum, striatum, and nucleus accumbens (88). Although studies *in vivo* suggest a low level of expression of mGluR 5 in glia, cultured astrocytes exhibit high expression (89). The expression of group II receptors is more restricted than group I, with mGluR 2 found in the cerebellum, pyramidal cells in the entorhinal cortex and the dentate gyrus, and presynaptically on corticostriatal afferents (90). The majority of the cerebellar Golgi cells have mGluR 2 but a minor subset express mGluR 5 in a complementary fashion (91). mGluR 3 is found in astrocytes throughout the brain and in neurons in the neocortex, caudate putamen, thalamic reticular nucleus, and granule cells of the dentate gyrus (92). With regard to group III, mGluR 4 is found in the thalamus, lateral septum, dentate gyrus, and cerebellar granule cells (92). mGluR 7 has a widespread distribution with prominent representation in sensory afferent systems including the dorsal root ganglia and the trigeminal nucleus in addition to the cerebral cortex, hippocampus, striatum, thalamus, and Purkinje cells (93). mGluR 6 is restricted to on-bipolar cells in the inner nuclear layer of the retina (94), with a highly specific synaptic distribution (95). Finally, mGluR8 is found in the mitral cells of the olfactory bulb, piriform cortex, and lateral thalamic reticular nucleus (96).

Ultrastructural studies have demonstrated that mGluRs differ in their predominant synaptic distribution from AMPA and NMDA receptors. Although AMPA and NMDA receptors are localized predominantly in the postsynaptic density, mGluRs are principally localized presynaptically and perisynaptically (97, 98 and 99). In addition, the mGluRs exhibit a high degree of specificity in this regard with mGluR7 (100, 101) and mGluR4 (102) (which are primarily present presynaptically) and mGluRs 1 and 5 (which are primarily present perisynaptically) (103, 104 and 105). These patterns suggest that synaptic localization is partially segregated by mGluR group (99), with group I primarily perisynaptic, surrounding the postsynaptic density, group II primarily presynaptic or extrasynaptic, and group III optimally situated as an autoreceptor on the presynaptic terminal. These synaptic distribution patterns position mGluRs to play a critical role in modulating excitatory neurotransmission.

Group I mGluRs stimulate phospholipase C and the hydrolysis of phosphoinositide. These two receptors have been reported to stimulate cAMP formation in different model systems (106). They also increase the excitability of neurons by reducing the K^+ currents, through a mechanism that appears to be independent of G-protein action (107). Although the AMPA receptor agonist, quisqualic acid, is the

most potent agonist at the group I mGluRs, 3,5-dihydroxyphenylglycine (3,5-DHPG) is the most specific agonist. Group II mGluRs inhibit adenylyl cyclase by coupling with the G_i-protein. (See ref. 43 for a detailed review of mGluR pharmacology.) Group II receptors also inhibit the N-type Ca^{2+} channels through GI-protein coupling. The group III mGluRs inhibit adenylyl cyclase via GI-protein, although they may utilize other transduction mechanisms.

The most specific agonist at group I mGluRs appears to be 2R, 4R-4-aminio pyrrolidine-2, 4 dicarboxylate (APDC). LY354740 is an exceptionally potent and selective agonist at group II mGluRs and is effective with systemic administration (108). Notably, N-acetylaspartyl glutamate (NAAG), an endogenous neuropeptide, is a relatively potent agonist at mGluR 3, although it also serves as an antagonist at the NMDA receptor (109). L-aminophosphonobutyric acid (L-AP4) is the most potent and selective agonist at the group III mGluRs with the exception of mGluR 7, where L-serine-O-phosphate has greater potency. Presently, 2-carboxy-3-phenylcyclopropyl glycine (CPCG) is the most potent antagonist against the group II mGluRs, and α-methyl-4-phosphonophenyl-glycine appears to be an effective antagonist against the group III mGluRs, although the pharmacology of these receptors remains less well developed than the group I mGluRs.

The heterogeneity of the mGluRs and their role in modulating glutamatergic neurotransmission make them attractive potential therapeutic targets for drug development. Thus, activation of group II and group III mGluRs has been associated with protection against excitotoxicity, whereas activation of group I mGluRs may actually enhance NMDA receptor-mediated neuronal degeneration (110, 111). Recently it has been shown that inhibition of GCP II, the enzyme that degrades the selective mGluR 3 agonist NAAG, provides potent protection against neuronal degeneration caused by transient occlusion of the middle cerebral artery (112). A similar reciprocal relationship has been observed with regard to the effects on epilepsy with group I agonists exacerbating and group II and III agonists attenuating seizures (113). Finally, metabotropic receptors, both in the dorsal root and thalamus, have been implicated in modulating neuropathic pain (114).

GLUTAMATE TRANSPORTERS

Part of "6 - The Diverse Roles of L-Glutamic Acid in Brain Signal Transduction "

The demonstration of sodium-dependent high-affinity transport of glutamate in synaptosomal preparations was the first evidence supporting the hypothesis that glutamate serves as a neurotransmitter (115). The presence of these transporters on excitatory nerve terminals was exploited to label putative glutamatergic pathways such as the climbing fibers of the cerebellum through the autoradiographic visualization of retrogradely transported radiolabel in axons and cell bodies. The transporters are capable of maintaining extraordinary gradients with the extracellular concentration of glutamate in brain low μM (i.e., below the threshold for iGluRs) in the face of a tissue concentration in the mM range (116). Energy deprivation not only collapses the sodium gradient across the membrane that drives the transporter, thereby inhibiting glutamate uptake, but also results in reverse transport with massive efflux of glutamate stores (117). Pharmacologic inhibition of glutamate transport in tissue culture models has been shown to promote excitotoxic neurodegeneration (118).

Early pharmacologic studies pointed to the existence of subtypes of sodium-dependent glutamate transporters in brain with cerebellum exhibiting a form that is much more sensitive to inhibition by L-α-aminoadipate and forebrain sensitive to dihydrokainate (119). Both the pharmacologic heterogeneity as well as the diverse cellular distribution of the sodium-dependent glutamate transporters have been illuminated recently by their cloning and molecular characterization. (See refs. 120 and 121 for review.) Although acronyms have varied with the sequence of discovery, five excitatory acidic amino acid transporters (EAAT) that are sodium dependent and chloride independent have been cloned. EAAT 1 or GLAST has its highest expression in brain but is also found in peripheral tissue and placenta. The cerebellum appears to have the highest level within brain, depending on the species. EAAT 2 (GLT 1) is primarily expressed in brain, although low levels have been reported in pancreas and placenta; the highest expression occurs in the forebrain, the lowest in the cerebellum. Its expression is predominantly if not exclusively astroglial in localization. The predominant neuronal transporter is EAAT 3, which is also expressed in kidney and to a lesser extent in other peripheral tissues. Consistent with the broad distribution of glutamatergic neuronal systems in brain, the levels of EAAT 3 are fairly uniform. EAAT 3 is not consistently expressed in all glutamatergic systems, and some nonglutamatergic systems express it (122). Thus, EAAT 3 does not appear to be a specific marker for glutamatergic neurons. Two additional minor forms have been identified: EAAT 4, which is expressed in cerebellar Purkinje cells; and EAAT 5, which is limited to the retina.

Like the mGluRs, the neuronal transporter EAAT3 (i.e., EAAC1) has been shown to have a synaptic distribution different from the AMPA or NMDA receptors in that it is primarily perisynaptic and presynaptic (44, 123). A double-label postembedding immunogold study demonstrated the value of such ultrastructural data for revealing the importance of differential distribution of these proteins with respect to the synapse (44). The double-label analysis targeted the AMPA subunit GluR2 and the glutamate transporter, EAAT3 (i.e., EAAC1), the neuron-specific glutamate transporter. This study revealed differential spatial distribution of these two proteins very clearly. At the light microscopic level, as expected, GluR2 was broadly colocalized with EAAC1 in hippocampal projection neurons, and both proteins

had substantial cytoplasmic pools. However, the postembedding immunogold localization offered additional insights into the spatial relationships between EAAT3 and GluR2 localization in and near the synapse, revealing morphologic and molecular constraints on excitatory synaptic transmission. Specifically, synaptic GluR2 was present primarily in the postsynaptic specialization, appropriately positioned to mediate the synaptic effects of glutamate. EAAT3 was not intermingled with GluR2 postsynaptically, but was generally present perisynaptically, often immediately outside the synaptic specialization, with a small but significant presynaptic pool as well (44). This arrangement positions EAAT3 to both confine glutamate to the synaptic site that contains the inotropic receptor molecules, as well as to regulate its levels in immediately adjacent presynaptic and postsynaptic domains. This distribution is also interesting with respect to the distribution of mGluRs, which are located perisynaptically and extrasynaptically (see the preceding). This suggests that EAAT3 is also optimally positioned to regulate the exposure of perisynaptic and presynaptic mGluRs to glutamate (44).

The EAATs exhibit affinities for glutamate in the low μM range, two orders of magnitude more avid than the vesicular transporter for glutamate, which is not sodium dependent. A generally accepted model for transport involves the binding of three Na^+, one H^+, and glutamic acid, which is linked to the counter transport of one K^+ (124). In addition, there is increasing evidence that individual EAAT subtypes may also subserve signal transduction activity; thus, EAATs have been implicated in inhibition of adenylyl cyclase, altering Ca^{2+} levels and Cl^- flux by mechanisms independent of glutamate transport (121).

Pharmacologic inhibition of EAAT activity potentiates excitotoxic effects in tissue culture (118). Mice homozygous for the nul mutation of EAAT 2 develop fatal epilepsy and exhibit increased vulnerability to excitotoxic insults (125), and mice homozygous for the nul mutation for EAAT 1 exhibit cerebellar dysfunction (126). Thus, in contrast to the original hypothesis of the essential role of neuronal glutamate transport in terminating excitatory neurotransmission, it is now apparent that the glial transporters play the dominant role in neuroprotection from glutamate. In this regard, astroglial processes are tightly interdigitated with glutamatergic and GABAergic synapses, where the transporters are expressed in high density, which accounts for the previous identification of the “synaptosomal” localization of glutamate transport (127).

The activity of the glutamate transporters is regulate by transcriptional as well as posttranslational mechanisms. (See ref. 128 for review.) GLT-1 expression, which is normally low in primary astrocyte cultures, is significantly increased in astrocytes by coculture with neurons (129). Furthermore, subsequent destruction of the neurons results in down-regulation of GLT-1 but an up-regulation of GLAST protein (130). Fornix transection results in down-regulation of both GLT-1 and GLAST in the innervation field (131). The neuronal signal mediating this interaction has proved to be somewhat elusive but may in fact be glutamate itself acting at AMPA/KA receptors on astrocytes. PKC has also been implicated in the regulation of glutamate transporter activity both directly and by altering trafficking (136).

GLUTAMATE AND GLIA

Part of "6 - The Diverse Roles of L-Glutamic Acid in Brain Signal Transduction "

The neuroprotective action of glutamate transporters expressed by astroglia represents only one facet of the critical role astroglia play in modulating glutamatergic neurotransmission. Astrocytes express a high-affinity Na^+-dependent transporter for glycine, GlyT-1, which maintains concentrations of glycine that are subsaturating for its modulatory site (K_d = 20 nM) on the NMDA receptor in spite of μM levels in cerebrospinal fluid (CSF) (133). In addition, forebrain astroglia express serine racemase, which generates D-serine, a potent agonist at the glycine modulatory site (31). The metabolism of tryptophan by a series of enzymes expressed in glia generates both positive and negative modulators of the NMDA receptor (134). Of these, quinolinic acid is an agonist at NMDA receptors. Although its affinity for the receptor is relatively low, lack of efficient clearance mechanisms renders it a pathophysiologically significant NMDA receptor agonist. For example, the levels can achieve toxic concentrations in HIV encephalopathy with the activation of microglia and infiltration of macrophages highly expressing quinoline (135). Kynurenic acid, another metabolite of tryptophan, is a noncompetitive antagonist at the NMDA receptor acting at the glycine modulatory site. The synthesis of kynurenic acid in brain takes place almost exclusively in astrocytes and is regulated by cellular energy status, ionic environment, local 2-oxo acid concentration, and dopaminergic neurotransmission (136). Altered levels of kynurenic acid in disease states such as Huntington’s disease (HD) and schizophrenia appear to correlate with NMDA receptor dysregulation (137).

N-acetylaspartyl glutamate is an abundant neuropeptide found in many but not all glutamatergic systems and several well-characterized nonglutamatergic systems such as the locus ceruleus and motor neurons. Located in storage vessels and subject to evoke release by a Ca^{2+}-dependent process, NAAG is a noncompetitive antagonist at NMDA receptors (138) and a selective agonist at the mGluR 3 (60). It is metabolized to N-acetylaspartate and glutamate by GCP II, which is selectively expressed by astrocytes (139). Postmortem studies indicate reduced activity of GCP II in hippocampus, temporal cortex, and frontal cortex in schizophrenia, a disorder potentially involving hypofunction of NMDA receptors (140), and increased activity in motor cortex and dorsal horn, which would increase extracellular glutamate generated from NAAG in the neurodegenerative disorder ALS (141).

GLUTAMATE AND NEURODEGENERATION

Part of "6 - The Diverse Roles of L-Glutamic Acid in Brain Signal Transduction "

The term “excitotoxicity” was coined by Olney 30 years ago to designate a selective form of neurodegeneration caused by systemic treatment of newborn rodents with monosodium glutamate (5). Degeneration of neurons with their perikarya in the arcuate nucleus of the hypothalamus was apparent 90 minutes after injection; notably, axons passing through the lesion and glia were spared. As the neurotoxic effects of glutamate analogues correlated with their excitatory potency, Olney hypothesized that the neuronal degeneration resulted from excessive activation of glutamate receptors expressed on neurons. Through the use of potent excitatory analogues of glutamate, the relevance of this phenomenon to neurodegenerative diseases became apparent. Thus, Coyle and Schwarcz reported that intrastriatal injection of kainic acid in the rat replicated the neuropathologic and synaptic neurochemical alterations that occur in HD (142). Systemic treatment with kainic acid produced a behavioral syndrome and histopathology associated with temporal lobe epilepsy. GluR-mediated neurodegeneration now has been implicated in a broad range of neurodegenerative conditions including stroke, ALS, cerebellar degeneration, and trauma (5, 143, 144).

Our knowledge of the role of iGluRs in neurodegenerative diseases has greatly increased since the realization that excitotoxicity is linked to programmed cell death (PCD) in many neurodegenerative disorders. A seminal paper by Kerr and colleagues (145) illustrated the morphological differences between apoptosis and necrosis. Subsequently, several genes that regulate cell death in *C. elegans* were identified, leading to the discovery of the caspases and Bcl-2 and homologues (146). As a consequence, the idea that cells could control their own death through the synthesis of new proteins was formulated. Subsequently, inhibitors of macromolecular synthesis were proved to prevent the naturally occurring cell death in both sensory and motor neurons. Recently, numerous molecular pathways and their components that activate or prevent neuronal cell death in response to iGluR activation have been identified.

A major effort has been undertaken to identify the specific iGluRs and the downstream events following receptor stimulation that mediate the death processes. Nevertheless, effective therapies to prevent or limit neuronal damage in neurodegenerative diseases remain elusive, reflecting an incomplete understanding of the mechanisms of neuronal death *in vivo*. It has become apparent that the boundary between apoptosis and necrosis is not well defined, leading to the realization that there exists a gradual shift from an apoptotic to a necrotic cell death in many cases, referred to as the “apoptotic-necrotic” continuum (6). Weaker insults typically promote apoptosis, whereas stronger ones favor necrosis. In other cases the apoptotic mechanism is activated along with the necrotic one, hampering attempts to distinguish the two (147).

Apoptotic cell death is typically associated with caspase activation, chromatin condensation, DNA laddering, and cell membrane blebbing that lead to cell shrinkage (6). Necrosis, on the other hand, is usually associated with the failure of ion pumps that causes cells to swell and burst, and is identified in tissues by the presence of invading macrophages and disruption of plasma membrane integrity, whereas in cell culture the absence of apoptotic markers and the rapid time course of death are the best indicators. Proteolysis by calpain and the caspases is often an early event following iGluR activation (148). Calcium overload mediated by iGluRs has a significant role in neurodegeneration (149). In addition, reactive oxygen species (ROS) play an important role in neuronal death mediated by iGluRs (150).

Mitochondria are almost invariably involved in the pathways triggered by iGluR activation. There are several general mechanisms at play, including release of proteins that activate caspases, disruption of electron transport, and alteration of cellular redox potential. The discovery that Bcl-2 is localized to the mitochondria directed attention toward the role of this relationship in cell death (151). Subsequently, it was found that Bcl-2 could prevent cytochrome c release, an inducer of apoptosis, from mitochondria. Bcl-2 also blocks the onset of the mitochondrial permeability transition (MPT) (152). The MPT represents an increase in permeability of the mitochondrial inner membrane to solutes of 1,500 daltons or less that results in membrane depolarization, uncoupling of oxidative phosphorylation, ion release, and mitochondrial swelling (153). Many of the insults that lead to the opening of the MPT function in a positive feedback manner (154). Glutamate can induce either early necrosis or delayed apoptosis in cultures of cerebellar granule cells, with mitochondrial function a critical factor that determines the mode of neuronal death (6).

Excitotoxicity is more commonly associated with necrosis because activation of iGluRs results in cation flux into the cell; however, apoptosis can follow stimulation of both AMPA/KA and NMDA receptors. The iGluRs may activate apoptosis using existing cellular components; for example, Simonian and colleagues demonstrated that kainate neurotoxicity in cerebellar granule cells was apoptotic but independent of protein synthesis (155). Alternatively, cells may require a prior insult or the addition or withdrawal of a trophic factor to become sensitive to iGluR activation that ordinarily would not be toxic. Cultured cerebellar granule cells remain resistant to AMPA–receptor-mediated toxicity when maintained in medium containing serum or insulin-like growth factor I (IGF-I), but become sensitive 4 to 5 days following the removal of trophic factors (156). In other cases, iGluR activation triggers PCD that utilizes a signaling pathway. Jiang and associates reported that NMDA receptor-mediated influx of extracellular Ca^{2+} rapidly and transiently activated ERK1/2, leading to apoptosis in cultured rat cortical neurons (157). Activation of the NMDA receptor

up-regulated p53 expression in cultured cerebellar granule cells, whereas blockade of p53 induction by an antisense oligonucleotide resulted in a complete inhibition of apoptosis (158). Similarly, systemic administration of kainate increased p53 mRNA levels in neurons exhibiting morphological features of damage within kainate-vulnerable brain regions (159).

Apoptosis may be a favored route in PCD partly because the reactive microglia that usually accompany necrosis often stimulate secondary cell death. Caspase-mediated degradation of AMPA receptor subunits occurs early during periods of cell stress in cultured rat hippocampal neurons (160). This may favor apoptosis, because levels of the AMPA receptor subunits GluR1 and GluR4 are rapidly decreased in neurons undergoing apoptosis in response to withdrawal of trophic support, whereas levels of NMDA receptor subunits NR1, NR2A, and NR2B are unchanged. Activation of calpain I by NMDA in cultured hippocampal neurons prevented the entry of cells into a caspase-dependent cell death program after the mitochondrial release of cytochrome c, possibly by inhibiting the processing of procaspase-3 and -9 into their active subunits (161). Thus, moderate NMDA receptor activation can prevent apoptosis without stimulating caspase-independent cell death, whereas a more severe stimulus favors apoptosis.

Necrotic cell death following iGluR activation is often attributed to alterations in receptor desensitization, subunit expression or other regulatory mechanisms. Human NT2-N neurons, which express calcium-permeable AMPA receptors, become vulnerable to excitotoxicity when desensitization is blocked with cyclothiazide (162). Necrosis is induced by insulin treatment within 48 hours in cultured mouse cortical neurons (163). Insulin exposure increased the level of the NR2A subunit of the NMDA receptor without altering NR1 or NR2B levels. Macromolecular synthesis inhibitors and NMDA antagonists blocked cell death, suggesting that an activity-dependent emergence of excitotoxicity contributed to insulin neurotoxicity. Cultured rat hippocampal neurons pretreated with BDNF exhibited increased levels of NR1 and NR2A, greater calcium responses to NMDA, and enhanced vulnerability to excitotoxic necrosis and reduced vulnerability to apoptosis (164). Cultured cerebellar granule cells, which show primarily an apoptotic death following KA treatment, undergo necrosis when L-type voltage-dependent calcium channels are blocked (147).

GLUTAMATE AND BRAIN DISORDERS

Part of "6 - The Diverse Roles of L-Glutamic Acid in Brain Signal Transduction "

Neurodegenerative Diseases

HD is an autosomal dominant, progressive neurodegenerative disease that typically has its symptomatic onset in midlife. Its manifestations include chorea, dementia, and death 15 to 20 years after onset. Afflicted individuals have an expanded CAG repeat in the gene encoding huntingtin on chromosome 4, resulting in an elongated series of glutamines. The number of CAG repeats is 10 to 34 in normal individuals and 37 to 100 in HD patients (165). The identification of the HD gene has enabled the production of mouse models transgenic for huntingtin such as line R2/6, which has exon 1 with 92 repeats as well as transgenic cell lines that reiterate cellular characteristics of the disease (see the following).

HD was the first neurodegenerative disease for which iGluR-mediated neurodegeneration was implicated. Intrastriatal injection of kainate in the rat caused a striatal neuronal degeneration resembling HD (142); however, subsequent studies revealed that NMDA receptor agonists replicated the selective neuronal vulnerability in HD much more faithfully (166). Chronic treatment of rats with the mitochondrial toxin 3-nitropropionic acid elevated striatal lactate and selective striatal neuronal degeneration mediated by NMDA receptors (167). In this regard, lactate is elevated in the cerebral cortex and basal ganglia of HD patients. There is also reduced phosphocreatine/inorganic phosphate in resting muscle of HD patients, and mitochondrial electron transport enzymes are reduced in HD postmortem tissue. (See ref. 168 for review.) Consistent with these observations, mitochondria from HD lymphoblasts and fibroblasts display an increased tendency to depolarize (169). It may be that as a consequence of lowered energy levels, striatal neurons in HD can not maintain the resting membrane potential (thereby relieving the Mg^{2+} block), leading to increased $[Ca^{2+}]_i$ via NMDA receptors and ultimately cell death. Noteworthy is a report by Ferrante and associates that dietary creatine supplementation improved survival, slowed the development of striatal atrophy, and delayed the formation of huntingtin-positive aggregates in mice transgenic for huntingtin exon 1 with the expanded CAG repeat (170). Creatine may exert neuroprotective effects by increasing phosphocreatine levels or stabilizing the MPT, either of which could mitigate excitotoxicity mediated by GluRs.

Altered expression or composition of iGluR subunits may also contribute to neuronal death in HD. The editing of GluR2 mRNA is compromised in a region-specific manner in HD as well as in schizophrenia and AD, although there is still a large excess of edited GluR2 in each of these disorders (171). Chen and co-workers found that coexpression of huntingtin containing 138 repeats with NMDA receptors resulted in an increased number of functional NR1/NR2B-type receptors at the cell surface as compared to cells with normal huntingtin (172). Striatal spiny neurons are selectively vulnerable in HD and ischemia, whereas large aspiny (LA) cholinergic interneurons of the striatum are spared in these pathologic conditions. Because NR1/NR2B is the predominant NMDA receptor expressed in medium spiny neostriatal neurons, this may contribute to the selective vulnerability of these neurons in HD (172). Calabresi and associates found that membrane depolarization and inward currents produced by AMPA, KA, and NMDA were

much larger in spiny neurons than LA interneurons (173); moreover, concentrations of agonists producing reversible membrane changes in LA interneurons caused irreversible depolarization in spiny cells. The striatal and cortical neurons of R6/2 mice and mice with 94 CAG repeats displayed more rapid and increased swelling following NMDA treatment than controls, whereas AMPA and KA treatments had no differential effects. These findings suggest that NMDA antagonists or compounds that alter sensitivity of NMDA receptors may be useful in the treatment of HD (174).

The mGluRs may adversely affect iGluR function within the striatum in HD. The selective group I mGluR agonist 3,5-DHPG strongly enhanced membrane depolarization and intracellular calcium accumulation induced by NMDA application in striatal spiny neurons but not in LA interneurons, indicating a positive interaction between NMDA receptors and group I mGluRs, which are differently expressed between these two neuronal subtypes (175). Cha and colleagues found that 12-week-old R6/2 mice displayed decreased expression of AMPA- and KA- but not NMDA-type iGluR receptors compared to age-matched littermate controls. These mice also had decreased expression of mGluR1-3 that preceded the appearance of motor symptoms; therefore, altered mGluR function may contribute to subsequent pathology (176).

Approximately half of the variation in onset age for HD can be explained by the size of the repeat expansion. MacDonald and associates examined a TAA repeat polymorphism, which is closely linked to the GluR6 gene, in 258 unrelated HD-affected persons and found that younger onset age of HD was associated with linkage disequilibrium for this polymorphism (177). Rubinsztein and co-workers found that 13% of the variance in the age of onset of HD that was not accounted for by the CAG repeat size could be attributed to GluR6 genotype variation (178). These data implicate GluR6-mediated excitotoxicity in the pathogenesis of HD in addition to NMDAR-mediated neurodegeneration.

Alzheimer's disease (AD) is a progressive dementia characterized by a cortical neurodegeneration, particularly in the entorhinal cortex, hippocampal CA1 region, and subiculum. The etiology of AD is complex, with age, trauma, health, and environmental and genetic factors all playing a role (179). iGluR-mediated excitotoxicity is postulated to play a role in the neurodegeneration of AD (5). Mutations in the presenilin-1 (PS1) gene are causally linked to many cases of early-onset inherited autosomal dominant AD. Mice transgenic for the PS1M146V gene are hypersensitive to seizure-induced synaptic degeneration and necrotic neuronal death in the hippocampus (180). Cultured hippocampal neurons from PS1M146V knock in mice display increased vulnerability to glutamate, which is correlated with perturbed calcium homeostasis, increased oxidative stress, and mitochondrial dysfunction. Glutamate toxicity is potentiated by ROS mediated inhibition of EAATs; two studies have shown that ROS generated by Aß peptide inhibits astrocyte glutamate uptake (181, 182).

Immunocytochemical studies indicate that virtually all projection neurons in the hippocampus express iGluR subunits from each receptor class; however, regional differences in immunoreactivity were apparent in AD versus normal brain. In the vulnerable regions (i.e., CA1), GluR1, GluR2(4), GluR5/6/7, and NR1 were reduced, presumably owing to cell loss (183). In contrast, GluR2(4) immunolabeling appeared to be increased in the inner portion of the molecular layer of the dentate gyrus. Quantitative receptor autoradiography was also used to measure the laminar distribution of NMDA and AMPA receptors in three areas of visual cortex in control and AD postmortem human brains. The hierarchical pattern of the laminar loss of NMDA receptor binding correlated with the increasing complexity of associational visual cortices and increasing numbers of neurofibrillary tangles; however, AMPA receptor losses did not directly correlate with the pathology (184). Hyman and colleagues found no difference for the pattern of immunostaining between control and AD in either hippocampi or adjacent temporal cortices for GluR1, GluR2/3, and GluR4 (185); however, age-related loss of GluR2/3 immunoreactivity prior to degeneration has been reported in nucleus basalia of Meynert (186) and entorhinal cortex (187), suggesting that an increase in calcium permeability of AMPA receptors may leave these neurons vulnerable to degeneration in AD. Western blot analysis revealed average reductions of approximately 40% for GluR1 and GluR2/3 in the entorhinal cortex of patients with AD pathology versus age-matched controls, but neither GluR1 nor GluR2/3 protein concentration correlated significantly with tangle density (188). Thus, the relationship between excitotoxicity and neuronal loss in AD is complex and requires additional investigation.

Amyotrophic lateral sclerosis is a disorder characterized by a selective and progressive degeneration of motor neurons in the spinal cord and pyramidal neurons in the motor cortex, with onset in midlife (189). Death results from complications of the progressive paralysis. The two forms of ALS, sporadic and familial (FALS), have similar clinical symptoms and neuropathology, although the latter only accounts for 10% of the cases. Rosen and associates first reported a tight genetic linkage between FALS and the gene encoding Cu/Zn superoxide dismutase (SOD1), and identified 11 different SOD1 missense mutations in 13 different FALS families (190). Expression of high levels of a mutant form of human SOD1 for which the glycine at position 93 was replaced with an alanine (G93ASOD1; a change that has little effect on enzyme activity) caused a progressive motor neuron disease resulting in death by 6 months in transgenic mice (191). Because the mouse gene for SOD1 is unaffected in the transgenic mice, the results indicate that these mutations in SOD1 cause a gain-of-function that results in motor neuron death.

The reason for the selective vulnerability of motor neurons in ALS is unknown. Various molecular and neurochemical features of human motor neurons may render this cell group differentially vulnerable to such insults. Motor neurons are large cells with long axonal processes that require a high level of mitochondrial activity and have greater neurofilament content than other neuronal groups. Motor neurons have a very high expression of the cytosolic free radical scavenging enzyme Cu/ZnSOD1, which may render this cell group more vulnerable to genetic or posttranslational alterations interfering with the function of this protein. The low expression of calcium binding proteins and GluR2 AMPA receptor subunit by vulnerable motor neuron groups may render them unduly susceptible to calcium-mediated toxic events following GluR activation (192).

High levels of mRNA for GluR1, GluR3, and GluR4 are expressed in normal human spinal motor neurons; however, GluR2 subunit mRNA was not detectable in this cell group, predicting that normal human spinal motor neurons express calcium-permeable AMPA receptors unlike most neuronal groups in the human CNS (193); however, this has not been borne out in studies of mouse spinal cord in the context of the mouse models of ALS, where GluR2 is well represented in spinal cord motor neurons (194). AMPA or kainate exposure triggers substantial mitochondrial calcium loading in motor neurons, but causes little mitochondrial accumulation in forebrain GABAergic interneurons, neurons that express large numbers of calcium-permeable AMPA/kainate channels but do not degenerate in ALS. Brief exposure to either AMPA or kainate caused mitochondrial depolarization in motor neurons, whereas these effects were only observed in the GABAergic neurons after exposure to the nondesensitizing AMPA receptor agonist kainate. Finally, blocking mitochondrial calcium uptake attenuated AMPA/kainate receptor-mediated motor neuron injury. Thus, mitochondrial calcium uptake and consequent ROS generation may be central to the injury process (195). Quantification of mRNA expression in spinal cord showed a significant widespread loss of NR2A from both dorsal and ventral horns with losses of 55% and 78%, respectively, in ALS as compared to control. These results were substantiated by analysis of spinal cord homogenates, which showed a significant total decrease of 50% in NR2A message for ALS as compared to control (196).

Riluzole, which attenuates the glutamate neurotransmitter system, has been shown to prolong survival in patients with ALS (197). Riluzole affects neurons using three mechanisms: by inhibiting excitatory amino acid release, inhibiting events following stimulation of iGluRs, and stabilizing the inactivated state of voltage-dependent sodium channels. Mennini and associates studied inotropic glutamate receptor subtypes and the effect of chronic treatment with NBQX in the spinal cord of motor neuron disease (mnd) mice. NBQX significantly improved the behavioral scores in mnd mice. These findings suggest that selective antagonism of inotropic non–NMDA receptors may be of value in the treatment of motor neuron disease (198). Further research may allow the development of therapies that target specific glutamate receptor subunits and modulate “downstream” events within motor neurons, aimed at protecting vulnerable molecular targets in specific populations of ALS patients.

SCHIZOPHRENIA

Part of "6 - The Diverse Roles of L-Glutamic Acid in Brain Signal Transduction "

Kim and associates reported diminished concentrations of glutamate in CSF of patients with schizophrenia and first proposed that hypofunction of glutamatergic systems might cause the disorder (199). This finding has been replicated by some studies but not by several others (200, 201, 202 and 203). In a postmortem study, Tsai and associates (140) studied eight brain regions and found decreased concentrations of glutamate and aspartate in the frontal cortex and decreased concentration of glutamate in the hippocampus of patients with schizophrenia as compared to controls. Furthermore, the concentration of NAAG was increased in the hippocampus and the activity of GCPII was selectively reduced in the frontal cortex, temporal cortex, and hippocampus of people with schizophrenia. Subsequent studies with magnetic resonance spectroscopy have revealed significant reductions in the level of N-acetylaspartate (NAA), the product of NAAG by GCPII, in the very same regions—frontal cortex, temporal cortex, and hippocampus (204).

Initial ligand binding studies in postmortem schizophrenic brain have revealed increases in the non–NMDA iGLURs in the prefrontal cortex (205, 206) and decreases in the hippocampus (207, 208). Strychnine-insensitive binding, which labels the glycine modulatory site on the NMDA receptor, is increased throughout the primary sensory cortex and related associational fields in schizophrenia (209). Molecular approaches have shown a reduction in mRNA encoding luR2 in the hippocampus and parahippocampus of people with schizophrenia, and reduced editing of GluR2 in the prefrontal cortex (210, 211). Although the density of NMDA receptors in the prefrontal cortex of people with schizophrenia was normal, the relative subunit composition differed significantly from controls with a large increase observed for NR2D (212).

A convincing link between glutamatergic dysfunction and schizophrenia came from anecdotal and subsequent controlled studies of the neuropsychologic effects of dissociative anesthetics, which are noncompetitive antagonists of the NMDA receptor (213). When chronically abused, PCP produces a syndrome in normal individuals that closely resembles schizophrenia and exacerbates symptoms in patients with chronic schizophrenia. Subanesthetic doses of ketamine administered to normal subjects produces positive symptoms, including delusions and thought disorder, negative symptoms, and frontal lobe cognitive impairments characteristic of schizophrenia (214). When administered

to schizophrenic subjects, subanesthetic doses of ketamine exacerbate delusion, hallucinations, and thought disorders that are consistent with the patient's typical pattern of psychotic relapse (215, 216). These effects are attenuated by the atypical antipsychotic clozapine but not haloperidol.

Although acute administration of ketamine to normal subjects causes increased (217) prefrontal cortical perfusion, chronic exposure to PCP is associated with the classical "hypofrontality" of schizophrenia (218, 219). Chronic PCP treatment produced more perseveration and fewer nonspecific cognitive deficits in monkeys that persisted after discontinuation. Notably, these memory deficits were prevented by clozapine treatment (220).

Administration of NMDA receptor antagonists markedly increased the release of dopamine and glutamate in prefrontal cortex and subcortical structures in rats (221, 222), which was associated with impaired performance on a memory task sensitive to prefrontal cortical function (217); these alterations could be ameliorated by treatment with an AMPA/KA receptor antagonist. Furthermore, administration of a group I mGluR agonist blocked PCP-induced glutamate release without affecting dopamine release (223). These effects of NMDA receptor antagonism observed in the rodent have been shown to be comparable to humans in a positron emission tomographic study in which [^{11}C]-raclopride binding in striatum was used to measure dopamine release; subanesthetic doses of ketamine cause increased dopamine release in human subjects (224).

If the symptoms of schizophrenia result from hypofunction of NMDA receptors, then agents that enhance NMDA receptor function would be predicted to reduce symptoms. Because full agonists could be excitotoxic, studies have focused primarily on agents that act via the glycine modulatory site (225). Electrophysiologic studies in the hippocampal slice indicate that the glycine modulatory site is not fully occupied because of efficient transport of glycine by the GLYT-1 transporter on astroglia so that the modulatory site is subject to pharmacologic manipulation (133). In most of the studies, the drugs were added to typical antipsychotics in stable patients with prominent negative symptoms. Javitt and colleagues have performed a series of placebo-controlled crossover trials in which high doses of glycine (30 to 60 g per day) were added to antipsychotic drugs. They demonstrated improvement in negative symptoms and cognitive function without effects on psychotic symptoms or extrapyramidal side effects (226, 227 and 228). Tsai and associates added D-serine at a dose of 30 mg per kg to typical antipsychotic drugs for 8 weeks and found significant improvements in negative symptoms, cognitive function (as measured by the Wisconsin Card Sorting test), and psychosis (229). The more robust effect of D-serine may reflect the fact that it has better penetrance of the blood–brain barrier, is a full agonist and has a higher affinity than glycine.

Another drug that has been extensively studied is the antitubercular agent, D-cycloserine, which is a partial agonist at the glycine modulatory site with 60% efficacy and readily crosses the blood–brain barrier (230). A blinded dose finding study in patients receiving typical antipsychotics and exhibiting prominent negative symptoms revealed a U-shaped dose–response curve with significant reductions in negative symptoms and improvement in cognitive function at 50 mg per day (231). van Berckel and associates observed improvement in negative symptoms at a D-cycloserine dose of 100 mg per day in a small open trial with medication-free schizophrenics (232). D-cycloserine at 50 mg per day significantly improved negative symptoms when added to conventional antipsychotics in an 8-week fixed dose placebo-controlled parallel group trial with patients meeting criteria for deficit syndrome of schizophrenia (233); however, performance on a cognitive battery did not change. Notably, full response for negative symptoms was not achieved until after 4 to 6 weeks of treatment.

It was of interest to determine whether the addition of D-cycloserine would have further ameliorative effects in clozapine responders because clozapine has substantial effects on negative symptoms in many patients who respond poorly to typical antipsychotics. To the contrary, two separate trials of D-cycloserine at 50 mg per day added to clozapine resulted in worsening of negative symptoms (234, 235). In contrast, trials in which the full agonists, glycine or D-serine, were added to clozapine yielded no additional change in negative symptoms or cognitive function (236, 237). A plausible explanation for these findings is that clozapine may exert its effects on negative symptoms and cognitive functions in part by increasing occupancy of the glycine modulatory site on the NMDA receptor, thereby transforming the partial agonist D-cycloserine into an antagonist. Support for this inference comes from electrophysiologic studies in the hippocampal slice where clozapine enhances NMDA receptor currents (238).

As hippocampal interneurons appear more sensitive to NMDA receptor antagonists owing to the presence of NR2C (239), hypofunction of these NMDA receptors because of an excess of endogenous antagonists such as NAAG or kynurenic acid could account for many features of schizophrenia. The disinhibition of cortico-hippocampal efferents appears to increase subcortical dopamine release associated with positive symptoms (240). This would also interfere with the precision of cortical/hippocampal activations consistent with schizophrenic subjects' inability to increase hippocampal neuronal activity in a memory task because of a ceiling effect (241). The effects of glycine modulatory site activation, particularly on negative symptoms and cognitive impairment, are consistent with this model. Finally, the fact that ketamine reproduces the eye tracking impairments found in schizophrenics and some of their first-degree relatives suggest that NMDA receptor hypofunction could be part of the endophenotype (242).

Age-Associated Memory Impairment

Glutamate receptors have also been implicated in the functional decline seen in normal aging in the absence of neurodegeneration. Spatial memory is particularly vulnerable to aging (243), and is also disrupted by pharmacologic blockade of NMDA receptor function (244) or hippocampal knockout of NR1 (245). Electrophysiologic investigations of aging in rat hippocampus have revealed that certain aspects of excitatory synaptic transmission are unaffected or even compensatory, whereas others are compromised (246). One component of synaptic transmission that is compromised is maintenance and induction of long-term potentiation (LTP) that could be related to impaired NMDA receptor-mediated processes and the decreased stability of spatial information coding by “place cell” in aged rats (247). At the regional level, receptor binding studies have reported decreases in NMDA binding in hippocampus (248) with confirmatory declines in mRNA expression (249); however, other studies suggested that there is no change in NMDA receptors with aging (250).

In studying age-related changes in receptors, it is particularly important to be able to take the analysis from the regional level to that of cell classes, circuits, individual neuronal compartments, and synapses, because the changes are very likely to be cell-, circuit-, and synapse-specific and therefore difficult to resolve at the regional level; for example, age-related shifts in NR1, have been reported in the molecular layer of the dentate gyrus (251). The projection from the entorhinal cortex (ERC) to the DG is strictly confined to the outer molecular layer (OML), that is, the distal dendrites of granule cells; whereas other excitatory inputs terminate in a nonoverlapping fashion in the inner molecular layer (IML), the proximal dendrites. Aged monkeys, compared to young adult monkeys, exhibit a decrease in the fluorescence intensity for NR1 in the OML of the DG as compared to the IML. Given the tight laminar organization of these circuits, this pattern means that decreased NR1 levels primarily affect the input from the ERC, pointing to the ERC input to the hippocampus as a key element in age-related changes, and suggests that the intradendritic distribution of a neurotransmitter receptor is modified in an age-related and circuit-specific manner (251).

Although these results suggest that age-related circuit-specific shifts in NMDA receptors might underlie memory defects, they were not done in behaviorally characterized animals, and need to be followed up in the context of behavior. In addition, the data on NR1 changes were limited to the dendrite and did not directly address the GluRs at the synapse. Thus, these data need to be extended, particularly in the nonhuman primate model. Species issues may be particularly relevant because in rat hippocampus decreases in presynaptic markers such as synaptophysin correlate with age-associated memory impairment more directly than do any age-related shifts in GluRs (252, 253).

CONCLUSION

Part of "6 - The Diverse Roles of L-Glutamic Acid in Brain Signal Transduction "

In closing, glutamate sits at the epicenter of signal transduction in brain, not only mediating excitatory neurotransmission, but also modulating neuroplasticity at the genetic, synaptic, and structural levels. Furthermore, insufficient glutamatergic signaling causes the degeneration of immature neurons through apoptosis (254), whereas excessive activation of iGluRs kills neurons through necrosis and/or apoptosis. Dysregulation of glutamatergic neurotransmission has been implicated in an expanding number of neuropsychiatric disorders. Although the clinical pharmacology of glutamate is currently embryonic, the remarkable advances in the molecular characterization of this system hold promise for the development of a rich array of specific drugs in the future.

HISTORICAL PERSPECTIVES

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

In 1948 Sir Geoffrey Harris first proposed the concept that the hypothalamus plays a primary role in the regulation of the pituitary-adrenocortical axis. Subsequently, during the 1950s, Guillemin and Rosenberg, and Saffran and Schally independently observed the presence of a factor in hypothalamic extracts (termed corticotropin-releasing factor, CRF) that could stimulate the release of adrenocorticotropic hormone (ACTH, corticotropin) from anterior pituitary cells *in vitro*. Although CRF was the first hypothalamic hypophysiotropic factor to be recognized, its chemical identity remained elusive until 1981, when Wylie Vale and colleagues at the Salk Institute reported the isolation, characterization, synthesis, and *in vitro* and *in vivo* biological activities of a 41-amino acid hypothalamic ovine CRF (1). Just over a decade later, Vale and colleagues were the first to report the cloning of the human CRF_1 receptor from a single human Cushing's corticotropic adenoma using an expression cloning techniques (2). This initial discovery led to the identification of a second receptor subtype (termed CRF_2), which has now been localized and characterized in a variety of species (see the following).

This chapter provides an overview of the CRF system and its related receptor targets. More detailed and comprehensive information on CRF is available in recent reviews (3 ,4) and books (5 ,6) on the topic.

CHARACTERISTICS OF THE CRF PEPTIDE AND GENE SEQUENCES

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

Amino Acid Sequence and Structure of CRF

The sequence of CRF has been determined in a variety of species including sheep, humans, rats, pigs, goats, and cows. In all species, CRF is a 41-amino acid residue single chain polypeptide (Fig. 7.1). Rat and human CRFs are identical to one another and differ from ovine CRF by seven amino acid residues. All three CRFs have close amino acid homology and share some biological properties with sauvagine, a 40-amino acid peptide that exists in frog skin, and urotensin I, a 41-amino acid peptide derived from fish urophysis. Caprine and ovine CRF are identical and differ from bovine CRF by one amino acid. Porcine CRF more closely resembles rat and human CRF. CRF and related peptides are amidated at their carboxy terminal; CRF COOH-terminal-free acid has less than 0.1% of the potency of native CRF, suggesting the importance of amidation to biological activity of the peptide. Studies to determine the solution structure of CRF using proton nuclear magnetic resonance suggest that human CRF comprises an extended N-terminal tetrapeptide connected to a well-defined α-helix between residues 6 and 36 (7). An α-helical oCRF(9-41) has been demonstrated to be an antagonist of CRF (8), which underscores the necessity of the α-helical conformation for receptor binding and biological activity.

FIGURE 7.1. Amino acid sequences of ovine and rat/human corticotropin-releasing factor (CRF) and related peptides including human and rat urocortin. Rat CRF and human CRF are identical and differ from ovine CRF by seven amino acid residues, which are denoted by the shading. All peptides are amidated at the carboxy terminus; the amidation is essential for biological activity. See color version of figure.

Organization of the CRF Gene and Protein Precursor

The nucleotide sequences encoding ovine and rat CRF cDNA precursors as well as human, rat, and ovine CRF

genes have been determined (9 ,10). The locus of the CRF gene is on chromosome 8q13 in the human. The CRF genes are quite similar to one another, containing two exons separated by intervening intron 686 to 800 base pairs long. The first exon encodes most of the 5′-untranslated region of the mRNA and the second encodes the entire prepro-CRF precursor polypeptide, which is 187 to 196 amino acids long; the carboxy end of the precursor contains the 41-amino acid peptide sequence. The high incidence of homology among species suggests that the gene has been highly conserved through evolution.

As previously demonstrated for other systems, the 5′-flanking DNA sequences are most likely to contain the DNA sequence elements responsible for glucocorticoid, cAMP and phorbol ester regulation, tissue-specific expression, and enhancer activity. Although a consensus cAMP response element has been identified, located 200 base pairs upstream from the major transcription initiation site, no obvious glucocorticoid response elements or activation protein (AP) 1-binding elements are present. A potential AP-2 binding site, which may mediate the responses to protein kinase A and C, is present 150 base pairs upstream from the major start site.

ANATOMY OF CRF

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

Distribution of CRF in the CNS

The distribution and localization of CRF mRNA in the central nervous system (CNS) have been evaluated using Northern blot analysis and *in situ* hybridization histochemistry, respectively. Radioimmunoassay and immunohistochemical studies have been critical in the determination of the neuroanatomic organization of CRF immunoreactive cells and fibers in the CNS. Overall, there is good concordance between studies demonstrating a widespread distribution of CRF cell bodies and fibers in the CNS. Detailed descriptions of the organization of CRF immunoreactive cells and fibers in rat brain have been published (11 ,12 and 13).

Morphologic data clearly indicate that the paraventricular nucleus of the hypothalamus (PVN) is the major site of CRF-containing cell bodies that influence anterior pituitary hormone secretion. These neurons originate in the parvocellular portion of the PVN and send axon terminals to the capillaries of the median eminence. CRF is also present in a small group of PVN neurons that project to the lower brainstem and spinal cord; this group of neurons may be involved in regulating autonomic nervous system function. Other hypothalamic nuclei that contain CRF cell bodies include the medial preoptic area, dorsomedial nucleus, arcuate nucleus, posterior hypothalamus, and mammillary nuclei.

The neocortex contains primarily CRF interneurons with bipolar, vertically oriented cell bodies predominantly localized to the second and third layers of the cortex and projections to layers I and IV. In addition, scattered cells are present in the deeper layers that appear to be pyramidal cells. Although CRF-containing neurons are found throughout the neocortex, they are found in higher densities in the prefrontal, insular, and cingulate areas. CRF neurons in the cerebral cortex appear to be important in several behavioral actions of the peptide, including effects on cognitive processing; furthermore, dysfunction of these neurons may contribute to many CNS disorders (see the following).

Large and discrete populations of CRF perikarya are present in the central nucleus of the amygdala, bed nucleus of the stria terminalis, and substantia innominata. CRF neurons in the central nucleus of the amygdala project to the parvocellular regions of the PVN, the parabrachial nucleus of the brainstem, and thus may influence both neuroendocrine and autonomic function in addition to behavioral activity. CRF neurons originating in the bed nucleus of the stria terminalis send terminals to brainstem areas such as the parabrachial nuclei and dorsal vagal complex, which coordinate autonomic activity. CRF fibers also interconnect the amygdala with the bed nucleus of the stria terminalis and hypothalamus. Scattered CRF cells with a few fibers are also present in telencephalic areas such as regions of the amygdala in addition to the central nucleus, septum, diagonal band of Broca, olfactory bulb, and all aspects of hippocampal formation, including the pyramidal cells, dentate gyrus, and subiculum.

Several groups of CRF cell bodies are present throughout the brainstem. In the midbrain, CRF perikarya are present in the periaqueductal gray, Edinger-Westphal nucleus, dorsal raphe nucleus, and ventral tegmental nucleus. Projections from the dorsal-lateral tegmental nucleus to a variety of anterior brain areas such as the medial frontal cortex, septum, and thalamus have also been described. In the pons, CRF cell bodies are localized in the locus ceruleus, parabrachial nucleus, medial vestibular nucleus, paragigantocellular

nucleus, and periaqueductal gray. CRF neurons originating in the parabrachial nucleus project to the medial preoptic nucleus of the hypothalamus. In the medulla, the large groups of cell bodies are present in the nucleus of the solitary tract and dorsal vagal complex with ascending projections to the parabrachial nucleus. Scattered groups of cell bodies are also present in the medullary reticular formation, spinal trigeminal nucleus, external cuneate nucleus, and inferior olive. The inferior olive gives rise to a well-defined olivocerebellar CRF pathway with projections to the Purkinje cells of the cerebellum. No CRF cell bodies are present in the cerebellar formation.

Within the spinal cord, CRF cell bodies are present in laminae V to VII and X and in the intermediolateral column of the thoracic and lumbar cord. CRF fibers originating in the spinal cord form an ascending system terminating in the reticular formation, vestibular complex, central gray, and thalamus. This ascending CRF system may play an important role in modulating sensory input. In addition, spinal cord CRF neurons may represent preganglionic neurons that modulate sympathetic outflow.

Distribution of CRF in Peripheral Tissues

In addition to its CNS distribution, CRF has been localized in a variety of peripheral tissues (14). CRF-like immunoreactive fibers are present in the intermediate lobe of the pituitary; these fibers originate in the hypothalamus. A physiologic role has been proposed for CRF in regulating pro-opiomelanocortin (POMC)-derived peptide secretion from the intermediate pituitary. CRF has also been localized in the adrenal medulla of a variety of species and is increased following stimulation of the splanchnic nerve stimulation and hemorrhagic stress. CRF-like immunoreactivity and CRF mRNA have been detected in lymphocytes, where they may play a role in regulating immune function. Other tissues in which CRF has been localized include the testis (Leydig cells and advanced germ cells), pancreas, stomach, and small intestine. Although CRF is not detected in the circulation under normal circumstances, very high levels have been measured in the plasma of pregnant women; the source of CRF in pregnancy appears to be the placenta. (See CRF-Binding Protein .)

UROCORTIN: A NOVEL MAMMALIAN CRF-RELATED PEPTIDE

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

Urocortin is the newest member of the CRF peptide family and has been demonstrated to possess many of the intrinsic properties of CRF itself as well as some unique properties of its own. Originally, the nonmammalian CRF-related analogues urotensin I (teleost fish) (15) and sauvagine (frog) (16) were thought to subserve the functions of CRF in the respective species; however, the discovery of peptides even closer to the structure of CRF in those species (17 ,18) led to the suggestion that other forms of CRF may exist in mammals. Furthermore, with the cloning of the CRF_2 receptor subtype, it became apparent that because sauvagine and urotensin had even higher affinity and activity at this subtype than CRF itself (19), a mammalian form of these peptides may exist that would serve as the endogenous ligand for the CRF_2 subtype. Indeed, a mammalian form of urotensin was recently discovered termed “urocortin” and the cDNA cloned from the rat (20) and human (21), respectively.

Amino Acid Sequence and Structure of Urocortin

The sequence of urocortin has been determined in both rats and humans. In rat, urocortin was identified using a library derived from rat midbrain and a carp urotensin cDNA probe. A full-length cDNA was described and encoded a putative 40-amino acid peptide that was related to CRF (20). The human form was subsequently identified using a cDNA probe encoding the peptide region of rat urocortin and screening a human genomic library (21). The resulting putative peptide demonstrated 88% identity to rat at the nucleotide level and 95% identity at the amino acid level (Fig. 7.1). In both species, urocortin is a 40-amino acid residue single-chain polypeptide; the two forms differ by only two amino acids at positions 2 (Asn to Asp) and 4 (Ser to Pro) (21). In addition to the homology between the species, the deduced amino acid sequence of rat and human urocortin exhibits sequence identity with urotensin I (63%) and human CRF (45%) (20). Consistent with the other CRF-related peptides, urocortin is also amidated at its carboxy terminal, again suggesting the importance of amidation to this family of peptides (Fig. 7.1).

Anatomic Distribution of Urocortin

The distribution of urocortin in rat tissues was elucidated first by examining the cellular localization of urotensin-like immunoreactivity and correlating that distribution with the *in situ* hybridization of urocortin mRNA. The highest areas of correlation and overlapping localization were the Edinger-Westphal nucleus and the lateral superior olive (20). In addition, cellular staining was observed in the external plexiform layer of the rat olfactory bulb and lateral hypothalamus. Interestingly, terminal projection fields in the lateral septum also demonstrated distinct localization where CRF_2 receptors have been uniquely localized (see the following). Although the localization of urocortin appears to be in very discrete brain regions, these regions demonstrate no CRF mRNA, suggesting that urocortin subserves some unique functionality within the CRF system. As described in the following, its affinity and functional activity at the

CRF_2 receptor subtype suggest that this may be one endogenous ligand for this subtype.

In Vitro and In Vivo Pharmacologic Effects

Urocortin binds with high affinity to all the known effectors of CRF function, including CRF_1, $CRF_{2\alpha}$, CRF_{2B} receptors, and CRF-binding protein (described in the sections that follow). This profile makes urocortin unique in the CRF system because endogenous r/hCRF has been shown to have relatively low affinity for the CRF_2 receptor subtypes and oCRF, which also has lower affinity for the CRF_2 subtype, also has very low affinity at the CRF-binding protein. Urocortin binds to cells stably transfected with the CRF_1, $CRF_{2\alpha}$, or CRF_{2B} receptors with affinities in the 100 to 500 pM range and has 100 pM affinity for the CRF-BP (20). In *in vitro* studies, urocortin stimulates cAMP accumulation in cells transfected with either CRF receptor subtype, and is extremely potent in stimulating ACTH release from cultured anterior pituitary cells (20). The effects on the CRF_1 receptor subtype are comparable to the effects of CRF itself; however, the activities observed at both CRF_2 receptor isoforms are approximately tenfold more potent than CRF itself (20 ,21). Furthermore, as has been shown for CRF, the presence of CRF-BP can decrease the ability of urocortin to stimulate ACTH release *in vitro*. Moreover, specific CRF-BP inhibitors such as r/hCRF(9-33) can restore the ability of urocortin to stimulate ACTH, further confirming the functional activity of urocortin at the CRF-BP (21).

In unanesthetized freely moving rats, urocortin administered IV was fivefold more potent than CRF in increasing plasma ACTH concentrations and demonstrated a longer duration of action. Similarly, urocortin reduced mean arterial pressure more potently and for a longer period of time than CRF or urotensin I (20). Thus, although capable of interacting with the CRF_1 receptor with equivalent potency and activity, the anatomic distribution, localization, and potency at the CRF_2 subtypes support the notion that urocortin is likely one endogenous ligand for this receptor subtype. Clearly, further study is required to determine the specific role that this novel endogenous peptide plays in the regulation of the CRF system.

CRF RECEPTORS

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

Cloning of CRF Receptor Subtypes

Molecular cloning studies have enabled the elucidation of receptor subtypes for the CRF system. Structurally, the CRF receptor subtypes all contain seven putative transmembrane domains and share considerable sequence homology with one another. These receptors are members of the family of “brain-gut” neuropeptide receptors, which includes receptors for calcitonin, vasoactive intestinal peptide, parathyroid hormone, pituitary adenylate cyclase-activating peptide, growth hormone-releasing factor, glucagon, and secretin. In addition, the known members of this neuropeptide receptor family also belong to the superfamily of G-protein coupled receptors; thus far, all have been shown to stimulate adenylate cyclase in response to their respective agonist activation.

The CRF_1 receptor was cloned first from a human Cushing’s corticotropic adenoma using an expression cloning technique and characterized as a 415-amino acid protein with potential N-linked glycosylation sites, protein kinase C phosphorylation sites in the first and second intracellular loops and in the C-terminal tail, as well as casein kinase II and protein kinase A phosphorylation sites in the third intracellular loop (2). Independently, this receptor subtype was also identified in mouse (22) and rat (23 ,24). In all three species, CRF_1 receptor mRNAs encode proteins of 415 amino acids, which are 98% identical to one another. The potential N-linked glycosylation sites on the N-terminal extracellular domain are characteristic of most G-protein coupled receptors and confirm the glycosylation profiles determined by chemical affinity cross-linking studies (25). In those studies, although the molecular weights of the proteins labeled from brain or pituitary appeared different when labeled with [^{125}I]oCRF, the deglycosylation and peptide mapping studies suggested that the protein itself was identical and that the differences were owing to posttranslational modification (25). Indeed, the molecular weight predicted from the deglycosylated forms of the CRF_1 receptor was virtually identical to that obtained from the cloned amino acid sequence. These data taken together established the fact that the CRF_1 receptor subtype is the dominant form in both the brain and pituitary.

CRF_2 Receptors

Following the cloning of the CRF_1 subtype, two forms of a second family member were discovered in the rat and termed $CRF_{2\alpha}$ and CRF_{2B}. The rat $CRF_{2\alpha}$ receptor (19) is a 411-amino acid protein with approximately 71% identity to the CRF_1 receptor. The CRF_{2B} receptor has been cloned from both rat (19) and mouse (24 ,26), and is a 431-amino acid protein that differs from the $CRF_{2\alpha}$ subtype in that the first 34 amino acids in the N-terminal extracellular domain are replaced by 54 different amino acids. The genomic structure and corresponding cDNA of the human $CRF_{2\alpha}$ receptor subtype was cloned and characterized. The cDNA sequence in the protein-coding region had 94% identity with the previously reported rat $CRF_{2\alpha}$ receptor (27). In addition, the human $CRF_{2\alpha}$ receptor protein was found to be a 411-amino acid protein that had an overall 70% identity with the human CRF_1 receptor sequence (less in the N-terminal extracellular domain; 47%). In stably transfected cells, the human $CRF_{2\alpha}$ receptor had the same pharmacologic characteristics as those demonstrated for the

rat and increased intracellular cAMP levels in response to either sauvagine or CRF (see the following for details). Very recently, the human form of the CRF_{2B} receptor was cloned from human amygdala and demonstrated 94% identity to human $CRF_{2\alpha}$ receptors at the protein level. Preliminary characterization of this novel human isoform indicated that this form also had higher affinity for sauvagine and urotensin than for r/hCRF (28). The $CRF_{2\gamma}$ receptor was the most recently identified isoform and has thus far only been found in human brain. This splice variant uses yet a different 5′ alternative exon for its amino terminus and replaces the first 34-amino acid sequence of the $CRF_{2\alpha}$ receptor with a unique 20 amino acid sequence. Thus, although the CRF_2 receptor exists as three isoforms, $CRF_{2\alpha}$, CRF_{2B}, and $CRF_{2\gamma}$, there are at present no known functional splice variants for the CRF_1 receptor. Figure 7.2 illustrates the differences among human $CRF_{2\alpha}$, CRF_{2B}, and $CRF_{2\gamma}$ in the N-terminal extracellular domain. Between the CRF_1 and CRF_2 receptors, there exist very large regions of amino acid identity, particularly between transmembrane domains five and six. This similarity strongly argues for conservation of biochemical function because this region is thought to be the primary site of G-protein coupling and signal transduction. All three CRF_2 receptor subtypes contain five potential N-glycosylation sites, which are analogous to those found on the CRF_1 receptor subtype. The genomic structure of the human CRF_2 receptor gene is similar to that of the mouse CRF_1 receptor described in the preceding and has 12 introns, the last ten of which interrupt the coding region in identical positions. These gene sequences, however, diverge significantly at the 5′ end, and the chromosomal mapping of the human CRF_2 gene has been localized to chromosome 7 p21-p15.

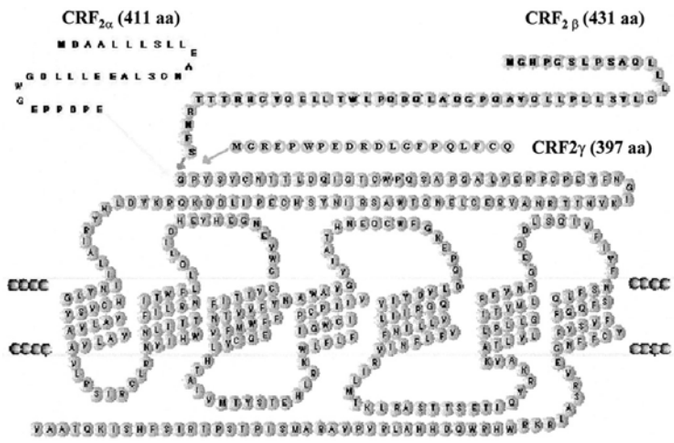

FIGURE 7.2. Amino acid sequences of the human $CRF_{2\alpha}$, CRF_{2B}, and $CRF_{2\gamma}$ receptor subtypes. The CRF_2 receptor isoforms are demonstrated with the seven putative transmembrane domains. The arrows indicate where the different CRF_2 receptor isoforms diverge at the N-terminus. See color version of figure.

Pharmacologic Characteristics

The literature is replete with information on the pharmacologic and biochemical characterization of CRF receptors in a variety of tissues and animal species. (See refs. 29 and 30 ,31 ,32 and 33 for reviews.) The radioligand binding characteristics of CRF receptors that have been performed thus far in brain, endocrine, and immune tissues have used the available radioligands at the time, which were [^{125}I]-Tyr^0 oCRF, [^{125}I]-Tyr^0 r/hCRF, and [^{125}I]-Nle^{21}-Tyr^{32} r/hCRF. These ligands have all demonstrated high affinity for the CRF_1 receptor subtype and lower affinity for the CRF_2 subtypes (as described in the following). Thus, the discovery of the CRF_2 receptor subtype and its isoforms has not confused the earlier literature owing to the apparent “selectivity” of the r/hCRF and oCRF analogue radioligands for the CRF_1 receptor. Recently, [^{125}I]-Tyr^0 sauvagine, a novel radioligand for the CRF_2 receptor, has been described that binds to both receptor subtypes with equal affinity and has become a useful tool in the study of CRF_2 receptors (34).

CRF receptors fulfill all of the criteria for bona fide receptors. The kinetic and pharmacologic characteristics of CRF_1 receptors are comparable in brain, pituitary, and spleen. The binding of [^{125}I]oCRF in a variety of tissue homogenates as well as in CRF_1 receptor-expressing cell lines is dependent on time, temperature, and tissue concentration, and is saturable, reversible, and of high affinity with K_d values of 200 to 400 pM. The pharmacologic rank order profile of these receptors from various tissues has been compared using closely related analogues of CRF. Bioactive analogues of CRF have high affinity for [^{125}I]oCRF binding sites, whereas biologically inactive fragments of the peptide and unrelated peptides are all without inhibitory binding activity in brain, endocrine, and immune tissues.

CRF_1 receptors exhibit the typical properties of neurotransmitter receptor systems linked to the adenylate cyclase system through a guanine nucleotide binding protein. In *in vitro* radioligand binding studies, divalent cations (e.g., magnesium ions) have been shown to enhance agonist binding to receptors coupled to guanine nucleotide binding proteins by stabilizing the high-affinity form of the receptor–effector complex. In contrast, guanine nucleotides have the ability to selectively decrease the affinity of agonists for their receptors by promoting the dissociation of the agonist high-affinity form of the receptor. Consistent with CRF receptors being coupled to a guanine nucleotide regulatory protein, the binding of [^{125}I]oCRF to pituitary, brain, and spleen homogenates is reciprocally increased by divalent cations such as Mg^{2+} and decreased by guanine nucleotides. Furthermore, in expressed cell lines using a ß-galactosidase reporter system, CRF and related analogues could stimulate the production of ß-galactosidase in whole cells with the same pharmacologic rank order of potencies as those in a variety of tissues from different species (35).

The cloning of the CRF_2 receptor subtype gave the first indication that other family members of this receptor system exist and have unique properties that could subserve functions that were previously undefined. As mentioned, a fundamental element in the characterization of any receptor system is the availability of high-affinity and selective ligands that can be used to label the proteins in a reversible manner. The initial observations clearly demonstrated that the CRF_2 receptor subtype recognized the nonmammalian analogues of CRF with high affinity (similar in profile to the CRF_1 subtype) but unlike the CRF_1 receptor, had low affinity for the endogenous CRF ligands (r/hCRF and its analogues) (19). Thus, the available radioligands used in the initial studies of CRF receptors were not useful in providing information about this subtype.

The development of a high-affinity radioligand suitable for the characterization of the CRF_2 receptor subtype was recently described (34). Using one of the high-affinity nonmammalian analogues of CRF (sauvagine), a radiolabel was developed, and its binding specificity and selectivity determined. [^{125}I]Tyr^0-sauvagine was found to bind reversibly, saturably, and with high affinity to both the human CRF_1

and $CRF_{s\alpha}$ receptor subtypes expressed in mammalian cell lines. The specific signal for the labeling of the human $CRF_{a\alpha}$ receptors was greater than 85% over the entire concentration range of the radioligand, which suggested very low nonspecific binding in the expressed cell line. The radioligand bound in a reversible, time- and protein-dependent manner, reaching equilibrium within 60 minutes with the binding being stable for at least 4 hours at 22°C. Scatchard analyses demonstrated an affinity of about 200 pM for the CRF_2 receptor subtype and a maximum receptor density in the expressing cells of about 180 fmol/mg protein (34).

The pharmacologic rank order of potencies for the CRF_2 receptor labeled with [^{125}I]sauvagine was essentially identical to the *in vitro* effects of the same unlabeled peptides in the production of cAMP in cells expressing the receptor as described. That is, the nonmammalian analogues sauvagine and urotensin I that were more potent in stimulation of cAMP production were also more potent at inhibiting the binding of [^{125}I]sauvagine than oCRF or r/hCRF. Interestingly, the putative antagonists for CRF receptors, D-PheCRF(12-41) and α-helical CRF(9-41) exhibited approximately equal affinity for the two receptor subtypes either in inhibiting [^{125}I]sauvagine binding or inhibiting sauvagine-stimulated cAMP production (34). These data clearly indicated that although distinct pharmacologic differences exist between the two receptor subtypes of the same family (in terms of their rank order profile), they still must share some structural similarities. Further study is required to determine the precise common structural features of these two family members.

In addition to the pharmacologic rank order profile, [^{125}I]sauvagine binding to the CRF_2 receptor was guanine nucleotide-sensitive, confirming the agonist activity of this peptide for the receptor. Although there is as yet no direct evidence, this modulation of the binding of [^{125}I]sauvagine to the human $CRF_{2\alpha}$ receptor by guanine nucleotides suggests that this receptor exists in two affinity states for agonists coupled through a guanine nucleotide binding protein to its second messenger system. Unfortunately to date, the only ligands available for the biochemical study of these receptors have been agonists, making it very difficult to examine the proportions and affinities of high- and low-affinity states of these receptors. Further study is required, possibly using labeled antagonists as tools in order to characterize the affinity states of these receptors.

The high affinity of the nonmammalian CRF analogues for this subtype has raised the possibility that other endogenous mammalian ligands exist that have high affinity and selectivity for this receptor subtype. As described, the recent discovery of urocortin (36), although not selective for the CRF_2 subtype, has provided the first evidence for one such endogenous molecule that has high affinity for the CRF_2 receptor. With the increase in the complexity of the CRF system recently elucidated, it is highly likely that more members, from both the receptor and ligand families, remain to be discovered that will lead to a much more comprehensive understanding of this system and its role in both normal and pathologic physiology.

Autoradiographic Localization of CRF Receptor Subtypes

Many studies to date have described the distribution of CRF receptors in various tissues, including the pituitary, brain, and spleen (29 ,31 ,32 and 33). The autoradiographic localization of CRF_1 receptors in the anterior pituitary demonstrates a clustering of binding sites that corresponds to the distribution of corticotrophs. The intermediate lobe shows a more uniform distribution of binding sites characteristic of the homogeneous population of POMC-producing cells in this lobe. Overall, the distribution pattern of CRF_1 receptors within the pituitary supports the functional role of CRF as the primary physiological regulator of POMC-derived peptide secretion from the anterior and intermediate lobes of the pituitary.

Receptor autoradiography and binding studies in discrete areas of rat and primate CNS demonstrate that, in general, the highest concentration of CRF binding sites are distributed in brain regions involved in cognitive function (cerebral cortex), limbic areas involved in emotion and stress responses (amygdala, nucleus accumbens, and hippocampus), brainstem regions regulating autonomic function (locus ceruleus and nucleus of the solitary tract), and olfactory bulb. In addition, there is a high density of CRF_1 receptor sites in the molecular layer of the cerebellar cortex and the spinal cord where the highest concentrations are present in the dorsal horn.

CRF receptors in spleen are primarily localized to the red pulp and marginal zones. The localization of [^{125}I]oCRF binding sites in mouse spleen to regions known to have a high concentration of macrophages suggests that CRF receptors are present on resident splenic macrophages. The absence of specific [^{125}I]oCRF-binding sites in the periarteriole and peripheral follicular white pulp regions of the spleen suggests that neither T nor B lymphocytes have specific high-affinity CRF receptors comparable to those localized in the marginal zone and red pulp areas of the spleen or in the pituitary and brain.

The availability of nucleotide sequences for CRF_1 and CRF_2 receptors has allowed a detailed examination of the regional and cellular distribution of CRF receptor subtype mRNA expression utilizing both RNAse protection assays and *in situ* hybridization histochemistry. A comparison of the distribution of CRF_1 and CRF_2 mRNA and receptor protein defined by ligand autoradiography is demonstrated in adjacent horizontal sections of rat brain (Fig. 7.3).

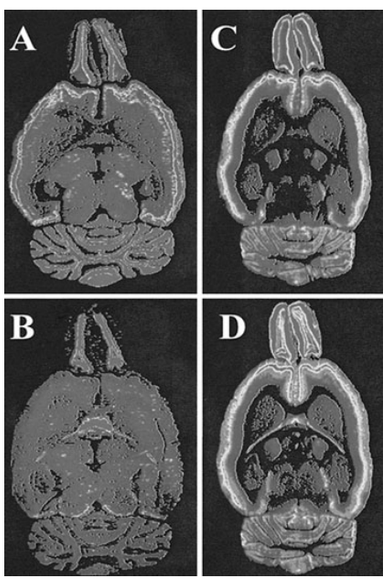

FIGURE 7.3. Digitized, color-coded images of CRF_1 *(Panel A)* and CRF_2 *(Panel B)* receptor mRNA expression and receptor autoradiography in adjacent horizontal sections of rat brain. The highest levels of mRNA expression are coded in red, whereas the lowest concentrations are coded in blue. Similarly, the highest densities of receptors labeled with either [^{125}I]oCRF (CRF_1 only; *Panel C*) or [^{125}I]sauvagine (CRF_1 and CRF_2; *Panel D*) are coded in red. There was a good correspondence between the message for a particular receptor subtype and its protein localization; the pharmacologic selectivity was retained for the two radioligands. (Compare *Panels C* and *D*.) See color version of figure.

The distribution of CRF_2 message clearly differs from that of the CRF_1 and exhibits a distinct subcortical pattern. In the rat brain, the CRF_1 mRNA was most abundant in neocortical, cerebellar, and sensory relay structures and generally

corresponded to the previously reported distribution of [^{125}I]oCRF binding sites (Fig. 7.3). On the other hand, the CRF_2 receptor mRNA was localized primarily in subcortical regions such as the lateral septal nuclei, hypothalamic nuclei, bed nucleus of the stria terminalis, and amygdaloid nuclei. Using the radioligand [^{125}I]sauvagine described, CRF_2 receptors could be localized to areas of high CRF_2 message. In addition, because [^{125}I]sauvagine has equal affinity for both receptor subtypes (34), the autoradiography revealed the localization of both the CRF_1 and CRF_2 receptor subtypes, demonstrating the utility of this novel radioligand. (See ref. 37 for a complete and detailed account of the mRNA distribution patterns of CRF_1 and CRF_2 receptors.)

The heterogeneous distribution of CRF_1 and CRF_2 receptor mRNA and protein suggests distinctive functional roles for each receptor within the CRF system. For example, the lateral septum, by virtue of widespread reciprocal connections throughout the brain, is implicated in a variety of physiologic processes. These range from higher cognitive functions such as learning and memory to autonomic regulation, including food and water intake (38). In addition, the septum plays a central role in classical limbic circuitry and thus is important in a variety of emotional conditions, including fear and aggression. Thus, the lack of CRF_1 receptor expression in these nuclei suggests that CRF_2 receptors may solely mediate the postsynaptic actions of CRF inputs to this region and strongly suggests a role for CRF_2 receptors in modulating limbic circuitry at the level of septal activity. In addition, the selective expression of CRF_2 receptor mRNA within hypothalamic nuclei indicates that the anxiogenic and anorexic actions of CRF in these nuclei may likely be CRF_2 receptor-mediated. In contrast, within the pituitary, there is a predominance of CRF_1 receptor expression with little or no CRF_2 expression in either the intermediate and anterior lobes, indicating that it is the CRF_1 receptor that is primarily responsible for CRF regulation of the HPA axis.

In addition to the differences in distribution between the CRF_1 and CRF_2 receptor subtypes, there exists a distinct pattern of distribution between the CRF_2 isoforms ($CRF_{2\alpha}$ and CRF_{2B}) as well. The $CRF_{2\alpha}$ isoform is primarily expressed within the CNS, whereas the CRF_{2B} form is found both centrally and peripherally. Within the brain, the $CRF_{2\alpha}$ form is the predominant one, whereas the CRF_{2B} form is localized primarily to non-neuronal structures, the choroid plexus of the ventricular system, and cerebral arterioles (37 ,39). The identification of the CRF_{2B} form in cerebral arterioles suggests a mechanism through which CRF may directly modulate cerebral blood flow. Peripherally, the highest detectable levels of mRNA were found in heart and skeletal muscle with lower levels detected in lung and intestine (24 ,39). Taken together, the results of these studies demonstrating a distinct heterogeneous distribution pattern of CRF receptor subtypes in brain and peripheral tissues, strongly suggest that these receptor subtypes subserve very specific physiological roles in CRF related function both centrally and peripherally.

Second Messengers Coupled to CRF Receptors

Radioligand binding studies have demonstrated that CRF receptors in the brain-endocrine-immune axis are coupled to a guanine nucleotide regulatory protein. In all of these tissues, the primary second messenger system involved in transducing the actions of CRF is stimulation of cAMP

production (29 ,31 ,32 and 33 ,40). CRF initiates a cascade of enzymatic reactions in the pituitary gland beginning with the receptor-mediated stimulation of adenylate cyclase, which ultimately regulates POMC-peptide secretion and possibly synthesis. POMC-derived peptide secretion mediated by the activation of adenylate cyclase in the anterior and neurointermediate lobes of the pituitary is dose-related and exhibits appropriate pharmacology. Similarly in the brain and spleen, the pharmacologic rank order profile of CRF-related peptides for stimulation of adenylate cyclase is analogous to the profile seen in pituitary and in keeping with the affinities of these compounds for receptor binding. In addition, the putative CRF receptor antagonist α-hel ovine CRF(9-41) inhibits CRF-stimulated adenylate cyclase in brain and spleen homogenates.

In addition to the adenylate cyclase system, other signal transduction mechanisms may be involved in the actions of CRF. For example, CRF has been shown to increase protein carboxyl methylation, and phospholipid methylation in AtT-20 cells (41). Preliminary evidence suggests that CRF may regulate cellular responses through products of arachidonic acid metabolism (42). Furthermore, although the evidence in anterior pituitary cells suggests that CRF does not directly regulate phosphatidylinositol turnover or protein kinase C activity (42), stimulation of protein kinase C either directly or by specific ligands (vasopressin or angiotensin II), enhances CRF-stimulated adenylate cyclase activity, ACTH release, and inhibits phosphodiesterase activity (42). Thus, the effects of CRF on anterior pituitary cells and possibly in neurons and other cell types expressing CRF receptors are likely to involve complex interactions among several intracellular second messenger systems.

CRF-BINDING PROTEIN

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

CRF and Its Binding Protein in Human Plasma

Under normal conditions, the plasma levels of CRF remain low; however, CRF levels are markedly elevated in plasma during the late gestational stages of pregnancy (43 ,44 and 45). The source of the pregnancy-associated CRF is most likely the placenta because previous studies have demonstrated that the human placenta synthesizes CRF (46). The CRF in the maternal plasma is bioactive in releasing ACTH from cultured pituitary cells (44). In spite of the high levels of CRF in the maternal plasma, there is no evidence of markedly increased ACTH secretion or hypercortisolism in pregnant women (43). A plausible explanation for this paradoxic situation could be the presence of a binding protein in the plasma of pregnant women that could specifically inhibit the biological actions of CRF (44 ,45). This hypothesis was validated by the isolation of a CRF-binding protein (CRF-BP) from human plasma and its subsequent cloning and expression (see the following).

cDNA and Amino Acid Sequences

The CRF-BP was first isolated and purified to near homogeneity for sequencing and generation of oligonucleotide probes (47). Screening a human liver cDNA library using probes generated from the original amino acid sequence revealed a full-length cDNA containing a 1.8-kb insert that coded for a novel protein of 322 amino acids (48). A single putative N-linked glycosylation site was found at amino acid 203, which agrees with the previous observation of the presence of asparagine-linked sugar moieties on the native protein (49). Subsequent screening of a rat cerebral cortical cDNA library, revealed the presence of a single clone containing a 1.85-kb insert predicting a protein of 322 amino acids, which was 85% identical to the human CRF-BP. The putative glycosylation site on the rat protein seems to be conserved between the rat and human sequences (48). The pharmacology of these proteins appears to be similar with both the rat and human binding proteins having high affinity for the rat/human CRF (K_d ~ 0.2 nM) and very low affinity for the ovine form of CRF (K_d ~ 250 nM). Although there may be some similarities in the binding domains of the binding protein and the CRF receptor (as evidenced by the equal affinity of r/hCRF), these are distinct proteins, each with unique characteristics and distributions.

Distribution in Brain and Pituitary

Although the human and rat forms of the CRF-BP are homologous (as indicated), there is a somewhat different anatomic distribution pattern in the two species. The human form of the binding protein has been found abundantly in areas including liver, placenta, and brain, whereas in the rat levels of mRNA for the binding protein have only been localized in the brain and pituitary (48). Peripheral expression of the binding protein may have its greatest utility in the modulation and control of the elevated levels of CRF in circulating plasma induced by various normal physiologic conditions (see the preceding). In addition, expression of this binding protein in the brain and pituitary offers additional mechanisms by which CRF-related neuronal or neuroendocrine actions may be modulated.

CRF-binding protein has been localized to a variety of brain regions including neocortex, hippocampus (primarily in the dentate gyrus), and olfactory bulb. In the basal forebrain, mRNA is localized to the amygdaloid complex with a distinct lack of immunostained cells in the medial nucleus. CRF-binding protein immunoreactivity is also present in the brainstem particularly in the auditory, vestibular, and trigeminal systems, raphe nuclei of the midbrain and pons, and reticular formation (50). In addition, high expression levels of binding protein mRNA are seen in the anterior pituitary, predominantly restricted to the corticotrope cells. Expression of this protein in the corticotropes strongly suggests that the CRF-BP is involved in the regulation of neuroendocrine

functions of CRF by limiting and/or affecting the interactions of CRF with its receptor, which is also known to reside on corticotropes; however, the detailed role of the binding protein in regulating pituitary–adrenal function remains to be elucidated.

CRF REGULATION OF NEUROENDOCRINE FUNCTION

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

Regulation of Pituitary Hormone Secretion

CRF is the major physiologic regulator of the basal and stress-induced release of ACTH, B-endorphin, and other POMC-derived peptides from the anterior pituitary. (See refs. 3 , 4 , and 51 for reviews.) CRF stimulates the release of POMC-derived peptides in anterior pituitary cells in culture and *in vivo;* these actions of CRF can be antagonized by the CRF receptor antagonist α-helical ovine CRF(9-41) or by immunoneutralization with an anti-CRF antibody. Several other lines of evidence support a critical role for endogenous CRF in regulating ACTH secretion. For example, increases in CRF in the hypophysial portal blood are observed following application of stress. Administration of CRF antisera or the CRF receptor antagonist results in attenuation of stress- or adrenalectomy-induced ACTH secretion further substantiating a role for CRF in regulating ACTH secretion from the anterior pituitary. In addition to effects in the anterior pituitary, CRF also has been reported to stimulate POMC-derived peptide secretion from the intermediate lobe of the pituitary gland.

Central administration of CRF inhibits the secretion of luteinizing hormone (LH) and growth hormone without any major effects on follicle-stimulating hormone, thyroid stimulating hormone, or prolactin secretion (3 ,4). The effects of CRF to inhibit LH secretion appear to be mediated at the hypothalamic level through effects of CRF to inhibit gonadotropin releasing hormone secretion. CRF-induced inhibition of LH secretion may also involve endogenous opioids since the effects are attenuated by administration of naloxone or antiserum to B-endorphin (3 ,4).

Regulation of Hypothalamic CRF Release

Plotsky and associates (52) and Owens and Nemeroff (4) provide a comprehensive review of the neurotransmitter regulation of hypothalamic CRF release. Most studies demonstrate stimulatory effects of cholinergic and serotonergic neurons on CRF release. The muscarinic and/or nicotinic cholinergic receptor subtypes involved in the stimulatory effects of acetylcholine on CRF secretion remain to be precisely elucidated. The effects of serotonin to stimulate CRF release appear to be mediated by a variety of receptor subtypes, including 5-HT_2, 5-HT_{1A}, and 5-HT_{1C} receptors. The effects of catecholamines and opioids on hypothalamic CRF release are less well defined. Norepinephrine has been reported to have both stimulatory and inhibitory effects on CRF release that may be a consequence of the dose administered as well as the receptor subtype involved. For example, in studies sampling hypophysial portal concentrations of CRF, Plotsky and colleagues (52) noted that low doses of norepinephrine stimulated CRF release *in vivo* via α-adrenergic receptors and inhibited CRF release at high doses via B-adrenergic receptors. Similarly, opioids have been reported to either inhibit or stimulate CRF release depending on the nature of the opioid tested, dose utilized, and receptor specificity (μ versus κ) involved. Drugs acting at GABA–benzodiazepine–chloride ionophore complex are potent inhibitors of CRF secretion.

Stress is a potent general activator of CRF release from the hypothalamus. The extent and time course of changes in CRF in the paraventricular nucleus and median eminence of the hypothalamus following application of stress are highly dependent on the nature of the stressor as well as the state of the animal. The effects of stress to increase the release and synthesis of CRF are mediated by many of neurotransmitter systems described in the preceding.

Glucocorticoids, which are involved in the negative feedback regulation the hypothalamic–pituitary–adrenocortical axis, are potent inhibitors of CRF release. Conversely, the absence of glucocorticoids following adrenalectomy results in marked elevations in the synthesis and release of CRF. The actions of glucocorticoids to inhibit CRF release are mediated directly at the level of the paraventricular nucleus of the hypothalamus as well as indirectly through actions on receptors in the hippocampus.

Modulation of Pituitary CRF Receptors

Stress (29 ,32 ,33 ,53) or adrenalectomy (29 ,32 ,33) result in hypersecretion of CRF and a consequent down-regulation of receptors in the anterior pituitary. The adrenalectomy-induced decreases in anterior pituitary receptors can be prevented by glucocorticoid replacement with corticosterone or dexamethasone (29 ,32 ,33). In addition, chronic administration of corticosterone has been reported to cause dose-dependent decreases in anterior pituitary CRF receptor number (29 ,32 ,33). An age-related decline in anterior pituitary CRF receptors has also been reported (54). In contrast, lesions of the paraventricular nucleus that result in dramatic reductions in hypothalamic CRF secretion have been reported to increase the density of pituitary CRF receptors (4). Thus, CRF receptors in the anterior pituitary appear to be reciprocally regulated by hypothalamic CRF release.

CRF REGULATION OF CNS ACTIVITY

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

Electrophysiologic Effects of CRF

CRF stimulates the electrical activity of neurons in various brain regions that contain CRF and CRF receptors, including

locus ceruleus (55), hippocampus (56), cerebral cortex, and hypothalamus as well as in lumbar spinal cord motor neurons (3 ,4). In contrast, CRF has inhibitory actions in the lateral septum, thalamus, and hypothalamic PVN (3 ,4). The electrophysiologic effects of CRF on spontaneous and sensory-evoked activity of locus ceruleus neurons are well documented (55). Activation of the locus ceruleus, a brainstem nucleus comprising of noradrenergic cells, results in arousal and increased vigilance. Furthermore, dysfunction of this nucleus has been implicated in the pathophysiology of depression and anxiety. Centrally administered CRF increases the spontaneous discharge rate of the locus ceruleus in both anesthetized and unanesthetized rats, while decreasing evoked activity in the nucleus (55). Thus, the overall effect of CRF in the locus ceruleus is to decrease the signal to noise ratio between evoked and spontaneous discharge rates.

The effects of CRF on EEG activity have been reviewed in detail (3 ,4 ,57). CRF causes a generalized increase in EEG activity associated with increased vigilance and decreased sleep time. At CRF doses below those affecting locomotor activity or pituitary–adrenal function, rats remain awake, vigilant and display decreases in slow-wave sleep compared to saline-injected controls (57). Higher doses of the peptide, on the other hand, cause seizure activity that is indistinguishable from seizures produced by electrical kindling of the amygdala, further confirming the role of CRF in brain activation.

Autonomic Effects of CRF

A great deal of anatomic, pharmacologic, and physiologic data support the concept that CRF acts within the CNS to modulate the autonomic nervous system (3 ,4 ,58 ,59). For example, central administration of CRF results in activation of the sympathetic nervous system resulting in stimulation of epinephrine secretion from the adrenal medulla and noradrenergic outflow to the heart, kidney, and vascular beds. Other consequences of central administration of CRF include increases in the mean arterial pressure and heart rate. These cardiovascular effects of CRF can be blocked by the ganglionic blocker chlorisondamine underscoring the sympathetic actions of the peptide. In contrast, CRF acts in brain to inhibit cardiac parasympathetic nervous activity. (See ref. 58 for review.) Peripheral administration of CRF causes vasodilation and hypotension in a variety of species including humans (3 ,4 ,58 ,59). The physiologic role of CRF in regulating the autonomic nervous system is supported by data demonstrating central effects of the CRF receptor antagonist, α-helical ovine CRF(9-41) to attenuate adrenal epinephrine secretion resulting from stressors such as insulin-induced hypoglycemia, hemorrhage, and exposure to ether vapor (59). Overall, these data substantiate a major role for CRF in coordinating the autonomic responses to stress.

Gastrointestinal Effects of CRF

Studies examining the gastrointestinal effects of CRF have determined that CRF modulates gastrointestinal activity by acting at central and possibly peripheral sites, and that these effects are qualitatively similar to those observed following exposure to various stressors. (See refs. 3 , 4 , and 60 for reviews.) CRF inhibits gastric acid secretion, gastric emptying, and intestinal transit while stimulating colonic transit and fecal excretion in a dose-dependent manner when administered centrally or systemically to dogs or rats. CRF is equipotent in inhibiting gastric emptying in both species following both central and peripheral routes of administration. The central effects of CRF on gastric acid secretion do not appear to result from leakage of the peptide into peripheral blood because measurable quantities of CRF are not present in the circulation following injection of CRF into the third ventricle of the dog. Furthermore, an intravenous injection of anti-CRF serum completely abolishes the peripheral but not the central effect of CRF on gastric acid secretion. These data strongly implicate CRF in the mechanisms through which various stressors alter gastrointestinal function and are consistent with its proposed role in integrating the autonomic nervous system’s response to stress.

Behavioral Effects of CRF

The behavioral effects of CRF in the CNS have been reviewed extensively (3 ,4 ,61). The effects of CRF on behavior are dependent on both the dose of peptide administered and the specific conditions under which the tests are performed. In a familiar or “home” environment, central administration of CRF produces a profound increase in locomotor activity. Although very low doses of CRF produce locomotor activation when tested in an open field test, higher doses produce a dramatic decrease in locomotor activity. CRF administered intracerebrally also produces additional behavioral effects including increases in sniffing, grooming, and rearing in a familiar environment, increased “emotionality” and assumption of a freeze posture in a foreign environment, decreased feeding and sexual behavior, and increased conflict behavior. The behavioral effects of CRF are not an indirect consequence of actions of the peptide to activate pituitary–adrenocortical hormone secretion because they are not seen following peripheral administration of CRF or following pretreatment with doses of dexamethasone that adequately block pituitary–adrenal activation. Of critical importance is the observation that these effects of CRF can all be blocked by administration of the peptide antagonist α-helical ovine CRF(9-41), strongly supporting a specific CRF receptor-mediated event in these behaviors. Furthermore, the CRF receptor antagonist by itself attenuates many of the behavioral consequences of stress underscoring the role of endogenous peptide in mediating many of the stress-related behaviors.

ROLE FOR CRF IN NEUROPSYCHIATRIC DISORDERS AND NEURODEGENERATIVE DISEASES

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

Major Depression and Anxiety Disorders

Many patients with major depression are hypercortisolemic and exhibit an abnormal dexamethasone suppression test. Given the primary role of CRF in stimulating pituitary–adrenocortical secretion, the hypothesis has been put forth that hypersecretion or hyperactivity of CRF in brain might underlie the hypercortisolemia and symptomatology seen in major depression. (See refs. 62 and 63 for review.) The concentration of CRF is significantly increased in the cerebrospinal fluid (CSF) of drug-free individuals (4 ,64 ,65), and a significant positive correlation is observed between CRF concentrations in the CSF and the degree of postdexamethasone suppression of plasma cortisol (66). Furthermore, the observation of a decrease in CRF binding sites in the frontal cerebral cortex of suicide victims compared to controls is consistent with the hypothesis that CRF is hypersecreted in major depression (67). The elevated CSF concentrations of CRF seen in depressed individuals are decreased following treatment with electroconvulsive therapy (68). In addition, a blunted ACTH response to intravenously administered ovine or human CRF is observed in depressed patients when compared to normal controls (69). The blunted ACTH response to exogenous CRF seen in depressed patients may be caused by the intact negative feedback of cortisol on the corticotrophs, a compensatory decrease in CRF receptors subsequent to chronic hypersecretion of the peptide, and/or desensitization of the pituitary corticotrophs to respond to CRF.

A number of studies suggest that anxiety-related disorders (e.g., panic disorder and generalized anxiety disorder) and depression are independent syndromes that share both clinical and biological characteristics. The role that has been proposed for CRF in major depressive disorders along with preclinical data in rats demonstrating effects of CRF administration to produce several behavioral effects characteristic of anxiogenic compounds (61) have led to the suggestion that CRF may also be involved in anxiety-related disorders. A role for CRF in panic disorder has been suggested by observations of blunted ACTH responses to intravenously administered CRF in panic disorder patients when compared to controls (70). The blunted ACTH response to CRF in panic disorder patients most likely reflects a process occurring at or above the hypothalamus, resulting in excess secretion of endogenous CRF.

Anorexia Nervosa

Anorexia nervosa is an eating disorder characterized by tremendous weight loss in the pursuit of thinness. There is similar pathophysiology in anorexia nervosa and depression, including the manifestation of hypercortisolism, hypothalamic hypogonadism, and anorexia. Furthermore, the incidence of depression in anorexia nervosa patients is high. Like depressed patients, anorexics show a markedly attenuated ACTH response to intravenously administered CRF (4 ,64 ,65). When the underweight anorexic subjects are studied after their body weight had been restored to normal, their basal hypercortisolism, increased levels of CRF in the CSF, and diminished ACTH response to exogenous CRF all return to normal at varying periods during the recovery phase (4 ,64 ,65). CRF can potently inhibit food consumption in rats, which further suggests that the hypersecretion of CRF may be responsible for the weight loss observed in anorexics. In addition, the observation that central administration of CRF diminishes a variety of reproductive functions (4 ,65) lends relevance to the clinical observations of hypogonadism in anorexics.

Alzheimer's Disease

Several studies have provided evidence in support of alterations in CRF in Alzheimer's disease (AD) (4 ,65 ,71 ,72 ,73 and 74). There are decreases in CRF content and reciprocal increases in CRF receptors in cerebral cortical areas affected in AD such as the temporal, parietal, and occipital cortex. The reductions in CRF and increases in CRF receptors are all greater than 50% of the corresponding control values. The up-regulation in cerebral cortical CRF receptors in AD under conditions in which the endogenous peptide is reduced suggests that CRF-receptive cells may be preserved in the cortex in AD. Chemical cross-linking studies have demonstrated a normal pattern of labeling of cerebral cortical CRF receptors in AD when compared to age-matched controls (75). Although these decreases in CRF content have a modulatory action on the receptors (up-regulation), there appears to be no effect on the concentration or levels of CRF-binding protein in cerebral cortical areas affected in AD (76). The reduction in cortical CRF content may be owing to selective degeneration of CRF neurons intrinsic to the cerebral cortex or dysfunction of CRF neurons innervating the cortex from other brain areas. Additional evidence for a role for CRF in AD is provided by observations of decreases in CRF in other brain areas including the caudate (71) and decreased concentrations of CRF in the CSF (77 ,78). Furthermore, a significant correlation is evident between CSF CRF and the global neuropsychological impairment ratings, suggesting that greater cognitive impairment is associated with lower CSF concentrations of CRF (79).

Immunocytochemical observations demonstrating morphologic alterations in CRF neurons in AD complement the studies described in the preceding. In AD, swollen, tortuous CRF-immunostained axons, termed fiber abnormalities, are clearly distinguishable from the surrounding normal neurons and are also seen in conjunction with amyloid deposits associated with senile plaques (80). Furthermore, the total

number of CRF-immunostained axons is reduced in the amygdala of Alzheimer's patients (80). Interestingly, the expression of CRF antigen in neurons is not globally reduced in Alzheimer's patients. CRF immunostaining of perikarya and axons located in the hypothalamic paraventricular nucleus is much more intense in AD patients than controls (80). Increased immunostaining of the paraventricular neurons in AD, if truly representative of increased content of CRF, could be related to increased amounts of CRF mRNA in these cells or increased translation of available mRNA. The increased expression and/or release of CRF from the paraventricular nucleus of the hypothalamus would provide a reasonable explanation for the hypercortisolemia often seen in Alzheimer's patients.

At present, the cerebral cortical cholinergic deficiency seems to be the most severe and consistent deficit associated with AD. Reductions in cerebral cortical CRF correlate with decreases in choline acetyl transferase (ChAT) activity (72). In Alzheimer's, there are significant positive correlations between ChAT activity and reduced CRF in the frontal, temporal, and occipital lobes. Similarly, significant negative correlations exist between decreased ChAT activity and increased number of CRF receptors in the three cortices. These data suggest that the reported reciprocal changes in presynaptic and postsynaptic markers in CRF in cerebral cortex of patients with AD may be, in part, a consequence of deficits in the cholinergic projections to the cerebral cortex. Additional studies are necessary to determine the functional significance of the interaction between CRF and cholinergic systems.

Other Neurological Disorders

Alternations in brain concentrations of CRF have been reported in other neurological diseases. For example, in cases of Parkinson's disease (PD) with dementia that also show pathologic features of AD, CRF content is decreased and shows a pattern similar to those cases exhibiting the pathology of AD alone (74 ,81). Specimens from patients with PD who did not have the histopathology characteristic of AD also demonstrate reductions of CRF content, although the reductions are less marked than in cases of combined AD and PD. Normal levels of CRF have been reported in the hypothalamus in PD (82), suggesting that the loss of CRF in the cerebral cortex is not generalized. CRF is deceased to approximately 50% of the control values in the frontal, temporal, and occipital lobes of patients with progressive supranuclear palsy (74 ,81), a rare neurodegenerative disorder that shares certain clinical and pathologic features with AD.

The similarity of the changes in CRF found in the context of the three neurological diseases associated with Alzheimer-type pathology raised the possibility that cerebral cortical reduction is nothing more than a nonspecific sequela of the disease process. In Huntington's disease (HD), a neurological disorder in which minimal cerebral cortical pathology is present, the CRF content in the frontal, temporal, parietal, occipital, and cingulate cortices and in the globus pallidus is not significantly different from that seen in neurologically normal controls (73). However, the CRF content in the caudate nucleus and putamen of the basal ganglia (a brain area that is severely affected in the disease) is less than 40% of the CRF concentrations seen in controls (73). The localization of the CRF changes to only affected brain regions in the four neurodegenerative disorders described suggest that CRF has an important role in the pathology of these dementias.

POTENTIAL THERAPEUTIC STRATEGIES DESIGNED FOR THE CRF SYSTEM

Part of "7 - Corticotropin-Releasing Factor: Physiology, Pharmacology, and Role in Central Nervous System Disorders "

Nonpeptide CRF-Binding Protein Ligand Inhibitors

As mentioned, the CRF-binding protein has the capacity to bind and functionally inactivate CRF. Peptide CRF-BP ligand inhibitors have been shown *in vitro*, to release CRF from the binding protein making it available for binding to its receptor and have been theorized to have efficacy in diseases that are associated with low levels of CRF such as Alzheimer's disease (76). Interestingly, unlike the direct i.c.v. administration of CRF, inhibition of the CRF-BP by ligand inhibitors that release functional CRF does not cause anxiogenic-like activity in animal models, validating the approach for diseases that require an increase in CRF function (76). Thus, compounds that act to dissociate CRF from its binding protein complex will act to selectively increase synaptic concentrations of CRF in discrete brain regions and may provide a novel treatment opportunity for disorders associated with low levels of CRF. To date, however, no nonpeptide CRF-BP ligand inhibitors have been discovered to test this hypothesis. On the other hand, small molecule nonpeptide CRF receptor antagonists have shown encouraging preliminary results in this complex system.

Nonpeptide CRF Receptor Antagonists

As indicated in this and previous reviews of the CRF system, there are a number of neuropsychiatric indications where clinical and preclinical data have shown that the CRF system is hyperactivated as evidenced by abnormally high levels of CRF within the CNS. For example, in clinical studies of major depression, increased CRF concentrations in the cerebrospinal fluid, increased HPA activity, blunted ACTH responsiveness to exogenously administered CRF, and pituitary and adrenal hypertrophy have all indicated hypersecretion of CRF associated with this disorder. (See refs. 4 , 5 , 32 , 65 , and 83 for review.) It follows that for these indications the therapeutic strategy would involve functional blockade of the actions of CRF. This can be achieved

through inhibition of CRF synthesis and secretion, inactivation of CRF (either by antibody neutralization or increased metabolism), or direct antagonism by specific receptor blockade. Although anti-CRF antibodies have demonstrated antiinflammatory effects (84), these types of therapies are limited to peripheral use and could not be readily formulated for oral administration for central activity. Nevertheless, these therapeutics could be useful for the treatment of disorders with peripheral elevations of CRF such as rheumatoid arthritis.

The best strategy for the blockade of elevated CRF levels is to design specific and selective nonpeptide receptor antagonists. Particularly for use in the brain, these molecules can be designed to have receptor subtype specificity, good oral bioavailability, and rapid penetration across the blood–brain barrier; characteristics that are difficult to optimize with peptide therapies. The recent surge in combinatorial chemistry techniques, coupled with recent technological advances in robotic high-throughput screening and data management of large libraries of molecules have enabled the field of small molecule drug discovery. These advancements have led to the identification of several patented structural series of molecules known to antagonize the effects of CRF at the CRF_1 receptor subtype. (See ref. 85 for a complete review.) Several of these small molecules have recently appeared in the literature and reported to have good CRF_1 receptor antagonistic activity. Compounds such as CP 154,526 (86), NBI 27914 (87), Antalarmin (88), and most recently DMP 696 (89), all demonstrate a good *in vitro* profile, showing selectivity for the CRF_1 receptor subtype. Systemic administration of these compounds have been found to attenuate stress-induced elevations in plasma ACTH levels in rats, demonstrating that CRF_1 receptors can be blocked in the periphery. Furthermore, nonpeptide CRF_1 antagonists administered peripherally have also been demonstrated to inhibit CRF-induced seizure activity (90). Until recently, however, these compounds have suffered from poor solubility and pharmacokinetics, thus limiting their utility in *in vivo* characterization of the individual compounds as well as the overall proof of concept for the mechanism of CRF receptor efficacy. One compound has very recently been described as a water-soluble nonpeptide CRF_1 receptor antagonist (NBI 30775, also referred to as R121919) that demonstrates high affinity, and has a superior *in vitro* and *in vivo* profile compared to other nonpeptide CRF receptor antagonists (91).

NBI 30775, is a pyrazolopyrimidine with high affinity for the CRF_1 receptor and over 1,000-fold weaker activity at the CRF_2 receptor subtype. This compound does not interact at all with the CRF binding protein and was shown to be as potent as the peptide antagonist D-Phe CRF(12-41) at inhibiting the CRF-stimulated cAMP accumulation from cells that express the human CRF_1 receptor and CRF-stimulated ACTH release from cultured rat anterior pituitary cells *in vitro. In vivo*, this molecule potently attenuated the plasma elevations of ACTH observed following a stressful stimulus in the rat, and demonstrated both dose- and time-dependent CRF_1 receptor occupancy concomitant with the levels of drug measured in whole brain (91). Owing to the promising preclinical profile of this compound this particular compound was assessed in full Phase I clinical trials and an initial open label Phase IIa study where the compound was assessed in patients with major depressive disorder.

First Clinical Experience with CRF_1 Receptor Antagonists

Preclinically, studies have demonstrated that attenuation of the CRF system, either by decreasing synthesis and release or by selective blockade of the CRF receptor, results in decreased anxiety and behavioral activation in stressed animals; however, clinically it will probably not be beneficial to the overall outcome of the patient if the stress axis is maximally compromised. The preclinical studies described, prompted the development of NBI 30775 in Phase I safety studies in humans and in an open-label clinical trial in patients with major depressive disorder (92). In this latter study severely depressed patients were given NBI 30775 orally once daily in a dose-escalating manner and their hypothalamic-pituitary adrenal (HPA) function assessed. In addition, the patients' level of depression or anxiety was measured using the Hamilton depression (HAM-D) and anxiety (HAM-A) scales. The results demonstrated that this compound was safe and well tolerated under the conditions of this study. Moreover, the data suggested that blockade of the CRF_1 receptor in these patients did not result in an impairment of the HPA axis either at baseline or following an exogenous CRF challenge (92). This demonstration was critical in setting this potential therapy apart from existing therapies that blunt basal functioning of multiple neurotransmitter systems. Furthermore, although under the limited conditions of an open-label trial, there was a statistically significant dose-dependent reduction in the depression and anxiety scores using both clinician and patient ratings, suggesting that this mechanism may provide an exciting novel therapy in patients suffering with major depressive disorder. Although it is of great importance at this stage to develop these compounds as tools in the ultimate understanding of the CRF system and the role it plays in neuropsychiatric disorders, evidence is now beginning to emerge that compounds of this class, and more importantly of this mechanism, will prove beneficial in neuropsychiatric disorders such as depression or anxiety. Should compounds such as this continue to demonstrate efficacy in these disorders without severely compromising the stress axis as a whole, they would validate the CRF hypothesis for depression and anxiety and provide an entirely novel treatment for these devastating diseases.

CONCLUSION

Corticotropin-releasing factor is the key regulator of the organism's overall response to stress. CRF has hormone-like effects at the pituitary level to regulate ACTH secretion that, in turn coordinates the synthesis and secretion of glucocorticoids from the adrenal cortex. CRF also functions as a bona fide neurotransmitter in the CNS. CRF neurons and receptors are widely distributed in the CNS and play a critical role in coordinating the autonomic, electrophysiologic, and behavioral responses to stress.

Clinical data have implicated CRF in the etiology and pathophysiology of various endocrine, psychiatric, and neurological disorders. Hypersecretion of CRF in brain may contribute to the symptomatology seen in neuropsychiatric disorders such as depression, anxiety-related disorders, and anorexia nervosa. In contrast, deficits in brain CRF are apparent in neurodegenerative disorders such as AD, PD, and HD as they relate to dysfunction of CRF neurons in brain areas affected in the particular disorder. The recent discovery of novel receptor family members as well as novel alternative ligands for these subtypes serve not only to increase our understanding of the system but provide a basis for selective and rational drug design for the treatment of disorders that are associated with aberrant levels of CRF. Strategies directed at developing specific and selective CRF agents have yielded many nonpeptide small molecule CRF_1 receptor antagonists and a preliminary proof-of-concept has encouraged the further development of such agents. Compounds such as those described in this chapter may hold promise for novel therapies for the treatment of these various neuropsychiatric disorders without severely compromising this highly complex hormonal system. Clearly with the recent advances made within a very short period of time, it now seems possible to begin a full understanding of this increasingly complex neurohormone system.

Neurogenesis in Adult Brain

Fred H. Gage

Henriette Van Praag

Fred H. Gage and Henriette van Praag: The Laboratory of Genetics, The Salk Institute for Biological Studies, La Jolla, California.

HISTORIC PERSPECTIVE

Part of "8 - Neurogenesis in Adult Brain "

The idea that the adult brain retains the capacity to generate new neurons has been proposed several times over the last 40 years, and in each case both conceptual and technical constraints have led to resistance. Joseph Altman first reported that some dividing cells in the adult brain survived and differentiated into cells with morphology similar to neurons using tritiated thymidine autoradiography (1). Over the subsequent years he and his colleagues confirmed these initial observations and focused on the few areas where neurogenesis was apparent in the adult, at the light microscopic level, while systematically documenting the birth dates of neurons throughout the brain during development (2). When contrasting adult neurogenesis with the extensive neurogenesis in development, adult neurogenesis seemed almost like an epiphenomenon. The continued skepticism surrounding adult neurogenesis and the absence of definitive phenotypic markers limited the development of the field. In the mid-1970s and early 1980s Michael Kaplan reexamined the initial observations using the electron microscope and added substantial confidence that not only could neurogenesis occur in the adult brain, but also that the cells appear ultrastructurally, similar to sister cells in the dentate gyrus of the hippocampus, one of the structures shown to be neurogenic (3). In the mid-1980s, Fernando Nottebohm and his student Steve Goldman further stimulated this fledgling field by showing that songbirds experience a seasonal cell death and neurogenesis in a region of the brain important for song production (4). They have continued to reveal more about the environment and molecular regulators of this process in the adult avian brain (5). Despite these observations of neurogenesis in the adult brain, confusion over the mechanism origin of cell genesis in the adult brain persisted. In the early 1990s a series of papers in the adult mouse and rat revealed that cells with stem cell properties could be isolated and expanded in culture. Under a variety of culture conditions with different factors, these isolated cells can be induced to differentiate into glia and neurons (6 ,7 ,8 and 9). This later observation provided a mechanism for the neurogenesis in the adult. Mature committed neurons were not dividing, but rather a population of immature stem-like cells exists in the brain and it is likely that it is the proliferation and differentiation of this population that is resulting in neurogenesis. With this conceptual framework the original statement by Cajal that, “Once development was ended, the fonts of growth and regeneration of the axons and dendrites dried up irrevocably. In adult center, the nerve paths are something fixed and immutable: everything may die, nothing may be regenerated,” still holds true for most areas of the adult brain. The new lesson that we have learned is that development never ended in some areas of the brain.

CHARACTERIZATION OF CELL GENESIS *IN VIVO*

Part of "8 - Neurogenesis in Adult Brain "

Areas of Neurogenesis

Neurogenesis is a process that includes cell division, migration, and differentiation. There appear, at present, to be only two areas of the brain where stems cells initially reside and proliferate prior to migration and differentiation. Those areas are the lateral subventricular and subgranular zones of the dentate gyrus. The exact cell that corresponds to the initiating stem cell in the lateral ventricle is a point of contention. One view is that this cell is the ependymal cell facing the ventricle (10), whereas an alternative view is that a glial population one cell layer in from the ependyma are the stem cells (11). In any case, after cell division one of the stem cells begins to differentiate and migrate in what Alvarez-Buylla has described as “chain migration” along the rostral migratory stream toward the olfactory bulb where they differentiate into interneurons in the bulb (12). This process continues throughout life; the functional importance and consequences of this process are not understood. The stem cell in the adult mammalian subgranular zone of the dentate gyrus is likely an ectopically displaced cell

originating from the developing ventricular zone. It remains formally possible that a more primitive cell exists elsewhere in the adult brain in a quiescent state, and migrates to the dentate gyrus where the cells begin to divide. However, from the subgranular zone, one of the progeny migrates into the granule cell layer once the cells divide; there the majority become neurons with axons extending to the CA3 pyramidal neurons and receiving synaptic connections. The function of these newly born cells is being investigated.

Although these are the two principal areas where neurogenesis occurs in the mammalian brain, cell genesis occurs throughout the adult brain including cortex, optic nerve, spinal cord, and many brainstem and forebrain structures. To date the function of this cell genesis in the normal intact brain and spinal cord is not known, but some of these new cells can become glial cells (13). A clear challenge for the future is to document all the areas of the adult brain where cell genesis continues, and to understand the normal function as well as the factors that regulate this process.

Mammalian Species in Which Adult Neurogenesis Is Documented

The first studies demonstrating adult neurogenesis were in the rat. Subsequently, rabbit and cat were shown to exhibit similar characteristics, although little additional work has been done in those animals since the original publications (14 ,15). It was not until 1997 that Kempermann and associates showed the mice retain neurogenesis and that significant genetic variability exists among mouse strains (16). These findings, together with the important role for environmental stimulation as a regulator of neurogenesis, have placed adult neurogenesis as paradigm for examining the interactions of nature and nurture (17 ,18). Although there was debate in the mid-1980s as to whether nonhuman primates retained adult neurogenesis, a series of papers by Fuchs and associates beginning with tree shrew followed by marmosets and finally with Rhesus monkeys demonstrated and confirmed that neurogenesis in occurs in adult nonhuman primates (19 ,20). Recently, Gould presented data suggesting that neurogenesis occurs in the adult primate frontal cortex and concluded that the cells are derived from the subventricular zone where they migrate to specific cortical regions of the adult primate brain. This observation awaits confirmation (21). One of the markers for determining cell division is bromo-deoxyuridine (BrdU); a traceable analogy of uridine, which in incorporated into the genome of, cells undergoing cell division. Administering BrdU and then examining cell proliferation in tumor biopsies is occasionally used to monitor tumor progression in patients with cancer. Because BrdU is a small soluble molecule, it is distributed throughout the body including the brain, thus can be a marker for cell and neurogenesis in humans. In 1998 Eriksson and colleagues (22) reported that in five of the cancer patients they examined who received BrdU at between 15 days and over 2 years early, all of them showed neurogenesis as revealed by colabeling of BrdU with markers of mature neurons in the dentate gyrus. Together these studies clearly demonstrate that neurogenesis, at least in the dentate gyrus, is a process that persists throughout life and in all mammalian species (Fig. 8.1).

The extent to which or whether neurogenesis can occur in other brain areas remains an area of intense investigation.

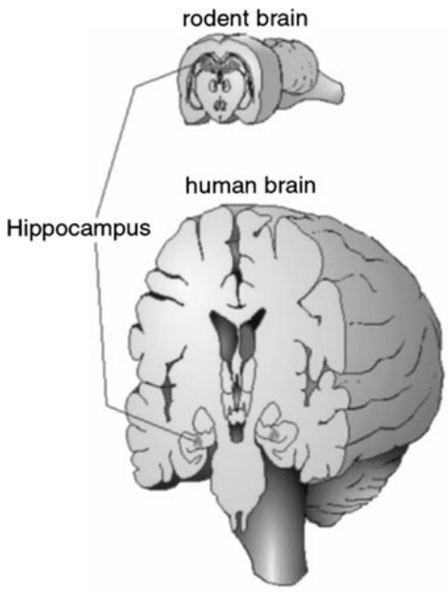

FIGURE 8.1. Birth of new neurons in the adult hippocampus has been documented in a variety of species, including rodents and humans. See color version of figure.

PROPERTIES OF STEM CELLS *IN VITRO*

Part of "8 - Neurogenesis in Adult Brain "

CNS Areas from Which Stem Cells Can Be Isolated

Neural stem cells can be derived from the adult brain and propagated *in vitro* (6 ,7 and 8 ,10 ,11 ,23 ,24 ,25 and 26). Ongoing adult neurogenesis, however, has only been documented convincingly in two brain areas, the subventricular zone/olfactory system and the dentate gyrus of the hippocampus. Interestingly, stem cells are found not only in these regions, but also have been isolated from areas that are non-neurogenic such as the septum, striatum (27), spinal cord (28), cerebral cortex, corpus callosum, and optic nerve (29) and eye (30). In culture, these cells are multipotent and can give rise to neurons and glia. However, cells isolated from areas outside of the hippocampus and subventricular zone require high levels of FGF-2 in order to give rise to neurons, rather than only glial cells (29). These findings suggest that either different

populations of stem cells exist in the nervous system or that they require unique culture conditions to become multipotent. Alternatively, the cells isolated from different CNS regions may already be committed toward a specific lineage. Indeed, there are no antigenic markers that allow unambiguous identification of stem cells in the nervous system. In the subventricular zone, stem cells are suggested to divide slowly, whereas and their offspring, progenitor cells, may divide more frequently (31). Stem cells in this area have been suggested to ependymal cells (10) or a subclass of glial cells in the subependymal zone (11). The location and identity of the hippocampal stem cell remains to be determined.

Factors That Affect Proliferation and Differentiation of Stem Cells In Vitro

A variety of cytokines, neurotrophins, and conditioned media are used to culture neural progenitor cells (32 ,33 and 34). The two major factors are EGF and FGF. Progenitor cells responsive to EGF have been isolated and cultured from adult mouse subventricular zone (6 ,7 ,31). FGF-2 has been found to be mitogenic for adult neural progenitors from brain and spinal cord (9 ,27 ,28). FGF-2, however, is member of a family of 10 related, but genetically and functionally distinct polypeptides. Among those, only FGF-2 and FGF-4 are mitogens for neural progenitor cells. Moreover, a comparison of amino acid sequences between the FGFs revealed a striking similarity between a 10-amino acid sequence of FGF-2 and FGF-4. This 10-amino acid sequence was been shown to elicit the mitogenic effects of FGF-2 and FGF-4 on neural progenitor cells, whereas similar regions in FGF-1 and -5 were found to be inactive (35).

Several factors have been found to be important for neuronal differentiation in cultured progenitor cells. In particular, retinoic acid and cAMP increase neuronal differentiation (27 ,36 ,37). In addition, neurotrophins such as NGF, BDNF, and NT-3 have been found to influence neuronal differentiation and transmitter phenotype (34 ,37 ,38), whereas CNTF can regulate glial differentiation of precursor cells (39).

Transplanted Cells and Responses to Local Cues

Progenitor cells may play an important role in brain or spinal cord repair. In particular, grafting of progenitor cells into degenerated or injured areas may be used to replace cells that are no longer functional. The phenotype and function that these cells acquire appears to be very much dependent on the specific environment into which they are transplanted. Thus, cultured hippocampal progenitors become granule cell neurons when grafted into the dentate gyrus, tyrosine hydroxylase, and calbindin positive neurons in the olfactory bulb after grafting into the rostral migratory stream (40). In addition, after implantation into the developing retina these cells showed properties of several types of retinal neurons (37). Moreover, progenitors isolated from a non-neurogenic area such as the spinal cord, acquired the morphologic characteristics of granule cell neurons when grafted into the dentate gyrus, and had a glial phenotype when grafted back in to the spinal cord (41). These studies suggest that neural stem cells derived from the adult mammalian brain retain multipotentiality. Recent research suggests that neuronal stem cells are multipotent outside the CNS as well. It was reported that neural progenitor cells repopulate experimentally depleted bone marrow and reconstitute the hematopoietic system (42). It remains to be determined what the local cues are, that are driving the neuronal precursor cells to acquire such specific fates when transplanted *in vivo*.

REGULATION OF PROLIFERATION AND DIFFERENTIATION *IN VIVO*

Part of "8 - Neurogenesis in Adult Brain "

The mechanisms that generate new granule cells in the dentate gyrus are poorly understood. A variety of environmental, behavioral, genetic, neuroendocrine, and neurochemical factors can regulate adult neurogenesis. Two critical processes that lead to neurogenesis, cell proliferation and the subsequent differentiation and survival of newborn neurons, can undergo differential regulation by these factors (Table 8.1).

TABLE 8.1. REGULATION OF CELL PROLIFERATION AND NEUROGENESIS IN THE DENTATE GYRUS *IN VIVO*

Genetics

In 1997 Kempermann and colleagues found that strains of mice differ with respect to rate of cell division and amount of cell survival and neurogenesis. Comparisons were made among C57BL/6, BalB/c, CD1, and 129/SVJ strains. Proliferation was found to be highest in C57BL/6 mice; however, net neurogenesis was highest in the CD1 strain. 129/SVJ produced relatively more astrocytes and fewer neurons than other strains (16). The degree to which environmental, behavioral, and biochemical factors can affect cell proliferation and neurogenesis may also differ depending on the species or strain of animal involved. Indeed, exposure to an enriched environment (18) had different effects on two of these strains of mice, C57BL/6 and 129/SVJ, respectively. In C57BL/6 mice enrichment promoted the survival of progenitor cells but did not affect proliferation, whereas the net increase in neurogenesis in 129/SVJ mice was accompanied by a twofold increase in proliferation (18). Thus, strain differences not only influence the baseline rate of adult hippocampal neurogenesis, but also influence how adult hippocampal neurogenesis is regulated in response to environmental stimulation. Indeed, proliferation, survival and differentiation of progenitor cells and their progeny are each separately influenced by inheritable traits and are not uniformly

up-regulated in response to environmental stimulation.

Growth Factors

During development, growth factors provide important extracellular signals for regulating the proliferation and fate determination of stem and progenitor cells in the CNS (43). Several studies have been carried out to investigate progenitors in the adult brain respond to such growth factors. Intracerebroventricular infusion of EGF and FGF-2 in adult rats increased proliferation in the subventricular zone (44). Neither EGF nor FGF enhanced proliferation in the subgranular zone of the dentate gyrus. With regard to differentiation, EGF promoted glial differentiation, whereas FGF-2 did not influence phenotype distribution (44). In another series of experiments, FGF was administered systemically during the first postnatal weeks and in the adult rat. Cell proliferation was increased the dentate gyrus of infant rats but not in the adult hippocampus (45 ,46). Recent research has shown that intracerebral infusion of IGF increases both cell proliferation and neurogenesis in hypophysectomized rats (47). In songbirds, seasonal regulation of adult neurogenesis depends on testosterone levels that mediate their effect through BDNF (48). In addition, IGF-1, FGF mRNA, and BDNF mRNA are elevated in rodents by exercise (49 ,50 ,51 and 52). Expression of BDNF (53) and GDNF is increased by exposure to an enriched environment (54). Both running and enrichment increase net neurogenesis (17 ,55 ,56). The effects of intracerebral administration of trophins such as BDNF, NT-3, and GDNF remain to be determined; however, it appears that growth factors do play a role in *in vivo* regulation of proliferation and neurogenesis in the adult hippocampus. Better understanding of their mechanisms of action may lead to therapeutic application of these factors after brain injury or disease.

Neuroendocrine Factors and Stress

McEwen and Gould at Rockefeller University first investigated the effects of glucocorticoids or stress on adult hippocampal neurogenesis. The initial study reported that adrenalectomy, which leads to a reduction in serum glucocorticoid levels, elicits cell division in the dentate gyrus. This effect could be reversed by corticosterone replacement (57). Conversely, stress or increased levels of glucocorticoid hormones inhibit proliferative activity in the dentate gyrus (58 ,59). For example, administration of high levels of corticosterone diminishes cell division in the adult rat hippocampus (59). In addition, exposure of a rat to the odor of a natural predator (fox), causing stress and elevated corticosterone levels, transiently suppressed cell proliferation in the

adult rat dentate gyrus (60). Furthermore, exposure of marmoset monkeys to a resident intruder causes stress and results in a decrease in cell proliferation (61). In a recent study, rats that are highly reactive to novelty and exhibit a prolonged corticosterone secretion in response to novelty and stress were found have reduced dentate gyrus cell proliferation (62). Aging is accompanied by a reduction in neurogenesis (63), which may be caused in part by elevated glucocorticoid levels. Adrenalectomy in aged rodents has been shown to increase cell proliferation and neurogenesis (64). The effects of glucocorticoids on cell genesis appear to be mediated via a downstream effect on NMDA glutamate receptors (65). Thus, glucocorticoids and stress associated with increased corticosterone secretion inhibit cell genesis in the hippocampus. Enhanced stress or glucocorticoid levels therefore may impair hippocampal function, and lead to deficits in learning and memory. In contrast to the glucocorticoids, other steroid hormones, such as testosterone, enhance neurogenesis in birds (66), whereas estrogen results in a transient increase in proliferation in rats (67). Thyroid hormone can affect neuronal differentiation of hippocampal progenitor cells *in vitro* (27). *In vivo*, hypothyroidism interferes with cell migration (68), but does not affect postnatal cell proliferation (69).

Neurotransmitters

Neurotransmitters have also been suggested to play a role in adult dentate gyrus neurogenesis. Systemic injection of glutamate analogs inhibits birth of new cells, whereas an antagonist, such as MK801, enhances cell division (65 ,70). Recently, another class of neurotransmitters, the monoamines, has been suggested to be important as well. Prolonged administration of fluoxetine, as well as therapeutic agents acting on norepinephrine and dopamine receptors, and electroconvulsive shock enhance the number of BrdU-positive cells in rats (71 ,72 and 73). Acute administration of fluoxetine did not affect cell genesis (73). Grafting of fetal raphe neurons also stimulated granule proliferation in the hippocampus, whereas embryonic spinal tissue had no effect (74). Furthermore, depletion of serotonin reduces stem cell proliferation in the dentate gyrus (75). It is possible that these effects are mediated by the 1A receptor, because administration over 4 days of a specific 1A receptor antagonist (WAY) reduced basal rate of cell proliferation (Jacobs et al., unpublished observations). Taken together, these findings suggest that induction of cell proliferation is dependent on chronic administration of monoamines, consistent with the therapeutic time course for antidepressant treatments. Indeed, these studies have led to the hypothesis that therapeutic interventions that increase serotonergic transmission may act in part by augmenting dentate neurogenesis, promoting recovery from depression (76 ,77). It is of interest to note in this context that voluntary exercise increases cell proliferation (55), enhances monoamine levels and has an antidepressant effect (78). Thus, monoamines can affect cell genesis in the dentate gyrus. The receptors and mechanisms by which they exert their effects as well as possible interactions with other classes of neurotransmitters and/or growth factors remain to be determined.

Experience

As mentioned, stress (19) and depression may reduce the birth of new neurons. In addition, the aging process is accompanied by a decrease in neurogenesis (63); however, there are several environmental and behavioral interventions that can enhance neurogenesis (Fig. 8.2). In 1997 Kempermann and colleagues carried out the first of these studies comparing mice living under standard conditions with those housed in an enriched environment (17). Exposure to an enriched environment, consisting of larger housing; toys; and more opportunity for social stimulation, physical activity, and learning than standard laboratory conditions (79), resulted in a significant increase in neurogenesis, without affecting cell proliferation in mice and rats (17 ,80). Subsequent studies showed that the age-related decline in neurogenesis could be attenuated by enrichment (81). In addition, it was shown that enrichment inhibits cell death by apoptosis and prevents seizures (54). Moreover, it was determined that the most important components of enrichment are increased physical activity and possibly learning. Similar to enrichment, voluntary exercise in a running wheel increases net neurogenesis (55). In addition, running increases

cell proliferation in the dentate gyrus (55). It is interesting to note that enrichment and running had the same net effect on neurogenesis, but that running increased proliferation, whereas enrichment did not. Thus, not only the genetic factors mentioned, but also different environmental and behavioral factors can have differential effects on cell proliferation and neurogenesis. Others reported that hippocampus-dependent tasks, such as spatial learning in the Morris water maze (82), increases the number of surviving BrdU-positive cells (83 ,84); however, in our laboratory there was no effect of learning on proliferation or survival of newborn hippocampal cells (55).

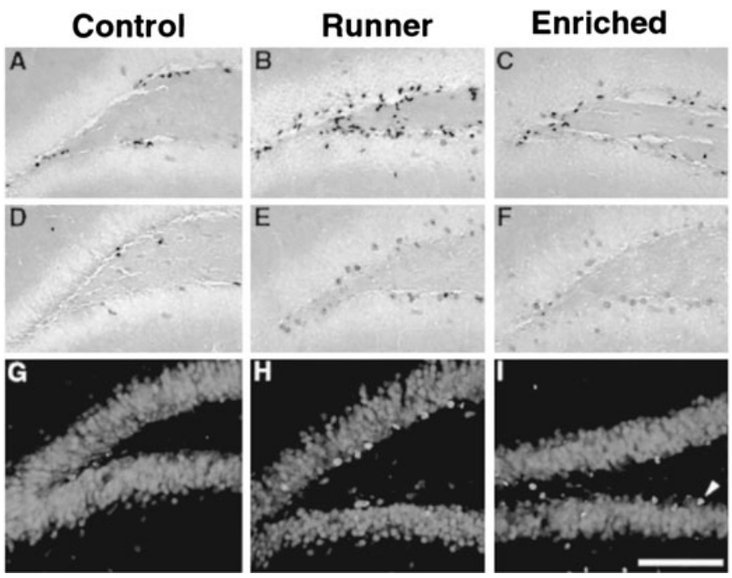

FIGURE 8.2. Proliferation and neurogenesis in the dentate gyrus. Photomicrographs of BrdU-positive cells 1 day *(a–c)* and 4 weeks *(d–f)* after the last injection in control *(a,d)*, running *(b,e)*, and enriched *(c,f)* mice. Confocal images of BrdU positive cells in control *(g)*, running *(h)*, and enriched *(i)* mice, 4 weeks after the last injection. Sections were immunofluorescent triple labeled for BrdU *(red)*, NeuN indicating neuronal phenotype *(green)*, and s100B selective for glial phenotype *(blue)*. Orange (*arrow*, newborn neuron) is red + green. Scale bar is 100 μm. See color version of figure.

Apart from these rather innocuous manipulations, there are several pathologic events that can affect granule cell number. Damage to the hippocampus by kindling (85 ,86), seizures (87 ,88 and 89), ischemia (90 ,91), or mechanical lesions (92) enhances proliferation. Thus, both normal and pathologic circumstances can affect cell genesis. Whether increased proliferation is beneficial for function or may represent compensation for lost cells and/or function remains to be determined.

FUNCTIONAL SIGNIFICANCE OF NEUROGENESIS

Part of "8 - Neurogenesis in Adult Brain "

Adult neurogenesis has been reported to exist over more than three decades, and to occur in a variety of species, including humans; however, the functional role of these new cells has yet to be determined. Given that the hippocampus is important for some forms of learning and memory and related mechanisms of neural plasticity such as long-term potentiation (LTP), much of the research has focused on finding a relationship between neurogenesis and memory function.

Behavior

It was found in several studies that animals living in an enriched environment not only had more new neurons, but also performed better on a spatial learning task (17 ,18 ,80). In addition, mice that were housed with a running wheel had more new neurons than their sedentary counterparts (55) and performed better on the water maze task (56). As mentioned, neurogenesis declines with aging (63); however, exposure to an enriched environment can restore some of the neurogenesis and improve performance on the water maze task in aging mice (81). Whether voluntary exercise in a running wheel would yield similar results in aged animals remains to be determined.

Electrophysiology

Although we can identify new granule cells using histologic and morphologic techniques, the question remains whether these cells are physiologic functional and if so, how similar or different are they from existing granule cells (Fig. 8.3). Moreover, what could be the functional significance of their (possible) neuronal activity? It has been shown that new hippocampal granule cells send axons along the mossy fiber tract to CA3 as do all other granule cells (93 ,94 and 95) and that they receive synaptic contacts (93). A recent study compared LTP, a physiologic model of certain forms of learning and memory (96) in the dentate gyrus, and CA1 in hippocampal slices from running and control mice. LTP amplitude was selectively enhanced in the dentate gyrus of running mice (56). It is possible that the newborn granule cell neurons play a role in increased dentate gyrus LTP because running increases learning and neurogenesis. Although the new cells are a small percentage of the granule cell layer, the possibility exists that they have greater plasticity than do mature cells. Indeed, dentate gyrus LTP last longer in immature rats than adults (97); however, in order to test this hypothesis it is necessary to record activity from individual new granule cells. In a recent study granule cells from the inner and outer layer of the dentate gyrus were compared. The inner layer cells were considered to be “young” cells and the outer layer “old” cells. The researchers found that the putative

young cells had a lower threshold for LTP and were unaffected by GABA-A inhibition, suggesting enhanced plasticity in the “young” cells (98); however, the problem with this study is that the definition of “young” cells is ambiguous. In our studies we have found newly generated cells throughout the granule cell layer. Moreover, the only way to be certain that a cell is a newborn neuron is by labeling the cell when it divides with a mitogenic marker. Ideally, recordings would be made from such a labeled cell and compared with preexisting neurons.

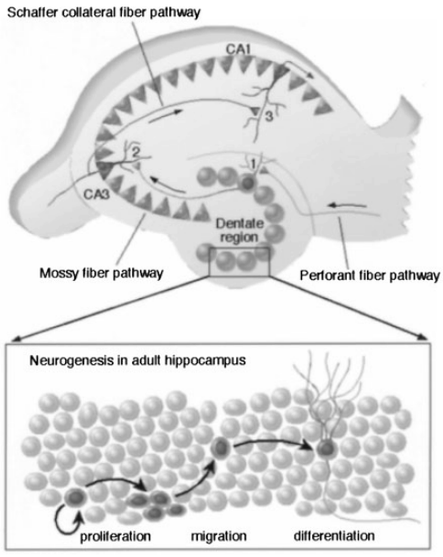

FIGURE 8.3. The three major areas of the hippocampus are the dentate gyrus, CA3, and CA1. The perforant pathway (1) from the subiculum forms excitatory connections with granule cells of the dentate gyrus. Both newborn and existing granule cells give rise to axons that form the mossy fiber pathway (2). This pathway projects to area CA3 pyramidal cells. The CA3 cells project to CA1 pyramidal cells by Schaffer collaterals. Within the hippocampal system, only the dentate gyrus gives rise to new neurons in the adult brain. These cells proliferate, migrate, and differentiate into mature neurons in the dentate gyrus (see box). See color version of figure.

In summary, adult hippocampal neurogenesis appears to be associated with memory function. Indeed, performance on a learning task is better in animals in which neurogenesis is stimulated, such as by running or enrichment, than in controls. This link may between neurogenesis and behavior may be causal rather than correlational, given that electrophysiologically measurable changes occur in the brain region where adult neurogenesis occurs.

POTENTIAL THERAPEUTIC IMPLICATIONS

Part of "8 - Neurogenesis in Adult Brain "

Several areas of interest emerge when considering the therapeutic potential for neurogenesis. First, a strategy that takes advantage of the ability of stem cells from the adult brain to be isolated and induced to divide in culture opens the opportunity for cellular transplantation to replace cells that have died because of injury or disease. Although evidence supports that ability of adult stem cells to survive grafting to the adult brain, the fate of the grafted cells appears to be dictated by the local environment. Thus, in order to accurately replace cells in damaged areas of the brain significant new information about the cellular and molecular mechanisms that control fate decisions is required in order to “train” the immature cells in culture to respond to the unique features of each of the environment to which they are grafted.

A second strategy emerges as a direct result of the fact that the adult brain retains stem cells *in situ* throughout life. By understanding the internal factors, molecules and mechanisms as well as the external stimuli and influences that control and regulate each of the steps in neurogenesis *in vivo*, eventually the potential of the endogenous cells could be harnessed. To this end, cell number could be amplified, direction of migration could be targeted, and finally terminal fate could be specified to the extent that a form of “self-repair” could be induced or orchestrated in the adult damaged brain. In all cases a more complete understanding the cellular and molecular events directing neurogenesis is a prerequisite for the use of this process in rational strategies for therapy.

Dopamine

Anthony A. Grace

Anthony A. Grace: Departments of Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, Pennsylvania.

Studies into the regulation of the dopamine (DA) system and its postsynaptic actions are often stymied by the myriad of actions that this neurotransmitter can produce. Thus, DA has been found to exert actions on the neurons it innervates both directly and via G-protein–coupled receptors. Moreover, this transmitter can modulate afferent input within these target regions, as well as alter intercellular communication via its actions on gap junctions. Finally, DA can potently modulate its own dynamics, acting via autoreceptors on DA nerve terminals and on DA neuron somata. In fact, the DA system is under potent dynamic regulation in the short term by a multitude of feedback systems, and in response to prolonged alterations is subject to powerful homeostatic mechanisms that can compensate for dramatic changes in DA system function. Such homeostatic alterations can be compensatory in nature, such as those that occur in response to a partial DA system lesion, or pathologic, such as the sensitization that can occur with repeated psychostimulant administration. Nonetheless, the importance of this neurotransmitter system in a broad array of human disorders ranging from Parkinson's disease to schizophrenia has driven an intensive array of investigations oriented toward increasing our understanding of this complex system in normal conditions as well as disease states. This chapter attempts to summarize some of the major research findings that have occurred within the last 5 years, and place them into a functional framework. This is not meant to be inclusive: A search of Medline indicated that there were over 16,000 papers published on DA during the past 5 years! Because of the exceedingly broad range that this topic encompasses, the focus is primarily on a subset of the numerous improvements that are most related to advancing our understanding of psychiatric disorders in particular. Topics related to specific disorders, such as drug abuse, schizophrenia, and so on, are deferred to the appropriate chapters in this volume.

DA NEURON ANATOMY AND PHYSIOLOGY

Part of "9 - Dopamine "

Both *in vivo* and *in vitro* studies have demonstrated that DA-containing neurons in the midbrain exhibit spontaneous spike firing that is driven by an endogenous pacemaker conductance (1 ,2 and 3), with their activity modulated by afferent inputs. One of the prominent regulators of DA neuron activity is the DA autoreceptor. It has been known for some time that DA neurons are very sensitive to DA agonists, which inhibit spike firing as well as cause a presynaptic inhibition of DA synthesis and release. Studies indicate that DA neuron somatodendritic autoreceptors are stimulated by an extracellular pool of DA released from the dendrites of neighboring DA neurons rather than exclusively by autoinhibition back onto the releasing neuron. This is supported by data showing that partial lesions of the DA system result in DA autoreceptor supersensitivity in the remaining neurons, which would only occur if the remaining neurons were responding to the decrease in DA caused by the loss of neighboring neurons (4). The autoreceptors are believed to exert a tonic down-regulation of DA neuron activity, maintaining their firing within a stable range of activity (4 ,5). These autoreceptors appear to be primarily of the D2 type, because D2-deficient mice do not show autoreceptor-mediated inhibition of firing (6). Moreover, inhibition of monoamine oxidase potentiates this inhibition (7 ,8), whereas inhibition of catechol-o-methyl transferase does not alter this response (9).

Exogenous transmitters also potently regulate dopamine neurons. Thus, GABA afferents both from striatonigral neurons as well as from local circuit neurons in the midbrain cause inhibition of DA neuron activity (10) by both a GABA-A– and GABA-B–mediated action (11 ,12 and 13). Glutamate has also been shown to exert multiple actions on DA neuron activity. Glutamate applied *in vivo* increases burst firing (14). N-methyl-D-aspartate (NMDA) receptor activation mediates a slow excitatory postsynaptic potential (EPSP) in these neurons (8), whereas metabotropic glutamate agonists are reported to depress both excitatory and inhibitory afferent input to these neurons (15). This latter effect is apparently shared by muscarinic receptors, which also depress both excitatory and inhibitory afferents, presumably via a presynaptic action (16 ,17).

Burst Firing

Studies have shown that DA neuron discharge is an essential component of the DA release process (18). The firing pattern of DA neurons also is effective in modulating release, with burst firing in particular being an important regulator of DA transmission. Thus, studies have shown that burst firing in DA neurons is associated with induction of c-fos and NG1-A in postsynaptic sites (19 ,20), and this response demonstrates a spatial and temporal specificity with respect to brain region, genes activated, and cell phenotype. One factor that is thought to regulate burst firing is the glutamatergic system. Several studies have shown that iontophoresis of glutamate onto DA neurons *in vivo* lead to burst firing (14), as do stimulation of glutamatergic afferents to DA neurons (21 ,22); however, the evidence for glutamate acting alone to induce burst firing *in vitro* is equivocal (23). In contrast, evidence shows that burst firing can be induced *in vitro* by blockade of apamin-sensitive potassium channels that modulate a nifedipine-sensitive calcium conductance (24). One source of glutamatergic input to ventral tegmental area (VTA) DA neurons is proposed to arise from the prefrontal cortex (PFC) (25); however, recent studies (26,27) show that the PFC input to the VTA innervates only the small proportion of VTA DA neurons that project to the PFC, providing a direct feedback loop, whereas the VTA-accumbens neurons innervated from the PFC are exclusively GABAergic neurons; therefore, it is unlikely that activation of the PFC can induce increased DA levels in the accumbens by a direct projection to these neurons (28). On the other hand, there is evidence that activation of the subiculum by excitatory amino acids increases accumbens DA (29 ,30) via activation of DA neurons that involves a pathway through the nucleus accumbens (31).

Afferent Input

The feedback systems between DA neurons and their postsynaptic targets appear to be quite complex, particularly in the primate. By analyzing a large number of retrograde and anterograde tracings, Haber and associates (32) found that different striatal subdivisions are linked by overlapping feedback to DA neurons, in a manner that suggests an ascending spiral of regulation extending from the shell to the core to the central striatum and finally to the dorsolateral striatum (Fig. 9.1). As pointed out by Haber, such an anatomic arrangement could account for the parallel psychomotor, affective, and cognitive disturbances seen in a variety of psychiatric disorders.

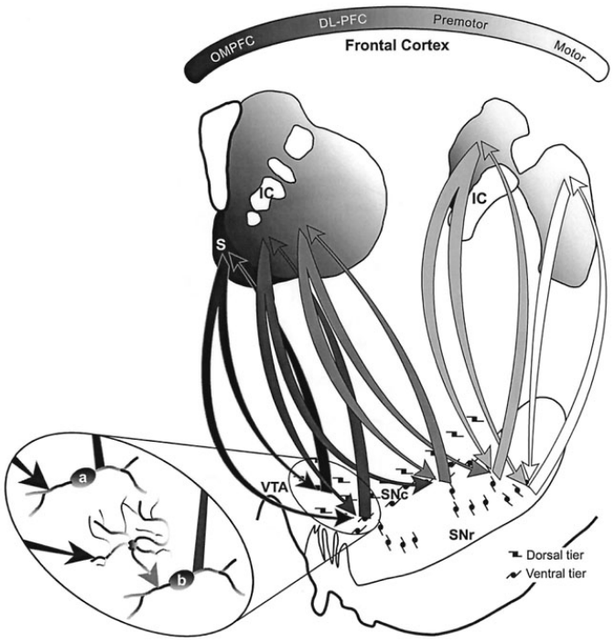

FIGURE 9.1. Studies using retrograde and anterograde tracers reveal that the feedback system between the midbrain DA neurons and their striatal targets contains both reciprocal and feed-forward components. The shell of the accumbens *(left)* receives inputs from hippocampus, amygdala, and limbic cortex, and projects to both the ventral tegmental area (VTA) and dorsomedial substantia nigra DA neurons. Projections from the VTA back to the shell form the "closed" portion of this loop. The core receives afferent input from the orbital and medial prefrontal cortex (OMPFC); the afferent projection to the core from the medial substantia nigra (SN) then forms the first part of the spiral. The core in turn projects to more ventrodorsal SN regions; therefore, ventral striatal regions can modulate the dopaminergic influence over more dorsal striatal regions via the spiraling midbrain-striatal-midbrain connections. The magnified insert shows a model of the reciprocal versus feed-forward loops. The reciprocal component is proposed to (a) directly inhibit the DA neuron, whereas the feed-forward, nonreciprocal component terminates on a GABAergic interneuron; or (b) indirectly excite the DA neuron by disinhibition. DL-PFC, dorsolateral prefrontal cortex; IC, internal capsule; S, shell; Snc, substantia nigra, zona compacta; Snr, substantia nigra, zona reticulata; VTA, ventral tegmental area. (From Haber et al., 2000; used with permission.)

The striatum provides a powerful feedback regulation of DA neuron firing. Thus, alterations in striatal activity potently affect DA cell activity states. Striatal neuron activation is known to cause an activation of DA neuron firing (10 ,33). Moreover, single-pulse stimulation of the striatum directly, or indirectly via activation of the PFC in rats, causes an inhibition/excitation response pattern (10 ,25). This relationship can be altered by manipulation of second messenger systems in the striatum. One system in particular that seems to affect striatal activation, leading to an alteration

in DA neuron activity, is the nitric oxide (NO) system. Increasing NO in the striatum by infusion of the substrate for the synthetic enzyme nitric oxide synthetase (NOS), coupled with striatal or cortical stimulation, was found to increase the firing rate of striatal neuron DA neurons. This effect was mimicked by infusion of the nitric oxide generator hydroxylamine. In contrast, NOS inhibitors failed to affect baseline DA cell firing but did increase their response to stimulation (34); therefore, NO signaling in the striatum facilitates DA neurotransmission by modulation of corticostriatal and striatonigral pathways. NO also appears to have a role in regulating terminal DA release (see the following).

Stress and DA Neuron Activity

Stress appears to affect many monoamine systems. Stress plays a role both in acute behavioral responses and adaptations to chronic stressful conditions. Although the noradrenergic system has played a major role in these processes, recent evidence supports a role for the DA system as well. Studies have shown that, on presentation of stress, there are differential increases in DA dynamics depending on the brain regions involved. Thus, stressful stimuli tend to cause the largest increase in DA levels in the PFC region, with markedly smaller changes in the limbic and dorsal striatal regions (35); however, this relationship is altered by lesions of different nuclei. Thus, stress causes release of DA in the amygdala (36), and lesions of the amygdala tend to block stress-induced increases in PFC DA levels (37). Lesions of the PFC also affect this response. Studies in which the PFC DA innervation is lesioned show that subsequent stressors cause a much larger increase in DA levels within the nucleus accumbens, particularly with respect to the duration of the response (38). This suggests that PFC DA released in response to stress actually blunts the responsiveness of the subcortical limbic DA system. In contrast, 6-OHDA lesions of PFC DA levels were found to decrease the basal electrophysiologic activity of VTA DA neurons (39). Given that basal DA levels in the accumbens are normal, one interpretation is that the DA release system has adapted to the diminished DA neuron drive, allowing normal levels of DA transmission to occur. However, if a stimulus then causes an increase in DA neuron firing, the compensated release mechanism would produce an augmented response. Thus, the magnitude of increase in action potential-dependent DA release into the accumbens that occurs in response to a challenge may be augmented when the PFC DA response is attenuated (39).

Repeated stress also has important clinical implications with regard to the DA system and exacerbation of schizophrenia. A recent study examined how chronic stress in the form of cold exposure affects the discharge of VTA DA neurons. Thus, after exposing rats to cold, there was a 64% decrease in the number of spontaneously active DA neurons, with no significant alteration in their average firing rate. Nonetheless, there was a subpopulation of neurons that exhibited excessive burst activity in the exposed rats (40). Therefore, unlike acute exposure to stressful or noxious stimuli, chronic stress actually attenuates DA neuron baseline activity. Such a decrease in baseline activity could enable the system to show a magnified response to activating stimuli, thereby producing a sensitized DA response.

REGULATION OF DA RELEASE

Part of "9 - Dopamine "

DA appears to be released by multiple factors within its postsynaptic target; moreover, once it is released, there are several mechanisms that can modulate its site of action. In general, the majority of evidence suggests that DA is released primarily in a spike-dependent manner, because inactivation of DA neuron firing virtually eliminates DA release within the striatum (18). Carbon fiber recordings, which allow rapid measurement of DA overflow, show that stimulation of DA axons causes rapid release of transmitter. Moreover, the release varies with tissue content, with PFC showing much lower levels of release compared to accumbens at a given stimulus frequency (41). DA released by impulse flow is then rapidly removed via the DA transporter, because mice with knockouts of this transporter exhibit 300 times longer clearance half-life compared to controls (42). The amount of DA released by impulses appears to depend on several factors. Previous volumes in the *Generations of Progress* series have detailed how DA release can be modulated by both synthesis- and release-modulating autoreceptors on DA terminals. It is becoming more evident that heteroceptors also play a significant role in modulating DA release (43).

DA release appears to occur via two functionally distinct components. One is the DA that is released in a high-amplitude, brief pulsatile manner by means of action potentials, and then is rapidly removed from the synaptic cleft via reuptake. This has been termed the phasic component of DA release (44), and is believed to underlie most of the behavioral indices of this transmitter. The other is the level of DA present in the extrasynaptic space. This tonic DA exists in very low concentrations; too low to stimulate intrasynaptic DA receptors, but of sufficient level to activate extrasynaptic receptors, including DA terminal autoreceptors (thereby causing feedback-inhibition of phasic DA release) and other extrasynaptic receptor sites. It is this tonic DA compartment that is sampled by slower measures of DA dynamics, such as microdialysis. Recently, evidence has been advanced to define what factors may contribute to the regulation of this tonic DA compartment.

Although studies suggest that neuronal impulse flow is necessary for DA overflow in the striatum, there is substantial evidence that the released DA can be controlled locally by a number of factors. For example, stimulation of cortical inputs increases DA release within the striatum, and evidence suggests that this can occur via afferents to DA cell bodies or presynaptically onto DA terminals, depending on the preparation and site of stimulation. Thus, infusion of excitatory amino acids into the hippocampus subiculum increases

DA neuronal activity (31) and DA levels in the striatum in a manner that is dependent on DA neuron impulse flow (29). It is proposed that this subicular-driven DA release may be involved in the modulation of investigatory response to novel and conditioned stimuli (45). Stimulation of the PFC also appears to result in impulse-dependent DA release in the striatum (28). On the other hand, there is evidence suggesting that DA can be released in a manner not dependent on DA neuron firing via stimulation of the hippocampal afferents (46), or amygdala afferents (47) to the accumbens, all of which use glutamate as a transmitter. This purported presynaptic action on DA terminals appears to occur via activation of either NMDA receptors on DA terminals (48) or by metabotropic glutamate receptors (49 ,50 and 51). There is also evidence that glutamate can release acetylcholine or serotonin in the striatum, which in turn can trigger DA release (43). Glutamate may also stimulate DA release via an action on other local systems, such as those producing NO. NO is known to be released from striatal interneurons containing the enzyme NOS, and exert actions on neuronal elements in the vicinity of the release site. Infusion of NOS substrates or NO generator compounds was found to facilitate the release of both glutamate and DA within the striatum in a calcium-dependent manner, and is dependent on vesicular stores (52 ,53). Moreover, the NO-induced efflux of striatal glutamate was found to indirectly enhance extracellular DA levels in the striatum in a manner dependent on NMDA and AMPA receptors (53 ,54). Therefore, it is likely that excitatory amino acids and NO interact with DA neuron firing to regulate DA release from presynaptic sites within the striatum.

The ability of cortical glutamate to release tonic DA in the striatum is supported by studies showing that lesions of the cortical input to the striatum cause a decrease in extracellular DA and glutamate within the striatum (55), which would thereby increase in the behavioral response to amphetamine (56). Thus, evidence indicates that alterations in tonic DA levels produced by cortical afferents can potently alter spike-dependent DA release, and thereby modulate DA-dependent behaviors (43 ,44 ,57). Such tonic down-modulation of spike-dependent DA release could play a particular role when the uptake system is inactivated by psychostimulants. Thus, although the DA transporter is normally highly effective at removing DA from the synaptic cleft before it can escape into the extracellular space, blockade of the DA transporter would allow substantially higher levels of DA to escape the cleft and contribute to the tonic extracellular DA pool (57). Such a condition is thought to underlie some of the therapeutic actions of psychostimulants in attention deficit/hyperactivity disorder (ADHD) (58).

One problem in attempting to examine the relationship between DA neuron firing rate and DA overflow is the potential disruption in the system caused by probe implantation. This was found to be a significant issue when testing the effects of chronic antipsychotic drug treatment-induced DA neuron depolarization block (59) on DA levels in the striatum. Thus, implantation of a microdialysis probe was found to disrupt DA neuron depolarization block when DA cell activity was assessed 24 hours following probe implantation. However, if the probe was inserted via a preimplanted guide cannula, depolarization block was maintained, and the DA levels were found to be approximately 50% less than in control conditions. Moreover, the relationship between DA neuron firing and release was altered. Thus, although there was no significant correlation between DA cell population burst firing and DA release in control rats, there was a significant correlation between burst firing in the remaining cells and DA levels following administration of chronic antipsychotic drug (60). Thus, correlations between cell firing patterns and DA levels postsynaptically appear to depend on the state of the system.

It is also possible that there may be local fluctuations in tonic DA stimulation that may be a consequence of increases in DA neuron firing. Indeed, studies using voltametric measures have shown that brief elevations in extracellular DA may occur as a consequence of rapid burst firing, overwhelming the DA uptake process (61). This relationship is particularly important during administrations of drugs that interfere with the uptake process, such as cocaine or amphetamine (57 ,58). Such drugs would cause phasic DA release to rapidly augment tonic DA levels, leading to high extracellular DA and abnormal levels of down-regulation of spike-dependent DA release. In a similar nature, in mice lacking the DA transporter, the extracellular DA is already elevated fivefold over control (62); therefore, there appears to be a tight dynamic interdependence on DA neuron activity levels and DA uptake that determines the contribution of phasic and tonic DA to activity within this system. This tonic/phasic balance has been proposed to underlie normal and dysfunctional DA regulation as it relates to the pathophysiology of schizophrenia, drug abuse, and the treatment of ADHD (44 ,57 ,58).

Given the importance of tonic DA system regulation, a literature has emerged regarding the functional relevance of extrasynaptic DA receptors. Indeed, studies have shown that in the PFC, the DA terminals located in the deep layers of cortex do not contain DA transporters (63). As a consequence, the DA released from these sites would be free to diffuse to a much greater extent than in areas such as the striatum and accumbens. This is further substantiated by evidence that a substantial portion of the DA that is released in the PFC is actually taken up and deaminated in norepinephrine (NE) terminals (64). This arrangement would have substantial functional implications. First, it would provide a mechanism for stimulation of the numerous extrasynaptically located D1 terminals on pyramidal neurons (65), which have been proposed to regulate information flow between compartments on pyramidal neurons (66 ,67 ,68 and 69). Moreover, such a condition could imply that NE uptake

blockers could serve to increase the functional actions of DA in the PFC by preventing its removal via NE terminals. This may also have implications regarding the clinical actions of NE-selective antidepressant drugs within this brain region.

POSTSYNAPTIC EFFECTS OF DA

Part of "9 - Dopamine "

DA exerts a myriad of actions on postsynaptic systems. These actions can occur at the level of individual cells in terms of direct postsynaptic actions, as well as altering cellular interactions (via presynaptic effects and network modulation). Moreover, the nature of these effects can vary depending on both the specific region examined and the time course of DA agonist administration.

Striatum

D1 stimulation decreases excitability of dorsal striatal and accumbens neurons (67 ,68 and 69), although others have reported excitation by this agonist (70). Within the dorsal striatum, D1 receptor stimulation decreases current-evoked action potential discharge in hyperpolarized neurons, although an enhancement in excitability can be obtained with longer duration or higher frequency current pulses (71). The decrease in spiking is believed to be owing to a reduction in the peak amplitude of the fast sodium conductance (72 ,73), and occurs through activation of protein kinase-A (PKA) (74). Studies show that the D1-mediated inhibition can act synergistically with D2 stimulation-induced inhibition when the agonists are applied simultaneously. However, the D1-mediated decrease in excitability can be reversed to facilitation if the D2 agonist is administered subsequently (75). This temporal dependence of D1 and D2 activation may have functional implications with regard to the tonic/phasic model of DA system regulation (44). For example, if the DA system exhibits sustained activation such as during a reward process, the large phasic DA release that results should stimulate both D1 and D2 receptors located within synapses. In addition, the large DA level released should be sufficient to escape the synaptic cleft, with the resultant elevated tonic DA levels stimulating the extrasynaptic D1 receptors (76 ,77). According to our data, this should produce synergistic inhibition. On the other hand, if the activity is maintained, there would be tonic stimulation of the extrasynaptic D1 receptors. Under this condition, subsequent stimulation of the D2 receptors preferentially located in the synaptic cleft (78) would be attenuated (75). Thus, the system appears to be oriented to provide a maximal initial response, whereas continuous activation would cause an attenuation of subsequent responses.

In addition to effects on sodium conductances, D1 stimulation also affects high voltage-activated calcium conductances. Thus, both D1 agonists and cAMP analogues reduce both N- and P-type calcium currents via a PKA-mediated process; however, these manipulations also enhance L-type calcium currents (79). In contrast, D2-receptor stimulation has been shown to modulate voltage-dependent potassium conductances in the striatum (80).

Evidence shows that a large part of the response to D1 stimulation requires the participation of a messenger cascade involving the phosphorylation of dopamine- and cAMP-regulated phosphoprotein (DARPP-32) (81). In particular, this phosphoprotein is a required component in the cascade mediating D1 function (Fig. 9.2). Moreover, mice with knockouts of DARPP-32 have been shown to lack D1 modulation of glutamate function, as well as other biochemical processes and behavioral responses known to involve D1 receptors (82). Recent studies have shown that DARPP-32 is also present in other, non–D1-containing neurons as well, including the enkephalin-containing striatal neurons (83). In this case, D2-receptor stimulation has been shown to cause a dephosphorylation of DARPP-32 via calcineurin activation by calcium influx. DARPP-32 is also present in striatal efferent projection areas, including the globus pallidus, entopeduncular nucleus, and substantia nigra (SN) (83). Thus, DARPP-32 is positioned to exert modulatory influences on DA function by affecting striatal outflow.

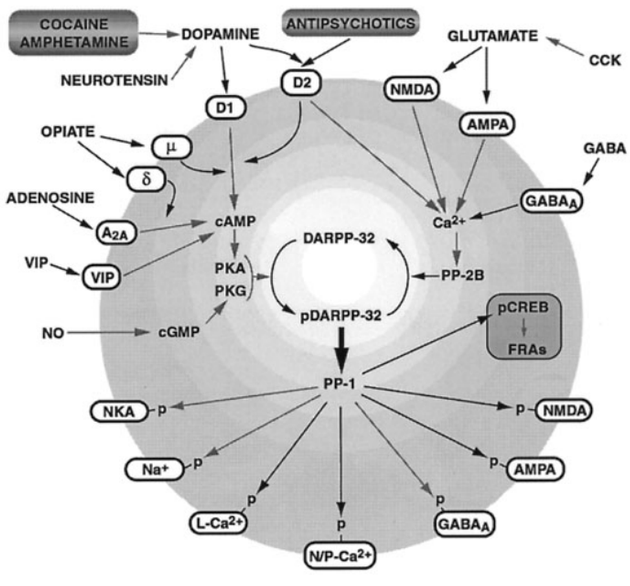

FIGURE 9.2. The DARPP-32 signaling pathway has a central role in mediating signal transduction within medium spiny neurons in the striatum. A variety of neurotransmitters act on systems regulating the phosphorylation of DARPP-32, which in turn modulates the activity of protein phosphatase-1 (PP-1). DA stimulation of D1 receptors acts via cAMP and PKA to phosphorylate DARPP-32, which in turn inhibits PP-1; this works in synergy with different protein kinases to increase the level of protein phosphorylation of their targets. In contrast, stimulation of D2 receptors attenuates D1 activation of adenylate cyclase as well as leading to calcium stimulation of protein phosphatase 2B; together, this decreases the phosphorylation state of DARPP-32. (From Greengard et al., 1999; used with permission.)

Modulation of Intercellular Coupling

In addition to its effects on single neurons, DA also is capable of affecting neuronal interactions on a network level. In

particular, substantial evidence has shown DA to have a potent effect over interactions among neighboring neurons in a region via its modulation of gap junction conductance. The DA system appears to regulate this coupling in two ways: (a) acutely, presumably by opening gap junctions that are already present between neurons in its target structures, and (b) as a compensatory change in response to a chronic compromise of the DA system.

Studies have shown that neurons within the dorsal and ventral striatum exhibit dye coupling, which is the morphologic correlate of gap junctions between neurons. In striatal slices recorded *in vitro*, application of the D2 agonist quinpirole causes a substantial increase in coupling, from nearly undetectable levels in the basal state to approximately 80% coupling after the agonist. D1 agonists, in contrast, do not affect coupling in a measurable way; however, in brain slices derived from a DARPP-32 knockout rat, the basal level of coupling is significantly higher than in control, and furthermore, the D2 agonist fails to increase coupling above this elevated baseline (75). These data suggest that coupling is normally suppressed by an action of DARPP-32, and that this suppression can be overcome by D2 agonist administration.

Dye coupling is also affected by maintained changes in DA system function. Changes in coupling are observed following lesions of the DA system with the neurotoxin 6-hydroxydopamine. Only the rats that exhibit severe loss of the DA innervation (i.e., >95%) also show a substantial increase in the level of dye coupling among striatal neurons (84). In all cases, the coupling was present only between cells of the same morphologic class; that is, between medium spiny neurons or between aspiny neurons. In addition, withdrawal from repeated drug treatment such as amphetamine (Fig. 9.3) (85) or antipsychotic drugs (86 ,87) cause a regionally selective increase in dye coupling. Amphetamine and antipsychotic drugs increase coupling in limbic striatum, whereas classic antipsychotic drugs also cause an increase in coupling in the motor-related dorsal striatum. These effects are only observed following withdrawal from the drug. Given that changes in gap junction composition are observed during repeated cocaine administration (88), it is possible that the system compensates for the presence of the drug by altering gap junctions to allow coupling to be maintained at its basal state. Under these conditions, the alteration is only observed when the adapted state is altered by withdrawal of the drug. Indeed, the observation that coupling is maintained for weeks following drug withdrawal suggests that the system may have reached a new stable steady state that could leave it more susceptible to destabilizing influences (85).

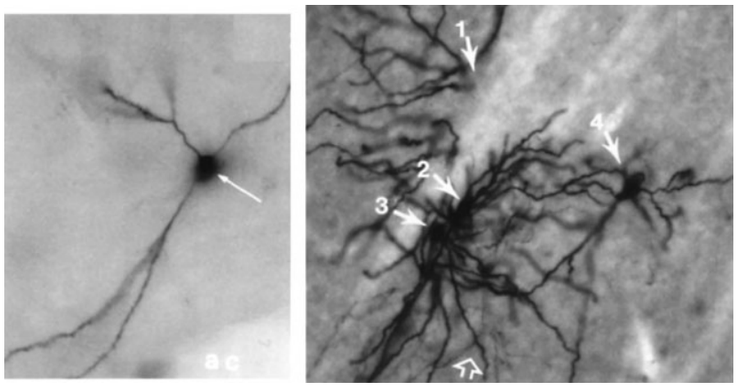

FIGURE 9.3. Long-term alterations in DA transmission lead to changes in dye coupling within the striatal complex. Medium spiny neurons in the nucleus accumbens were injected during *in vivo* intracellular recording with Lucifer yellow, which was then converted into a dense stain using antibodies. In a control rat, injection of Lucifer yellow typically labels only a single neuron *(left)*; overall, less than 15% of accumbens neurons injected in control rats exhibit labeling of more than a single neuron. In contrast, in rats that had been administered amphetamine for 2 to 4 weeks and then withdrawn for at least 7 days, the majority of injected neurons exhibited dye coupling (>60% of cells injected). In this case, four neurons were labeled after injecting a single neuron with Lucifer yellow. This increase in coupling persisted for at least 28 days following amphetamine withdrawal, but was not present if the rats were tested during the treatment phase. (From Onn and Grace, 2000; used with permission.)

Interactions with Other Neurotransmitters

DA has also been shown to affect the response of striatal neurons to other neurotransmitters. Thus, DA was found to

modulate the response of striatal neurons to glutamatergic excitation (89). Specifically, D1-receptor stimulation enhances NMDA-mediated currents (90), which may occur via a combination of two effects: (a) a facilitation of L-type calcium conductances on dendrites (90), and (b) activation of cAMP-PKA cascade (91). A similar D1-mediated cascade also attenuates responses to GABA in the striatum (92 ,93). In contrast, D2 stimulation appears to preferentially attenuate non–NMDA-mediated responses (89). There is also evidence that the activation of DA neuron firing by stimulation of DA axons (70 ,94) occurs via a D1-mediated facilitation of glutamate transmission (94). This response, which occurs in parallel with a D1-mediated increase in c-fos in striatonigral neurons (20), is more potent when the DA axons are stimulated in a burst-firing pattern (70). This suggests that, under physiologic conditions, D1-induced facilitation of glutamate transmission in the striatum is mediated by burst-firing–dependent phasic DA release (44).

In addition to its ability to modulate neurotransmitter actions on postsynaptic neurons in the striatum, DA also plays a significant modulatory role in the presynaptic regulation of neurotransmitter release. D2 stimulation is reported to presynaptically decrease GABA release from intrinsic neurons (95) and glutamate release from corticostriatal terminals. Several studies report that D2 agonists cause a down-regulation of glutamate-mediated EPSPs on neurons in the nucleus accumbens (96 ,97 ,98 and 99). This is consistent with biochemical studies showing D2-mediated down-regulation of stimulated glutamate release in striatal tissue (100 ,101) and the presence of D2 receptors on presynaptic terminals making asymmetric synapses in the striatum (78), which are presumed to be the glutamatergic corticostriatal afferents. Interestingly, D2 stimulation does not inhibit all corticostriatal EPSPs in normal preparations (97 ,99); however, after acute depletion of endogenous DA, all corticoaccumbens EPSPs are sensitive to DA (99). This suggests that under normal circumstances, the presynaptic DA receptors may already be saturated with DA, as suggested by the observation that sulpiride increase EPSP amplitude in a majority of cases when administered alone (99). This unusual pharmacology may reflect a contribution of presynaptic D4 receptors on the corticoaccumbens terminals to this response (102). Although another group has reported a D1-mediated presynaptic action EPSPs evoked by intrastriatal stimulation in slices, which was interpreted as a presynaptic effect on corticostriatal terminals (103), this study employed exceedingly high doses of the D1 agonist to achieve these effects (i.e., 100 μM, which is approximately two orders of magnitude higher than should be required for a selective D1 action). Moreover, anatomic studies have shown that D1 immunoreactive axons are exceedingly rare in the striatum (77). In contrast, recent studies suggest that DA acting on postsynaptic D1 receptors may actually cause a transsynaptic feed-forward inhibition of glutamate release. Both NMDA antagonists and adenosine antagonists can block this effect. These data suggested that dopamine depresses the excitatory postsynaptic conductance (EPSC) by causing an NMDA receptor-dependent increase in extracellular adenosine, which acts presynaptically to depress glutamate release (104). The D1–NMDA-R interaction appears to be postsynaptic and acts via PKC activation (105). It is of interest to note that there is other evidence of interdependence between DA and adenosine. Thus, a recent study by Ginés and colleagues (106) have shown that D1 and adenosine A1 receptors have the capacity to form heteromeric complexes, which appear to play a role in receptor desensitization and trafficking.

Consequently, there appears to be a complex, dynamic equilibrium between dopamine and glutamate transmission within the striatal complex, with glutamate contributing to DA release and DA causing a two-pronged inhibition of glutamate release, both directly via D2 presynaptic receptors and indirectly using adenosine as an intermediary. Finally, glutamate-released NO also appears to play a significant role in modulating DA systems and striatal neuron responsivity. The tight interdependence and coregulation between DA and glutamate suggest that the system is designed to maintain stable levels of transmission to the striatal neurons over the long term, whereas short-term changes in activity in either system in response to a signal are amplified by their coordinated effects on each of these interdependent processes.

LTP and LTD

DA also appears to have a role in short- and long-term synaptic plasticity within the striatum. Specifically, DA was found to influence two opposite types of synaptic plasticity within the striatum that depend on the history of synaptic input to this structure. In cases in which striatal excitatory amino acid afferents arising from the cortex are stimulated with high frequencies in the absence of magnesium (to enhance NMDA conductances), a long-term facilitation in synaptic transmission is induced, known as long-term potentiation. In contrast, if the stimulation is carried out at a low frequency, the opposite type of plasticity is induced; that is, long-term depression (LTD) (107). These forms of synaptic plasticity have been proposed to play a major role in learning and memory formation in other structures, such as the hippocampus. Such plasticity within the striatum may be involved in such phenomena as the acquisition of complex motor skills. Repetitive stimulation of corticostriatal fibers to release glutamate is required for the induction of LTP and LTD, which only occurs in the presence of DA afferent input (108). Thus, D1 and/or D2 antagonist pretreatment prevents the induction of LTD (107), suggesting that a synergistic interaction between these receptor subtypes is required for this process to occur. In contrast, cortical stimulation-induced LTP is blocked selectively by D1 antagonists, but is actually enhanced by D2 antagonists or in D2 receptor knockout mice (109).

Prefrontal Cortex

The effects of DA within the PFC have been controversial, in that several groups have failed to produce consistent results. Thus, although studies done *in vivo* have consistently shown that direct DA application inhibits PFC neuron firing, studies using *in vitro* slice preparations have found a DA-mediated increase (110 ,111) and a decrease (112 ,113) in neuronal excitability in this region. D1 stimulation has been shown to affect sodium conductances by increasing the sodium plateau potential and shifting the activation of sodium currents to more negative potentials (114). This increase in excitability was augmented by a D1-induced decrease in slow potassium conductances (110). D1 stimulation may also activate L-type calcium conductances located in proximal dendrites of pyramidal neurons to further increase excitability in these neurons (66). Such an interaction has been postulated to differentially modulate afferent input to these neurons (Fig. 9.4). Indeed, the highly organized DAergic input onto virtually every dendrite of PFC pyramidal neurons in the primate provides a means for this neurotransmitter to regulate nearly the entire complement of glutamatergic afferents to this cell type (115). In contrast, at least part of the inhibitory action of DA on PFC pyramidal neurons may occur by DA-induced excitation of GABAergic interneurons (116), which also receive a direct DA innervation (115 ,117).

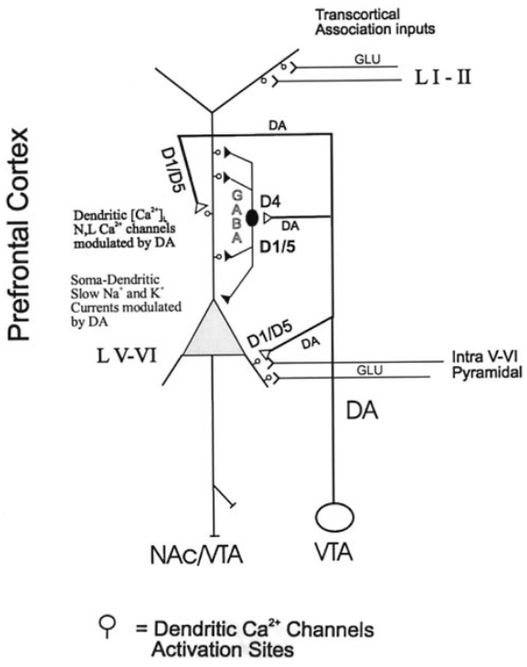

FIGURE 9.4. A simplified diagram illustrating the basic processing units within the prefrontal cortex. Each unit consists of a deep layer pyramidal neuron that projects to the nucleus accumbens or the ventral tegmental area (VTA), and a GABAergic interneuron. The apical and basal dendrites of the pyramidal neuron receive functionally segregated inputs from various cortical and subcortical regions, whereas the GABAergic interneuron, which is also modulated by DA, exerts inhibitory influences over both the apical dendrite and soma of the pyramidal neuron. By acting on both the interneuron and pyramidal neuron dendrites, the DA input has the capacity to modulate the integration of the functionally diverse array of inputs to this neuron. DA acting on D1/D5 receptors to modulate calcium channel subtypes on the apical dendrite are proposed to "sharpen" or, with greater stimulation, attenuate afferent signals arising from these distal regions. DA activation of the GABAergic interneuron can also serve to suppress information input from the apical dendrites. In contrast, DA modulation of conductances at the somatodendritic region amplifies low-level afferent inputs from neighboring pyramidal neurons. In this way, the DAergic input is proposed to change the pyramidal neuron from responding primarily to long-loop afferents to a state in which it responds primarily to local circuit interactions that may subserve working memory functions. (From Yang et al., 1999, with permission.)

It is known that PFC neurons *in vivo* exhibit bistable membrane potentials, which alternate between a hyperpolarized, nonfiring condition and a depolarized plateau state where they fire action potentials. Moreover, studies have shown that the effects of DA vary depending on the state of the membrane potential at which it is administered. In particular, DA and D1 agonists cause an increase in excitability of PFC neurons in the depolarized state but not at the hyperpolarized state (118). Furthermore, studies combining *in vivo* microdialysis administration of drugs with intracellular recording (119) found that DA could potentiate glutamate-driven bistable states of PFC neurons (Fig. 9.5). Therefore, the state of the membrane may significantly influence the response to DA observed.

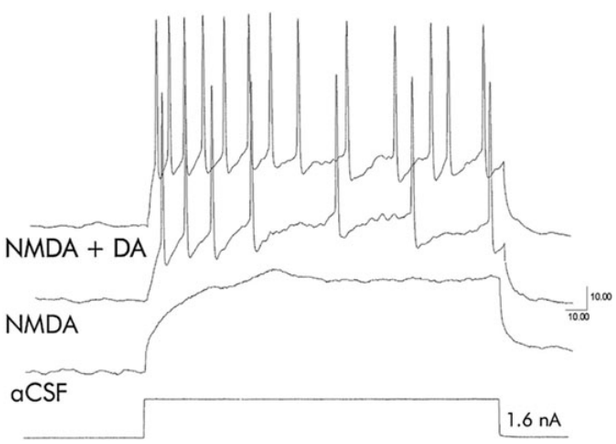

FIGURE 9.5. *In vivo* intracellular recordings from a pyramidal neuron in the frontal cortex of a chloral hydrate anesthetized rat is illustrated. The neuron was located near a microdialysis probe implanted to deliver the compounds to be tested by reverse dialysis to the environment of the cell. Administration of NMDA (20 μM) increases the number of spikes evoked by brief depolarizing pulses. Following washout, administration of NMDA + DA (30 μM) greatly increases the spikes evoked per unit current. This occurs despite the fact that DA did not appear to significantly affect current threshold. In the case of NMDA alone, the increase in the number of spikes per unit current occurs with (and may be secondary to) a decrease in current threshold; that is, the cell is simply more excitable.

In the case of DA added to NMDA, the cell fires more spikes during the current-induced depolarization, but the current threshold is not further decreased; therefore, DA allowed the cell to respond maximally to the NMDA input without altering the threshold for spiking. (From Moore et al., 1998b, with permission.)

Ventral Pallidum

The ventral pallidum (VP) receives a DA innervation from the midbrain (120), and is believed to play a significant role in several of the behavioral aspects of DA system function (121), particular related to drug sensitization (122). *In vivo* dopamine iontophoresis is known to: (a) increase and decrease VP neuronal firing (120 ,123); (b) potentiate or attenuate the excitatory effects of glutamate iontophoresis (124); and (c) modulate the firing rate enhancements produced in VP neurons by activating the amygdala (123) and attenuating the excitatory influences of the amygdala on pallidal cell firing at local concentration that are below that required to alter spontaneous firing (123). Dopamine receptors for the D1 and D2 class have been identified in the ventral pallidum (120), and electrophysiologic and behavioral evaluations have revealed that these two classes operate in opposition in this region (which contrasts the "enabling" effects reported for striatal regions and other pallidal regions). Local D1 activation induces a robust attenuation of cell firing (125) and enhances locomotor activity (126), whereas D2 activation slightly attenuates or has no effect on firing (125) and is largely without influence on motor activity (126).

Because the VP is positioned anatomically at the crossroads of the limbic and extrapyramidal system, DA modulation in this area has the ability to potently influence motivated behavior by its actions in this region (121).

Mediodorsal Thalamus

Anatomic studies have revealed the presence of a DA innervation of the mediodorsal (MD) thalamic nucleus arising from the midbrain. Using *in vitro* intracellular recordings, DA was found to alter MD neuron activity via a D2-mediated effect. In particular, quinpirole was found to increase membrane excitability and enhance the low threshold spike in these neurons (127). This was mediated at least in part via an alteration in potassium conductances. By increasing the low threshold spike, DA was found to facilitate oscillatory activity within the MD, which would potently impact thalamocortical information processing in this region.

Basolateral Amygdala

The basolateral nucleus of the amygdala (BLA) exhibits a substantial innervation from the midbrain DA neurons. The effects produced by DA in the BLA are dependent on the type of neuron recorded (128). DA causes an overall decrease in the firing rate of presumed projection neurons by two mechanisms: (a) a direct effect on the projection neuron, and (b) an activation of the firing of putative interneurons, which may be analogous to the interactions occurring in the PFC. In addition, DA produced effects on afferent drive of these neurons that was dependent on the origin of the projection system. Thus, DA attenuates afferents from limbic structures such as the PFC and MD thalamus, whereas afferent input from auditory association cortex (Te3) is potentiated (Fig. 9.6). Intracellular recordings revealed that this was a consequence of a D1-mediated decrease in PFC-evoked EPSP amplitude, combined with a D2-mediated increase in BLA input resistance that potentiated Te3 afferent drive (129). PFC stimulation also caused an excitation of BLA interneurons, which lead to a subsequent attenuation of input arising from Te3; however, in the presence of DA stimulation, the ability of the PFC stimulation to attenuate responses from Te3 was diminished (129). These data suggest that the PFC is normally capable of attenuating amygdala responses to sensory inputs, which could be a mechanism for decreasing emotional responses to familiar or nonthreatening stimuli. However, with excessive DA stimulation, the ability of the PFC to suppress amygdala-mediated emotional responses may be lost.

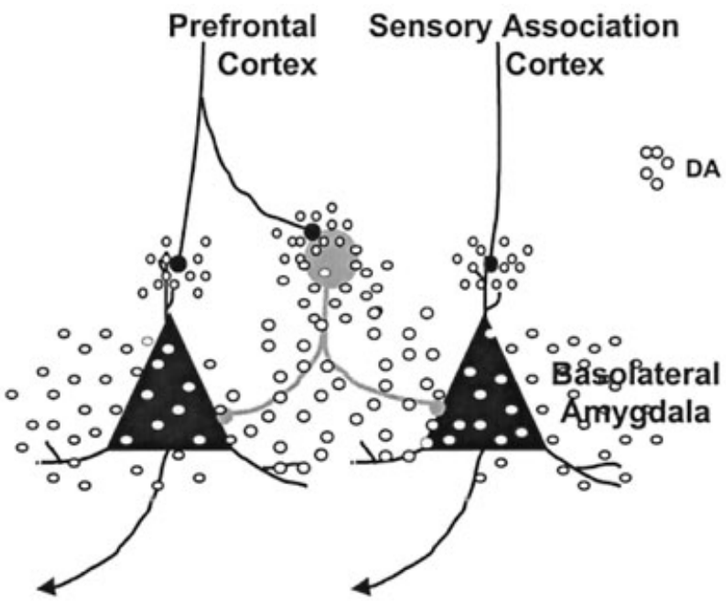

FIGURE 9.6. DA attenuates prefrontal cortex (PFC) modulation of basolateral amygdala (BLA) neuronal responses. The PFC provides a direct drive of BLA projection neurons and interneurons, whereas inputs from the sensory association cortex project only to the output neurons. As a result, the PFC inhibits the ability of the sensory association cortex to activate BLA neuron firing. However, the PFC inputs are attenuated by elevated DA levels in the BLA, removing a source of inhibition on BLA projection neurons. Furthermore, elevated DA levels in the BLA increase the input resistance of BLA projection neurons, leading to augmentation of nonsuppressed inputs to BLA neurons. Thus, DA receptor activation enables sensory-driven amygdala-mediated affective responses by removal of regulatory inputs and augmenting sensory inputs. (From Rosenkranz and Grace, 2001, with permission.)

Substantia Nigra

In addition to the effects of DA on DA neuron autoreceptors within the substantia nigra, there are also DA receptors

located on striatonigral afferents to this region. Locally evoked IPSCs in neurons of the substantia nigra zona reticulata (ZR) are GABAergic in nature, and are believed to arise from striatal afferents. These IPSCs are depressed by DA acting on D1 but not D2 receptors. The fact that this depression was accompanied by increased paired-pulse facilitation and not by a change in membrane potential or conductance indicates that the effect is likely presynaptic in origin (130). It is interesting to note that the striatonigral neurons that exhibit terminal D1 receptors do not exhibit D1 receptors on their local collaterals within the striatum (77). This suggests that these neurons can selectively traffic presynaptic receptors to long projection sites.

BEHAVIORAL CORRELATES OF DA SYSTEM FUNCTION

Part of "9 - Dopamine "

DA is known to play an important role in working memory and response sequencing in the PFC. In particular, DA acting on D1 receptors has been shown to exert dual actions on these types of behaviors. Thus, D1 agonist administration into the PFC of rats with poor performance on attentional function tasks significantly improved their performance, whereas impairing performance in rats that had higher baseline attentional skills (131). This is consistent with studies suggesting that optimal DA levels are required to maintain function in the PFC, with both too high or low D1 stimulation leading to impaired working memory function (132 ,133).

Several studies have shown that the DA system is activated by rewarding stimuli, such as food (134 ,135); however, it is becoming evident that DA is not the reward signal per se, but instead is necessary for the acquisition of reinforcing stimuli. In some cases, DA has been described as a type of error signal (136), in which the predicted occurrence of reward does not correlate with the behavioral response emitted to generate this reward. Thus, when a task is well learned, DA neuron firing no longer is a necessary correlate of the reward signal. But if reward is absent, DA neuron firing appears to decrease (137). Studies of DA overflow in the nucleus accumbens show that DA is released when the DA cell bodies are stimulated electrically. However, when the stimulation is contingent on a bar press by the rat, the DA overflow does not occur even in the presence of the electrical stimulus (138). These data suggest that the lack of DA system activation during a well-learned contingent reinforcement task is not simply a failure to activate DA neuron firing, but instead may represent an offsetting inhibitory influence over the DA system, either at the level of the DA cell body or the terminal. Indeed, the reports of an anticipatory increase in extracellular DA in the accumbens prior to self-administration of a DA drug such as cocaine (139) could potentially increase extracellular DA sufficiently to inhibit phasic DA release occurring via stimulation of the DA cell bodies (44).

Overall, studies support the suggestion that DA actions in the PFC may have a greater involvement in the regulation of novel circumstances, with the striatum involved more in expression of learned behaviors (140). This model is consistent with the physiologic studies cited that show that DA can selectively activate circuits within frontal cortex and striatal complex, potentially facilitating information flow along new pathways when a change occurs, but playing less of a role once a new stable steady state is achieved at which the internal representation is at equilibrium with the predicted external events.

SUMMARY OF DA ACTIONS

Part of "9 - Dopamine "

It is clear from the preceding that DA exerts multiple actions at each level of integration within the cortico-striato-pallido-thalamo-cortical loop. The actions exerted at each stage of this loop appear to have marked differences, however. For example, DA acting on primary inputs to this circuit (e.g., the amygdala and PFC) affect both primary neurons and interneurons, with the net effect being a selective potentiation of particular afferent drive sources. Within the striatum, DA exerts actions on presynaptic terminals containing glutamate, as well as affecting the actions of glutamate on postsynaptic neurons. Combined with the reciprocal feedback interactions between glutamate and DA terminals, this system appears to be designed to facilitate rapid changes in input states while attenuating any long-term alterations that may occur. Moreover, the effects of DA on cellular coupling provide a type of reversible hardwiring, which may facilitate performance of well-learned motor actions (141). Within the VP and MD, DA has effects that would alter the behavioral output by changing the state of neuronal activity within these structures. Therefore, DA could enable multiple state transitions within these regions, selecting among competing inputs, facilitating information transfer, and altering states that would ultimately feed back via the thalamus to reinforce cortical activity that is most pertinent to the task at hand (58 ,141).

The actions of DA may best be described not in terms of inhibition or excitation, but rather as related to the gating of inputs and modulation of states of neuronal elements. This modulation of information integration is then further influenced at the network level via the actions of DA on interneurons or cell coupling. Such a description is consistent with the behavioral actions of this transmitter as well, in that it does not directly produce a motor output or reward signal, but instead modulates inputs and adjusts the states of the organism in order to redirect the stimulus-response output to achieve the most effective behavioral strategy. Given these constraints, one could imagine how dysfunctions in such a system could produce the profound pathologic states that have been attributed to DA.

Astrocytes

Pierre J. Magistretti

Bruce R. Ransom

Pierre J. Magistretti: Institut de Physiologie, University of Lausanne Medical School, Lausanne, Switzerland

Bruce R. Ransom: Department of Neurology, University of Washington Medical School, Seattle, Washington 98195

The astrocyte is a ubiquitous type of glial cell that is defined in part by what it lacks: axons, action potentials, and synaptic potentials. Astrocytes greatly outnumber neurons, often 10:1 and occupy 25% to 50% of brain volume (1 ,2 and 3). Although these cells are anatomically obvious, their functions have been difficult to determine. Discoveries in the last 25 years, however, have revealed some of their functions and established the essential nature of interactions between neurons and astrocytes for normal brain function. We briefly review several basic facts about astrocytes and then selectively survey some of their functions, particularly emphasizing recent findings about metabolic interactions between astrocytes and neurons. We also discuss features of astrocyte function as they relate to synaptic plasticity and emerging concepts in the pathophysiology of psychiatric disorders.

STRUCTURAL AND PHYSIOLOGIC PROPERTIES

Part of "10 - Astrocytes "

The form of astrocytes is important in thinking about their functions. Astrocytes are stellate cells (hence their name) with multiple fine processes. Astrocytes in white matter are complex cells with 50 to 60 long branching processes that radiate from the cell body and terminate in end-feet at the pial surface, on blood vessels, or freely among axons; white matter astrocytes are usually called fibrous astrocytes (4). Astrocytes in gray matter, called protoplasmic astrocytes, have profuse, short stubby processes that contact blood vessels and the pial surface, and surround neurons. Astrocytic end-feet cover the entire surface of intraparenchymal capillaries (5). These end-feet express glucose transporters of the GluT 1 type (6) and are a likely site of glucose uptake. In gray matter, astrocytic processes ensheath virtually every synapse; the ensheathing membranes constitute about 80% of total membrane surface and are devoid of organelles (7). Thus, astrocytes are polarized cells with some processes contacting cells of mesodermal origin (i.e., endothelial cells of the capillary or fibroblasts of the pia mater), whereas other processes are intimately intertwined with neuronal processes and synapses (4 ,7).

Astrocytes are the only cells in the brain that contain the energy storage molecule glycogen (8). The importance of this is discussed elsewhere in this chapter. They also contain distinctive 9-nm intermediate filaments composed of a unique protein called glial fibrillary acidic protein (GFAP). Fibrous astrocytes contain more of these filaments than protoplasmic astrocytes. Recent work has assessed the functional significance of this defining astrocytic protein using genetic knockout experiments (9 ,10 and 11). Astrocytes in GFAP knockout animals have disturbed neuronal plasticity manifest as a loss of long-term depression (10), late-onset dysmyelination (9), and increased susceptibility to ischemia (12). It is not known how GFAP deficiency causes these changes.

Astrocytes are strongly coupled to one another by gap junctions (13), aqueous pores that are permeable to ions and other molecules with a molecular weight less than 1,000. A broad range of biologically important molecules, including nucleotides, sugars, amino acids, small peptides, cAMP, Ca^{2+} and inositol triphosphate (IP_3) have access to this pathway. Such intercellular communication is believed to mediate the coordinated action of adjacent but individual cells in terms of electrical and biochemical activity (13), and equalizes their intracellular ion concentrations (14). Gap junction permeability is strongly reduced by intracellular acidification or large increases in intracellular [Ca^{2+}].

The membrane potential (V_m) of astrocytes is more negative than that of neurons. For example, astrocytes have a V_m of about -85 mV, whereas neuronal membrane potential is about -65 mV. Although glial cells express a variety of K^+ channels, inwardly rectifying K^+ channels seem to be important in setting the resting potential (15). These channels are voltage sensitive and are open at membrane potentials more negative than about -80 mV, close to the observed resting potential of astrocytes. Astrocytes express many other voltage-activated ion channels, previously thought to be restricted to neurons (15). The significance

of voltage-activated Na^+ and Ca^{2+} channels in glial cells is unknown. Because the ratio of Na^+ to K^+ channels is low in adult astrocytes, these cells are not capable of regenerative electrical responses like the action potential.

One consequence of the high K^+ selectivity of astrocytes, compared to neurons, is that the membrane voltage of astrocytes is more sensitive to changes in extracellular $[K^+]$ ($[K^+]_o$). For example, when $[K^+]_o$ is raised from 4 to 20 mM, astrocytes depolarize by ˜25 mV, compared to only ˜5 mV for neurons (16). This relative insensitivity of neuronal resting potential to changes in $[K^+]_o$ in the "physiologic" range may have emerged as an adaptive feature that stabilizes the resting potential of neurons in the face of the transient increases in $[K^+]_o$ that accompany neuronal activity. In contrast, natural stimulation, such as viewing visual targets of different shapes or orientations, can cause depolarizations of up to 10 mV in astrocytes of the visual cortex (17). The accumulation of extracellular K^+ that is secondary to neural activity may serve as a signal to glial cells that is proportional to the extent of the activity. For example, small increases in $[K^+]_o$ cause breakdown of glycogen (18), perhaps providing fuel for nearby active neurons (see later).

Neurons and glial cells do not make functional synaptic or gap junction contacts with one another; therefore, interactions between these cell types must occur via the narrow extracellular space (ECS) between them (16). There may be rare exceptions to this rule (19 ,20). In the mammalian central nervous system (CNS), the ECS is a uniform and very small compartment formed by adjacent cell membranes that are, on average, separated by approximately by 0.02 µm. Brain ECS is a dynamic compartment in terms of its ionic contents and even its dimensions (15 ,21). Because of the extreme narrowness of the ECS, molecules released from one cell diffuse almost instantly to adjacent cells. Glial cells interact with neurons by influencing the contents (e.g., ions, energy metabolites, neurotransmitters, etc.) of the ECS. It should be emphasized that nearly every neuron in the brain shares common ECS with adjacent astrocytes, and astrocytic processes entirely surround synapses. It has been surprising to discover that glial cells release and express receptors for a wide range of informational molecules, including neurotransmitters (22); this greatly expands the possibilities for glial–neuronal interactions. Indeed, astrocytes are in a position to sense and modulate synaptic transmission through the pervasive lamellar processes that surround synaptic contacts (7).

FUNCTIONS

Part of "10 - Astrocytes "

Ion Homeostasis

One of the best-established functions of astrocytes is regulation of brain $[K^+]_o$. Astrocytes are also likely to participate in the regulation of extracellular pH, but this aspect of astrocyte function is still evolving and is not considered further here (23 ,24). Neural activity can rapidly increase $[K^+]_o$, which is tightly regulated to a resting level of about 3 mM (25). A single action potential increases the instantaneous $[K^+]_o$ by ˜0.75 mM (26). The increase in $[K^+]_o$ is proportional to the intensity of neural activity but has a so-called "ceiling" level of accumulation of 10 to 12 mM (27 ,28), which is only exceeded under pathologic conditions (29). If diffusion alone were responsible for dissipating K^+ released from neurons, it is easily calculated that extracellular K^+ accumulation would exceed 10 mM during normal neural activity, whereas measured increases in $[K^+]_o$ are in the range of 1 to 3 mM indicating powerful control mechanisms (30). Homeostatic control of $[K^+]_o$ is needed because brain $[K^+]_o$ can influence transmitter release (31), cerebral blood flow (32), ECS volume (33 ,34), glucose metabolism (35), and neuronal activity (36). Unchecked increases in $[K^+]_o$ act as an unstable positive feedback loop increasing excitability.

Astrocytes expedite the removal of evoked increases in $[K^+]_o$ and limit its accumulation to a maximum level of 10 to 12 mM, the ceiling level seen with intense activity such as epileptic discharge (37 ,38). Neurons, and perhaps blood vessels, also participate in $[K^+]_o$ regulation, but glial mechanisms are probably most important. Two general mechanisms of astrocyte K^+ removal have been proposed (39): 1) net K^+ uptake into astrocytes (by transport mechanisms and/or Donnan forces) and 2) K^+ redistribution through astrocytes, which is known as K^+ spatial buffering. The relative importance of these two mechanisms of $[K^+]_o$ regulation remains an open question and may depend on the nature of the $[K^+]_o$ increase as well as brain region (38).

If glial cells take up K^+ during neural activity and release it thereafter, a transient increase in glial $[K^+]_i$ should result. Astrocyte $[K^+]_i$ does transiently increase during neural activity and has a similar time course to the K^+ lost from active neurons and the increase in $[K^+]_o$, indicating that the K^+ released from neurons is passing by way of the ECS into glial cells (40 ,41 and 42). Uptake of K^+ into glial cells depends on the glial Na^+ pump (38 ,42 ,43 and 44), an anion transporter that cotransports K^+ and Na^+ with Cl^- (43) and Donnan forces that propel KCl into glial cells in the face of elevated $[K^+]_o$ (42) (Fig 10.1). It has not been determined with certainty which of these mechanisms is quantitatively most important for K^+ uptake. The astrocyte Na^+ pump, however, is exquisitely sensitive to elevations of $[K^+]_o$. Even a 1 mM increase in $[K^+]_o$ activates the Na^+ pump in these cells indicating, perhaps, that this is the major mechanism of K^+ sequestration (44). Neurons, of course, must eventually reaccumulate K^+ lost during activity using their Na^+ pump, but only glial cells show net accumulation of K^+ (Fig. 10.1). It is interesting to note that the neuronal Na^+ pump is not sensitive to small increases in $[K^+]_o$ and is probably activated mainly by increases in intracellular $[Na^+]$ (45).

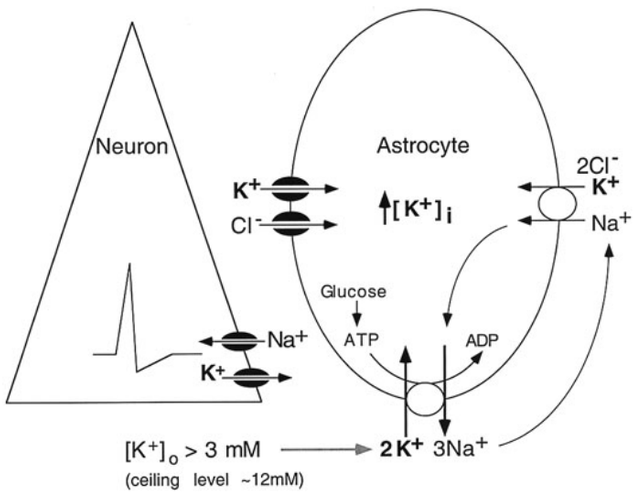

FIGURE 10.1. Schematic representation of mechanisms of K^+ uptake in astrocytes. K^+ released by firing neurons is actively accumulated by astrocytes in three ways. The sodium pump and an anion transporter both take up K^+; the sodium pump relies directly on the availability of ATP, whereas the anion transporter is indirectly powered by the energy stored in the transmembrane Na^+ gradient. The presence of channels for Cl^- and K^+, allow Donnan forces to produce KCl influx. These mechanisms along with K^+ spatial buffering (see text), prevent $[K^+]_o$ from exceeding ˜12 mM. Increases in $[K^+]_i$ are seen during neural activity as $[K^+]_o$ increases.

The idea that focal increases in $[K^+]_o$ could be redistributed by glial cells was introduced by Kuffler and colleagues (46). They realized that the selective K^+ permeability of glia coupled with their low-resistance intercellular connections (mediated by gap junctions), would permit them to transport K^+ from focal areas of high $[K^+]_o$, where a portion of the glial network would be depolarized, to areas of normal $[K^+]_o$, where the glial network would have a near normal membrane potential (46). Experiments suggest that under conditions of focal increases in $[K^+]_o$, five times as much K^+ moves by way of glial cells as through the ECS, except where only very localized K^+ gradients are involved (25). A further specialization that contributes to spatial buffering is a nonuniform distribution of K^+ channels on a single cell. The density of K^+ channels on the cell membrane of retinal Müller cells, which are specialized astrocytes, is highest on the cell's end-foot. Because the end-foot of the Müller cell, which abuts the vitreous humor of the eye, has the highest density of K^+ channels, accumulated $[K^+]_o$ is preferentially transported to the vitreous, which acts as a disposal site. It is not known if nonuniform K^+ channel distribution is a general feature of astrocytes.

Anoxia/ischemia causes rapid increases in $[K^+]_o$ in both gray matter (to ~60 to 80 mM) and white matter (to ~12 to 15 mM *in vitro*) of the brain (27 ,47). The increases in $[K^+]_o$ result because energy-dependent ion gradients can no longer be maintained and K^+ entering the ECS can no longer be taken up by glial cells, which also depend on ATP (48). In fact, under conditions of diminished energy supply, glial cells actually contribute K^+ to the ECS, rather than take it up (49).

Transmitter Synthesis

Glutamate is one of the most common amino acids in the brain, present at millimolar concentrations in brain tissue homogenate. It is also the predominant excitatory neurotransmitter (50). Only a small fraction of total brain glutamate is packaged for synaptic release and astrocytes are intimately involved in the synthesis of this crucial vesicular pool of glutamate.

Although glutamate can be derived from neuron glucose metabolism, carbon-labeling experiments reveal that astrocyte-derived glutamine is the principal precursor of synaptically released glutamate (51 ,52). The synthesis and release of glutamine by astrocytes is part of a biochemical shuttle mechanism called the glutamate-glutamine cycle (53) (Fig 10.2). After release from the presynaptic terminal, glutamate is taken up primarily by astrocytes (54 ,55). In the glial cell, glutamate is converted to glutamine through the ATP-dependent enzyme glutamine synthetase, located exclusively in astrocytes (56). In fact, glutamine synthetase is localized to astrocytic processes surrounding glutamatergic synapses (57).

Glutamine is released by the glial cells and taken up by the neurons through specific uptake carriers. In the presynaptic terminal, glutamine is converted to glutamate through glutaminase, a phosphate-dependent enzyme preferentially localized to synaptosomal mitochondria (58 ,59). The newly synthesized glutamate is then packed into vesicles and becomes available for release. The glutamate-glutamine cycle is a clear and important example of cooperativity between astrocytes and neurons (Fig. 10.2). It mediates removal of potentially toxic excess glutamate from the extracellular space and provides the neuron with a synaptically inert precursor for resynthesis of glutamate. (Glutamine does not bind to neurotransmitter receptors.)

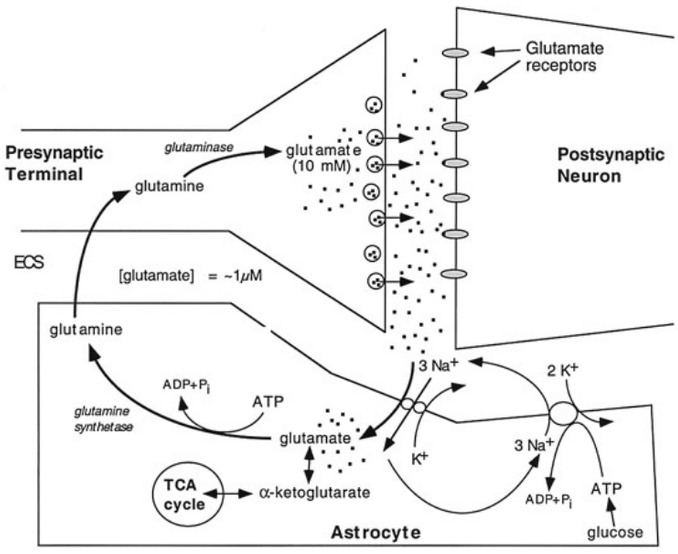

FIGURE 10.2. Scheme showing how astrocytes are involved in glutamate metabolism and uptake. Only astrocytes contain the enzyme glutamine synthetase, which converts glutamate to glutamine in an ATP-requiring reaction. Glutamine is transported to nearby presynaptic terminals where it is converted to glutamate for synaptic release. Finally, the released glutamate is recaptured by astrocytes via a high affinity glutamate uptake system. Although glutamate transporters are present in neurons, astrocytes are the most active in removing glutamate (see text). In the absence of the normal transmembrane Na^+ gradient, maintained by the ATP-dependent Na^+ pump, the glutamate transporter ceases to remove glutamate and can run in reverse so that it pumps glutamate into the extracellular space (ECS).

The cycle is surprisingly rapid. After a 6-min incubation of slices of rabbit hippocampus in [^{14}C] glutamine, half of the radioactivity was in the form of glutamate. Removal of glutamine from the bathing solution of the hippocampal slices decreased glutamate efflux by 60% to 80% after only 6 min (52).

Not all of the glutamate taken up by astrocytes is directly converted to glutamine. Glutamate can also enter the TCA cycle through its conversion to α-ketoglutarate (KG). Three enzymatic reactions can yield KG: one catalyzed by aspartate amino transferase and another by alanine aminotransferase, both reactions involving the transfer of an α-amino group. The third reaction is the direct conversion of glutamate to KG via the action of glutamate dehydrogenase (60) (Fig. 10.2). Theoretically, therefore, neurons *might not* get back in the form of glutamine (from astrocytes) all of the glutamate that they release for two reasons: (a) some of the glutamate diffuses away or is taken up by postsynaptic neurons, or (b) not all of the glutamate that enters astrocytes becomes glutamine. Two possibilities can be considered for stabilizing the pool of vesicular glutamate in neurons. First, contrary to the preceding premise, astrocytes might be able to compensate neurons for their loss of glutamate by appropriate adjustments in glutamine export. This would be possible because the pool of cytosolic glutamate in astrocytes is in equilibrium with TCA cycle intermediates, which in turn can be replenished by the carboxylation of pyruvate derived from glucose. The signal for more glutamine export could be extracellular (glutamine), which would fluctuate in response to the needs of glutamatergic neurons. Second, recent data have demonstrated that neurons can generate glutamate directly from pyruvate obtained from glucose or lactate (61 ,62). Indeed, lactate produced by astrocytes in response to synaptically released glutamate (see the following) appears to be taken up by neurons and could be a substrate for glutamate formation.

GABA, the most common inhibitory neurotransmitter in the brain, is synthesized from glutamate. Consequently, glutamine and α-ketoglutarate are used for GABA synthesis as well (63). Depolarization-released GABA is preferentially synthesized from glutamine supplied by astrocytes (64). Inhibition of astrocyte glutamine synthetase with methionine sulfoximine produces a significant decrease in GABA production both *in vivo* and in brain slices (65%); however, because a 90% decrease in glutamine did not fully suppress GABA synthesis, an additional metabolic source is considered to be likely (65).

Astrocytes, it would seem, are essential for normal glutamate- and GABA-mediated synaptic transmission. Indeed, selective inhibition of glial cells in the guinea pig hippocampus using the glial-specific metabolic blocker, fluoroacetate, decreases transmission at glutamate synapses (66). Intracellular recordings verified the integrity of neurons in fluoroacetate-treated slices and the persistence of normal responses to glutamate applied iontophoretically. A modulatory role of astrocytes in excitatory synaptic transmission is supported by this study.

Transmitter Removal

In addition to being the most important excitatory neurotransmitter in the brain, glutamate is also a potent neurotoxin and has been implicated in stroke, amyotrophic lateral sclerosis, and epilepsy. Highly efficient glutamate transporters remove synaptically released glutamate and also keep the extracellular concentration of this amino acid at about 2 μM (67). Glutamate transporters are expressed in oligodendrocytes, neurons, microglia, and astrocytes, but transporters in astrocytes are quantitatively the most important in regulating glutamate at synapses and in the extracellular space (Fig. 10.2). (See ref. 55 for review.)

Five main types of glutamate transporters have been described: GLAST (EAAT 1), GLT-1 (EAAT 2), EAAC 1 (EAAT 3), EAAT 4, and EAAT 5 (55). The latter two appear to be predominantly localized in cerebellum and retina, respectively. All have been cloned, functionally characterized, and their localization and distribution at the regional, cellular, and subcellular levels in the CNS are known (55 ,68). A detailed review of this fertile field of research is beyond the scope of this chapter. EAAC 1 transporters are neuronal, mostly localized on the cell body and dendrites, whereas GLAST and GLT-1 are predominantly glial (68). There are regional differences in the expression of GLAST and GLT-1; GLAST is more heavily expressed in the cerebellum and GLT-1 is more prevalent in the forebrain.

Glutamate uptake into astrocytes is driven by the electrochemical gradients of Na^+ and K^+, with a stoichiometry of 3 Na^+ and 1 H^+ in and 1 K^+ out with the uptake of each glutamate anion (55 ,69). The resulting increase in $[Na^+]_i$ must be corrected by a cycle of the Na^+ pump and ATP consumption (70). One advantage of a system where astrocytes take up most of the glutamate is that the metabolic burden of this work is offloaded from neurons (55).

Several lines of evidence support that astrocytes play an essential role in glutamate uptake in the brain (55): (a) Astrocytes preferentially accumulate glutamate transporter

substrate (71). (b) In the absence of astrocytes, neurons are 100-fold more vulnerable to glutamate toxicity (72). (c) Genetic down-regulation of GLAST or GLT-1, but not the neuronal subtype EAAC1, causes elevated extracellular levels of glutamate and neurotoxicity (73).

As emphasized, astrocytes form a ubiquitous part of all glutamatergic synapses. Astrocyte membrane facing a glutamate synapse expresses higher levels of GLAST than membrane facing other structures such as pia mater or capillaries (74). Most of the glutamate released at synapses appears to be taken up by the adjacent astrocytes (75), although there may be some regions in the brain where up to 20% of glutamate is transported into the postsynaptic neuron (55). The impact of astrocytic glutamate uptake at synapses is most emphatically detected when uptake is blocked. This increases both the amplitude and the duration of the excitatory postsynaptic current (76).

Metabolic Coupling with Neurons

Coupling of Synaptic Activity to Glucose Utilization

The cytoarchitecture of astrocytes is of particular relevance in a discussion about the coupling of synaptic activity to glucose utilization. As mentioned, astrocyte end-feet surround virtually all brain capillaries, whereas other astrocytic processes ensheath synaptic contacts (5 ,7) or end among axons (4). In addition, astrocytes possess receptors and reuptake sites for a variety of neurotransmitters, including the excitatory neurotransmitter glutamate (77), whereas astrocytic end-feet are enriched in the specific glucose transporter GLUT-1 (6). Thus, astrocytes possess the necessary features to sense synaptic activity, through receptors and reuptake sites for neurotransmitters, and to couple it with the entry of glucose into the brain parenchyma (78). Experimental evidence supporting this function is reviewed here.

Glutamate, the main excitatory neurotransmitter released by activated circuits, is a potent stimulator of glycolysis; that is, of glucose uptake and lactate production, in primary astrocyte cultures. (See refs. 60 and 79 for review.) The metabolic effect of glutamate is not mediated by receptors, but rather by glutamate transporters selectively expressed in astrocytes, in particular GLAST (80). These observations suggest a mechanism whereby astrocytes contribute to the uptake of glucose from the circulation into brain parenchyma in register with synaptic activity: The release of glutamate from synaptically active neurons stimulates glucose uptake in nearby astrocytes. The extent of glucose uptake would be proportional to the extent of activity, thereby "coupling" neuronal activity to glucose utilization (80). The Na-K-ATPase is critical for this coupling. Thus, ouabain, a specific inhibitor of the Na-K-ATPase, completely inhibits the glutamate-evoked glycolysis in astrocytes (80). Glutamate stimulates astrocytic Na-K-ATPase (81) by increasing intracellular Na^+ concentration ($[Na^+]_i$) via Na^+-dependent glutamate uptake by glutamate transporters (55 ,69) (Fig. 10.2 and Fig. 10.3). The overall stoichiometry of the molecular steps involved in the coupling between glutamate uptake and glucose utilization are as follows: one glutamate is taken up with 3 Na^+, whereas one glucose consumed through glycolysis produces two ATPs. One ATP is used by the Na^+/K^+ ATPase for the extrusion of 3 Na^+; the other ATP could be used for the synthesis of glutamine from glutamate by glutamine synthase (Fig. 10.3) (82). The glutamate-stimulated glycolytic processing of glucose results in approximately two lactate molecules produced per one glucose molecule; that is, an expected stoichiometric relationship between glucose and lactate. This scheme is, of course, primarily relevant for synaptic regions of the brain (i.e., gray matter). The mechanism that "couples" axonal activity to glucose utilization in white matter is not established. Because axonal activity produces proportional increases in $[K^+]_o$ (28) and increases in $[K^+]_o$ increase astrocyte glucose utilization (35 ,83), it is tempting to speculate that activity-dependent changes in $[K^+]_o$ in white matter play an analogous role to glutamate release in gray matter.

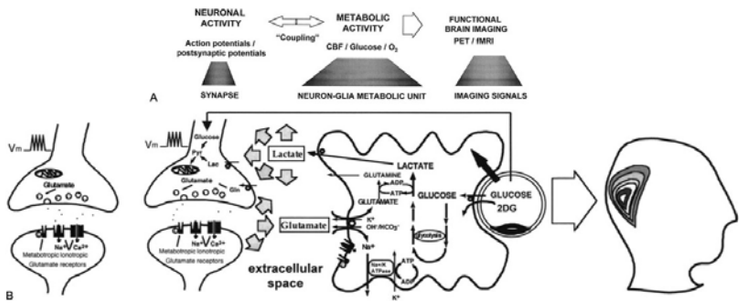

FIGURE 10.3. Schematic representation of the mechanism for glutamate-induced glycolysis in astrocytes during physiologic activation and its relevance for functional brain imaging. At glutamatergic synapses, presynaptically released glutamate depolarizes postsynaptic neurons by acting at specific receptor subtypes. The action of glutamate is terminated by an efficient glutamate uptake system located primarily in astrocytes. Glutamate is cotransported with Na^+, resulting in an increase in the intra-astrocytic concentration of Na^+, leading to an activation of the astrocyte Na^+/K^+ ATPase. Activation of the Na^+/K^+ ATPase stimulates glycolysis (i.e., glucose utilization and lactate production). Lactate, once released by astrocytes, can be taken up by neurons and serve them as an adequate energy supply. The proposed model of glutamate-induced glycolysis in astrocytes implies that the activity-linked uptake of 18FDG monitored with PET, reflects primarily an astrocyte-based signal. Because neuronally released glutamate triggers the cascade of events that leads to glucose uptake, the 18FDG-PET signal faithfully reflects activation of neuronal circuits. The model is also consistent with the transient lactate peak detected during activation by MRS in humans and by microdialysis and electrochemical detection in animals (see text for details).

Is the lactate released by astrocytes in this model used as fuel by neurons? A vast array of experimental data indicate that *in vitro*, lactate in the absence of glucose can adequately maintain synaptic (84 ,85 and 86) or axonal activity (87 ,88). If astrocytes transfer lactate to neurons as a fuel source (Fig. 10.3), several conditions must be met. There must be appropriate enzymes for the creation of lactate in astrocytes and its use in neurons, and appropriate transport mechanisms for the movement of lactate. Indeed one isoform of lactate dehydrogenase (LDH5), which is enriched in lactate-producing glycolytic tissues such as skeletal muscle, is predominantly localized in astrocytes in the human brain, whereas the other isoform, LDH1, expressed in highly oxidative tissues such the heart, which utilize lactate, is mostly found in neurons (89). Monocarboxylate transporters (MCTs) mediate the exchange of lactate between astrocytes and neurons. These transporters show a cell-specific distribution, with MCT1 predominantly present in astrocytes, whereas MCT2 is enriched in neurons (90 ,91).

Glutamate-mediated neuron–glia metabolic interactions provide an initial basis to better understand the cellular and molecular steps involved in neuro metabolic coupling (Fig. 10.3). In particular, the model proposed according to which the activity-dependent synaptic release of glutamate triggers glucose uptake into the brain parenchyma coupled with a transient production of lactate, provides a possible basis for functional brain imaging techniques such as positron emission tomography (PET) (78 ,82). Indeed, a host of PET human studies have indicated an activity-dependent partial uncoupling between glucose utilization (^{18}F-deoxyglucose PET) and oxygen consumption (^{15}O PET), whereas magnetic resonance spectroscopy (MRS) analyses show a transient

lactate production. (See ref. 79 for review.) In addition, recent MRS studies provide strong support for a tight coupling between glutamate-mediated synaptic activity and glucose utilization. Thus, the simultaneous measurements, over a range of synaptic activity, of glucose oxidation and the cycling of glutamate to glutamine (a process that occurs exclusively in astrocytes) using ^{15}C MRS has revealed a striking stoichiometric relationship of 1:1 between glutamate cycling (a reflection of synaptic activity) and glucose utilization (92). According to these data, for each glutamate released from active terminals and taken up by astrocytes one glucose would be oxidized.

Implications for Imaging

The model proposed on the basis of studies at the cellular level suggests an initial glycolytic processing of glucose occurring in astrocytes during neuronal activation, resulting in a transient lactate overproduction, followed by a recoupling phase during which lactate would be oxidized by neurons (Fig. 10.3).

Results obtained in a variety of *in vivo* paradigms both in laboratory animals and humans, support the existence of such a transient lactate production during activation. Thus, microdialysis studies in rats indicate a marked increase in the concentration of lactate in the dialysate in striatum and hippocampus during physiologic sensory stimulation (93). Interestingly, this activity-linked lactate peak is completely inhibited when the glutamate uptake inhibitor THA is present in the perfusate, thus providing further supporting evidence for the existence of glutamate stimulated glycolysis during activation (93). In humans, MRS reveals a transient lactate peak in primary visual cortex during physiologic activation of the visual system (94). Thus, microdialysis and MRS data *in vivo* support the notion of a transient glycolytic processing of glucose during activation. In addition, some PET studies have shown that oxygen consumption does not increase commensurately with blood flow and glucose utilization in activated brain areas (95), suggesting the occurrence of an activity-dependent glycolytic processing of glucose. In contrast, using ^{13}C-glucose MRS, recent data are consistent with a significant increase in oxygen utilization during activation (96). These contrasting views relevant to the degree of oxygen utilization during activation can be reconciled by the model proposed (80), which suggests that glucose imported into the brain parenchyma during activation undergoes a *transient* glycolysis in astrocytes, resulting in the production of lactate that is then oxidized by neurons. This latter process would imply a metabolic recoupling with increased oxygen consumption. The spatial and temporal “window” during which a transient glycolysis occurs and a lactate peak can be detected, may depend on the rapidity and degree of recoupling existing between astrocytic glycolysis and neuronal oxidative phosphorylation.

This operational model for coupling is consistent with the notion that the signals detected during physiologic activation in humans with FDG PET may result from signaling and metabolic exchanges between neurons (glutamate release) and astrocytes (glycolysis) (82). This conclusion does not question the validity of these techniques for monitoring neuronal function because the triggering event is neuronal glutamate release; rather, this conclusion provides a cellular and molecular basis for these functional brain-imaging techniques (Fig. 10.3).

Glycogen

Another facet of neuron–glia metabolic interactions concerns glycogen. Glycogen, the storage form of glucose, is the largest energy reserve of the brain and it is almost exclusively localized in astrocytes. Although the levels of glycogen are low compared to muscle or liver, they appear to vary in register with synaptic activity and are tightly regulated by a variety of neurotransmitters (97). For example, somatosensory stimulation readily mobilizes glycogen in the corresponding somatosensory cortex as well as in subcortical relays (98). In contrast, during anesthesia glycogen levels increase dramatically. Plastic adaptations in glycogen regulation appear to occur in astrocytes as a consequence of acute or slow neuronal loss; indeed, glycogen deposits are often observed in reactive astrocytes present in acutely lesioned areas, as well as at sites of slow neurodegeneration, such as those observed in Alzheimer’s disease (97). These latter observations suggest that impaired synaptic activity associated with neuronal loss results in a glycogen-sparing situation in astrocytes; active mechanisms driving glycogen metabolism toward increased resynthesis may also be operative under such conditions. The mechanisms that underlie the regulation of glycogen metabolism at the cellular and molecular levels have been partially characterized. (See ref. 97 for review.) Whereas the role of brain glycogen remains to be fully elucidated, recent results indicate that astrocytic glycogen in white matter is readily available to axons, mainly as lactate, and sustains their function during glucose withdrawal (99). It also seems likely that glycogen mobilization by certain neurotransmitters is an adaptation designed to provide additional energy substrate to synaptically active neurons (see the following).

It is appealing to think that astrocytic glycogen serves to provide fuel to the brain when glucose is in short supply. Indeed, astrocytic glycogen *in vitro* is rapidly degraded when glucose is withdrawn (100), and glycogen falls rapidly *in vivo* during ischemia, with a time course that is closely related to (87) ATP depletion and accumulation of lactate (101). Some experimental evidence supports this concept. Neurons grown in astrocyte-rich cultures are less severely injured by glucose withdrawal than are neurons in astrocyte-poor cultures (102). This benefit appeared to derive from the presence of greater amounts of glycogen in the astrocyte-rich cultures because depleting glycogen negated the benefit (102).

Two possible mechanisms for this outcome were suggested but not tested: (a) Astrocytes themselves utilize the energy from glycogen breakdown to prevent the accumulation of toxic levels of glutamate (removing it by a sodium-gradient-dependent transporter); or (b) Glycogen provides fuel to neurons to sustain their energy metabolism.

The role of astrocytic glycogen in CNS white matter has been analyzed using the rat optic nerve, a representative white matter tract. Optic nerve function, measured as the compound action potential (CAP), persists for about 40 min in the absence of glucose (87 ,103), suggesting the presence of an intrinsic energy reserve such as astrocytic glycogen. The theory was tested that during glucose withdrawal, astrocytic glycogen is converted to lactate and transported into axons to act as an energy source. Glycogen content of the optic nerve falls during glucose withdrawal, compatible with rapid use in the absence of glucose. Up-regulation of glycogen content increases latency to CAP failure and improves CAP recovery after glucose withdrawal, whereas down-regulation of glycogen content has the opposite effects (99). Lactate can replace glucose as an energy source and appears to be transported by MCT out of astrocytes and into axons in the absence of glucose. These results indicate that astrocytic glycogen in white matter is readily available to axons, mainly as lactate, during glucose withdrawal (Fig. 10.4). Conceptually, they provide “proof of principle” that astrocytic glycogen is an energy reserve that can be shared with, and thus can prolong the function of, neural elements in times of need.

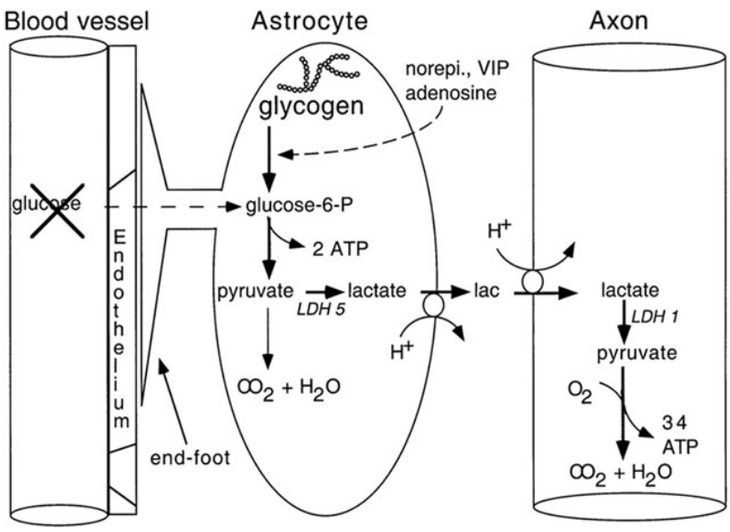

FIGURE 10.4. Schematic illustration of how astrocytic glycogen appears to fuel axons in the absence of glucose. Blood glucose first encounters astrocytic end-feet as it is transported into the brain. In the absence of glucose, astrocytic glycogen is broken down to lactate, which is transported to the extracellular space via a monocarboxylate transporter (MCT). It is then taken up by an MCT in axons and is oxidatively metabolized to produce energy needed to sustain excitability. LDH5 preferentially reduces pyruvate to lactate, whereas LDH1 preferentially oxidizes lactate to pyruvate. Neurotransmitters such as norepinephrine, vasoactive intestinal peptide, and adenosine, promote glycogenolysis. This scheme recognizes that astrocytes can subsist, at least transiently, on glycolytic energy metabolism, whereas axons require oxidative metabolism.

Glycogen levels in astrocytes are tightly regulated by various neurotransmitters. Several monoamine neurotransmitters, namely noradrenaline, serotonin, and histamine, are glycogenolytic in the brain, in addition to certain peptides such as vasoactive intestinal peptide (VIP) and pituitary adenylate cyclase activating peptide (PACAP), as well as adenosine and ATP (104 ,105). The effects of all these neurotransmitters are mediated by specific receptors coupled to second messenger pathways such as adenylate cyclase, for the ß-adrenergic, VIP/PACAP and adenosine A2 receptors, or phospholipase C for α-1 adrenergic receptors (106). The initial rate of glycogenolysis activated by VIP and noradrenaline is between 5 and 10 nmol/mg prot/min (106), a value that is remarkably close to glucose utilization of the gray matter as determined by the 2-DG autoradiographic method (107). This correlation raises the possibility that the glycosyl units mobilized in response to the glycogenolytic neurotransmitters are in register with the energy demands of the neuropil.

In addition to the rapid (within seconds) glycogenolysis, VIP, noradrenaline, and adenosine induce a long-lasting plastic response resulting in massive glycogen resynthesis (108). This effect is expressed after several hours and is transcriptionally regulated, involving the expression of new genes: two immediate-early and two late genes, all being induced in a cAMP-dependent manner in astrocytes. The immediate-early genes, C/EBP ß and δ are members of a family of transcription factors called CCAAT/enhancer binding protein. This family of transcription factors is predominantly involved in two types physiologic responses: inflammation, through the control of expression of several acute phase response genes, and energy metabolism, in particular through the regulation of cAMP-sensitive genes controlling glucose metabolism in peripheral tissues (109). The late genes regulated by VIP and NA are glycogen synthase (110) and protein targeting to glycogen (PTG) (111). The physiologic function of PTG appears to be that of a chaperone protein coordinating the activity and compartmentalization of glycogen-synthesizing enzymes (111).

Glycogen metabolism in astrocytes appears to be under the dynamic control of at least two neurotransmitters, VIP and NA, with the balance between short-term (glycogenolysis) and transcriptionally regulated long-term effects (glycogen resynthesis) setting the intracellular levels of glycogen.

Calcium Waves and Glial Signaling

The phenomenon of inducible waves of increased $[Ca^{2+}]_i$ moving through adjacent astrocytes was first reported in tissue culture by Cornell-Bell and associates (112). Such waves, stimulated by glutamate application or a mechanical

stimulus, are also known to occur in other cell types (113). It is of special interest that astrocyte Ca^{2+} waves may be elicited by activity in adjacent neurons (114). The mechanism of these waves, which move through cells at a rate of 10 to 20 μm/sec, is not entirely understood (115). It appears to involve the intracellular formation and intercellular transmission of inositol-1,4,5-trisphosphate (IP_3), and the release of an extracellular messenger substance, perhaps ATP (115). This phenomenon has become more interesting with the discovery that it is seen in intact brain tissue such as the retina (116).

The function of intracellular Ca^{2+} waves in astrocytes could be to coordinate the activity of these glial cells. A more intriguing possibility would be that the Ca^{2+} wave could influence neurons in its vicinity. Indeed, Ca^{2+} elevation in astrocytes can cause increases in neuronal $[Ca^{2+}]_i$ (117) and induce action potentials in hippocampal neurons (118 ,119). The most compelling demonstration to date of glia-to-neuron signaling mediated by Ca^{2+} waves, however, has come from studies in the rat retina (116). Mechanical stimulation of astrocyte Ca^{2+} waves led to changes in light-induced ganglion cell firing, usually inhibition, when the Ca^{2+} wave reached the neuron. The likely mechanism was the release of glutamate from the astrocytes with stimulation of inhibitory interneurons projecting to the ganglion cells. The importance of this fascinating observation for the normal operation of the nervous system remains unclear, but it suggests a unique form of glial modulation of neuronal activity.

Astrocytes and Synaptic Plasticity

Considerable attention has been given in recent years to the mechanisms of synaptic plasticity. It is now clear that plastic events outlast the early stages of nervous system development and are maintained, to different degrees, throughout adult life, providing the basis for the processes of learning and memory (120). Most experimental paradigms both *in vivo* and *in vitro*, such as the study of long-term potentiation in brain slices, have thoroughly explored the mechanisms of plasticity occurring as a consequence of intense activation of neuronal circuits purportedly associated with the learning process (12). For example, structural rearrangements at synapses characterized by an enhanced number of axodendritic synaptic contacts have been demonstrated (121), and the relative contribution of presynaptic adaptations (increased neurotransmitter release) versus postsynaptic ones (increased responsivity of the target elements) have been thoroughly investigated (122). The involvement of a variety of molecules, including glutamate and its receptors, nitric oxide, arachidonic acid, certain neurotrophins, and cell adhesion molecules, has been proposed (123).

However, few studies have explored the possible adaptations that may occur in glial elements, in particular at the astrocytic profiles that ensheath synapses, as a consequence of learning paradigms known to affect synaptic plasticity. The structural rearrangements occurring at synaptic contacts are likely to affect the morphology of the associated astrocytic profiles. Such an astrocytic structural plasticity has been well documented in the hypothalamus. Here, on physiologic stimulation (lactation, dehydration) the astrocytic profiles surrounding the soma and dendrites of oxytocin-containing neurons retract, allowing a marked increase in membrane surface available for synaptic contacts (124). This structural modification, in which a clear role for certain cell-adhesion molecules (e.g., PSA-NCAM, F3, and tenascin) has been shown (125), is reversible, being associated with the period of stimulation. A similar structural astrocytic plasticity has been shown in the arcuate nucleus during the estrous cycle (124). Evidence for activity-dependent astrocytic plasticity is beginning to be demonstrated also in extrahypothalamic areas of the brain. Striking structural modifications of astrocyte morphology surrounding synaptic contacts occur in parallel to neuronal plastic adaptations in brain areas activated by simple behavioral paradigms of learning. Thus, in animals reared in complex environments, the size and the number of GFAP-immunoreactive astrocytes was found to be increased in the visual cortex as compared to animals raised in normal laboratory cage environment (126 ,127 and 128). In addition, the extent of contact between astrocytic processes and synapses is increased under the same conditions (129). Similar astrocytic modifications are also observed in the cerebellum following synaptic plasticity induced by motor-skill learning (130). Following a spatial learning task (the Morris water maze test), an increase in the density of GFAP-immunoreactive astrocytes is observed in the hippocampus (131). This increase in GFAP is correlated with enhanced expression of basic-fibroblast growth factor. Considering the purported role of LTP in spatial learning (132), it is worth noting that induction of LTP *in vivo* by repeated high-frequency stimulation of the perforant pathway in the hippocampus causes a similar increase in numerical density, higher surface density, and closer apposition of astrocyte processes to the synaptic clefts, or dendritic spines in the potentiated synapses (133). The concept that glial cells, and in particular astrocytes, could contribute to plastic changes occurring after learning and memory or developmental paradigms has already been the subject of reviews (134).

In some of these learning paradigms involving structural plastic responses in astrocytes, long-lasting adaptations in local energy metabolism have been reported. Thus, increases in capillary formation, capillary branching, and surface area were reported in visual cortex following complex experience (127). Angiogenesis was also demonstrated in the cerebellum after motor skill learning (135), thus suggesting that a long-lasting enhancement in the supply of energy substrates (mostly glucose and O_2) is required in the activated area. Several studies have reported long-lasting changes in glucose utilization following various learning and memory tasks (136 ,137 ,138 and 139).

Spatial discrimination training was reported to cause persistent increases in glucose utilization, as measured with the 2-deoxyglucose autoradiographic technique in regions such as the hippocampus and various cortical areas (140).

GLIAL CELL FUNCTION: IMPLICATIONS FOR PSYCHIATRY

Part of "10 - Astrocytes "

From the overview presented in the preceding paragraphs, it clearly appears that all facets of intercellular communication in the brain are relevant to glial cell, and specifically astrocyte function. Thus, the presence on astrocytes of receptors for all chemical classes of neurotransmitters (amino acids, monoamines, and peptides) indicates that the receptor-mediated effects of psychoactive drugs can involve astrocytes. To take a simple example, increasing synaptic levels of noradrenaline with certain classes of antidepressants, by activating ß-adrenergic receptors on astrocytes, is likely to result in induction of genes that regulate glycogen metabolism. Plasticity is no longer exclusive to neurons, providing the conceptual background for considering the activity- and drug-induced adaptations observed in the function of specific circuits as also involving astrocyte-based mechanisms. As recently reviewed, alterations in excitatory neurotransmission, which appear to be involved in neuropsychiatric disorders such as schizophrenia or Alzheimer's disease, may well include an astroglial component (141). Recent neuroimaging studies have shown that the volume of the subgenual prefrontal cortex is reduced in familial forms of major depressive and in bipolar disorders. This decrease in cortical volume could be ascribed to a marked decrease in the number of glial cells (142). Functional imaging in patients suffering from both clinical conditions show a significant decrease in glucose utilization determined by ^{18}F-deoxyglucose PET (143). In addition to providing indirect evidence for the involvement of glia in certain psychiatric disorders, this set of observations is consistent with the proposed role of astrocytes in the ^{18}F-deoxyglucose PET signal (80). Chronic treatment with neuroleptics has been associated with increased glial density in the primate prefrontal cortex (144). Although these examples still need validation in terms of their relevance in the pathophysiology of certain neuropsychiatric disorders, they provide, along with advances in the understanding of glial cell biology, sufficient grounds for opening the scope of psychiatric neuroscience to the study of what Joseph Coyle and Robert Schwarcz have recently called "mind glue" (the term glia, meaning glue in German) (141). This is a major step indeed from "neuron-centric" dominated psychiatric theory and one that is justified by the available facts.

Synaptic Plasticity

Robert C. Malenka

Robert A. Malenka: Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Palo Alto, California.

The most fascinating and important property of the mammalian brain is its remarkable plasticity, which can be thought of as the ability of experience to modify neural circuitry and thereby to modify future thought, behavior, and feeling. Thinking simplistically, neural activity can modify the behavior of neural circuits by one of three mechanisms: (a) by modifying the strength or efficacy of synaptic transmission at preexisting synapses, (b) by eliciting the growth of new synaptic connections or the pruning away of existing ones, or (c) by modulating the excitability properties of individual neurons. *Synaptic plasticity* refers to the first of these mechanisms, and for almost 100 years, activity-dependent changes in the efficacy of synaptic communication have been proposed to play an important role in the remarkable capacity of the brain to translate transient experiences into seemingly infinite numbers of memories that can last for decades. Because of its fundamental importance, there has been an enormous amount of work describing the many forms of synaptic plasticity and their underlying mechanisms.

Synaptic transmission can either be enhanced or depressed by activity, and these alterations span temporal domains ranging from milliseconds to enduring modifications that may persist for days or weeks and perhaps even longer. Transient forms of synaptic plasticity have been associated with short-term adaptations to sensory inputs, transient changes in behavioral states, and short-lasting forms of memory. More lasting changes are thought to play important roles in the construction of neural circuits during development and with long-term forms of memory in the mature nervous system. Given these diverse functions, it is not surprising that many forms and mechanisms of synaptic plasticity have been described. In this chapter, I provide a brief overview of some of the forms of synaptic plasticity found at excitatory synapses in the mammalian brain, focusing on long-term potentiation (LTP) and long-term depression (LTD).

SHORT-TERM SYNAPTIC PLASTICITY

Part of "11 - Synaptic Plasticity "

Virtually every synapse that has been examined in organisms ranging from simple invertebrates to mammals exhibits numerous different forms of short-term synaptic plasticity that last on the order of milliseconds to a few minutes (for detailed reviews, see 1 and 2). In general, these result from a short-lasting modulation of transmitter release that can occur by one of two general types of mechanisms. One involves a change in the amplitude of the transient rise in intracellular calcium concentration that occurs when an action potential invades a presynaptic terminal. This occurs because of some modification in the calcium influx before transmitter release or because the basal level of calcium in the presynaptic terminal has been elevated because of prior activity at the terminal. A second mechanism occurs downstream of calcium elevation in the presynaptic terminal and involves some modulation of the biochemical processes involved in synaptic vesicle exocytosis.

Paired-Pulse Facilitation and Depression

When two presynaptic stimuli are delivered within a short interval, the synaptic response to the second stimulus can be either enhanced or depressed relative to the first stimulus. Paired-pulse depression is commonly observed at all synapses at short (less than 20 milliseconds) interstimulus intervals. It may result from inactivation of voltage-dependent sodium or calcium channels or from a transient depletion of the synaptic vesicles that are “docked” adjacent to the presynaptic plasma membrane, waiting to be released. Many synapses at longer interstimulus intervals (20 to 500 milliseconds) exhibit paired-pulse facilitation that is thought to result from the influx of calcium that occurs in response to the first action potential. One simple idea is that the “residual” calcium left over from the first action potential combines with the calcium influx during the second action potential, and because the relationship between calcium concentration in the terminal and release is highly nonlinear, this small increase in resting calcium may cause substantial facilitation. However, with a single action potential, the increase in resting calcium concentration is very small, and

thus additional mechanisms are likely involved. Currently, there is much interest in the possibility that transient modulation, by activation of protein kinases, of some of the presynaptic phosphoproteins that are known to be involved in the control of transmitter release may play an important role in very short-term synaptic plasticity. For example, knockout mice lacking one or more of the synapsins (3 ,4), or lacking the small guanosine triphosphate–binding protein rab3A (5 ,6), exhibit abnormal short-term synaptic plasticity.

Whether a specific synapse displays paired-pulse facilitation or depression depends on the initial state of the synapse and its recent history of activation. Because these forms of plasticity largely result from changes in the probability of transmitter release, synapses that begin with a very high probability of release tend to show depression, whereas those with a low probability of release exhibit facilitation. Consistent with this idea, activation of presynaptic receptors that cause a decrease in transmitter release almost always causes an increase in the magnitude of paired-pulse facilitation (or even a conversion of paired-pulse depression to paired-pulse facilitation).

Facilitation and Depression Following Trains of Stimuli

Longer-lasting forms of plasticity are observed following repetitive or tetanic stimulation of synapses with prolonged (approximately 200-millisecond to 5-second) trains of stimuli applied at high frequencies (10 to 200 Hz). *Augmentation* and *posttetanic potentiation* refer to enhancements of transmitter release that can last anywhere from seconds (augmentation) to several minutes (posttetanic potentiation). They are thought to result in large part to the buildup of calcium concentration in the presynaptic terminal during the trains of stimuli. This residual calcium may both combine with the calcium influx elicited by subsequent single action potentials and lead to biochemical modifications of proteins in the presynaptic terminal. At some synapses, repetitive activation leads to depression that can last for several seconds or even minutes. As in paired-pulse depression, this generally occurs at synapses that exhibit a high probability of release and is thought to result, at least in part, from a transient depletion of the synaptic vesicles that are poised to be released by an action potential.

In large part because of these short-term forms of synaptic plasticity, the strength of communication between pairs of neurons can be modified even during short bursts of presynaptic activity (e.g., five to ten action potentials at 20 to 50 Hz) (7). The functional relevance of such short-term synaptic dynamics has received much less attention than long-lasting forms of synaptic plasticity and is just beginning to be explored (8). One potential role of these short-term forms of synaptic plasticity is to transform incoming information in the temporal domain into a spatially distributed code (9 ,10). Furthermore, given that presynaptic proteins that may be involved in short-term plasticity may be abnormal in neuropsychiatric disorders (11), it is not unreasonable to speculate that abnormal short-term synaptic dynamics in specific neural circuits may contribute to the pathophysiology of any number of mental illnesses.

LONG-TERM SYNAPTIC PLASTICITY

Part of "11 - Synaptic Plasticity "

During the last decade, there was enormous interest in elucidating the mechanisms responsible for activity-dependent long-lasting modifications in synaptic strength. The great interest in this topic is largely based on the simple idea that external and internal events are represented in the brain as complex spatiotemporal patterns of neuronal activity, the properties of which result from the pattern of synaptic weights at the connections made between the neurons that are contributing to this activity. The corollary to this hypothesis is that new information is stored (i.e., memories are generated) when activity in a circuit causes a long-lasting change in the pattern of synaptic weights. This simple idea was put forth by Ramon y Cajal almost 100 years ago, but experimental support for such a process was lacking until the early 1970s, when it was demonstrated that repetitive activation of excitatory synapses in the hippocampus caused an increase in synaptic strength that could last for hours or even days (12 ,13). This long-lasting synaptic enhancement, LTP, has been the object of intense investigation because it is widely believed that LTP provides an important key to understanding the molecular mechanisms by which memories are formed (14 ,15) and, more generally, by which experience modifies behavior. Furthermore, the activity- and experience-dependent refinement of neural circuitry that occurs during development shares features with learning, and thus a role for LTP in this process has been proposed (16 ,17 and 18).

Long-Term Potentiation

No form of synaptic plasticity has generated more interest and has been more extensively studied than LTP in the CA1 region of the hippocampus. The excitement surrounding this phenomenon derives mainly from four sources. First, there is compelling evidence from studies in rodents and higher primates, including humans, that the hippocampus is a critical component of a neural system involved in various forms of long-term memory (19). Second, several properties of LTP make it an attractive cellular mechanisms for information storage (20 ,21). Like memories, LTP can be generated rapidly and is prolonged and strengthened with repetition. It is also input specific in that it is elicited at the synapses activated by afferent activity and not at adjacent synapses on the same postsynaptic cell. This feature dramatically increases the storage capacity of individual neurons

that, because synapses can be modified independently, can participate in the encoding of many different bits of information. Third, LTP is readily generated in *in vitro* preparations of the hippocampus, thus making it accessible to rigorous experimental analysis. Indeed, much of what we know about the detailed mechanisms of LTP derives from studies of LTP at excitatory synapses on CA1 pyramidal cells in hippocampal slices. Fourth, LTP has been observed at virtually every excitatory synapse in the mammalian brain that has been studied. Table 11.1 gives a list of the brain regions in which LTP has been demonstrated, and it can be seen that regions thought to be particularly important for various forms of learning and memory are prominent. Although LTP is not a unitary phenomenon, most synapses appear to express a form of LTP that is identical or highly analogous to the LTP found at excitatory synapses on CA1 pyramidal cells. Thus, this form of LTP is the focus of the remainder of this section.

Hippocampus	Amygdala

TABLE 11.1. AREAS OF BRAIN IN WHICH LTP HAS BEEN DEMONSTRATED

Triggering of LTP: A Critical Role for NMDA Receptors and Calcium

It is well established that the triggering of LTP requires synaptic activation of postsynaptic *N*-methyl-D-aspartate (NMDA) receptors, a subtype of ionotropic glutamate receptor (see Chapter 6) and postsynaptic depolarization, which is accomplished experimentally by repetitive tetanic stimulation of synapses or by directly depolarizing the cell while continuing low-frequency synaptic activation (a so-called “pairing protocol”). How do these requirements explain the properties of LTP? During basal low-frequency synaptic transmission, synaptically released glutamate binds to two different subtypes of ionotropic glutamate receptor, termed AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) and NMDA receptors, which are often, but not always (see later), co-localized on individual dendritic spines. The AMPA receptor has a channel that is permeable to monovalent cations (Na^+ and K^+), and activation of AMPA receptors provides most of the inward current that generates the excitatory synaptic response when the cell is close to its resting membrane potential (Fig. 11.1). In contrast, as described in Chapter 6 , the NMDA receptor exhibits a strong voltage dependence because of the block of its channel at negative membrane potentials by extracellular magnesium. As a result, NMDA receptors contribute little to the postsynaptic response during basal synaptic activity. However, when the cell is depolarized, magnesium dissociates from its binding site within the NMDA receptor channel and allows calcium as well as sodium to enter the dendritic spine (Fig. 11.1). The resultant rise in intracellular calcium is a necessary and perhaps sufficient trigger for LTP. This local source of calcium within the dendritic spine accounts for the input specificity of LTP.

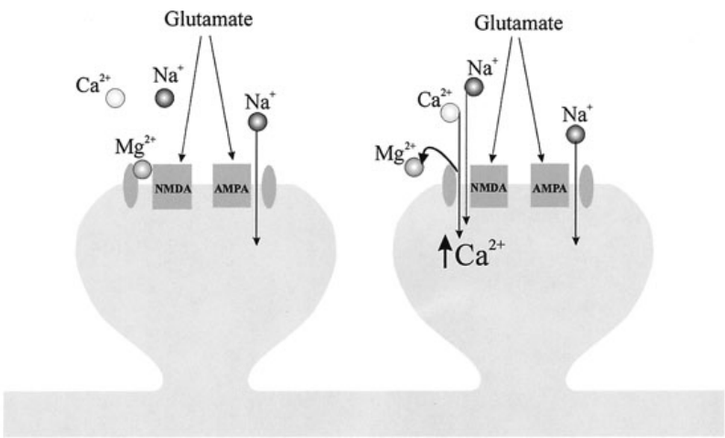

FIGURE 11.1. Model for the induction of long-term potentiation (LTP). During normal synaptic transmission (*left*), synaptically released glutamate acts on both NMDA and AMPA receptors. Na^+ flows through the AMPA receptor channel but not through the NMDA receptor channel because of the Mg^{2+} block of this channel. Depolarization of the postsynaptic cell (*right*) relieves the Mg^{2+} block of the NMDA receptor channel and allows Na^+ and Ca^{2+} to flow into the cell. The resultant rise in Ca^{2+} in the dendritic spine is a necessary trigger for the subsequent events leading to LTP.

The evidence in support of this model for the initial triggering of LTP is compelling. Specific NMDA receptor antagonists have minimal effects on basal synaptic transmission but block the generation of LTP (22 ,23). Preventing the rise in calcium by loading cells with calcium chelators blocks LTP (24 ,25), whereas directly raising intracellular calcium in the postsynaptic cell mimics LTP (25 ,26). Furthermore, imaging studies have demonstrated that NMDA receptor activation causes a large increase in calcium level within dendritic spines (see 23 for references). The exact properties of the calcium signal that is required to trigger LTP are unknown, but a transient signal lasting only 1 to 3 seconds appears to be sufficient (27). Whether additional sources of calcium, such as release from intracellular stores, are required for the generation of LTP is unclear. It is also uncertain whether additional factors provide by synaptic activity are required. Various neurotransmitters found in the hippocampus such as acetylcholine and norepinephrine can modulate the ability to trigger LTP, and such modulation

may be of great importance for the functional in vivo roles of LTP. However, there is no compelling evidence to suggest that any neurotransmitter other than glutamate is required to trigger LTP.

Signal Transduction Mechanisms in LTP

A bewildering array of signal transduction molecules has been suggested to play a role in translating the calcium signal that is required to trigger LTP into a long-lasting increase in synaptic strength (28). However, for only a few of these has compelling evidence of a mandatory role in LTP been presented. A major limitation of much of the work on this topic is that investigators have not adequately distinguished molecules that are key components of the signal transduction machinery absolutely required for LTP from biochemical processes that modulate the ability to generate LTP or play a permissive role. For example, any manipulation that modifies the activity of NMDA receptors may affect LTP. Therefore, several requirements must be met for a signaling molecule to be considered a key component of the biochemical machinery that triggers LTP. First, it must be activated or produced by stimuli that trigger LTP but not by stimuli that fail to do so. Second, inhibition of the pathway in which the molecule participates should block the generation of LTP. Third, activation of the pathway should lead to LTP.

Strong evidence indicates that calcium/calmodulin–dependent protein kinase II (CaMKII) fulfills these requirements and is a key component of the molecular machinery for LTP. Inhibiting its activity pharmacologically by directly loading postsynaptic cells with CaMKII inhibitors or genetic knockout of a critical CaMKII subunit blocks the ability to generate LTP (29 ,30 and 31). Conversely, acutely increasing the postsynaptic concentration of active CaMKII increases synaptic strength and occludes LTP (32 ,33). Furthermore, CaMKII undergoes autophosphorylation after the triggering of LTP (34 ,35). That this autophosphorylation is required for LTP was demonstrated by the finding that genetic replacement of endogenous CaMKII with a form lacking the autophosphorylation site prevented LTP (36).

Several other protein kinases have also been suggested to play roles in the triggering of LTP, but the experimental evidence supporting their role is considerably weaker than for CaMKII. Activation of the cyclic adenosine monophosphate–dependent protein kinase (PKA), perhaps by activation of a calmodulin-dependent adenylyl cyclase, has been suggested to boost the activity of CaMKII indirectly by decreasing competing protein phosphatase activity (37 ,38). This presumably happens by phosphorylation of inhibitor-1, an endogenous protein phosphatase inhibitor (see section on LTD later). Protein kinase C may play a role analogous to CaMKII, whereas the tyrosine kinases Fyn and Src may indirectly modulate LTP by affecting NMDA receptor function (see 23 for references). The mitogen-activated protein kinase (MAPK) has also been suggested to be important for LTP, albeit in unknown ways.

Expression Mechanisms and LTP

In the 1990s, tremendous confusion and controversy surrounded the seemingly simple issue of whether LTP is caused primarily by presynaptic or postsynaptic modifications. The great challenge to answering this question largely stemmed from the great technical difficulties inherent in examining the changes the occur at individual synapses that are embedded in a complex network in which each cell receives 10,000 or more synapses. Most neurobiologists studying this question agree that the simplest postsynaptic change that could cause LTP would be a change in AMPA receptor function or number, whereas the simplest presynaptic change would be an increase in the probability of neurotransmitter release.

Most studies examining this issue have used electrophysiologic assays, and most of these are inconsistent with the hypothesis that the release of glutamate increases significantly during LTP (23 ,39). For example, changes in transmitter release probability invariably influence various forms of short-term synaptic plasticity such as paired-pulse facilitation, yet these phenomena are not affected by LTP. To measure glutamate release more directly, two approaches were used. One took advantage of the finding that glial cells tightly ensheath synapses and respond to synaptically released glutamate by activation of electrogenic transporters that generate a current directly proportional to the amount of glutamate released (40 ,41). The other took advantage of use-dependent antagonists of the NMDA receptor or of a mutant AMPA receptor that lacks the GluR2 subunit. These antagonists decrease synaptic currents at a rate that is directly proportional to the probability of transmitter release (42 ,43). LTP had no discernible effect on these measures, even though they were affected in the predicted fashion by manipulations known to increase transmitter release.

In addition to these negative findings, certain electrophysiologic and biochemical measures were found to increase during LTP. An increase in the amplitude of miniature electrophysiologic synaptic currents (mEPSCs), which represent the postsynaptic response to the spontaneous release of a single quantum of neurotransmitter, normally indicates an increase in the number or function of postsynaptic neurotransmitter receptors. Such an increase occurs during LTP (44), as well as after manipulations that load dendritic spines with calcium (45 ,46). A more direct way of monitoring changes in AMPA receptors is to measure the postsynaptic response to direct application of agonist,

and such responses have also been reported to increase, albeit gradually (47).

That LTP is caused by a modification of AMPA receptors is supported by the finding that LTP causes an increase in the phosphorylation of the AMPA receptor subunit GluR1 at the site that is known to be phosphorylated by CaMKII (as well as PKC) (35 ,48 ,49). Using expression systems, this phosphorylation has been shown to increase the single-channel conductance of AMPA receptors (50). Because an increase in single-channel conductance of AMPA receptors has been reported to occur during LTP (51), one mechanism that seems likely to contribute to LTP is CaMKII-dependent phosphorylation of GluR1. Consistent with this idea, genetic knockout of GluR1 has been found to prevent the generation of LTP (52).

Silent Synapses and Quantal Synaptic Transmission

Although the evidence presented thus far makes a strong case for postsynaptic changes contributing to LTP, there remained one reproducible experimental result that was difficult to reconcile with this idea. This result derived from experiments that took advantage of the finding that the action potential-dependent release of quanta of neurotransmitter at individual synapses is probabilistic, and therefore release occurs only 10% to 40% of the time. Therefore, if a single synapse or a very small number of synapses is activated once every few seconds, on some of the trials no postsynaptic response is recorded, that is, a so-called failure occurs. An extensively replicated finding is that LTP causes a decrease in the proportion of failures that occur (see 53 for review). Because these failures were assumed to result from failures of neurotransmitter release, it was concluded that LTP involves an increase in the probability of transmitter release.

How can this result be reconciled with all the evidence suggesting that LTP is caused by modulation of AMPA receptors and is not accompanied by an increase in glutamate release? One straightforward idea to explain this apparent discrepancy is the *silent synapse hypothesis* (54), which predicts that some synapses express only NMDA receptors, whereas others express both AMPA and NMDA receptors (Fig. 11.2). Synapses with only NMDA receptors would be functionally silent at hyperpolarized membrane potentials, and thus, when transmitter is released, they would not yield a response. However, LTP at such silent synapses could occur by the rapid expression of AMPA receptors, and such a mechanism would account for the apparent change in failure rate.

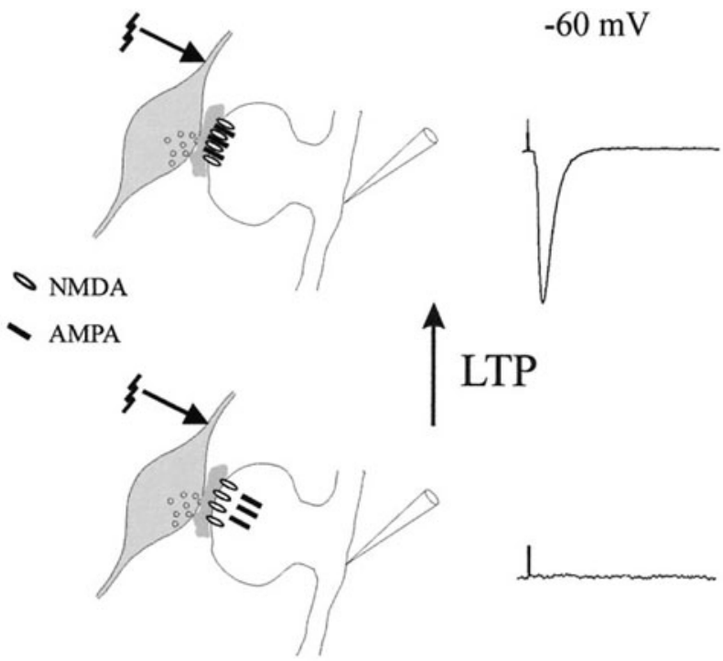

FIGURE 11.2. Diagram of the silent synapse hypothesis. A synapse is functionally silent when it expresses NMDA receptors but not AMPA receptors in its plasma membrane (bottom). **The induction of LTP causes the insertion of AMPA receptors (top)** from a putative cytosolic pool. To the right of each diagram are the synaptic currents (i.e., EPSCS) that would be recorded from the corresponding synapse.

There is now strong evidence to support this model of LTP. First, it is possible to record EPSCs that are mediated solely by NMDA receptors, and applying an LTP induction protocol at such synapses causes the rapid appearance of AMPA receptor-mediated EPSCs (55 ,56). Second, immunocytochemical analysis demonstrates that AMPA receptors are not found at a significant percentage of hippocampal synapses, whereas all synapses appear to contain NMDA receptors (see 23 for references). Third, LTP has been shown to cause the delivery of green fluorescent protein (GFP)-tagged AMPA receptors to dendritic spines and the insertion of recombinant AMPA receptors into the synaptic plasma membrane (57 ,58). Fourth, AMPA and NMDA receptors interact with different proteins at the synapse (59), a finding suggesting that they are regulated independently. Fifth, interference with membrane fusion and presumably exocytosis in the postsynaptic cells impairs LTP (60) and AMPA receptors can interact with proteins involved in membrane fusion (61). These findings are consistent with the idea that membrane fusion may be an important mechanism for the delivery of AMPA receptors to the synaptic plasma membrane.

Virtually all the data presented thus far are consistent with the simple model that LTP, at least initially, is caused by the phosphorylation of AMPA receptors and the delivery or clustering of AMPA receptors within the synaptic plasma membrane (23). These events will presumably occur both at synapses that already contain functional AMPA receptors and ones that are functionally silent. As discussed later, LTD appears to involve the converse process, that is, the removal or endocytosis of AMPA receptors. At the end of this chapter,

I discuss how these changes in the number of AMPA receptors at individual synapses may lead to more permanent structural changes, which, in turn, may mediate long-lasting forms of experience-dependent plasticity.

Long-Term Depression

Like LTP, LTD has been demonstrated in a large number of different brain regions and comes in a variety of different forms (62 ,63 and 64). This section focuses on the NMDA receptor-dependent form of LTD found at excitatory synapses on CA1 pyramidal cells and that appears to result, in large part, from a reversal of the processes that mediate LTP.

Triggering of LTD: A Critical Role for NMDA Receptors and Calcium

LTD is normally generated by prolonged (3- to 15-minute) low-frequency (1- to 5-Hz) afferent stimulation or by a pairing protocol during which the cell is held at approximately -50 mV. It shares many features with LTP including input specificity, and it can completely reverse LTP, a process often termed *depotentiation*. Surprisingly, the triggering of LTD requires NMDA receptor activation and an increase in postsynaptic calcium concentration (65 ,66). This can occur because at resting membrane potentials, the voltage-dependent block of the NMDA receptor channel by magnesium is not 100% effective, and thus, each stimulus will cause a very small amount of calcium entry. Current evidence suggests that the specific properties of the intracellular calcium signal dictate whether LTP or LTD is generated by a specific pattern of synaptic activity, with LTD requiring a modest rise in calcium (67) and LTP requiring a large rise beyond some critical threshold value (68). The temporal characteristics of this calcium signal may also be important.

Signal Transduction Mechanisms in LTD: A Role for Protein Phosphatases

If calcium is the critical triggering signal for LTD, it must be capable of activating biochemical processes that reverse LTP. Because LTP results, at least in part, from activation of protein kinases, a reasonable hypothesis is that LTD is caused by preferential activation of protein phosphatases, several of which are known to be found at excitatory synapses (69). This idea was first proposed in a theoretic article (70) that presented a specific model that accounted for the bidirectional control of synaptic strength by calcium (Fig. 11.3). It proposed that a balance between CaMKII activity and protein phosphatase 1 (PP1) influenced synaptic strength by controlling the phosphorylation state of unidentified synaptic phosphoproteins. Small rises in calcium favored activation of PP1, whereas large rises were required to increase CaMKII activity. Because PP1 is not directly influenced by calcium, a well-established calcium-dependent phosphatase cascade was invoked to translate the calcium signal into increased PP1 activity (69). This cascade (Fig. 11.3) begins with activation of the calcium/calmodulin–dependent phosphatase calcineurin (also known as protein phosphatase 2B or PP2B). PP2B then dephosphorylates inhibitor 1 (I1), a phosphoprotein that, in its phosphorylated state, is a potent inhibitor of PP1. Thus, activation

of PP2B causes an increase in PP1 activity through a mechanism of disinhibition. An attractive feature of this model is that the affinity of PP2B for calcium/calmodulin is significantly greater than that of CaMKII. Therefore, PP2B will be preferentially activated by small increases in synaptic calcium levels. Furthermore, a large rise in calcium will preferentially increase protein kinase activity not only by directly activating CaMKII but also by leading to the activation of PKA, which phosphorylates I1 and thereby further inhibits PP1.

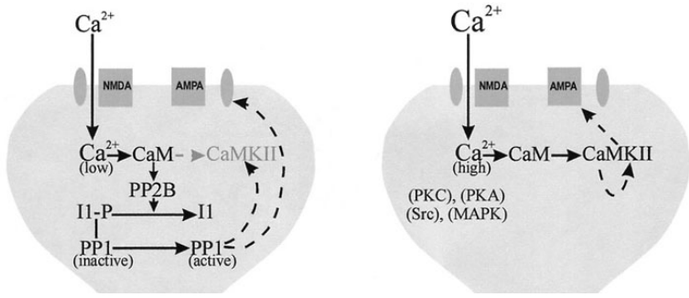

FIGURE 11.3. Model for the signaling cascades responsible for LTD and LTP. LTD is generated when a low rise in Ca^{2+} binds to calmodulin (cam) and activates calcineurin (PP2B). Calcineurin then dephosphorylates inhibitor 1 (I1), which therefore no longer inhibits protein phosphatase 1 (PP1). Active PP1 may act on any number of substrates including camkii or AMPA receptors (*left*). LTP is generated when a high rise in Ca^{2+} activates camkii. Other protein kinases that may also be involved in triggering LTP are protein kinase C (PKC), cAMP-dependent protein kinase (PKA), the tyrosine kinase src (Src), and MAP kinase (MAPK)(*right*).

Several experimental results are consistent with this model, which currently remains the leading hypothesis for the triggering of LTD. Pharmacologic inhibitors of PP1 or PP2B, when loaded directly into CA1 pyramidal cells, prevent the generation of LTD (71 ,72). Furthermore, loading cells with the phosphorylated form of I1 blocked LTD. However, although the results of such inhibitor studies are consistent with an important role for protein phosphatases in triggering LTD, other interpretations are possible, and more experimental work testing this hypothesis needs to be performed. Most notably, if PP1 plays a role in LTD analogous to that played by CaMKII in LTP, it should be possible to increase PP1 activity directly in postsynaptic cells and to mimic LTD.

Expression Mechanisms of LTD: A Role for Endocytosis of AMPA Receptors

The silent synapse hypothesis discussed earlier suggested that LTP involves the insertion of AMPA receptors into the synaptic plasma membrane. Consistent with the idea that LTD is a reversal of LTP, there is now considerable evidence that LTD involves removal (i.e., endocytosis) of synaptic AMPA receptors. The first direct evidence that the synaptic localization of AMPA receptors could be rapidly modified was the demonstration that, in cultured hippocampal neurons, short application of glutamate receptor agonists caused rapid a loss of synaptic AMPA receptors with no significant effect on the synaptic localization of NMDA receptors (73). This agonist-induced loss of synaptic AMPA receptors was subsequently shown to result from dynamin-dependent endocytosis (74). Perhaps more important, synaptically triggered LTD in the cultured neurons was accompanied by a decrease in the number of synaptic surface AMPA receptors with no discernible effect on the distribution of NMDA receptors (75). Consistent with these findings, loading CA1 pyramidal cells with inhibitors of endocytosis prevented the generation of LTD (76). These inhibitors also caused a gradual increase in the size of the synaptic responses, whereas inhibitors of exocytosis caused a gradual decrease (76). These results suggest that there is a pool of AMPA receptors that cycle into and out of the synaptic plasma membrane fairly rapidly and that LTP and LTD may involve a modification of the kinetics of these processes.

Structural Changes and Long-Term Synaptic Plasticity

How are the changes in synaptic strength that occur following the triggering of LTP or LTD maintained for periods lasting weeks or perhaps even years? Although the answer to this question is unknown, recent evidence suggests that the mechanisms described previously may be the initial steps in a more profound anatomic restructuring of synapses, including perhaps the growth of new synapses and the pruning away of preexisting ones. Dendritic spines, the postsynaptic sites that presynaptic boutons contact, have a complex ultrastructure and come in a large variety of shapes (77). With technical advances in microscopy and the use of recombinant fluorescent proteins such as GFP, it has become possible to image individual spines in living neurons. Such experiments have shown that spines are not static but can undergo rapid shape changes (78 ,79) that are influenced by activity (80). Furthermore, strong synaptic activation of the type that triggers LTP causes an NMDA receptor-dependent growth of spines as well as filopodia, which may be the precursors of spines (81 ,82). Prolonged application of NMDA to cultured neurons also can cause the loss of spines (83), a finding indicating that, like synaptic strength, the growth and loss of dendritic spines may be under the control of NMDA receptors.

Changes in synapse structure in response to activity also have been extensively explored using more standard electron microscopic techniques. One specific morphologic modification repeatedly associated with increased neuronal activity involves a reorganization of the postsynaptic density (PSD), the electron-dense thickening that contains synaptic glutamate receptors. Specifically, it has been suggested that LTP is associated with an increase in the fraction of synapses that contain discontinuities in their PSDs, termed *perforated synapses* (see 84 for references). This idea is strongly supported by studies in which the synapses activated by strong tetanic stimulation were identified in electron microscopic sections and were found to have larger total PSD surface areas and a larger proportion of perforated synapses (85 ,86). Several lines of evidence suggest that this growth of PSDs and their eventual perforation may be initiated by increasing the number of AMPA receptors in the PSD (see 84 for references).

The insertion of new AMPA receptors in the PSD and the generation of perforated synapses may also be early events in the generation of new synapses by a process of splitting or duplication of existing spines (87 ,88). Consistent with this hypothesis, LTP may be associated with an increase in spine density (84), as well as the frequency of multiple-spine synapses in which two adjacent spines arising from the same dendrite contact a single presynaptic bouton (86).

These types of observations have led to a model (Fig. 11.4) (84) that proposes a sequence of events by which the insertion of AMPA receptors leads to a growth and perforation of the PSD and eventually to multiple-spine synapses. Subsequently, retrograde communication perhaps involving cell adhesion molecules would cause appropriate presynaptic structural chances such that a completely new, independent synapse is formed. An attractive corollary to this hypothesis is that LTD involves a shrinkage of the PSD and eventually leads to a complete loss of the dendritic spine and its corresponding presynaptic bouton. However, minimal work on the structural changes associated with LTD has been performed.

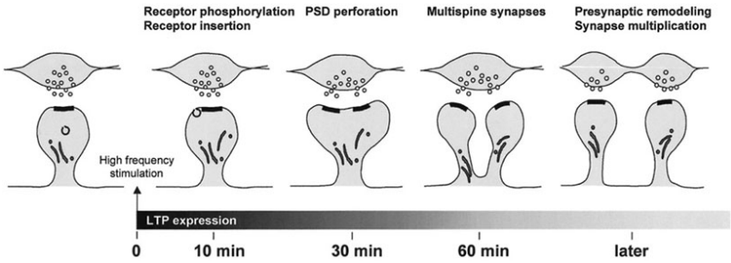

FIGURE 11.4. Model for sequence of events leading to structural changes following triggering of LTP. Within 10 minutes of LTP induction, AMPA receptors are phosphorylated and inserted into the postsynaptic membrane. This process leads to an increase in the size of the postsynaptic density (PSD) and the production of perforated synapses within 30 minutes. By 1 hour, some perforated synapses split and form multispine synapses. Eventually, retrograde communication, perhaps involving cell-adhesion molecules, leads to presynaptic structural changes and the production of new synapses.

An attractive feature of incorporating structural changes into the mechanisms of long-term synaptic plasticity is that it provides a straightforward means by which the activity generated by experience can cause very long-lasting modifications of neural circuitry. Structural changes also may explain the well-known requirement of long-lasting forms of synaptic plasticity for new protein synthesis and gene transcription (see 89 ,90 and 91 for reviews).

CONCLUSIONS

Part of "11 - Synaptic Plasticity "

This is a brief review of some of the most common forms of synaptic plasticity found at excitatory synapses throughout the mammalian brain. Although relatively little is known about the functional roles of these phenomena, such changes in synaptic function and structure remain the leading candidates for some of the fundamental mechanisms by which experiences of any type cause the reorganization of neural circuitry and thereby modify thoughts, feelings, and behavior. One hopes that it is also apparent why understanding the mechanisms of synaptic plasticity has important implications for many branches of clinical neuroscience. For example, the development of many pathologic behaviors, such as drug addiction, likely depends on the maladaptive use of neural mechanisms that normally are used for adaptive learning and memory (92). Similarly, the recovery of function following brain injury or the successful pharmacologic and behavioral treatment of mental illness also certainly must result from the reorganization of neural circuitry that is in part achieved by synaptic plasticity mechanisms. Thus further elucidation of the mechanisms of phenomena such as LTP and LTD will continue to have implications for all those interested in the neural basis of cognition and behavior.

Gaba

Richard W. Olsen

Richard W. Olsen: Department of Molecular and Medical Pharmacology, University of California Los Angeles School of Medicine, Los Angeles, California.

GABA IS THE MAJOR INHIBITORY NEUROTRANSMITTER IN THE NERVOUS SYSTEM

Part of "12 - Gaba "

Several amino acids are found in high concentrations in brain, and some have been established as neurotransmitters. *L-Glutamic acid (glutamate)* is the major neurotransmitter for fast excitatory synaptic transmission, whereas *γ-aminobutyric acid (GABA)* is the major neurotransmitter for fast inhibitory synaptic transmission. Glycine is a secondary rapid inhibitory neurotransmitter, especially in the spinal cord (1 ,2). Because of the widespread presence and utilization of glutamate and GABA as transmitters, one could say that they are involved in all functions of the central nervous system (CNS), as well as in all diseases. At any point in the CNS, one is either at a cell that uses or responds to glutamate and GABA or no more than one cell removed. Many clinical conditions including psychiatric disorders appear to involve an imbalance in excitation and inhibition, and therapeutics thus involve attempts to restore the balance. The GABA system is the target of a wide range of drugs active on the CNS, including anxiolytics, sedative-hypnotics, general anesthetics, and anticonvulsants (3). See the chapters on GABA in previous editions of this book (1 ,4).

Since its discovery in the CNS in the early 1950s (5 ,6), GABA was shown to fulfill the criteria for establishment as a neurotransmitter (Fig. 12.1). It is synthesized by a specific enzyme, L-glutamic acid decarboxylase (GAD), in one step from L-glutamate. Thus, in addition to its role in protein synthesis, in cofactors such as folic acid and in hormones such as thyrotropin-releasing hormone, and its action as a neurotransmitter itself, glutamate must be available in certain nerve endings for biosynthesis of GABA. Much of the glutamate and GABA used as neurotransmitter is derived from glial storage pools of glutamine (2 ,6). Two genes for GAD have been cloned, and the two forms of the enzyme are proposed to differ in their affinity for the cofactor pyridoxal phosphate and the subcellular localization (7). GABA was shown to be released from electrically stimulated inhibitory nerve cells (8), and a mechanism of rapid removal from the synaptic release site was demonstrated by identification of high-affinity transporter proteins (9 ,10). The application of GABA and structural analogues to cells innervated by GABAergic neurons produces effects on that target cell identical to those produced by stimulating the inhibitory innervation (11).

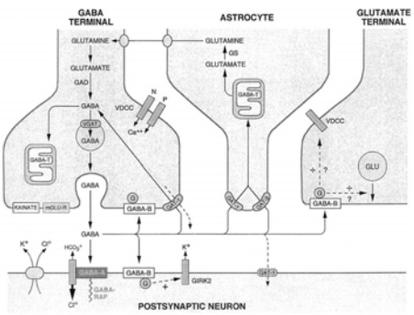

FIGURE 12.1. Schematic GABA synapse. Diagram showing the main features of the GABA synapse. Transporters are indicated by oval symbols, receptors and ion channels by rectangular symbols. **A:** Transporters: GAT-1, GAT-3, plasma membrane GABA transporters; VGAT, vesicular GABA transporter. **B:** Receptors: GABA-A, ionotropic GABA receptor; GABA-B, G-protein–coupled GABA receptor; KAINATE, presynaptic kainate receptor; MGLUR, metabotropic glutamate receptor. **C:** Ion channels: GIRK2, G-protein–coupled inwardly rectifying K^+ channel; VDCC: voltage-dependent calcium channel. **D:** Enzymes: GABA-T, GABA transaminase; GAD, glutamic acid decarboxylase; GS, glutamate synthetase. (Courtesy of O.P. Ottersen; design G. Lothe.)

PHYSIOLOGY AND PHARMACOLOGY OF $GABA_A$, $GABA_B$, AND $GABA_C$ RECEPTORS

Part of "12 - Gaba "

GABA-mediated synaptic inhibition involves rapid, less than 100-millisecond, inhibitory postsynaptic potentials and slower, more than 100-millisecond, inhibitory postsynaptic potentials. The former were shown by voltage clamp to involve increased chloride ion permeability and to be blocked by the plant convulsant drug picrotoxin, as seen with GABA action in invertebrates, such as crayfish muscle and nerve preparations (12). The rapid chloride current defined a physiologic receptor mechanism termed the *$GABA_A$receptor*, also pharmacologically defined by the antagonist bicuculline, as well as picrotoxin, and the agonist muscimol (Fig. 12.2). Thus, the $GABA_A$ receptor is a chloride channel regulated by GABA binding, and it is now grouped in the superfamily of ligand-gated ion channel receptors, which includes the well-characterized nicotinic acetylcholine receptor, present at the skeletal neuromuscular junction (13 ,14).

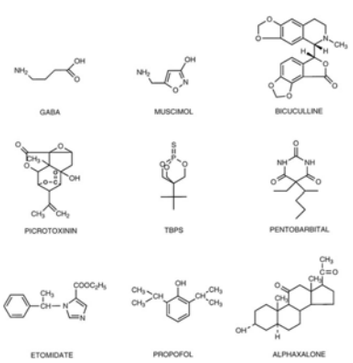

FIGURE 12.2. Chemical structures of $GABA_A$ receptor drugs.

Chloride channel gating is generally inhibitory on a neuron by virtue of stabilizing the membrane potential near the resting level. However, under conditions of high intracellular chloride, for example, in immature neurons with low capacity to maintain a chloride gradient, increasing chloride permeability can depolarize the membrane potential. This depolarization could be sufficient to fire the cell, and it would be likely to activate certain voltage-gated ion channels, including calcium, that can, in turn, regulate other cellular events. Variable permeability to bicarbonate ions for some subtypes of $GABA_A$ receptor (GABAR) could

also play a role in depolarization (15). Such depolarizing GABAR action has been proposed as an important excitatory system in developing brain (16), and it may explain the well-known trophic action of GABA to promote both survival and differentiation during development (17).

The slow inhibitory polysynaptic potentials were shown to be insensitive to $GABA_A$ drugs such as bicuculline, but to be activated by ß-chlorophenyl GABA (the antispastic drug baclofen) and to be mediated by a G-protein–coupled receptor that increases potassium conductance (18), now called the $GABA_B$ receptor. A further inhibitory GABA response was observed in some cells to be "non-A, non-B," neither bicuculline nor baclofen sensitive and sometimes called $GABA_C$ (19), and generally sensitive to the GABA analogue *cis*-aminocrotonic acid. $GABA_C$–type inhibition was shown to involve a rapid chloride conductance, as with $GABA_A$ receptors; however, it was not only insensitive to bicuculline, but also not modified by other $GABA_A$ drugs, such as benzodiazepines and anesthetics (19). The eventual cloning of a retinal-specific subunit cDNA ρ that produced bicuculline-insensitive GABA chloride channels appeared to account for $GABA_C$ receptors (20). However, because of the structural and functional homology with $GABA_A$ receptors, the International Union of Pharmacology subcommittee on nomenclature recommended that these ρ receptors not be called $GABA_C$ receptors, but rather a subtype of pharmacologically unique $GABA_A$ receptors (21).

$GABA_B$ receptors were shown to mediate presynaptic inhibition on some nerve endings and postsynaptic inhibition on some cell bodies or dendrites. The coupling mechanism depends on the cell location, because several G-protein–coupled effectors can be used, involving negative modulation of adenylate kinase and negative modulation of inositol tris phosphate production. These lead to activation of potassium channels or inhibition of voltage-gated calcium channels (22). Presynaptic inhibition of GABA release

by GABA involves $GABA_B$ autoreceptors, and their activation would be overall excitatory, as opposed to inhibition of glutamate release, which would be overall inhibitory. Considerable effort was therefore expended to determine whether different $GABA_B$ receptors could mediate these very different functions, possibly allowing the development of receptor subtype-specific drugs. Although some classic pharmacology studies supported this hypothesis (18, 22), it was the long-awaited cloning of the $GABA_B$ receptor (23) that established the true situation. The first receptor exists as two splice variants, and additional clones for $GABA_B$ receptor subtype genes have been isolated. Surprisingly, the $GABA_B$ receptors appear to exist as heterodimers, previously unknown for G-protein–coupled receptors. The dimers produce the diverse pharmacologic specificity for the GABA site and the diverse coupling mechanisms observed in nature (24). It seems that the pharmacology of $GABA_B$ receptors is in a very promising infancy.

STRUCTURE AND FUNCTION OF $GABA_A$ RECEPTORS

Part of "12 - Gaba "

The GABARs are the major players in CNS function and relevance to psychopharmacology. These receptors, defined by pharmacologists using electrophysiologic and other techniques (14 ,22), were identified in brain homogenates by radioligand binding (25), and are shown to have the correct specificity for GABA analogues expected from the neuropharmacology (26 ,27). The GABAR protein (Fig. 12.3) also contains binding sites for benzodiazepines, picrotoxin, barbiturates, and other anesthetics, all of which allosterically interact with each other (28). One or more polypeptides of 45 to 60 kd on sodium dodecylsulfate–polyacrylamide gel

electrophoresis were identified in brain homogenates as constituents of the GABAR by photoaffinity labeling with the radioactive benzodiazepine flunitrazepam (29 ,30), and monoclonal antibodies were developed to the partially purified bovine receptor, which recognized the photolabeled peptides using Western blotting (31).

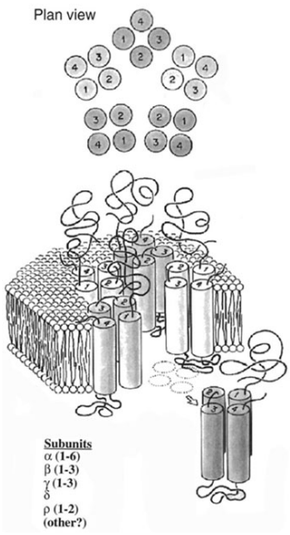

FIGURE 12.3. Schematic $GABA_a$ receptor structure. The chloride channel is shown as a pore in the center of five equivalent subunits, each with four membrane-spanning domains (see the isolated subunit at the **bottom**). Because of the existence of subunit families, many such heteropentamer combinations are possible, each with multiple drug sites. Ligand sites: GABA: agonists (muscimol), antagonists (bicuculline); Benzodiazepine: agonists (flunitrazepam), antagonists (flumazenil), inverse agonists (DMCM); Picrotoxin/Convulsant (TBPS); Barbituate (phenobarbitol); Steroid (alphaxalone, allopregnanolone); Volatile Anesthetic (halothane). (Modified from Olsen RW, Tobin AJ. Molecular biology of $GABA_A$ receptors. *FASEB J* 1990;4:1469–1480, with permission.)

The GABAR proteins were purified using benzodiazepine affinity chromatography (32), which allowed partial protein sequencing and expression cloning of two receptor genes (13). GABA-activated currents were demonstrated in *Xenopus* oocytes using cDNAs for two polypeptides that contained the partial sequences within their coded sequence, and these were designated α and ß. At first, these were thought (incorrectly) to correspond to the two bands seen in the purified protein (32). These two subunits were related to each other and also to the nicotinic acetylcholine receptor family of subunits, a finding indicating a superfamily of receptor polypeptide genes and a likely heteropentameric structure (Fig. 12.3) (13 ,14). These two cDNAs were used as probes to clone additional family members with more or less sequence homology to the first two. Those with high homology were named with the same Greek letter, whereas those with less homology were given other Greek letters. The current repertoire involves α1 to 6, ß1 to 3, γ1 to 3, δ, ε, θ, π, and ρ1 to 3 (21). There are also a few splice variants; for example, γ2 exists in two forms differing in an eight-amino acid insert in the intracellular loop that includes a substrate serine for protein kinase C (33). All the subunits are related to each other and have molecular weights of about 50 kd. The purified receptor protein thus actually contains about a dozen subunit polypeptides, of varying amount (6). Hydropathy plots show that they have a long extracellular N-terminal domain, which has glycosylation sites and is believed to carry the GABA binding site. They have four membrane-spanning domains (M1 to M4) of about 25 residues each, a long intracellular loop between M3 and M4, and a short extracellular C-terminal tail. These subunits are arranged as heteropentamers (Fig. 12.3), several of which are common in nature, but whose expression varies with both age and brain region. The different receptor subtypes have biological differences, such as location, affinity for GABA, and channel properties, as well as pharmacologic heterogeneity. Most receptors contain two copies of one type of α subunit, two copies of one type of ß subunit, and a γ subunit. Rarely, another subunit (δ, ε, θ) can substitute for γ (30 ,33). The presence of a γ subunit is needed for benzodiazepine sensitivity, and other subunits affect the detailed specificity. For example, the α subunits define the benzodiazepine pharmacology, and some subunits α4 and α6 do not bind classic benzodiazepine agonists; the detailed pharmacology depends on the small differences in polypeptide sequence for the various subunits (6 ,34 ,35 and 36). Because of the unique location of receptor subtypes, and thus unique functions of the circuits involved, great hope for new drugs of improved pharmacologic profile has been expressed. The GABAR strategy has certainly not been exhausted.

$GABA_A$ RECEPTORS ARE THE SITES OF ACTION OF BENZODIAZEPINES AND BARBITURATES

Part of "12 - Gaba "

The actions of several classes of CNS depressant drugs had for some time been suggested to involve enhancement of inhibitory synaptic transmission. In particular, the anxiolytic effects of benzodiazepines were shown probably to result from potentiation of GABA action (37 ,38). When the benzodiazepine receptors were discovered using radioligand binding to brain homogenates (1 ,4 ,39 ,40), it was quickly determined that the benzodiazepine binding sites were physically present on the $GABA_A$ receptor–chloride channel complex (28 ,41). The various types of drug binding site on the $GABA_A$ receptor allosterically interact with each other in the test tube. Barbiturates and related sedatives also enhance $GABA_A$ receptor–mediated inhibition, and their pharmacologic spectrum overlaps with that of the benzodiazepines and related substances, such as zolpidem, zopiclone, and abecarnil (Fig. 12.4). The selective actions of benzodiazepines not shown by barbiturates or vice versa are believed to arise from heterogeneity in GABA receptor sensitivity to the drugs, and corresponding heterogeneity in brain regions, circuits, and functions. Further, some GABARs are insensitive to benzodiazepines but not to barbiturates, as well as additional nonoverlapping, nonGABA actions of high doses, especially barbiturates. In addition, the two classes of drugs have a different mechanism of action at the molecular channel level; barbiturates prolong the lifetime of GABA currents, in addition to gating channels directly at high concentrations, whereas benzodiazepines increase the frequency of opening of GABAR channels and do not directly open channels in the absence of GABA (3 ,42).

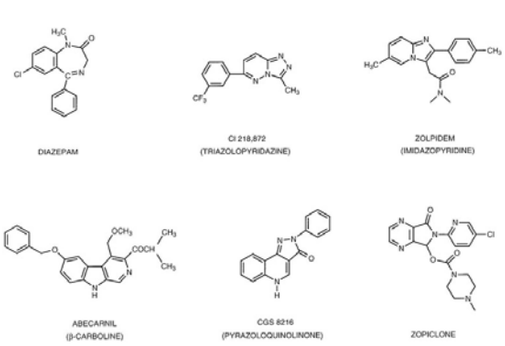

FIGURE 12.4. Chemical structures of drugs active at the benzodiazepine site on the $GABA_A$ receptor–chloride channel complex.

The classical benzodiazepines such as diazepam (Valium) have had a tremendous history in psychopharmacology, reaching tremendous sales, primarily for clinical anxiety (38 ,43 ,44 and 45). Other uses of benzodiazepines include sedation, muscle relaxation, and a significant utilization for treatment of panic (1 ,45). Various structural analogues were developed by numerous firms, with slight variations in pharmacokinetics and other details, and quite a few nonbenzodiazepine structures were discovered that act at the benzodiazepine site on the GABAR to enhance GABA-mediated inhibition (Fig. 12.4) (46). This group includes compounds called ß-carbolines, some of which were isolated from biological tissues (47). However, neither the ß-carbolines nor any peptides have been demonstrated to act as biological ligands at benzodiazepine receptor sites (45). Surprisingly, some ß-carbolines, and indeed, benzodiazepines and other types of chemical structures active on the benzodiazepine site, were found to have the opposite pharmacologic efficacy as classic benzodiazepine ligands such as diazepam; that is, they are anxiogenic and proconvulsant in animals and inhibit GABAR function in cells, while binding to the same sites as agonist benzodiazepine site ligands. These compounds were given the name *inverse agonists* (48 ,49).

Given this spectrum of efficacy, it would be expected that compounds with true antagonist efficacy would exist, and these were found, for example, Ro15-1788, or flumazenil (50). This compound does not affect GABAR function on its own, but it blocks the actions of both agonists to enhance GABAR function and inverse agonists to inhibit GABAR function. In animals, it also reverses the pharmacologic actions of both agonists and inverse agonists (50). Thus, an antagonist can be used to treat overdose of agonist, or inverse agonist, and it triggers withdrawal in individuals treated on a long-term basis with agonists (45 ,51). Flumazenil administration to rats after long-term administration of diazepam was found to reverse tolerance rapidly and permanently, and treated animals showed no long-lasting effects but resembled treatment-naive animals (52 ,53). This finding suggested that benzodiazepine antagonists may be useful in reversing benzodiazepine dependence and also potentially for other GABAR drugs, such as ethanol. This has not proved effective so far, however (43 ,45).

Certain benzodiazepines have considerable success in the treatment of some types of epilepsy (38). Every emergency medical cart contains injectable benzodiazepine (diazepam, clonazepam, lorazepam) for convulsions and status epilepticus. However, long-term therapy of epilepsy with benzodiazepines is often prevented by the development of tolerance to the anticonvulsant actions, without change in blood levels (54). The development of tolerance to long-term administration of benzodiazepines, and also of withdrawal signs (43 ,45 ,55), is consistent with the development of psychological and physical dependence with these drugs. The potential for abuse with CNS depressant drugs in general and benzodiazepines in particular is well known, as is the interaction with ethanol. This has led to a considerable drop in prescriptions of these agents for routine anxiety. Because the danger of fatal overdose with benzodiazepines is lower than that of ethanol and barbiturates, and because withdrawal symptoms are less dangerous for benzodiazepines than for alcohol, benzodiazepines reached considerable popularity in treatment of alcoholism. However, the two drugs show cross-tolerance and cross-dependence, so substitution of benzodiazepines for ethanol is merely substituting one addiction for another (55).

Conversely, an interesting observation was made with the benzodiazepine partial inverse agonist Ro15-4513. This compound was found to antagonize the behavioral effects of ethanol (49), as well as the *in vitro* action of ethanol to enhance GABAR function (56). (Ethanol and GABA are discussed further later.) Moreover, the action of Ro15-4513 to antagonize ethanol occurred under conditions of assay, such as behavior, tissue, or species, in which Ro15-4513 itself did not exhibit inverse agonist activity or inhibit GABAR function, nor did it reverse the actions of pentobarbital (56 ,57 ,58 and 59). Thus, this compound or one like it had potential as an “alcohol antidote” in humans, by reducing intoxication and perhaps withdrawal and craving. Unfortunately, the ethical decisions involved in prescribing such a drug were made moot by discovery that Ro15-4513 was tremorigenic and proconvulsant in nonhuman primates, as well as other animals (60).

Understanding the mechanism of tolerance development has been a research topic of high interest, especially for epilepsy treatment, but also because of the relevance to brain plasticity. Whereas long-term administration of benzodiazepines may produce tolerance in part by down-regulation of receptor levels, considerable evidence suggests that receptors are not removed, but rather are altered in some way to produce tolerance (61 ,62 ,63 and 64). Besides tolerance development to long-term use of agonist benzodiazepines, sensitization to the actions of inverse agonists is observed; that is, excitatory benzodiazepine receptor ligands become more efficacious (65). This may resemble the kindling process seen with long-term administration of inverse agonists; that is, repeated administration of nonconvulsant doses of inverse agonists eventually leads to convulsions to that dose. This resembles the electrical kindling model of epilepsy, in which repeated electrical stimuli with nonconvulsive amplitude eventually evoke a seizure (66). Thus, long-term administration of benzodiazepine agonists or inverse agonists may shift the set point of the GABAR toward the excitatory or lower functional end of the spectrum (65 ,67). Dependence on benzodiazepines and alcohol resulting from long-term administration (abuse) may be exacerbated by a kindling-like development of increased severity of withdrawal symptoms, with an increased risk of relapse (68). Another aspect of the tolerance model is the possibility of replacing one type of GABAR subunit with another that still responds to GABA

but not to the chronically administered modulatory drug (69 ,70).

$GABA_A$ RECEPTORS ARE THE TARGETS OF ALCOHOL, GENERAL ANESTHETICS, AND NEUROSTEROIDS

Part of "12 - Gaba "

Alcohols are CNS depressants with a pharmacologic spectrum of action overlapping those of the benzodiazepines and barbiturates, known to act by enhancement of GABAR. Long-chain alcohols have anesthetic activity, as does ethanol at high doses (greater than 100 mM), whereas the intoxicating effects at lower concentrations (10 to 100 mM) have been suggested to involve blockade of *N*-methyl-D-aspartate (NMDA)–type glutamate receptors (71) or enhancement of GABAR (72 ,73 and 74). Because the latter effect varies considerably among, for example, laboratories, preparations, assays, and brain regions, unique ethanol-sensitive subtypes of GABAR were suggested, but they have not been established. Alternatively, and most popular currently, is the hypothesis that ethanol acts on GABAR indirectly to produce important aspects of its pharmacologic actions in cells and in animals (75). For example, ethanol may interact with membrane signaling proteins that regulate GABAR and NMDA receptors.

$GABA_A$ receptor function appears to be modulated by an endogenous substance: not a benzodiazepine-like or a picrotoxin-like peptide, but a barbiturate-like steroid. The neurosteroids are endogenous steroid hormone metabolites that have direct and rapid actions on cells not involving steroid hormone receptors or regulation of gene expression. Progesterone was shown to produce rapid sedative activity, a finding that led to the development of the clinical intravenous steroid anesthetic, alphaxalone. Progesterone has anxiolytic and anticonvulsant activity; discontinuation after long-term administration leads to withdrawal signs that are clearly CNS mediated: these actions are mediated by the progesterone metabolite, produced primarily in the adrenals but to some extent in brain, 3α-hydroxy-5-α-pregnane-20-one (76 ,77 and 78). The neuroactive steroids act principally by binding directly to membrane $GABA_A$ receptors and enhancing their function in a manner resembling the barbiturates (79 ,80).

Many related steroid compounds have been developed as lead compounds for potential use as antiepileptics, anxiolytics, and sedative-hypnotics (81). Whether these compounds are biologically relevant is uncertain, but this is suggested by considerable evidence. Endogenous steroids reach levels sufficient to modulate $GABA_A$ receptors during conditions of stress and anxiety, and during pregnancy (82 ,83). These compounds are probably involved in CNS plasticity responses to chronic stress and possibly epileptogenesis, and even drug dependence (84 ,85). The progesterone metabolite is the endogenous steroid that appears to be the most likely to be biologically relevant, but metabolites of testosterone and cortisone are also active (77 ,81). Pregnenolone sulfate, a biosynthetic intermediate in the synthesis of all the steroid hormones, present in high levels in the CNS, has weak activity as an antagonist of GABA function, but this appears to involve another mechanism and is unlikely to be biological (85). Neurosteroid action apparently has relevance to alcohol action. GABA-active steroids can substitute for ethanol in discriminative stimulus testing in rats and monkeys, and neurosteroids are synthesized in brain in response to ethanol administration and may mediate some of the pharmacologic actions (86). The neurosteroid-GABA connection potentially may be fruitful for new applications in psychopharmacology. As the endogenous functions of neurosteroids in stress control, seizure protection, attention and learning, and possibly even sleep, become better delineated, additional therapeutic approaches may arise.

Enhancement of $GABA_A$ receptor-mediated inhibition is currently the major candidate molecular mechanism for a generalized theory of general anesthesia. Everyone agrees that the anesthetic action of the steroid alphaxalone occurs by enhancement of GABAR (84 ,85), and many investigators believe that the actions of high-dose ethanol and other alcohols as anesthetics probably do also (75 ,87). Further, the sedative-hypnotic effects, and possibly anesthetic effects, of barbiturates and related drugs are considered to act through GABAR (88). Anesthetics are now believed to have a greater effect on membrane ion channels than on many other biological systems and to affect synaptic transmission more potently than nerve conduction. Ligand-gated ion channels, especially receptors for glutamate, glycine, and GABA, are most sensitive (89). All general anesthetics enhance GABA function at anesthetic concentrations (36 ,75). The ketamine-phencyclidine category of dissociative anesthetics enhances some GABA synapses, but these agents probably inhibit NMDA receptors more potently; further, they produce a different sort of anesthesia (90).

The *Meyer-Overton hypothesis* shows a high correlation for many drugs with respect to potency as a general anesthetic and partition in an oil-water biphasic system. The Meyer-Overton correlation has been found wanting, because of the existence of compounds with identical lipid solubility (oil-water partition coefficient), boiling point, and dipole moment, such as halogenated cyclobutane isomers, that differ in anesthetic potency: only the anesthetic isomers enhance $GABA_A$ receptors (91). Volatile anesthetics and alcohols (87), as well as intravenous agents such as barbiturates, propofol, neuroactive steroids, and etomidate, are all able at anesthetic concentrations to modulate $GABA_A$ receptor binding assays *in vitro* as well as to enhance $GABA_A$ receptor function in cells (36 ,88).

$GABA_A$ RECEPTORS ARE THE TARGETS OF MANY CNS EXCITANTS

Part of "12 - Gaba "

Many naturally occurring and synthetic convulsive agents are blockers of GABA-mediated inhibition (46). The prototypic $GABA_A$ channel blocker picrotoxinin (Fig. 12.2) is isolated from plants of the moonseed family, Menispermaceae, and its close relatives tutin and coriamyrtin, from the New Zealand tutu plant *Coriaria arborea* (92), known as a loco weed, which causes occasional poisonings in cows and even in people. A major category of synthetic potent neurotoxic chemicals (93), comprising the cage convulsants, was discovered to consist of noncompetitive $GABA_A$ receptor antagonists acting at the picrotoxinin site (93 ,94 and 95). One of these drugs, *t*-butyl bicylcophosphorothionate (Fig. 12.2), is a major research tool used to assay GABA receptors by radioligand binding (96). Synthetic butyrolactones with depressant and excitatory actions have also been described for the picrotoxinin site (97). In addition, this drug target appears to be the site of action of the experimental convulsant pentylenetetrazol (PTZ) and numerous polychlorinated hydrocarbon insecticides, including dieldrin, α-endosulfan, and lindane (93). The monoterpenoid thujone is the active constituent of oil of wormwood, the major ingredient of the famous green liqueur, absinthe, outlawed in about 1910. Absinthe was reputed to have hallucinogenic action and to be an inspiration for *fin de siècle* French artists and poets (92). Oil of wormwood has a history as a medicinal herb for treating intestinal worms and killing insects, and thujone is known to cause convulsions in high doses; thujone was demonstrated to be a $GABA_A$ receptor channel blocker like picrotoxinin (98). It remains anecdotal whether thujone/wormwood/absinthe produces psychic actions additional to those of the ethanol in the liqueur.

GABA-blocking agents thus have potential pharmacologic utility as excitants. Although at one time listed in the *Merck Index* and in pharmacology textbooks as a "barbiturate overdose antidote," picrotoxin is too dangerous as a convulsant to attempt to find an appropriate dose in the clinic. PTZ and related agents are known to show anxiogenesis in low doses, but also proabsence seizures. An alerting, attention-activation mechanism may figure to promote learning and memory in certain tasks, that is, nootropism. Partial inverse agonists at the benzodiazepine site, such as Ro15-4513, have been considered as candidates for memory enhancement (38 ,99), as well as for actions as antagonists and possible anticraving, antiwithdrawal agents for the treatment of addiction to benzodiazepines, alcohol, and many other drugs of abuse, as discussed earlier (1 ,60 ,69).

GENETIC ENGINEERING AND PSYCHOPHARMACOLOGY

Part of "12 - Gaba "

Gene targeting and transgenic mice have demonstrated several important roles for GABA in the CNS. Knockouts of both GAD67 and $GABA_A$ receptor subunit ß3 lead to cleft palate and early neonatal lethality (100 ,101 and 102). GAD65 knockout mice show increased anxiety, increased sensitivity to benzodiazepines, and impaired developmental plasticity in the cortex (103 ,104). Epilepsy results from knockout of GAD65, GABAR ß3, and GABAR δ subunit. Other phenotypic deficits include motor incoordination, movement disorders, cognitive defects, and other CNS circuitry problems resulting from lack of inhibitory synaptic transmission. In particular, the GABAR ß3 subunit is implicated in the human genetic disease Angelman syndrome, associated with mutation in maternal chromosome 15q and typified by severe mental retardation, epilepsy, motor incoordination, and sleep disorder (105). Mice targeted for this subunit have a phenotype remarkably similar to Angelman syndrome, especially the epilepsy, but also including the cognitive, motor, and sleep impairment (106).

The γ2 subunit knockout shows early neonatal lethality (107), without cleft palate, involving impaired clustering of $GABA_A$ receptors at synapses (108). Even heterozygotes, with presumably a partial deficit of γ2-containing GABAR, have impaired synapses and overanxious and paranoid behavior (109). Because GABARs are important drug targets, some GABAR subunit knockout mice have impaired sensitivity to drugs, such as decreased response to benzodiazepines in γ2 homozygous knockouts (107). Increased response to benzodiazepines is seen in γ2 heterozygous knockouts or in γ2L null mutants (109, 110). Reduced sensitivity to anesthetics was seen in ß3 but not α6 knockouts (102), and reduced sensitivity to neuroactive steroids is observed in the δ subunit knockout (111). This finding may be interesting in light of the apparent biological role of the neurosteroids in normal CNS. Gene targeting in mice also has been employed to "knock in" a mutation of the α1 subunit H101N, which prevents benzodiazepine binding to GABAR containing this subunit (112). The resulting animals have greatly impaired sensitivity to the sedative but not the anxiolytic actions of the benzodiazepines, whereas anticonvulsant activity is partially reduced. This finding indicates that the subtypes of GABAR containing the α1 subunit and the brain circuits in which they function are the substrates for benzodiazepine-stimulated sedation, whereas other GABARs, containing α2, α3, and α5, with α2 the most abundant and the major candidate, subserve specifically the role of GABARs in anxiety pathways sensitive to benzodiazepine therapy. (The observations of Rudolph et al., 1999 (112) were verified by McKernan et al., 2000 (113) for the role of the α1 subunit in the sedative actions of benzodiazepines, and extended by Low et al., 2000 (114) for the role of the α2 subunit in the anxiolytic actions of benzodiazepines.) Thus, new biotechnology applied to drug development is continuing to make new advances in psychopharmacology based on this now relatively "old" or at least well-known neurotransmitter system, GABA.

Substance P and Related Tachykinins

Nadia M.J. Rupniak

Mark S. Kramer

Nadia M.J. Rupniak: Department of Pharmacology, Merck Sharp & Dohme, Harlow, Essex, United Kingdom.

M.S. Kramer: Department of Clinical Neuroscience, Merck & Co., West Point, PA; University of Pennsylvania, Philadelphia, Pennsylvania.

Substance P belongs to a family of neuropeptides known as tachykinins that share the common C-terminal sequence: Phe-X-Gly-Leu-Met-NH2. The three most common tachykinins are substance P, neurokinin A (NKA), and neurokinin B (NKB); their biologic actions are mediated through specific cell-surface receptors designated NK_1, NK_2, and NK_3, with substance P the preferred agonist for NK_1 receptors, NKA for NK_2 receptors, and NKB for NK_3 receptors.

Preclinical studies with substance P antagonists have been complicated not only by phylogenetic differences in central nervous system (CNS) localization of tachykinin receptors, but also by species variants in NK_1 receptor pharmacology. This situation greatly complicates preclinical evaluation of selective substance P receptor antagonists because most of these have only low affinity for the rat receptor, which is the most commonly used preclinical species. Substance P and the NK_1 receptor have a widespread distribution in the brain and are found in brain regions that regulate emotion (e.g., amygdala, periaqueductal gray, hypothalamus). They are also found in close association with 5-hydroxytryptamine (5-HT) and norepinephrine-containing neurons that are targeted by the currently used antidepressant drugs.

The effects of substance P antagonists in preclinical assays for analgesic, antiemetic, antipsychotic, anxiolytic, and antidepressant drugs is reviewed. The process of elucidating the clinical uses of substance P antagonists raises certain fundamental issues that will apply to other novel neurotransmitter ligands in future. The difficulty of predicting clinical efficacy from preclinical data, and of testing novel therapeutic drugs in patients with psychiatric disorders, is discussed.

Substance P, NKA, and NKB are related neuropeptides that are widely distributed in the peripheral nervous system and the CNS. With the development of selective nonpeptide receptor antagonists, it has become possible to investigate the physiologic roles of these peptides and to explore their use as novel treatments for neurologic and psychiatric disorders. Because the substance P–preferring NK_1 receptor is the predominant tachykinin receptor expressed in the human brain, most compounds that have been developed for clinical use are substance P–preferring (NK_1) receptor antagonists.

TACHYKININ FAMILY OF PEPTIDES

Part of "13 - Substance P and Related Tachykinins "

Substance P belongs to a family of neuropeptides known as tachykinins that share the common C-terminal sequence: Phe-X-Gly-Leu-Met-NH_2. Two other mammalian tachykinins are NKA and NKB (Table 13.1). Their biologic actions are mediated through specific G-protein–coupled neurokinin receptors designated NK_1, NK_2, and NK_3, with substance P the preferred agonist for NK_1 receptors, NKA for NK_2 receptors, and NKB for NK_3 receptors. However, the receptor selectivity of these peptides is relatively poor, and it is possible that their actions could be mediated by activation of their less preferred receptors. Indeed, this possibility is suggested by the mismatch between tachykinin-containing neurons and fibers and their corresponding receptor that is seen in certain brain regions. This is particularly apparent in the case of NKA, because NK_2 receptor expression appears to be extremely low in the adult mammalian brain (1).

Substance P	Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-MetNH_2
Neurokinin A	His-Lys-Thr-Asp-Ser-Phe-Val-Gly-Leu-MetNH_2
Neurokinin B	Asp-Met-His-Asp-Phe-Phe-Val-Gly-Leu-MetNH_2

TABLE 13.1. MAMMALIAN TACHYKININS

Substance P was originally discovered in 1931 by von Euler and Gaddum as a tissue extract that caused intestinal contraction *in vitro;* its biologic actions and tissue distribution were further investigated over subsequent decades. NKA (previously known as substance K or neuromedin L) and NKB (originally known as neuromedin K), were isolated from porcine spinal cord in 1983 and were also found to stimulate intestinal contraction (2). Substance P and NKA are produced from a polyprotein precursor after differential splicing of a single precursor gene, preprotachykinin

A (3). NKB is produced from a distinct precursor protein encoded by preprotachykinin B (4).

The existence of several neurokinin receptors was originally suggested by the differential contractile responses elicited in various tissues by mammalian and nonmammalian tachykinins (5). Subsequently, specific binding sites labeled by Bolton Hunter substance P, NKA, and eledoisin were identified in the CNS (6), a finding suggesting that at least three receptors mediated the actions of tachykinins. This was confirmed by cloning of three distinct functional cDNA constructs corresponding to NK_1, NK_2, and NK_3 receptor, which preferentially bound substance P, NKA, and NKB, respectively (7 ,8 and 9). However, the endogenous neurokinins exhibit a high degree of cross-reactivity with these tachykinin receptors.

SPECIES DIFFERENCES IN THE DISTRIBUTION OF NEUROKININS AND THEIR RECEPTORS IN THE NERVOUS SYSTEM

Part of "13 - Substance P and Related Tachykinins "

The substance P–preferring NK_1 receptor has attracted most interest as a CNS drug target because it is the predominant tachykinin receptor expressed in the human brain, whereas NK_2 and NK_3 receptor expression is extremely low or absent (10 ,11 and 12). Therefore, it appears that the central actions of all tachykinins may be mediated predominantly through the NK_1 receptor in humans. However, understanding the role of substance P in the brain has been greatly complicated by marked differences in the distribution of tachykinin receptor subtypes in rodent species that are normally used for such studies. For example, in the rat and guinea pig brain, both NK_1 and NK_3 receptors are expressed (10), findings suggesting that the CNS functions mediated by NK_1 receptors in the human brain may be subserved by NK_1 and/or NK_3 receptors in rodents. NK_2 receptors appear to be absent in the adult mammalian brain of all species examined (10). For these reasons, interpretation of the effects of selective tachykinin receptor antagonists in preclinical assays requires great caution. If such compounds either succeed or fail to exhibit activity in rodent assays for psychiatric and neurologic disorders, this may merely reflect different roles of tachykinin receptors in rodent versus human brain. Hence there is a risk of both false-positive and false-negative extrapolations from preclinical species to humans.

Substance P is widely distributed throughout the CNS and in primary sensory neurons. The demonstration of substance P immunoreactivity in the cell bodies of dorsal root ganglia, in sensory nerve fibers, and in the dorsal horn of the spinal cord led to early speculation that substance P is involved in pain perception (13). Substance P and the NK_1 receptor have a widespread distribution in the brain and are found in brain regions that regulate emotion (e.g., amygdala, periaqueductal gray, hypothalamus) (14 ,15). They are also found in close association with major catecholamine-containing nuclei, including the substantia nigra and the nucleus tractus solitarius (16), as well as with 5-HT- and norepinephrine-containing neurons that are targeted by currently used antidepressant drugs. NKA and NKB are also expressed in varying ratios in the CNS and spinal cord (17 ,18) and in the rodent (but not human) brain, and NK_3 receptors and mRNA have also been demonstrated in various regions, including the substantia nigra, raphe nuclei, and locus ceruleus (19 ,20 and 21).

An interesting aspect of the neuroanatomic localization of substance P is that that it is coexpressed with 5-HT in approximately 50% of ascending dorsal raphe neurons in the primate brain (22 ,23). In contrast, coexpression of substance P and 5-HT in ascending raphe neurons is not seen in the rat brain (24). These findings provide further illustrations of the marked species differences in the neuroanatomy, and possibly physiology, of neurokinin systems. The functional significance of substance P and 5-HT coexpression in the human brain is not known, but it suggests that both neurotransmitters may be coreleased in certain brain regions receiving terminal innervation.

Other evidence suggests that substance P and NKB may also modulate ascending norepinephrine systems. NK_1 receptors (25) have been shown to be expressed on tyrosine hydroxylase–positive cell bodies in the rat locus ceruleus, and both substance P and senktide (a selective NK_3 receptor agonist) excite the firing of locus ceruleus neurons in rats and guinea pigs (26 ,27).

PHYLOGENETIC DIFFERENCES IN TACHYKININ RECEPTOR PHARMACOLOGY

Part of "13 - Substance P and Related Tachykinins "

Preclinical studies with NK_1 receptor antagonists have also been complicated by species variants in NK_1 receptor pharmacology (28 ,29). Compounds such as CP-96,345 were found have high (nM) affinity for the NK_1 receptor expressed in human, gerbil, rabbit, guinea pig, cat, and monkey brain, but they had considerably lower affinity for the mouse and rat NK_1 receptor. Subsequent mutation analysis revealed that subtle differences in the amino acid sequence between the human and the rat NK_1 receptor dramatically alter antagonist binding affinity (30). This feature has greatly hindered preclinical evaluation of high-affinity human NK_1 receptor antagonists because most of these have considerably lower affinity for the rat receptor, the most

commonly used preclinical species (Table 13.2). A few compounds have high affinity for the rat receptor (e.g., SR140333), but their utility for *in vivo* studies may be severely limited by poor brain penetration (31). Although these difficulties may be overcome by administering high doses of NK_1 receptor antagonists to rats, unspecific pharmacologic effects are then frequently encountered, mostly attributable to ion channel blockade. It has therefore been necessary to examine the preclinical pharmacology of these compounds in species with humanlike NK_1 receptor pharmacology (gerbils, guinea pigs, ferrets, hamsters) whenever possible. Pharmacologic differences among human, guinea pig, and rat NK_3 receptors also exist (32).

POTENTIAL FOR USE OF TACHYKININ RECEPTOR ANTAGONISTS TO TREAT PSYCHIATRIC AND NEUROLOGIC DISORDERS

Part of "13 - Substance P and Related Tachykinins "

The distribution of neurokinins in the central and peripheral nervous system has generated much speculation about the potential therapeutic uses of selective tachykinin receptor antagonists. The major hypotheses that are supported by preclinical data and have been investigated in clinical trials are considered here. Numerous clinical trials have now been conducted with NK_1 receptor antagonists to define their therapeutic potential in psychiatric and neurologic disorders. In all these studies, the compounds have been extremely well tolerated, with no significant side effects. There are as yet no reports of clinical trials with NK_2 or NK_3 receptor antagonists in patients with CNS disorders.

Pain

Radioligand-binding studies confirm the expression of tachykinin NK_1 and NK_3 (but not NK_2) receptors in the dorsal horn of the spinal cord (33 ,34 and 35). A role of spinal substance P and NKA in nociception is suggested by the reduction in response thresholds to noxious stimuli by central administration of NK_1 and NK_2 (but not NK_3) agonists (36 ,37 and 38). Based on these neuroanatomic and functional studies, it was anticipated that NK_1, and possibly NK_2, receptor antagonists could be developed as analgesic drugs.

Electrophysiologic studies on anesthetized or decerebrate animals provide evidence of potent and selective inhibition of facilitated nociceptive spinal reflexes by NK_1 receptor antagonists. Responses of dorsal horn neurons to noxious or repetitive electrical stimulation of a peripheral nerve was blocked by CP-96,345 (39); NK_1 receptor antagonists also blocked the flexor reflex facilitation produced by C-fiber–conditioning stimulation, but they did not affect protective nociceptive reflexes (40 ,41). NK_1 receptor antagonists have also been shown to inhibit the late-phase response to formalin in gerbils (42), to inhibit carrageenan and Freund adjuvant–induced hyperalgesia in guinea pigs (J. Webb, S. Boyce, and N. Rupniak, unpublished observations; 43), and to attenuate peripheral neuropathy in rats and guinea pigs (43 ,44). Overall, the profile of activity of NK_1 receptor antagonists in a range of assays is comparable to that seen with clinically used analgesic agents such as indomethacin (Table 13.3).

TABLE 13.3. PRECLINICAL EVIDENCE OF AN ANALGESIC PROFILE OF NK_1 RECEPTOR ANTAGONISTS

Assay	Morphine	Indomethacin	NK_1 Antagonist
Tail flick/hot plate	√	X	X
Paw pressure	√	X	X
Writhing	√	√	√
Formalin paw	√	√	√
Carrageenan paw	√	√	√
Nerve injury	√	X	√
CFA arthritis	√	√	√
Facilitated spinal reflex	√	√	√

The first clinical trials with NK_1 receptor antagonists were conducted in patients with various pain conditions. These trials uniformly failed to confirm the analgesic efficacy of these compounds in humans and are reviewed in detail elsewhere (45 ,46). The patient populations and compounds examined included the following: peripheral neuropathy, in which CP-99,994 had no analgesic effect (47); molar extraction, in which MK-869 was ineffective (48); and postherpetic neuralgia, in which MK-869 was ineffective (49). Further unpublished studies with other compounds support these conclusions. Thus, clinical studies to date indicate that NK_1 receptor antagonists do not have major potential as analgesics.

Less is known about the profile of NK_2 receptor antagonists in nociception assays. The NK_2 antagonist MEN 10207 completely blocked both facilitation and protective nociceptive reflex responses (40), and SR48968 reduced responses to both noxious and innocuous pressure applied to

the knee joint (50). In conscious rats, Sluka et al. found that pretreatment with SR48968 prevented the induction of hyperalgesia induced by intraarticular injection of kaolin and carrageenan (51), but it was not effective after hyperalgesia had been established.

Migraine

The vasculature of meningeal tissues such as the dura mater is densely innervated by nociceptive sensory afferents that run in the trigeminal nerve and contain substance P and other neuropeptides. The release of neuropeptides from these sensory fibers during a migraine attack is thought to cause neurogenic inflammation within the meninges and activation of nociceptive afferents projecting to the trigeminal nucleus caudalis (52). In rats, antidromic stimulation of the trigeminal nerve increases vascular permeability and causes plasma protein extravasation in the meninges that is inhibited by NK_1 receptor antagonists (53). These findings suggest that if meningeal plasma extravasation and inflammation of the meninges is involved in the pathogenesis of migraine, then NK_1 receptor antagonists should provide an effective antimigraine therapy. In addition, because of their potential analgesic activity, CNS-penetrant NK_1 antagonists may also be able to alleviate headache by preventing activation of sensory neurons in the trigeminal nucleus caudalis. However, this hypothesis was not confirmed in clinical trials in patients with migraine, in whom neither LY 303870 (54) nor GR205171 (55) gave headache relief.

Emesis

Substance P is present in the nucleus tractus solitarius and the area postrema (56), regions implicated in the control of emesis. Local application of substance P in the area postrema causes retching in ferrets (57), a finding suggesting that NK_1 receptor antagonists may be antiemetic. Consistent with this proposal, these compounds have emerged as an important new class of antiemetics in preclinical studies using ferrets. CP-99,994 completely abolished cisplatin-induced retching and vomiting and exhibited broad-spectrum activity against peripheral and centrally acting emetogens (58 ,59 and 60). Importantly, CP-99,994 markedly attenuated both acute and delayed emesis induced by cisplatin, a profile that distinguishes NK_1 receptor antagonists from established antiemetics (61 ,62). The ability of CP-99,994 to block both peripherally and centrally acting emetogens and the demonstration that direct injection of CP-99,994 into the region of the nucleus tractus solitarius inhibited cisplatin-induced emesis in ferrets (63) suggest that the antiemetic activity of NK_1 antagonists is centrally mediated. This proposal was confirmed by the use of a poorly brain-penetrant quaternary NK_1 receptor antagonist, L-743,310, which prevented cisplatin-induced retching in ferrets when it was infused directly into the CNS, but not systemically (64).

Evaluation of NK_1 receptor antagonists as antiemetics in patients has produced encouraging results. Three independent trials have confirmed that CP-122,721 (65), CJ-11974 (66), and MK-869 (67) are extremely effective in the prevention of acute and delayed emesis after cisplatin chemotherapy. CP-122,721 was also effective in preventing postoperative nausea and vomiting after gynecologic surgery (68), a finding suggesting the utility of NK_1 receptor antagonists as broad-spectrum antiemetics in humans. There are no published studies examining the effects of selective NK_2 and NK_3 receptor agonists and antagonists on emesis.

Schizophrenia

A rationale that NK_1 receptor antagonists may be useful as antipsychotic drugs has been built on evidence that substance P modulates the activity of the mesolimbic dopamine system through which established antipsychotic drugs are thought to act. Substance P–containing fibers have been shown to make synaptic contact with tyrosine hydroxylase–positive neurons in the ventral tegmental area (VTA) from which the mesolimbic dopamine projection arises (69). Infusion of substance P agonists into the VTA stimulates locomotor activity in rats, an effect attributed to the activation of dopamine neurons because this is accompanied by an increase in dopamine turnover in the terminal projection area (nucleus accumbens) (70). Consistent with this interpretation, the locomotor hyperactivity and changes in accumbens cell firing induced by intra-VTA infusion of substance P were blocked by the dopamine receptor antagonist haloperidol, an antipsychotic drug (71).

The ability of a monoclonal antibody to substance P, injected into the nucleus accumbens, to attenuate the locomotor response to amphetamine (72) was consistent with the proposal that endogenous substance P modulates the release of dopamine in the mesolimbic system. A subsequent study appeared to support this interpretation because the NK_1 receptor antagonist CP-96,345 reduced the firing of cells in the VTA in rats (73). However, other studies with NK_1 receptor antagonists are not consistent with these findings. Surprisingly, intra-VTA coinfusion of CP-96,345 was unable to block substance P agonist–induced locomotor activation in rats (71), and amphetamine-induced hyperactivity in guinea pigs was not selectively inhibited by CP-99,994.

A possible explanation for the lack of effect of NK_1 receptor antagonists in these studies is that the effects of substance P in the rodent VTA may be mediated by stimulation of NK_3, rather than NK_1, receptors, as is suggested by anatomic (19), electrophysiologic (74), and behavioral (75) evidence. Intra-VTA application of the NK_3 receptor agonist senktide was shown to enhance markedly the extracellular concentration of dopamine in the nucleus accumbens and

prefrontal cortex of anesthetized guinea pigs, and this was blocked by the selective NK_3 receptor antagonist SR142801 (76). SR142801 (but not the NK_1 receptor antagonist GR205171 or the NK_2 antagonist SR144190) was able to antagonize the increase in neuronal activity caused by acute administration of haloperidol in guinea pigs (77), a finding suggesting that NK_3 receptors play a key role in regulating midbrain dopamine neurons in this species.

Preliminary findings from an exploratory trial with MK-869 in patients with schizophrenia indicated that this compound did not ameliorate the core symptoms of acute psychosis (46).

Anxiety and Depression

Substance P and its preferred NK_1 receptor are highly expressed in brain regions that are critical for the regulation of emotion and neurochemical responses to stress (14 ,15 ,24). Direct central injection of substance P agonists produces a range of fear-related behaviors and defensive cardiovascular changes in animals (78 ,79 ,80 and 81). Neurochemical studies have revealed rapid reductions in substance P content in the mesolimbic system, hippocampus, septum, periaqueductal gray, and hypothalamus of rats after inescapable footshock (82 ,83) and immobilization stress (84). These findings indicate that activation of central substance P pathways occurs in response to noxious or aversive stimulation and suggest that NK_1 receptor antagonists may have anxiolytic or antidepressant-like properties.

Substance P antagonists are capable of attenuating psychological stress responses in paradigms using neurochemical and behavioral endpoints. This was first suggested by the demonstration that intra-VTA injection of a monoclonal antibody to substance P prevented stress-induced activation of mesocortical dopamine neurons (85). More recently, the NK_1 receptor antagonist GR205171 was shown to inhibit the stress-induced elevation in the dopamine metabolite DOPAC in the frontal cortex (86). Certain chemically diverse NK_1 receptor antagonists have also shown activity in a range of assays for anxiolytic and antidepressant drugs after intracerebral or systemic administration. One of the earliest reported studies demonstrated a direct substance P–ergic projection from the medial amygdala to the medial hypothalamus that regulates the expression of defensive rage in cats. Either systemic or intrahypothalamic injection of CP-96,345 inhibited amygdaloid facilitation of defensive rage (87). A second study examined the role of NK_1 receptors in the caudal pontine reticular nucleus and showed that injection of CP-96,345 or CP-99,994 into this region blocked potentiation of the acoustic startle response by footshock in rats (88). In the resident-intruder paradigm, L-760,735 reduced aggression in singly housed hamsters in a dose-dependent manner resembling the effect of fluoxetine (J. Webb, E. Carlson, N. Rupniak, unpublished observations) (Fig. 13.1). CGP 49823 has been reported to be active in the rat social interaction test for anxiolytic activity (89 ,90) and the forced swim test for antidepressant drugs (89). In guinea pig pups, the vocalization response elicited by maternal separation is inhibited by brain-penetrant NK_1 receptor antagonists (L-773,060, L-760,735, GR205171), a property also seen with clinically used antidepressant and anxiolytic drugs (91 ,92). The amygdala is a potential site of action for this effect of NK_1 receptor antagonists because separation stress caused internalization of NK_1 receptors (reflecting the release of substance P) in this brain region (91 ,93), and intraamygdala injection of L-760735 attenuated the neonatal vocalizations (93). Further evidence for an antidepressant-like preclinical profile of substance P antagonists is suggested by preliminary findings with L-733,060, which was active in the learned helplessness paradigm in rats (94), despite having only low affinity for the rat NK_1 receptor. These findings are summarized in Table 13.4 .

TABLE 13.4. PRECLINICAL EVIDENCE OF AN ANTIDEPRESSANT AND ANXIOLYTIC-LIKE PROFILE OF NK_1 RECEPTOR ANTAGONISTS

Assay	Species	BZ Anxiolytics	SSRI/TCA	NK_1 Antagonist
Neonatal vocalization	Guinea pig	√	√	√
Aggression	Hamster	√	√	√
Learned helpessness	Rat		√	√
Forced swim	Rat	X	√	√
Shock-potentiated startle	Rat	√		√
Social interaction	Rat	√		√

BZ, benzodiazepine; SSRI,-selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

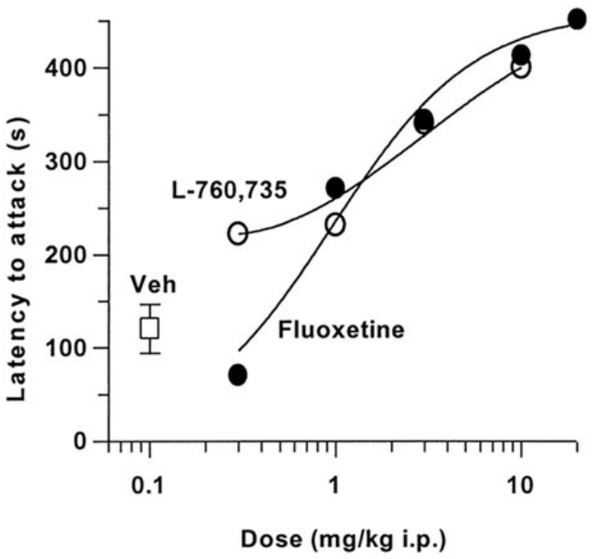

FIGURE 13.1. Activity of L-760,735 in the hamster residentintruder test. The subjects were individually housed adult male hamsters. On test days, both resident and intruder hamsters were dosed with the same drug and were returned to their own cages for 30 minutes before testing. Pretreatment with either fluoxetine (0.3 to 30 mg/kg intraperitoneally) or the selective NK_1 receptor antagonist L-760735 (0.3 to 10 mg/kg intraperitoneally) caused a dose-dependent increase in the latency to initiate an aggressive encounter.

The NK_2 receptor antagonists SR48968, GR100679, and GR159897 have been reported to exhibit anxiolytic-like effects in several preclinical assays (mouse light-dark box, rat social interaction test, rat elevated plus maze, and marmoset threat test) (95 ,96 and 97). However, these compounds were reported to be extremely potent, and the micrograms per kilogram anxiolytic dose range was considerably lower

than that required to block NK_2 agonist–mediated effects in peripheral tissues (mg/kg dose range) (98 ,99). A second difficulty concerns the failure to establish convincing expression of NK_2 receptors in the adult rat brain (100).

In rodents, there is evidence that NK_3 receptors are able to modulate monoaminergic neurotransmission. Because the clinical efficacy of currently used antidepressant drugs is ascribed to their ability to increase the synaptic availability of 5-HT and norepinephrine, modulation of these systems by NK_3 receptor ligands may suggest an antidepressant-like profile. The ability of central infusion of senktide to elicit a 5-HT behavioral syndrome (101) and to increase the release of norepinephrine in brain (27) indicates that monoamine systems can be activated by NK_3 receptor agonists. The ability of senktide to increase locus ceruleus firing, to increase norepinephrine release, and to decrease locomotor activity in animals was blocked by the selective NK_3 receptor antagonist SR142801 (102). These actions are not clearly indicative of an antidepressant-like profile of NK_3 receptor antagonists, and the low abundance of these receptors in human brain suggests that, like NK_2 receptor antagonists, NK_3 antagonists are less attractive candidates for clinical development in psychiatry than NK_1 receptor antagonists.

There is currently only one published study in which a tachykinin antagonist has been examined in patients with depression. The clinical efficacy of the NK_1 receptor antagonist MK-869 was comparable to that of paroxetine in outpatients with major depressive disorder and moderately high anxiety. As in other clinical trials, MK-869 was extremely well tolerated (94). Further studies are currently in progress with this and other NK_1 receptor antagonists in patients with depression and anxiety disorders.

CONCLUSIONS AND IMPLICATIONS FOR FUTURE STUDIES OF NEUROKININ ANTAGONISTS IN PSYCHIATRIC AND NEUROLOGIC DISORDERS

Part of "13 - Substance P and Related Tachykinins "

The process of elucidating the potential clinical uses of tachykinin receptor antagonists raises several fundamental issues that will apply to other novel neurotransmitter ligands in the future. Preclinical studies have suggested therapeutic potential of neurokinin antagonists in certain neurologic and psychiatric disorders, including migraine, pain, schizophrenia, anxiety, and depression. Of these, antagonists of tachykinin NK_1 receptors are the most attractive agents because this is the predominant receptor expressed in the human brain. However, expectations have been only partially fulfilled in clinical trials, and although preliminary findings suggest efficacy of NK_1 receptor antagonists in the control of emesis and depression, these compounds do not appear to possess analgesic or antipsychotic activity. It was not possible to predict this outcome from preclinical evidence, in which interpretation was complicated by species variants in tachykinin receptor pharmacology and possibly physiology, and this was coupled with uncertainty about whether relevant aspects of human disease can be accurately modeled in animals.

This chapter has focused on the intricacies of prioritizing efforts to identify the therapeutic uses of neurokinin antagonists for CNS disorders. However, there are many other potential uses for NK_1, NK_2, and NK_3 antagonists that have not yet been fully explored. These include inflammatory diseases such as cystitis and inflammatory bowel disease, asthma, cancer, glaucoma, ocular hypotension, cardiac disorders, and psoriasis.

Histamine

Jean-Charles Schwartz

Jean-Michel Arrang

Jean-Charles Schwartz and Jean-Michel Arrang: Unité de Neurobiologie et Pharmacologie Moléculaire de l'INSERM, Centre Paul Broca, Paris, France.

In a certain way, histaminergic systems have had a great, although indirect, historical importance in the development of neuropsychopharmacology. Indeed, the discovery of both the neuroleptic agents and the tricyclic antidepressant drugs in the 1950s was derived from the clinical study of behavioral actions of "antihistamines," a class of antiallergic drugs now designated *H_1-receptor antagonists*.

Nevertheless, the histaminergic neuronal system in the brain, although already understood by the mid-1970s, has remained largely unexploited in drug design. Thus, only the traditional brain-penetrating H_1-receptor antagonists, used as over-the-counter sleeping pills, are known to interfere with histaminergic transmissions in the central nervous system (CNS). This situation contrasts with the emergence, in the 1990s, of detailed knowledge of the system that revealed that it shares many biological and functional properties with other aminergic systems overexploited in CNS drug design.

Histamine and its receptors in the brain have been the subject of two comprehensive reviews (1 ,2). Therefore, to limit the length of the present chapter, we have deliberately elected to summarize the detailed information that can be found in these reviews and have added only more recent information and major references.

ORGANIZATION OF THE HISTAMINERGIC NEURONAL SYSTEM

Part of "14 - Histamine "

One decade after the first evidence by Garbarg et al. of an ascending histaminergic pathway obtained by lesions of the medial forebrain bundle (3), the exact localization of corresponding perikarya in the posterior hypothalamus was revealed immunohistochemically, and the distribution, morphology, and connections of histamine and histidine decarboxylase-immunoreactive neurons were determined. Data were comprehensively reviewed (4 , 5 , 6 and 7), and they are summarized only briefly here.

All known histaminergic perikarya constitute a continuous group of mainly magnocellular neurons (about 2,000 in the rat), located in the posterior hypothalamus and collectively named the *tuberomammillary nucleus* (Fig.14.1). It can be subdivided into medial, ventral, and diffuse subgroups extending longitudinally from the caudal end of the hypothalamus to the midportion of the third ventricle. A similar organization was described in humans, except histaminergic neurons are more numerous (approximately 64), and occupy a larger proportion of the hypothalamus (8). Besides their large size (25 to 35 µm), tuberomammillary neurons are characterized by few thick primary dendrites, with overlapping trees, displaying few axodendritic synaptic contacts. Another characteristic feature is the close contact of dendrites with glial elements in a way suggesting that they penetrate the ependyma and come in close contact with the cerebrospinal fluid, perhaps to secrete or receive still unidentified messengers. Neurons expressing mRNAs for histidine decarboxylase (EC 4.1.1.22), the enzyme responsible for the one-step histamine formation in the brain (2), were found by *in situ* hybridization in the tuberomammillary nucleus, but not in any other brain area (9). Tuberomammillary neurons possess the vesicular monoamine transporter 2 (10), which accounts for the histamine-releasing effect of reserpine (2).

The histaminergic neurons are characterized by the presence of an unusually large variety of markers for other neurotransmitter systems: glutamic acid decarboxylase, the γ-aminobutyric acid (GABA–synthesizing enzyme; adenosine deaminase, a cytoplasmic enzyme possibly involved in adenosine inactivation; galanin, a peptide co-localized with all other monoamines; (Met^5)enkephalyl-Arg^{6}Phe^7, a product of the proenkephalin A gene; and other neuropeptides such as substance P, thyroliberin, or brain natriuretic peptide. Tuberomammillary neurons also contain monoamine oxidase B, an enzyme responsible for deamination of telemethylhistamine, a major histamine metabolite in brain. Finally, a subpopulation of histaminergic neurons is able to take up and decarboxylate exogenous 5-hydroxytryptophan,

a compound that they do not synthesize, however (5). Discovering the functions of such a high number of putative cotransmitters in the same neurons remains an exciting challenge.

Like other monoaminergic neurons, histaminergic neurons constitute long and highly divergent systems projecting in a diffuse manner to many cerebral areas (Fig.14.1). Immunoreactive, mostly unmyelinated, varicose or nonvaricose fibers are detected in almost all cerebral regions, particularly limbic structures, and it was confirmed that individual neurons project to widely divergent areas. Ultrastructural studies suggest that these fibers make few typical synaptic contacts (6).

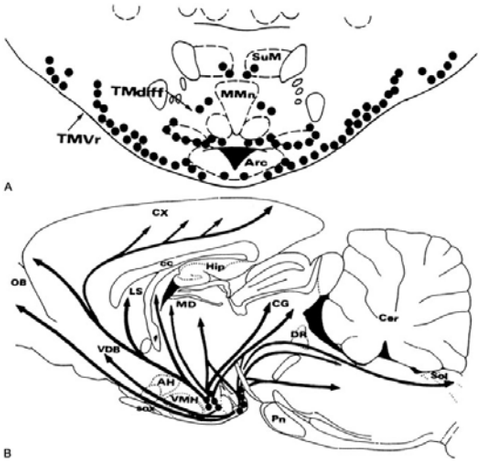

FIGURE 14.1. Localization of histaminergic perikarya *(closed circles)* in tuberomammillary nucleus and disposition of main histaminergic pathways *(arrows)* in rat brain. **A:** Frontal section of the caudal hypothalamus. **B:** Sagittal section of the brain. AH, anterior hypothalamic area; Arc, arcuate nucleus; cc, corpus callosum; Cer, cerebellum; CG, central gray; CX, cerebral cortex; DR, dorsal raphe nucleus; f, fornix; Hip, hippocampus; LS, lateral septum; MD, mediodorsal thalamus; MMn, medial mammillary nucleus median part; OB, olfactory bulb; Pn, pontine nuclei; Sol, nucleus of solitary tract; Sox, supraoptic decussation; sum, supramammillary nucleus; TMdiff, tuberomammillary nucleus diffuse part; TMVr, ventral tuberomamillary subgroup rostral part; VDB, nucleus of vertical limb of diagonal band; VMH, ventromedial hypothalamic nucleus.

Fibers arising from the tuberomammillary nucleus constitute two ascending pathways: one laterally, through the medial forebrain bundle, and the other periventricularly. These two pathways combine in the diagonal band of Broca to project, mainly in an ipsilateral fashion, to many telencephalic areas, for example, in all areas and layers of the cerebral cortex, the most abundant projections being to the external layers. Other major areas of termination of these long ascending connections are the olfactory bulb, the hippocampus, the caudate putamen, the nucleus accumbens, the globus pallidus, and the amygdaloid complex. Many hypothalamic nuclei exhibit a very dense innervation, for example, the suprachiasmatic, supraoptic, arcuate, and ventromedial nuclei.

Finally, a long descending histaminergic subsystem also arises from the tuberomammillary nucleus to project to various mesencephalic and brainstem structures such as the cranial nerve nuclei (e.g., the trigeminal nerve nucleus), the central gray, the colliculi, the substantia nigra, the locus ceruleus, the mesopontine tegmentum, the dorsal raphe nucleus, the cerebellum (sparse innervation), and the spinal cord.

Several anterograde and retrograde tracing studies established the existence of afferent connections to the histaminergic perikarya, namely, from the infralimbic cortex, the septum-diagonal band complex, the preoptic region, the hypothalamus, and the hippocampal area (subiculum) (7 , 11). Sleep-active GABAergic neurons in the ventrolateral preoptic nucleus provide a major input to the tuberomammillary nucleus (12 , 13). Histaminergic neurons also receive very dense orexin innervation originating from the lateral hypothalamus (14). Electrophysiologic studies provided evidence of inhibitory and excitatory synaptic control of tuberomammillary neuron activity by afferents from the diagonal band of Broca, the lateral preoptic area and the anterior lateral hypothalamic area (15). Projections from the brainstem to the tuberomammillary nucleus have also been demonstrated. Retrograde tracing studies combined with immunohistochemistry showed that monoaminergic inputs to the tuberomammillary nucleus originate mainly from the ventrolateral and dorsomedial medulla oblongata and from the raphe nuclei, with a low innervation originating from the locus ceruleus, the ventral tegmental area, and the substantia nigra (16).

MOLECULAR PHARMACOLOGY AND LOCALIZATION OF HISTAMINE RECEPTOR SUBTYPES

Part of "14 - Histamine "

Three histamine receptor subtypes (H_1, H_2 and H_3) have been defined by means of functional assays, followed by design of selective agonists and antagonists and, more recently, cloning of their genes (1). All three belong to the superfamily of receptors with seven transmembrane domains (TMs) and coupled to guanylnucleotide-sensitive G proteins (Table 14.1). In addition, histamine affects the glutamatergic *N*-methyl-D-aspartate (NMDA) receptor (17 ,18).

TABLE 14.1. PROPERTIES OF THREE HISTAMINE RECEPTOR SUBTYPES

	H_1	H_2	H_3
Coding sequence	491 a.a. (bovine) 488 a.a. (guinea pig) 486 a.a. (rat)	358 a.a. (rat) 359 a.a. (dog, human, guinea pig)	445 a.a. (human) H_{3L} 445 a.a., H_{3S} 415 a.a. (guinea pig) H_{3L} 445 a.a., H_{3S} 413 a.a. (rat)
Chromosome localization	3p25	5	20qTEL
Highest brain densities	Thalamus Cerebellum Hippocampus	Striatum Cerebral cortex Amydgala	Striatum Frontal cortex Substantia nigra
Autoreceptor	No	No	Yes
Affinity for histamine	Micromolar	Micromolar	Nanomolar
Characteristic agonists	2-(3-Trifluoromethyl) histamine	Impromidine Sopromidine	(R)α-Methylhistamine Imetit
Characteristic antagonists	Mepyramine	Cimetidine	Thioperamide Ciproxifan
Radioligands	[^{3}H]Mepyramine [^{125}I]Iodobolpyramine	[^{3}H]Tiotidine [^{125}I]Iodoamino-potentidine	[^{3}H](R)α-Methylhistamine [^{125}I]Iodoproxyfan
Second messengers	Inositol phosphates (+) Arachidonic acid (+) cAMP (potentiation)	cAMP (+) Arachidonic acid (–) Ca^{++} (+)	cAMP (–) Inositol phosphates (–) Arachidonic acid (+) Ca^{++} (–)

Histamine H_1 Receptor

The H_1 receptor was initially defined in functional assays (e.g., smooth muscle contraction) and in the design of potent

antagonists, the so-called *antihistamines* (e.g., mepyramine), most of which display prominent sedative properties. Biochemical and localization studies of the H_1 receptor were made feasible with the design of reversible and irreversible radiolabeled probes such as [^{3}H] mepyramine, [^{125}I]iodobolpyramine, and [^{125}I]iodoazidophenpyramine (19 ,20).

Various intracellular responses were found to be associated with H_1-receptor stimulation: inositol phosphate release, increase in Ca^{2+} fluxes, cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate accumulation in whole cells and arachidonic acid release (1).

The deduced amino acid sequence of a bovine H_1 receptor was disclosed after expression cloning of a corresponding cDNA. The latter was based on the detection of a Ca^{2+}-dependent Cl^- influx into microinjected *Xenopus* oocytes. After the transient expression of the cloned cDNA into COS-7 cells, the identity of the protein as an H_1 receptor was confirmed by binding studies (21).

Starting from the bovine sequence, the H_1 receptor DNA was also cloned in the guinea pig (22), a species in which the pharmacology of the receptor is better established, as well as from several other species including humans (1). Although marked species differences in H_1-receptor pharmacology had been reported (2), the sequence homology between the putative TMs of the proteins is high (90%).

The “anatomy” of the H_1 receptor, with a long third intracellular domain and a short C-terminal tail, is similar to that of other receptors positively coupled to phospholipases A_2 and C. Amino acid sequence homology between the TMs of the H_1 and those of the muscarinic receptors (approximately 45%) is higher than between those of H_1 and H_2 receptors (approximately 40%). H_1-receptor antagonists often display significant antimuscarinic activity but only limited H_2-receptor–antagonist properties.

A single gene seems to encode the guinea pig H_1 receptor, and mRNAs of similar size were detected in brain areas and peripheral tissues (22).The structure of the human gene was disclosed (23). Like other receptors of this superfamily, it contains an intron in the 5′ flanking untranslated region, close to the translation initiation codon, but the translated region is intronless.

When stably expressed in transfected fibroblasts, the guinea pig H_1 receptor was found to trigger a large variety of intracellular signals involving or not coupling to pertussis toxin-sensitive G proteins (G_i or G_o), namely, Ca^{2+} transients, inositol phosphates, or arachidonate release (24). H_1 receptor stimulation potentiates cAMP accumulation induced by forskolin in the same transfected fibroblasts, a response that resembles the H_1 potentiation of histamine H_2- or adenosine A_2-receptor–induced accumulation of cAMP in brain slices. All these responses mediated by a single H_1 receptor were known to occur in distinct cell lines or brain slices, but they could have resulted from stimulation of isoreceptors.

Constitutive activity of the recombinant human H_1 receptor

consisting in an agonist-independent increase in inositol phosphates accumulation in COS-7 cells was evidenced. Several H_1-receptor antagonists behaved as inverse agonists (i.e., reduced this constitutive activity), but the physiologic relevance of the process, such as in brain, was not established (25).

The H_1 receptor mediates various excitatory responses in brain (26). A reduction of a background leakage K^+ current was implicated in these responses, in cortical, striatal, and lateral geniculate relay neurons (27 ,28).

H_1-receptor distribution in the guinea pig brain was established autoradiographically using [^{3}H]mepyramine or the more sensitive probe [^{125}I]iodobolpyramine (20), and the information was complemented by *in situ* hybridization of the mRNA (22). For instance, the high density of H_1 receptors in the molecular layers of cerebellum and hippocampus seems to correspond to dendrites of Purkinje and pyramidal cells, respectively, in which the mRNA is highly expressed. H_1 receptors are also abundant in guinea pig thalamus, hypothalamic nuclei (e.g., ventromedial nuclei), nucleus accumbens, amygdaloid nuclei, and frontal cortex but not in neostriatum (20), whereas they are more abundant in the human neostriatum (29). The H_1 receptor was visualized in the primate and human brain *in vivo* by positron emission tomography using [^{11}C]mepyramine (30).

Blockade of H_1 receptors located in cerebral areas involved in wakefulness and cognition, and including those mediating excitation of thalamic relay neurons (31), neocortical pyramidal neurons (28) and ascending cholinergic neurons (32 ,33), presumably accounts for the sedative properties of “antihistamines” of the first generation.

Histamine H_2 Receptor

The molecular properties of the H_2 receptor remained largely unknown for a long time. Reversible labeling of the H_2 receptor was achieved using [^{3}H]tiotidine or, more reliably, [^{125}I]iodoaminopotentidine (2).

By screening cDNA or genomic libraries with homologous probes, the intronless gene encoding the H_2 receptor was first identified in dogs (34) and, subsequently, in other species including humans (1). The H_2 receptor is organized like other receptors positively coupled to adenylyl cyclase: it displays a short third intracellular loop and a long C-terminal cytoplasmic tail.

Using transfected cell lines, positive linkage of the H_2 receptor with adenylyl cyclase was confirmed, and unexpected inhibition of arachidonate release and stimulation of Ca^{2+} transients was evidenced (1). Hence H_2 receptor stimulation can trigger intracellular signals either opposite or similar to those evoked by H_1 receptor stimulation. Parallel observations were made for a variety of biological responses mediated by the two receptors in peripheral tissues.

Helmut Haas and colleagues showed that, in hippocampal pyramidal neurons, H_2-receptor stimulation potentiates excitatory signals by decreasing a Ca^{2+}-activated K^+ conductance, presumably by cAMP production (26). H_2-receptor activation depolarizes thalamic relay neurons slightly and increases apparent membrane conductance markedly, responses caused by enhancement of the hyperpolarization-activated cation current I_h (27). In addition to these short-lasting effects, histamine also induces very long-lasting increases in excitability in the CA1 region of the hippocampus through activation of H_2 receptors and the cAMP/cAMP-dependent protein kinase signal transduction cascade. This process is modulated by other receptors such as the H_1 receptor (35).

The sole selective H_2-receptor antagonist known to enter the brain is zolantidine, a compound used sometimes in animal behavioral studies but not introduced in therapeutics (36). However, some tricyclic antidepressants are known to block H_2-receptor–linked adenylyl cyclase potently and interact with [^{125}I]iodoaminopotentidine binding in a complex manner (37).

Autoradiographic localization of the H_2 receptor in guinea pig (20) and human brain (29) shows it distributed heterogeneously. The H_2 receptor is found in most areas of the cerebral cortex, with the highest density in the superficial layers, the piriform, and the occipital cortices, which contain low H_1-receptor density. The caudate putamen, the ventral striatal complex, and the amygdaloid nuclei (bed nucleus of the stria terminalis) are among the richest brain areas. In the hippocampal formation, the relative localizations of the H_2 receptor and its gene transcripts are similar to those observed for the H_1 receptor: the gene transcripts are expressed in all pyramidal cells of the Ammon horn and in granule cells of the dentate gyrus (38), whereas the H_2 receptor is expressed in the molecular layers of these areas, which contain the dendritic trees of the mRNA-containing neurons. The partial overlap with the H_1 receptor may account for their synergistic interaction in cAMP accumulation.

Histamine H_3 Receptor

The H_3 receptor was initially detected as an autoreceptor controlling histamine synthesis and release in brain. Thereafter, it was shown to inhibit presynaptically the release of other monoamines in brain and peripheral tissues as well as of neuropeptides from unmyelinated C fibers (39 ,40).

Reversible labeling of this receptor was first achieved using the highly selective agonist [^{3}H](R)α-methylhistamine (2), then [^{3}H]N^{α}-methylhistamine, a less selective agonist, was also proposed (19), as well as, more recently, [^{125}I]iodophenpropit and [^{125}I]iodoproxyfan, two antagonists (41).

The regulation of agonist binding by guanylnucleotides (39), and the sensitivity of several H_3-receptor–mediated

responses to pertussis toxin (42 ,43), suggested that the H_3 receptor was G_i/G_o protein coupled, a suggestion confirmed by the cloning of the corresponding human (44) and rodent (45) cDNAs. The H_3 receptor gene contains two introns in its coding sequence and several splice variants such as H_{3L} and H_{3S} differing by a stretch of 30 amino acids in the third intracellular loop, were identified (45). The existence of these variants may partly account for the apparent H_3-receptor heterogeneity in binding or functional studies (46).

Significant differences in the pharmacology of the human and rodent H_3 receptor (47) could be assigned to differences in only two amino acid residues in the third TM (48). In various cell lines, stimulation of the H_3 receptor, like that of other G_i-protein–coupled receptors, inhibits adenylate cyclase (44) or phospholipase C (42) and activates phospholipase A_2 (48a).

On neurons, the H_3 receptor mediates presynaptic inhibitions of release of several neurotransmitters, including histamine itself (2 ,39), norepinephrine, serotonin, dopamine, glutamate, GABA, and tachykinins (40), presumably by inhibiting voltage-dependent calcium channels (39 ,43).

Several H_3-receptor antagonists, such as thioperamide and ciproxifan, potently enhance histamine release *in vitro* and *in vivo* (2 ,39 ,49).This response was originally attributed to blockade of the inhibitory effects of endogenous histamine and was therefore used in many studies, such as behavioral studies, to delineate the functions of histaminergic neurons. However, these drugs were shown to act, in fact, as inverse agonists, and the native H_3 receptor in brain display high constitutive activity including *in vivo* (48a).

Autoradiography of the H_3 receptor in rat (50 ,51) and monkey brain shows it highly concentrated in the neostriatum, the nucleus accumbens, the cingulate and infralimbic cortices, the bed nucleus of the stria terminalis, and the substantia nigra pars lateralis. In contrast, its density is relatively low in the hypothalamus (including the tuberomammillary nucleus), which contains the highest density of histaminergic axons (and perikarya), a finding indicating that most H_3 receptors are not autoreceptors. In agreement with this concept, intrastriatal kainate strongly decreases H_3 binding sites in the forebrain (as well as in the substantia nigra, consistent with their presence in striatonigral neurons) (50 ,51). In the human brain, the high densities of H_3 receptors found in the striatum and globus pallidus (29) were lower in patients with Huntington disease, a finding suggesting that the H_3 receptor is also located on striatonigral projection neurons of the direct and indirect pathways (52). Consistent with the proposal that most H_3 receptors are not autoreceptors, a strong expression of H_3-receptor mRNAs was observed not only within the tuberomammillary nucleus, but also in various regions of the rat (44) and guinea pig (45) brain, including the cerebral cortex, the basal ganglia, and the thalamus.

Interaction with NMDA Receptors

Histamine potentiates NMDA-evoked currents in acutely dissociated and cultured hippocampal and cortical neurons, an effect that could not be ascribed to activation of the known histamine receptors (17 ,18), but rather of a novel recognition site on NMDA receptors containing the subunits NR1A/NR2B (53).

Histamine may play a role in modulating the functions of NMDA receptors *in vivo*. It facilitates the NMDA-induced depolarization of projection neurons in cortical slices (54) and phase shifts the circadian clock by a direct potentiation of NMDA currents in the suprachiasmatic nucleus (55). Histamine, presumably acting through NMDA receptors, facilitates the induction of long-term potentiation and causes long-lasting increases of excitability in the CA1 region of rat hippocampal slices (35).

The histamine-induced modulation of NMDA responses is higher under slightly acidic conditions (56), which occur during hypoxia or epileptiform activity. This may lead to enhancement of neurotransmission or histamine-mediated neuronal death such as that observed in a rat model of Wernicke encephalopathy (57).

HISTAMINERGIC NEURON ACTIVITY AND THEIR CONTROL

Part of "14 - Histamine "

Electrophysiologic Properties

Cortically projecting histaminergic neurons share with other aminergic neurons certain electrophysiologic properties evidenced by extracellular recording. They fire spontaneously slowly and regularly, and their action potentials are of long duration (26). Among the pacing events that may contribute to their spontaneous firing, tuberomammillary neurons exhibit a tetrodotoxin-sensitive persistent Na^+ current (58), a Ca^{2+} current probably of the low-threshold type (59), and multiple high-voltage–activated Ca^{2+} currents (43). In addition, they exhibit inward rectification attributed to an I_h current that may increase whole-cell conductance and may decrease the efficacy of synaptic inputs during periods of prolonged hyperpolarization, that is, when histaminergic neurons fall silent (60).

Modulation of Histamine Synthesis and Release In Vitro

The autoreceptor-regulated modulation of histamine synthesis in, and release from, brain neurons is well documented (2). It was initially evidenced in brain slices or synaptosomes after labeling the endogenous pool of histamine using the [^{3}H]histamine precursor. Exogenous histamine decreases the release and formation of [^{3}H]histamine induced by depolarization, and analysis of these responses led to the pharmacologic definition of H_3 receptors. The autoregulation

was found in various brain regions known to contain histamine nerve endings, a finding suggesting that all terminals are endowed with H_3 autoreceptors.

Regulation of histamine synthesis was also observed in the posterior hypothalamus (39), and somatodendritic H_3 autoreceptors inhibit the firing of tuberomammillary neurons (26) by modulating high-voltage–activated calcium channels (43).

Galanin, a putative cotransmitter of a subpopulation of histaminergic neurons, regulates histamine release only in regions known to contain efferents of this subpopulation, that is, in hypothalamus and hippocampus but not in cerebral cortex or striatum (61). In brain slices, galanin also hyperpolarizes and decreases the firing rate of tuberomammillary neurons (26). It is not known, however, whether these galanin receptors behave as “autoreceptors” modulating galanin release from histaminergic nerve terminals, inasmuch as the tuberomammillary nucleus receives a strong galaninergic innervation from the ventrolateral preoptic area (12 ,13). Other putative cotransmitters of histaminergic neurons failed to affect [^{3}H]histamine release from slices of rat cerebral cortex (62). However, GABAergic inhibitory postsynaptic potentials are mediated by $GABA_A$ receptors located on histaminergic neurons (63). To what extent these receptors play an autoinhibitory role is unclear. A subpopulation of histaminergic neurons contains GABA (5), but the tuberomammillary nucleus also receives dense GABAergic innervation (12 ,13 ,15).

[^{3}H]Histamine synthesis and release are inhibited in various brain regions by stimulation of not only autoreceptors but also α_2-adrenergic receptors, M_1-muscarinic receptors, and κ-opioid receptors (2). Because these regulations are also observed with synaptosomes (62), all these receptors presumably represent true presynaptic heteroreceptors. In contrast, histamine release is enhanced by stimulation of nicotinic receptors in rat hypothalamus (64) and by μ-opioid receptors in mouse cerebral cortex (2).

Some molecular mechanisms regulating neuronal histamine dynamics remain unclear. *N*-methylation catalyzed by histamine *N*-methyltransferase is the major process responsible for termination of histamine actions in the brain (2), and genetic polymorphisms for the enzyme have been associated with altered levels of its activity (65). No histamine transporter could be evidenced, and direct feedback inhibition of histidine decarboxylase by histamine has been excluded (2).

Changes in Histaminergic Neuron Activity In Vivo

Both neurochemical and electrophysiologic studies indicate that the activity of histaminergic neurons is high during arousal. In rat hypothalamus, histamine levels are low, whereas synthesis is high during the dark period, a finding suggesting that neuronal activity is enhanced during the active phase (2). In mouse cerebral cortex, striatum, and hypothalamus, telemethylhistamine levels are doubled at the end of the dark phase of the cycle as compared with the beginning of the light phase (66). Histamine release from the anterior hypothalamus of freely moving rats, evaluated by *in vivo* microdialysis, gradually increases in the second half of the light period and is maintained at a maximal level during the active phase (67). Such state-related changes are also found in single-unit extracellular recordings performed in the ventrolateral posterior hypothalamus of freely moving cats. Neurons with properties consistent with those of histaminergic neurons exhibited a circadian rhythm of their firing rate, falling silent during deep slow-wave or paradoxical sleep (2). An important determinant of this circadian rhythm of tuberomammillary histaminergic neuron activity is a GABAergic inhibitory pathway originating in the ventrolateral preoptic area and activated during sleep (12 ,15).

A feeding-induced increase in the activity of histaminergic neurons has also been shown by microdialysis performed in the hypothalamus of conscious rats (68). Histaminergic neurons are a target for leptin in its control of feeding. An enhancement of histamine turnover was observed after intracerebroventricular infusion of leptin (70). Changes in the metabolism and release of histamine observed *in vivo* after occlusion of the middle cerebral artery in rats suggest that the histaminergic activity is also enhanced by cerebral ischemia (71).

Whereas H_1 and H_2 receptors are apparently not involved, inhibition mediated by the H_3-autoreceptor constitutes a major regulatory mechanism for histaminergic neuron activity under physiologic conditions. Administration of selective H_3 receptor agonists reduces histamine turnover (2) and release, as shown by microdialysis (72). In contrast, H_3-receptor antagonists enhance histamine turnover (2 ,49) and release *in vivo* (73 ,74), a finding suggesting that autoreceptors are tonically activated.

Agents inhibiting histamine release *in vitro* through stimulation of presynaptic α_2-adrenergic or muscarinic heteroreceptors reduce histamine release and turnover *in vivo*, but systemic administration of antagonists of these receptors does not enhance histamine turnover, a finding suggesting that these heteroreceptors are not tonically activated under basal conditions.

Activation of central nicotinic receptors inhibits histamine turnover (75). Several types of serotonergic receptors are likely to modulate histamine neuron activity. 5-Hydroxytryptamine $(5\text{-HT})_{1A}$-receptor agonists inhibit (76), whereas 5-HT_2-receptor antagonists enhance (77), histamine turnover in various brain regions. Stimulation of D2 (but not D3) dopamine receptors by endogenous dopamine released by amphetamine increases histamine neuron activity (77 ,78).

Histamine turnover in the brain is rapidly reduced after administration of various sedative drugs such as ethanol, Δ^9-tetrahydrocannabinol, barbiturates, and benzodiazepines (2),

presumably as a result of their interaction with GABA receptors present on nerve endings and on perikarya of histaminergic neurons (63 ,79).

In contrast, stimulation of μ-opioid receptors enhances histamine turnover in brain (2). NMDA receptors increase *in vivo* release of histamine from the anterior hypothalamus (80). Activation of NMDA and non-NMDA receptors in the diagonal band of Broca, the lateral preoptic area, and the anterior hypothalamic area led to inhibition or enhancement of firing rates of tuberomammillary neurons (15).

PHYSIOLOGIC ROLES OF HISTAMINERGIC NEURONS

Part of "14 - Histamine "

In spite of many different suggestions mainly derived from the observations of responses to locally applied histamine, only a few physiologic roles of histaminergic neurons appear relatively well documented.

Arousal

Our initial proposal in 1977 (81) that histaminergic neurons play a critical role in arousal has been confirmed by data from a variety of experiments mainly performed by Lin and Jouvet in cats (33) and Monti in rats (2). In agreement with this concept, ablation of these neurons and inhibition of histamine synthesis, release, or action by the H_1 receptor decrease wakefulness and increase deep slow-wave sleep; conversely, inhibition of histamine methylation or facilitation of histamine release by H_3 receptor blockade increase arousal (49).

The arousing effect of histamine may result from H_1 and H_2-receptor–mediated depolarization of thalamic relay neurons that induces a shift of their activity from burst firing (predominating in deep sleep during which they are poorly responsive to sensory inputs) to single spike activity (predominating in arousal during which sensory information is more faithfully relayed) (31). Arousal may also result from H_1-receptor–mediated excitation of neocortical pyramidal neurons by the same mechanism as in thalamus, that is, reduction of a background leakage potassium current (28). Finally, arousal may occur indirectly by H_1-receptor–mediated excitation of ascending cholinergic neurons within the nucleus basilis or mesopontine tegmentum (32 ,33), which also induces cortical activation.

All these cellular actions of histamine, together with observations that tuberomammillary neuron firing is maximal during wakefulness, suggest that histaminergic systems make an important contribution to the control of arousal. The circadian changes in histaminergic neuron activity seem to be directed by two major neuronal inputs arising from the anterior hypothalamus. The first ones are slow-wave sleep-activated inhibitory GABA- and galanin-containing neurons arising from the ventrolateral preoptic area (12 ,13); in contrast, neurons releasing the neuropeptide orexin that emanate from the lateral hypothalamus appear to exert opposite actions because disruption of the orexin gene is associated with narcolepsy in dogs and knockout mice (14 ,82). Other monoaminergic neurons participating in control of sleep and wakefulness states as well as GABA/galanin ventrolateral preoptic neurons also receive inputs from orexin neurons, which are, themselves, likely influenced by photic signals from the suprachiasmatic nucleus. In turn, neurons from the suprachiasmatic nucleus and the preoptic area seem to be influenced in a complex manner by histaminergic inputs (83 ,84). Hence a complex neuronal network in the hypothalamus with reciprocal influences involving histaminergic neurons seems to control wakefulness.

The major part played by the H_1 receptor in these processes, confirmed in mutant mice lacking this receptor (85), accounts for the sedating effects of the first generation of “antihistamines,” that is, antagonists that easily enter the brain and are still ingredients of over-the-counter sleeping pills (86). It may also account for the sedative side effects of many antipsychotic or antidepressant drugs that are potent H_1 antagonists.

Cognitive Functions

The idea that histaminergic neurons may improve cognitive performance is consistent with projections of these neurons to brain areas such as the prefrontal and cingulate cortices or hippocampus, their excitatory influences therein, and their positive role in wakefulness.

Ciproxifan, a potent and selective H_3-receptor antagonist (or inverse agonist), which strongly enhances histamine turnover in brain, improved attentional performances in the rat five-choice test under conditions similar to those of drugs enhancing cholinergic transmissions (49). Various H_3 antagonists facilitate various forms of learning. They improve short-term social memory in rats (87), reverse the scopolamine- or senescence-induced learning deficit in a passive avoidance test in mice (88), and facilitate retention in a footshock avoidance test in mice (89).

Generally, H_3 agonists exert opposite effects, and the effects of H_3-antagonists are reversed by H_1 antagonists, a finding that suggests that these effects are attributable to enhanced histamine release. In contrast to the large body of experiments indicating a “procognitive” role of tuberomammillary neurons, Huston and coworkers repeatedly showed that excitotoxic lesions aimed at these neurons ablation result in improvement of learning in a variety of tests (e.g., ref. 90). The discrepancy with data from pharmacologic approaches may result from the difficulty to achieve selective histamine neuron ablation.

Control of Pituitary Hormone Secretion

Histamine affects secretion of several pituitary hormones (2 ,91). Magnocellular neurons of the supraoptic and paraventrical

nuclei are typically excited, an essentially H_1-receptor–mediated response resulting in enhanced blood levels of vasopressin and oxytocin. Histaminergic neurons are activated during dehydration, parturition, and lactation, and histamine release onto magnocellular neurons participates in the control of these physiologic processes by the neurohypophysial hormones (92 ,93).

Histaminergic neurons may also participate in the hormonal responses to stress. In agreement with this concept, they are activated during various forms of stress and heavily project to hypothalamic or limbic brain areas (e.g., the amygdala or bed nucleus of the stria terminalis) involved in these responses. Various pharmacologic studies have shown the participation of endogenous histamine by H_1- and H_2-receptor stimulation in the adrenocorticotropic hormone–corticosterone, prolactin, or renin responses to stressful stimuli such as restraint, endotoxin, or dehydration (94). Many histaminergic neurons contain estrogen receptors, project to luteinizing hormone–releasing hormone neurons in preoptic and infundibular regions, and may constitute, by H_1-receptor stimulation, an important relay in the estradiol-induced preovulatory luteinizing hormone surge (95).

Satiation

Weight gain is often experienced by patients receiving H_1 antihistamines as well as by patients taking antipsychotics or antidepressants displaying potent H_1-receptor antagonist properties. These effects reflect the inhibitory role of endogenous histamine on food intake mediated by the H_1 receptor, namely, on the ventromedial nucleus (97). Histamine neurons projecting to the hypothalamus may be responsible for the food intake suppression induced by leptin (70).

Seizures

The anticonvulsant properties of endogenous histamine were initially suggested from the occurrence of seizures in patients with epilepsy, particularly children, after administration of high doses of H_1-receptor antagonists crossing the blood–brain barrier, even those agents devoid of anticholinergic activity (86). These drugs, by completely occupying the H_1 receptor, as assessed by positron emission tomography studies (30), could block the histamine-induced reduction of a background-leakage K^+ current.

Drug-induced changes in histamine synthesis, release or metabolism confirmed the role of the endogenous amine acting through the H_1 receptor in preventing seizure activity elicited by pentetrazol, transcranial electrical stimulation, or amygdaloid kindling. Acquired amygdaloid kindling susceptibility appears associated with reduced histamine synthesis in limbic brain areas (97). In addition, kainic acid–induced limbic seizures are accompanied by up-regulation of the H_1-receptor mRNA in striatum and dentate gyrus, a finding consistent with a regulatory role of this receptor in seizure activity (98).

Nociception

The antinociceptive effects of histidine loads, H_3-receptor antagonists, and histamine *N*-methyltransferase inhibitors, as well as opposite effects of histamine synthesis inhibitors or H_3 agonists, support the idea that brain histamine inhibits nociceptive responses such as the mouse hot plate jump (99). In contrast, peripherally acting H_3-receptor agonists prevent nociceptive responses such as mouse abdominal constriction by inhibiting sensory C-fiber activity (100).

ROLE OF HISTAMINERGIC NEURONS IN NEUROPSYCHIATRIC DISEASES

Part of "14 - Histamine "

Among the various approaches that tend to establish the implication of other neuronal systems in neuropsychiatric diseases, so far only a few have been applied to histamine.

Histamine, Schizophrenia, and Antipsychotic Drug Actions

Overdose of various classic H_1 antagonists was repeatedly reported to result in toxic psychoses with hallucinations resembling schizophrenia, and the hallucinogenic potential of these drugs has even led to abuse (86). Conversely, metamphetamine, a drug with hallucinogenic potential and to which patients with schizophrenia seem hyperresponsive, releases histamine in rodent brain areas, an indirect effect mediated by stimulation of D2 and not D3 dopamine receptors (77 ,78). Even more, endogenous dopamine appears to exert a tonic stimulation of histamine neurons because typical neuroleptics, such as haloperidol, decrease their activity. In contrast, atypical neuroleptics, such as clozapine, enhance histamine turnover, an effect related to 5-HT_2 receptor blockade and possibly underlying their procognitive properties (77). The locomotor activation elicited in rodents by amphetamine and other dopaminergic agonists is attenuated by H_3-receptor blockade (101). Repeated amphetamine administration to rodents that results in behavioral sensitization to dopamine agonists, a cardinal feature of schizophrenia, is accompanied by enhanced histamine release, a finding that presumably reflects an enhanced tonic dopaminergic influence on histaminergic neurons (77 ,78). In one comprehensive study, an enhanced level of *t*-methylhistamine, the major histamine metabolite, was detected in the cerebrospinal fluid of patients with schizophrenia, who were either treated or untreated with neuroleptic agents (102).

In several open studies, famotidine, an H_2 antagonist, was found to improve schizophrenia in patients, a finding

that remains to be confirmed in control studies. A previous claim of association between polymorphisms of the H_2-receptor gene and schizophrenia could not be confirmed (103).

These various observations, although not readily forming a coherent picture, suggest that histaminergic neuron activity is enhanced in patients with schizophrenia, and blockade of H_2 or H_3 receptors could be useful in the treatment of this disease.

Histamine and Alzheimer's Disease

Neuropathologic studies have documented a deficit in histaminergic neurotransmission in Alzheimer's disease. In some, but not all, cortical areas (e.g., the frontal or temporal cortex) of brains affected by Alzheimer's disease, there is a decrease of histamine and histidine decarboxylase levels that may reach up to approximately 50% (104), and the expression of the *hdc* gene in neurons of the tuberomammillary nucleus is also reduced (S. Trottier, personal communication). Decreased histaminergic input may affect cholinergic neuron activity in the nucleus basilis (32) and acetylcholine release in cortical areas.

If one takes into account an additional direct positive influence of histamine on attention and memory, this indicates that enhancing histaminergic neurotransmission may constitute a novel symptomatic therapeutic approach to Alzheimer's disease. The drug tacrine was even more potent in inhibiting histamine-*N*-methyltransferase, the main histamine-metabolizing enzyme, than acetylcholinesterase (105).

Histamine and Other Neuropsychiatric Disorders

Anxiety may be increased by endogenous histamine acting at the H_1 receptor. In agreement with this concept, H_1-receptor knockout mice display significantly less anxiety in the elevated maze test (106). However, the utility of H_1-receptor antagonists in anxiety disorders is not established.

Patients with *attention-deficit disorders* may benefit from enhanced histamine release, as suggested by the therapeutic effect of amphetamine in children and the attention-enhancing effects of an H_3-receptor antagonist in the rat (49).

Antidepressant-like effects in the mouse forced swim test result from enhanced histamine release and H_1-receptor activation (107).

CONCLUSION

Part of "14 - Histamine "

This chapter describes how our knowledge of the molecular neurobiology of cerebral histaminergic systems and their implications in physiologic functions, such as arousal or hormonal regulations, have progressed over the years. In contrast, little is known, so far, about their possible implications in neuropsychiatric diseases and the therapeutic utility of psychotropic drugs to affect their activity. H_3-receptor antagonists (or inverse agonists) that markedly enhance brain histamine release are currently undergoing clinical trials. It seems likely that the next edition of this book will see their place in therapeutics established.

Purinergic Neurotransmission

Michael Williams

Michael Williams: Department of Molecular Pharmacology and Biological Chemistry, Northwestern University School of Medicine, Chicago, Illinois.

The purine nucleoside, adenosine, its nucleotides, adenosine triphosphate (ATP), adenosine diphosphate (ADP), and adenosine monophosphate (AMP), and the pyrimidine nucleotide, uridine triphosphate (UTP) (Fig. 15.1), play a critical role in central and peripheral nervous system homeostasis and function as extracellular messengers to regulate cell function. The effects of adenosine and the nucleotides are mediated by activation of distinct P1 (adenosine) and P2 (ATP) cell-surface receptors present on neurons, astrocytes, and microglia, as well as other cells that are present in the central nervous system (CNS) under different conditions (e.g., macrophage infiltration). These receptors are generically known as *purinergic receptors* (1).

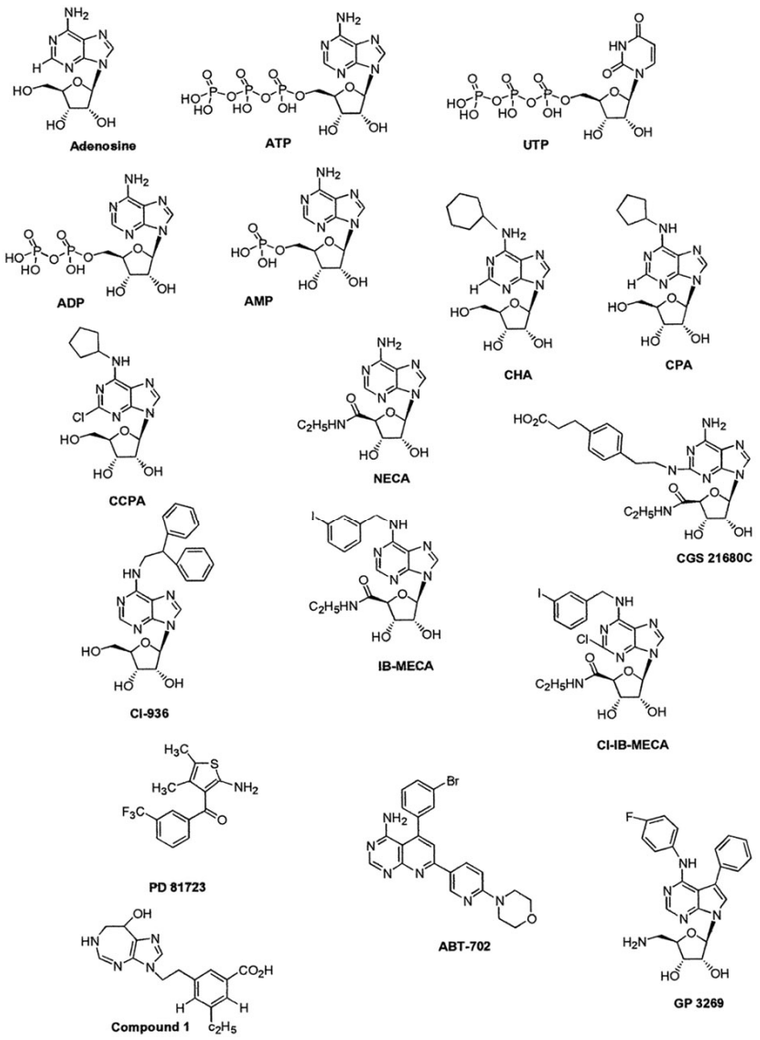

FIGURE 15.1. Structures of P1 and P2 agonists and modulators of adenosine availability.

Adenosine, ADP, and ATP, and, to a lesser extent, UTP are well-known intracellular constituents, intimately involved in all aspects of cell function acting as enzyme cofactors, sources of energy, and building blocks for DNA. Thus, the factors regulating their availability in the extracellular space as chemical messengers have been an area of active research and considerable debate since the late 1970s (2).

ATP can be released as a cotransmitter together with acetylcholine, norepinephrine, glutamate, γ-aminobutyric acid (GABA), calcitonin gene–related peptide, vasoactive intestinal peptide, and neuropeptide Y (3). ATP is available on demand, and the body can synthesize its own weight in ATP per day (4). Even though extracellular ATP levels can reach millimolar concentrations in the extracellular local environment after release or cellular perturbation (1), these concentrations are miniscule compared with the overall steady-state nucleotide content of the cell. Once released, in addition to interacting directly with P2 receptors, ATP can be hydrolyzed by a family of approximately 11 ectonucleotidases that metabolize ATP, ADP, diadenosine polyphosphates such as Ap4A, Ap5A (Fig. 15.2), and nicotinamide-adenine dinucleotide (5). Ecto-ATPases hydrolyze ATP to ADP, ectoapyrases convert both ATP and ADP to AMP, and ecto-5′-nucleotidase converts AMP to adenosine. The activities of ectoapyrase and ecto-5′-nucleotidase can change with cellular dynamics (6), and in guinea pig vas deferens, soluble nucleotidases are released together with ATP and norepinephrine (7), a finding representing a potential mechanism to limit the actions of extracellular ATP by enhancing its inactivation. The metabolic pathways linking ATP, ADP, AMP, and adenosine and the potential for each of these purines to elicit distinct receptor-mediated effects on cell function form the basis of a complex, physiologically relevant, purinergic cascade comparable to those involved blood clotting and complement activation (8) (Fig. 15.3).

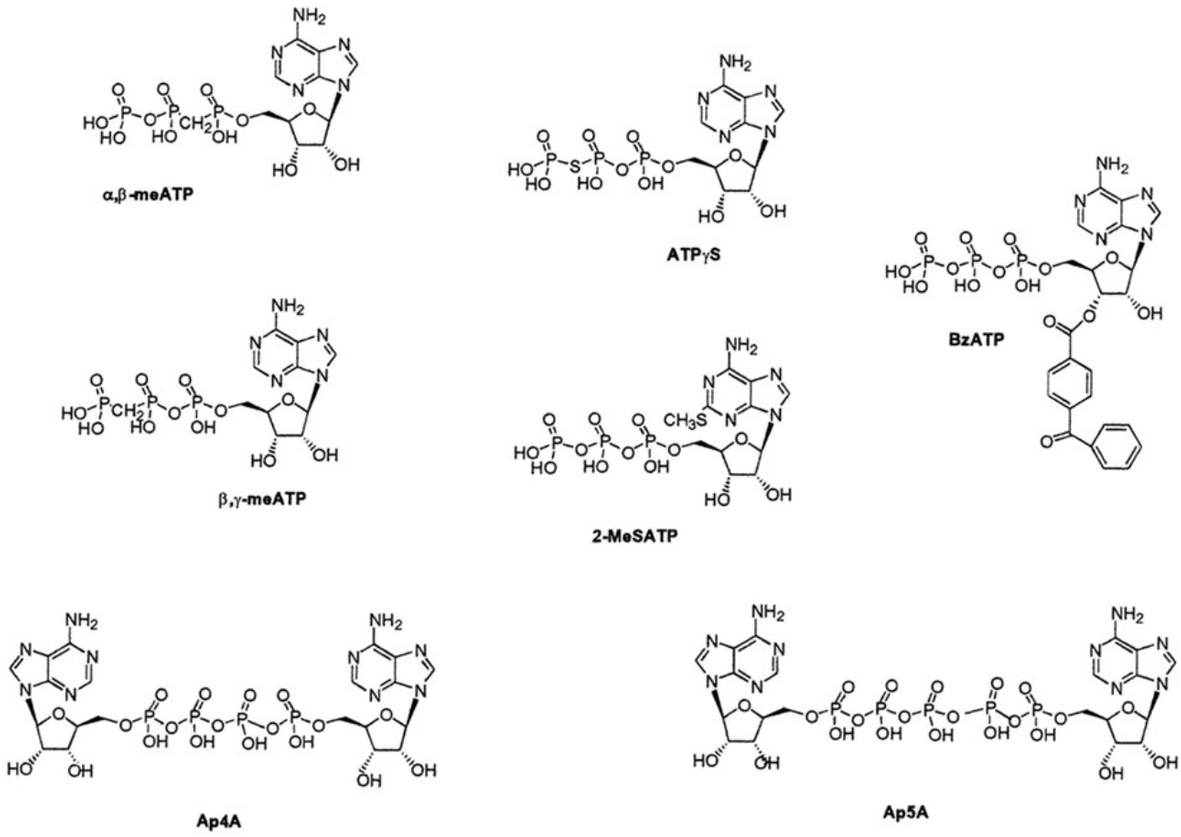

FIGURE 15.2. Structures of P2 receptor agonists.

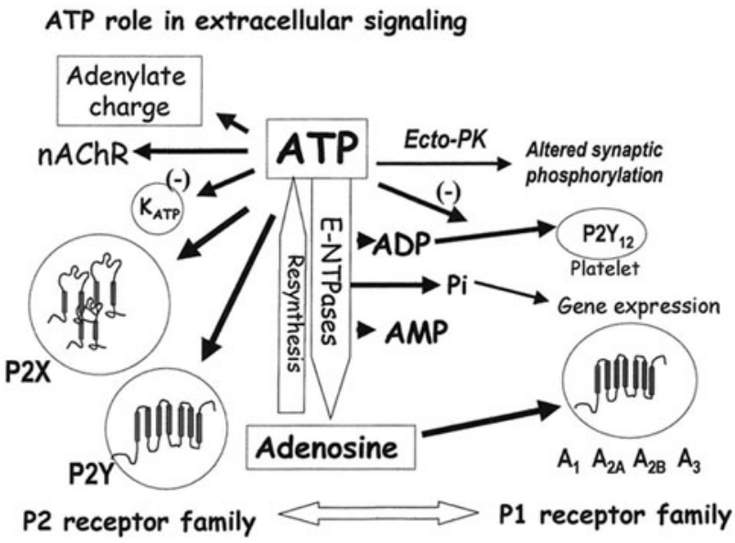

FIGURE 15.3. The purinergic cascade. ATP is released into the extracellular milieu from nerves or cells, where they can interact to form a purinergic cascade. ATP acts at a variety of P2 receptors (see text) and is sequentially degraded to ADP and AMP by ectonucleotidase activity. ADP interacts with P_{2T} receptors. AMP gives rise to adenosine, which can interact with the various P1 receptors (A_1, A_{2A}, A_{2B}, A_3). Adenosine can also be formed by intracellular 5′-nucleotidase activity. Adenylate charge indicates the transfer of energy in the form of adenine nucleosides or nucleotides from one cell to another (see ref. 13). KATP is an ATP-modulated potassium channel.

The extracellular effects of ATP on the various members of the P2 receptor family are terminated either by receptor desensitization or by dephosphorylation of the nucleotide, leading to the formation of ADP, AMP, and adenosine. These latter compounds have their own receptor-mediated functional activities, some of which are antagonistic to one another. For instance, ATP antagonizes ADP actions on platelet aggregation, whereas adenosine-elicited CNS sedation contrasts with the excitatory actions of ATP on nerve cells (9). In the broader framework of ATP-modulated proteins (or ATP-binding cassette proteins), ATP-sensitive potassium channels (K_{ATP}) undergo activation when intracellular ATP levels are reduced (10 ,11). Thus, as P2 receptor–mediated responses decrease because of ATP hydrolysis to adenosine, P1-mediated responses and K_{ATP}-mediated responses are enhanced. In addition to activating the as yet uncloned platelet $P2_T$ receptor, ADP also enhances its own availability. Activation of A_1 and A_{2A} receptors can inhibit ATP availability (1), and activation of hippocampal A_{2A} and A_3 receptors can desensitize A_1 receptor–mediated inhibition of excitatory neurotransmission (12). The transfer of purines transfer from one cell to another in the context of cellular adenylate charge (13) reflects another means by which purines can modulate cellular communication, in terms of both information transfer and alteration of the target environment. ATP also functions as a substrate for synaptic ectokinases, which modulate the phosphorylation state of the synaptic membrane (14) and, consequently, the intrinsic properties of the synapse. Once in the extracellular space, ATP thus has the ability to function as a pluripotent modulator of synaptic function.

The corresponding role of UTP in terms of functional synaptic signaling is less well understood (15), and although high concentrations of exogenous uracil have been shown to modulate dopaminergic systems in the CNS (16), data on the existence of a "uridine receptor" equivalent to the P1 receptor are limited (17).

Extracellular adenosine levels at rest are in the range of 30 to 300 nM (18), and they subserve a physiologic role in tissue homeostasis as reflected by the CNS stimulant actions of caffeine, a natural methylxanthine that acts as an antagonist to counteract the sedative actions of endogenous adenosine, and the role of the nucleoside as an endogenous hypnotic (19). Adenosine also acts as an autocrine homeostatic agent or, as conceptualized by Newby (20), a "retaliatory metabolite," to regulate the tissue energy supply-and-demand balance in response to changes in blood flow and energy availability and thus to conserve tissue function under adverse conditions. Reduced oxygen or glucose availability resulting from tissue trauma, such as during stroke, epileptogenic activity, and reduced cerebral blood flow, leads to ATP breakdown and the formation of ADP, AMP, and adenosine.

Under basal conditions, extracellular levels of adenosine are tightly regulated by ongoing metabolic activity. Bidirectional nucleoside transporters and the enzymes adenosine deaminase (ADA) and adenosine kinase (AK) regulate adenosine removal from the extracellular space (21). Numerous studies have shown that inhibition of AK is physiologically more relevant in increasing extracellular adenosine levels than inhibition of ADA or adenosine transport. AK inhibitors are also more effective in enhancing the neuroprotective actions of endogenous adenosine than inhibitors of ADA or adenosine transport (8 ,21). Selective AK inhibitors, such as GP 3269 and ABT-702 (Fig. 15.1), and ADA inhibitors, such as compound 1 (Fig. 15.1), are effective site- and event-specific agents that can locally enhance levels of adenosine in areas of tissue trauma and thus have the potential to avoid the potential cardiovascular side effects associated with a general elevation of extracellular levels of the purine (8). However, data have shown that *in vivo* administration of AK inhibitors (22), even at single doses close to where these agents show efficacy in animal models of epilepsy and pain, results in brain microhemorrhaging that can lead to minicerebral infarcts and cognitive impairment. Based on this finding, the AK approach to selective modulation of endogenous adenosine function does not appear to have a sufficient therapeutic window in CNS tissues to be a viable drug discovery target.

Adenosine has both presynaptic and postsynaptic effects on neurotransmission processes (12), whereas ATP has excitatory actions in a variety of neuronal systems including rat trigeminal nucleus, nucleus tractus solitarius, dorsal horn, and locus ceruleus. The nucleotide also functions as a fast transmitter in guinea pig celiac ganglion and rat medial habenula (9). Electrophysiologic studies on P2X and neuronal nicotinic receptor (nAChR)–mediated responses suggested that these two ligand-gated ion channels (LGICs) interacted with one another, with each receptor containing a inhibitory binding site for agonists active at the corresponding receptor and resulting in functional cross-talk between the systems (23). Recombination of nAChR α-subunits with P2X receptor subunits to form functional receptor constructs has also been reported (24), a finding further suggesting that heterooligimerization between these two different classes of LGICs may occurs and represents a molecular basis for the cross-talk hypothesis. This finding also adds a layer of further complexity to an already complex situation in understanding the precise subunit composition of functional P2X receptors. Dimerization of the A_1 subtype of the P1 (adenosine) G-protein–coupled receptor (GPCR) also occurs (25), a finding consistent with the emerging view that functional homooligimerization and heterooligimerization of a variety of GPCRs is the norm rather than the exception (26).

P1 AND P2 RECEPTORS

Part of "15 - Purinergic Neurotransmission "

Four distinct P1 receptors sensitive to adenosine and 12 P2 receptors sensitive to ADP, ATP, and UTP have been cloned and characterized (1), thus providing a diversity of discrete cellular targets through which adenosine, ADP, ATP, and UTP can modulate tissue function (Table 15.1). The four adenosine-sensitive P1 receptors are designated A_1, A_{2A}, A_{2B}, and A_3. Functional P2 receptors are divided into ionotropic P2X receptors, a family of eight LGICs ($P2X_1$ to $P2X_8$), and the metabotropic P2Y family, which consists of the $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, $P2Y_{11}$, $P2Y_{12}$, and $P2Y_{13}$ GPCRs. The missing numbers in the P2Y family sequence are proposed receptors that have been subsequently found to lack functional responses, are species variants, or have been inadvertently assigned to the P2 receptor family (1 ,8).

	Agonist Rank Order Potency	Antagonist Rank Order Potency
$P2X_1$	2-MeSATP ≥ ATP ≥ α,β-meATP > BzATP	Ip_5I >> suramin, PPADS > MRS 2220
$P2X_2$	2-MeSATP > ATP >> α,β-meATP	Suramin, PPADS ≥ TNP-ATP
$P2X_3$	2-MeSATP > ATP > BzATP	TNP-ATP >> suramin, PPADS
$P2X_4$	ATP > 2-MeSATP > α,β-meATP	TNP-ATP >> suramin
$P2X_5$	ATP > 2-MeSATP >> α,β-meATP	Suramin, PPADS
$P2X_6$	ATP > 2-MeSATP >> α,β-meATP	Suramin
$P2X_7$	BzATP > ATP > UTP >> α,β-meATP	KN-62 >> suramin, PPADS
$P2X_8$	ATP = 2meSATP> α,β-meATP > ATPγS	Suramin, PPADS

[a]Functional heteromers composed of $P2X_{1/5}$, $P2X_{2/3}$, $P2X_{2/6}$, and $P2X_{2/6}$ subunits have been described.

TABLE 15.1. P2X RECEPTORS

Adenosine (P1) Receptors

All four P1 GPCRs—A_1, A_{2A}, A_{2B}, and A_3 (Table 15.1)—are heterogeneously distributed in a variety of mammalian tissues including heart, smooth muscle, kidney, testis, platelets, leukocytes, and adipocytes. in addition to the CNS. The A_1 receptor is widely distributed in the CNS and is functionally coupled to inhibition of cyclic AMP (cAMP) formation, stimulation of potassium conductance, inhibition of N-channel–mediated calcium conductance, stimulation of phospholipase C production, and modulation of nitric oxide production (1 ,12). Selective agonists for the A_1 receptor are all adenosine analogues and include cyclohexyl (CHA; A_1 K_i = 1 to 5 nM), cyclopentyl (CPA; A_1 K_i = 0.6 nM), and 2-chlorocyclopentyl (CCPA; K_i = 0.6 nM) adenosine (27) (Fig. 15.1). Agonist effects at the

A_1 receptor are selectively blocked by the 8-substituted xanthines, cyclopentylxanthine (Fig. 15.3) (CPX; K_i = 0.46 nM) and CPT (K_i = 24 nM), and by nonxanthines such as N-0861 (K_i = 10 nM). The A_1 receptor shows distinct species pharmacology (8). Like other GPCRs, it can be allosterically modulated (28) by compounds such as PD 81,723 (Fig. 15.1) that, although not directly interacting with the agonist binding site of the receptor, stabilize an agonist-preferring conformation of the A_1 receptor independent of G-protein interactions (29).

The A_2 receptor exists in two distinct molecular and pharmacologically subtypes, both of which are linked to activation of adenylate cyclase (1). The A_{2A} receptor has high affinity for adenosine, may also use N- and P-type Ca^{2+} channels as signal transduction mechanisms, and is localized in the striatum, nucleus accumbens, and olfactory tubercle regions of mammalian brain. The lower-affinity A_{2B} receptor is more ubiquitously distributed throughout the CNS (1 ,30). The adenosine analogue, CGS 21680C (Fig. 15.1) (K_i A_{2A} = 15 nM), is the present agonist of choice for the A_{2A} receptor with the xanthine antagonists KF 17837 (Fig. 15.4) (K_i A_{2A} = 24 nM) and CSC 8-(3-chlorylstyryl) caffeine (K_i A_{2A} = 9 nM) and nonxanthines such as SCH 58261 (K_i A_{2A} = 2.3 nM) and ZM 241385 (K_i A_{2A} = 0.3 nM), being up to 6,800-fold selective for the A_{2A} receptor (27). Like the A_1 receptor, the A_{2A} receptor also shows species-dependent pharmacology (8). The A_{2B} receptor has been cloned and is widely distributed in brain and peripheral tissues (1 ,30). However, its functional characterization has proven difficult because of a paucity of selective ligands. Responses more potently elicited by the nonselective adenosine agonist, NECA (Fig. 15.1) and not by selective A_1-, A_{2A}-, or A_3-receptor agonists can be attributed to A_{2B}-receptor activation. Enprofylline (Fig. 15.3) is a selective, albeit weak, A_{2B}-receptor antagonist (30).

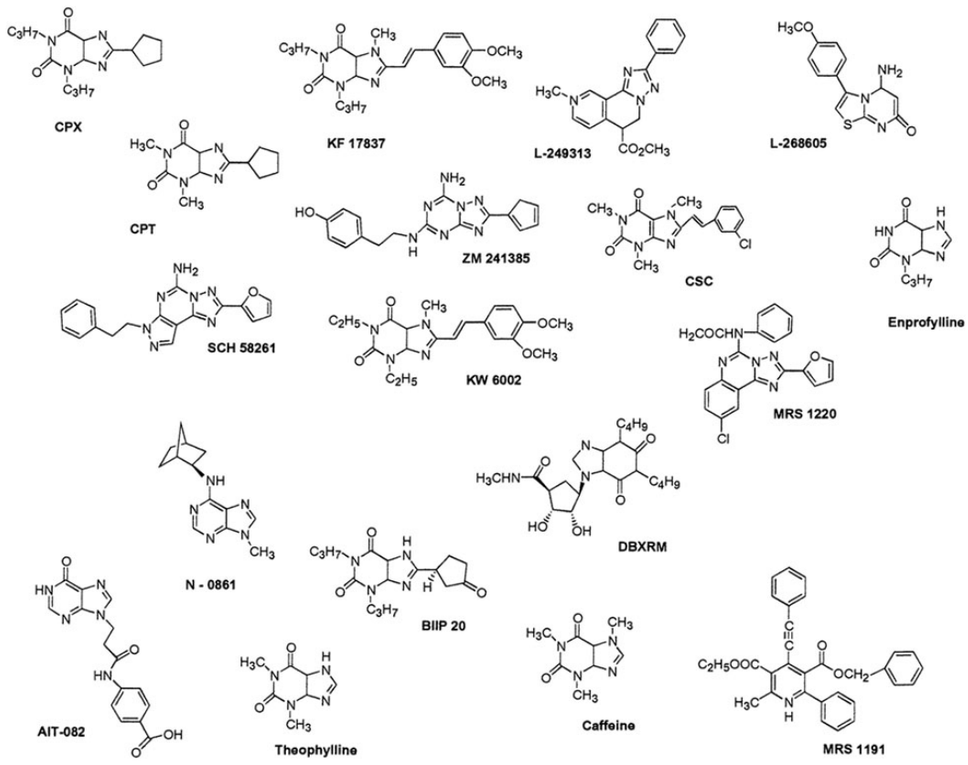

FIGURE 15.4. Structures of P2 receptor antagonists.

The A_3 receptor was the first P1 receptor identified by cloning rather than by pharmacologic characterization and is linked to inhibition of adenylate cyclase and elevation of cellular inositol 1,4,5-triphosphate (IP_3) levels and intracellular Ca^{2+}. It also shows distinct species-dependent pharmacology, especially in regard to xanthine antagonist blockade of the rat A_3 receptor (1 ,31 ,32), and it shows widespread distribution with low levels in brain. IB-MECA (Fig. 15.1) (K_i = 1nM) and its 2-chloro analogue (Cl^- IB-MECA; K_i = 0.3 - 0.7 nM) are potent and selective A_3-receptor agonists (27). The human, but not the rat, A_3 receptor is selectively blocked by xanthines (31), such as DBXRM (K_i A_3 = 229 nM), and by nonxanthines such as MRS 1191, MRS 1220, L-249313, L-268605, and MRE-1008-21M (Fig. 15.4). A_3 receptors are involved in mast cell function, eosinophil apoptosis, and the phenomenon known as preconditioning that occurs during ischemic reperfusion of the heart that protects against myocardial infarction (1 ,33).

P2 (ATP and UTP) Receptors

P2 receptors were originally classified on the basis of the rank-order potency of agonists structurally related to ATP. Most of these putative receptors (with the exception of the P_{2T} receptor) have been subsequently cloned and functionally characterized in various heterologous expression systems (1). However, their functional characterization in native tissues and in animals has been limited by a paucity of potent, selective, and bioavailable ligands, both agonists and antagonists. All known P2-agonist ligands are analogues of ATP, UTP, and ADP and, irrespective of their degree of chemical modification, show varying degrees of susceptibility to extracellular degradation and differences in intrinsic activity (27 ,34). The selectivity and potency of these agonists are thus very much dependent on the tissue preparation and species used and also on the experimental protocol. Indeed, few studies exist in which a systematic evaluation of the relative selectivity of P2-receptor agonists has been determined. BzATP (Fig. 15.2), which is widely used as a selective agonist for the $P2X_7$ receptor (EC_{50} = 18 μM), is, however, far more potent at transfected rat and human $P2X_1$ (EC_{50} = 1.9 nM) and $P2X_3$ (EC_{50} = 98 nM) receptors (35) and thus cannot be used, *a priori*, in defining a $P2X_7$-receptor–mediated response.

P2 receptors are present on excitable tissues, such as neurons,

glia, and smooth muscle cells (1), and can be grouped into three classes based on agonist effects (36). Group 1, comprising the $P2X_1$ and $P2X_3$ receptors, has high ATP affinity for ATP (EC_{50} = 1 μM) and is rapidly activated and desensitized. Group 2 includes the $P2X_2$, $P2X_4$, $P2X_5$, and $P2X_6$ receptors that have lower ATP affinity (EC_{50} = 10 μM), have a slow desensitization profile, and exhibit sustained depolarizing currents. The only receptor in Group 3 is the $P2X_7$ LGIC, which has low ATP affinity (EC_{50} = 300 - 400 μM) and shows little or no desensitization on agonist exposure.

P2X Receptors

P2X receptors are ATP-gated LGICs formed from various P2X subunits that share a common motif of two transmembrane-spanning regions (2TM). Like the amiloride-sensitive epithelial Na^+ channel, P2X receptor subunits have a large extracellular domain with both the N- and C-termini located intracellularly (1 ,37). A functional P2-receptor channel consists of multimeric combinations of the various P2X subunits to form a nonselective pore permeable to Ca^{2+}, K^+, and Na^+ that mediates rapid (approximately 10-millisecond) neurotransmission events. Available evidence indicates that functional P2X receptors are trimeric, in contrast to the typical pentameric structure of other LGICs (38). In addition to putative $P2X_1$ to $P2X_7$ homomers, $P2X_{1/5}$, $P2X_{2/3}$, and $P2X_{4/6}$ functional heteromers have been identified (1 ,39). $P2X_5$ and $P2X_6$ receptors do not appear to exist in homomeric form, but rather as heteromers with other P2X receptor subtypes. Unlike other LGICs, such as nAChRs, the 5-hydroxytryptamine ($5\text{-}HT_3$) receptor, little is known regarding the agonist (ATP) binding site on P2X receptor constructs or of ancillary sites that may modulate receptor function.

The utility of current P2-receptor antagonists, such as PPADS, DIDS, reactive blue-2, and suramin (Fig. 15.5) (27), is limited by their lack of selectivity for different P2

receptors and other proteins (34) or by their limited potency and bioavailability. These compounds can also inhibit the ectonucleotidases responsible for ATP breakdown, thus confounding receptor characterization (40). Radioligand-binding assays for P2 receptors are also far from robust; available ligands binding to cell lines lack any type of P2 receptor (41). The use of high throughput screening techniques to identify novel ligands thus depends on functional fluorescence assays such as FLIPR (fluorescence imaging plate redder) rather than binding.

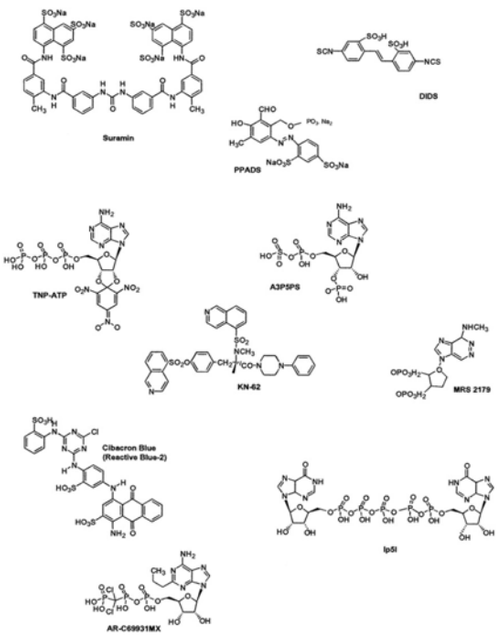

FIGURE 15.5. Structures of P1 receptor antagonists.

Among the newer P2X-receptor antagonists (Fig. 15.5) are the following: TNP-ATP, a noncompetitive, reversible allosteric antagonist at $P2X_1$ and $P2X_3$ receptors with nanomolar affinity (42) that also has weak activity at $P2X_4$ and $P2X_7$ receptors; Ip5I, a potent, selective $P2X_1$ antagonist (K_i < 100 nM) antagonist (43); KN-62, a potent (IC_{50} = 9 to 13 nM), noncompetitive antagonist of the human $P2X_7$ receptor that is inactive at the rat $P2X_7$ receptor (44). The ATP analogue, A3P5PS (Fig. 15.5), is a partial agonist–competitive antagonist at the turkey erythrocyte $P2Y_1$ receptor (27), with the derivative, MRS 2179 being a full $P2Y_1$-receptor antagonist (IC_{50} =330 nM). AR-C 69931-MX (Fig. 15.5) is a potent, selective antagonist at the ADP-sensitive $P_{2T}/P2Y_{AC}$ receptor involved in platelet aggregation that is currently in clinical trials as a novel antithrombotic agent (45).

$P2X_1$ receptors are activated by 2MeSATP, ATP, and αß-meATP (Fig. 15.2), and they exhibit rapid desensitization kinetics (Table 15.2) (1). $P2X_1$ subunits are present in the dorsal root, in trigeminal and celiac ganglia, and in spinal cord and brain. The $P2X_2$ receptor is activated by 2MeSATP and ATPγS but is insensitive to αß-meATP and ßγ-meATP (Fig. 15.2). It is present in brain, spinal cord, superior cervical ganglia, and adrenal medulla. $P2X_{2\text{-}1}$, $P2X_{2\text{-}2}$, $P2X_{2\text{-}3R}$, and $P2X_{2\text{-}3}$ receptors are splice variants of the $P2X_2$ receptor that have been localized, among other places, to the cochlear endothelium, an area in the ear associated with sound transduction (46). $P2X_1$ and $P2X_2$ receptors can be blocked by PPADS and suramin (1). The $P2X_3$ receptor has a rank order of activation in which 2MeSATP >> ATP > αß-meATP and is localized to a subset of sensory neurons that includes the dorsal root, trigeminal, and nodose ganglia (1). It has similar properties to the $P2X_1$ subtype including αß-meATP sensitivity and rapid desensitization kinetics. $P2X_2$ and $P2X_3$ subunits can form a functional heteromeric $P2X_{2/3}$ receptor *in vitro* (39) that combines the pharmacologic properties of $P2X_3$ (αß-meATP sensitivity) with the kinetic properties of $P2X_2$ (slow desensitization). $P2X_4$ receptors are activated by 2MeSATP and are only weakly activated by αß-meATP. The rat and human homologues of the $P2X_4$ receptor differ in their sensitivity to suramin and PPADS; the human $P2X_4$ receptor is weakly sensitive, and the rat $P2X_4$ receptor is insensitive to these P2X-receptor antagonists (1). The $P2X_4$ receptor is present in rat hippocampus, superior cervical ganglion, spinal cord, bronchial epithelium, adrenal gland, and testis, as well as human brain. The agonist profile for the $P2X_5$ receptor is ATP > 2MeSATP > ADP with αß-meATP being inactive. This receptor does not exhibit rapid desensitization kinetics but is blocked by suramin and PPADS. Message for the $P2X_5$ receptor is present in the central horn of the cervical spinal cord, in trigeminal and dorsal root ganglia neurons, and in the brain in the mesencephalic nucleus of the trigeminal nerve. The $P2X_6$ receptor is present in the superior cervical ganglion, cerebellar Purkinje cells, spinal motoneurons of lamina IX of the spinal cord, superficial dorsal horn neurons of lamina II, and trigeminal, dorsal root, and celiac ganglia (1). $P2X_4$ and $P2X_6$ subunits form functional heteromers *in vitro* (39).

TABLE 15.2. CLASSIFICATION OF P2Y RECEPTORS

	Agonist Rank Order Potency	Antagonist Rank Order Potency
$P2Y_1$	2-MeSADP > 2-MeSATP > HT-AMP > ADP > ADPβS > ATP > α,β-meATP > UTP inactive	MRS2179 > isoPPADS > A3′P5′P ≥ PPADS suramin
$P2Y_2$	ATP = UTP (100) > ATPγS = Ap_4A	
$P2Y_4$	UTP ≥ UTPγS > ATP	PPADS > reactive blue 2 > suramin > ATP (human)
$P2Y_6$	UDP >> UTP ≥ 2-MeSADP	Suramin > PPADS
$P2Y_{11}$	ATP > ADP >>> UTP	
$P2Y_{12}$	ADP	AR-C 69931MX = CT5054 >>> ATP
$P2Y_{13}$	ADP	2Me5ADP >> ATP

The $P2X_7$ receptor, also known as the $P_{2Z}/P2Z$ receptor before it was cloned (47), is present in the superior cervical ganglion and spinal cord, mast cells, and macrophages (48). Cerebral artery occlusion results in an increase in $P2X_7$ immunoreactivity in the stroke-associated penumbral region (49). The $P2X_7$ receptor has a long (240 amino acid) intracellular C-terminal region that allows the receptor to form

a large nonselective cytolytic pore on prolonged or repeated agonist stimulation (1 ,48). Exposure of the $P2X_7$ receptor to ATP for brief periods (1 to 2 seconds) results in transient pore opening that mediates cell-to-cell communication. Prolonged receptor activation triggers cytolytic pore formation with the initiation of an apoptotic cascade involving caspase-1 (interleukin 1ß convertase) and an associated release of IL-1ß from macrophages (48). The $P2X_7$ receptor is partially activated by saturating concentrations of ATP and is fully activated by the ATP analogue BzATP (Fig. 15.2). The ability to form a cytolytic pore was considered unique for the $P2X_7$ receptor, but other P2X receptors such as P2X and P2X show the same phenomenon on prolonged exposure to ATP, a finding indicating that the intracellular C-terminal tail is not a prerequisite for cytolytic pore formation (50 ,51).

P2Y Receptors

P2Y receptors are GPCRs activated by purine or pyrimidine nucleotides (1 ,52). The seven mammalian functional subtypes, $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, $P2Y_{11}$, $P2Y_{12}$, and $P2Y_{13}$, have been cloned and are coupled to Gq_{11}. Receptor activation results in stimulation of phospholipase C and IP_3 activation and subsequent release of calcium from intracellular stores. The P_{2T} receptor, present in platelets and preferentially sensitive to ADP, has been cloned, as the $P2Y_{12}$ receptor.

The $P2Y_1$ receptor is preferentially activated by adenine nucleotides, with 2MeSATP the most potent. UTP and UDP are inactive at this receptor. Suramin, PPADS, cibacron blue, A3P5PS, and MRS 2179 (Fig. 15.5) are competitive antagonists at this receptor (1 ,27). The $P2Y_2$ receptor is activated by both ATP and UTP; nucleotide diphosphates are inactive (1 ,52). Antagonists such as suramin are less efficacious at the $P2Y_2$ receptor. UTP is the preferred agonist for the $P2Y_4$ receptor, with ATP and the nucleotide diphosphates inactive. Diphosphates are more active at the $P2Y_6$ receptor than triphosphates, and this has led to the classification of the $P2Y_6$ receptor as a UDP-preferring receptor. The $P2Y_{11}$ receptor is unique among other P2Y receptors in that only ATP serves as an agonist for this receptor (53). The $P2Y_{12}$ and $P2Y_{13}$ receptors are ADP-selective receptors.

Diadenosine polyphosphates including Ap4A and Ap5A (Fig. 15.2) comprise another group of purine-signaling molecules that modulate cell function by activation of cell-surface P2 receptors (1 ,54). Whereas an Ap4A receptor that modulates neurotransmitter release and amphetamine-elicited Ap4A release has been pharmacologically characterized in nervous tissue, it is unclear whether diadenosine polyphosphate actions involve distinct receptor subtypes or reflect activation of known P2 receptors. Receptors for the diadenosine polyphosphates have not yet been cloned.

MITOCHONDRIAL PURINE RECEPTORS?

Part of "15 - Purinergic Neurotransmission "

In addition to functioning as the key source of ATP within the cell, mitochondria play a key role in the apoptotic cascade as the source of the cytochrome C that is released after changes in mitochondrial transition pore function elicited by members of the bcl-2 family of cell death proteins (55). The ability of the $P2X_7$ receptor to initiate an apoptotic cascade by activation of caspase-1 (48) and the key role of mitochondria in various degenerative diseases (56 ,57) raise the question whether intracellular P2 receptors are present on the outer mitochondrial membrane and may provide a direct mechanism for ATP to influence mitochondrial function.

THERAPEUTIC POTENTIAL OF PURINES IN NERVOUS TISSUE

Part of "15 - Purinergic Neurotransmission "

Adenosine potently inhibits the release of the neurotransmitters dopamine, GABA, glutamate, acetylcholine, serotonin, and norepinephrine and acts through presynaptic A_1 receptors (12). Adenosine acts preferentially on excitatory versus inhibitory neurotransmitter release, a finding suggesting a degree of physiologic specificity in modulating brain function. Adenosine also directly modulates postsynaptic neuronal excitability by activating A_1 and A_{2A} receptors resulting in hyperpolarization of the postsynaptic membrane.

Over the past 2 decades, many studies have provided evidence of involvement of purines in the actions of various CNS-active drugs including antipsychotics, antidepressants, anxiolytics, and cognition enhancers. These studies have come from experiments in which the effects of known CNS drugs representative of these therapeutic classes were examined for their ability to modulate adenosine-mediated responses in the CNS, or, alternatively, they studied the effects of various P1 ligands, both agonists or antagonists, on the effects of such prototypic CNS agents. In many instances, only single, somewhat high, concentrations of an isolated compound, or limited numbers of compounds, were used to generalize to a complete class of psychotherapeutic agents, often with no negative control data, thus limiting the value of the data (58).

For P2 receptors, the absence of ligands, agonists, and antagonists has limited the functional characterization of the various receptor subtypes. The delineation of a role for P2 receptors in CNS disorders has been postulated largely on the basis of *in situ* localization of the mRNAs encoding the different P2 receptor subtypes or of immunohistochemical studies.

Transgenic Models of P1 and P2 Receptor Function

For both P1 and P2 receptors, the use of mice either deficient in, or overexpressing, a targeted receptor can potentially

provide a unique means to assess the role of the given receptor, the phenotype of which will provide information on the role of the receptor. Although this approach is not always straightforward because some phenotypes are fatal and, in others, a knockout of one receptor leads to compensation in associated receptor systems such that the resultant mouse phenotype is atypical, knockouts can be helpful in the absence of selective antagonists or antisense probes.

P1 receptor knockouts show altered cardiovascular function (A_1) and reduced exploratory activity, aggressiveness, hypoalgesia, and high blood pressure (A_{2A}) (59). P2 knockouts are associated with decreased male fertility ($P2X_1$) (60), decreased nociception and bladder hyporeflexia ($P2X_3$) (61), decreased platelet aggregation and bleeding time ($P2Y_1$) (62), and reduced chloride secretion ($P2Y_2$) (63). A preliminary report on a $P2X_7$ knockout has appeared (64).

PURINERGIC THERAPEUTICS

Part of "15 - Purinergic Neurotransmission "

Three distinct classes of compound can modulate P1 and P2 receptor function: (a) conventional agonist, partial agonist and antagonist ligands; (b) allosteric modulators of receptor function; and (c) modulators of the endogenous systems that regulate the extracellular availability of ATP, adenosine, UTP, and their respective nucleotides. This last group includes the various ecto-ATPases that catalyze the degradation of nucleotides (5), ADA, AK, and the bidirectional member transporter systems that remove adenosine from the extracellular environment (21 ,65). From data on AK effects in brain tissue (22), it appears that modulation of endogenous adenosine levels by inhibition of AK is not a viable drug discovery approach.

Efforts over the last 25 years to develop directly acting P1-receptor agonists and antagonists as therapeutic agents (8) have proven less than successful because of a combination of the choice of disease states in which other therapeutic modalities are clearly superior (58) and side effects are associated with global receptor modulation. Partial agonists, allosteric modulators, and novel modulators of ATP metabolism may prove clinically useful agents with improved therapeutic indices (65).

Stroke and Ischemia

Extracellular adenosine levels are markedly increased after hypoxia and focal ischemia, a finding providing additional evidence that the purine acts as a homeostatic neuroprotective agent (8). Adenosine-receptor agonists such as CHA reduce stroke-related cell death and hippocampal neurodegeneration, whereas adenosine antagonists exacerbate ischemic brain damage by enhancing glutamate release. The neuroprotective effects of adenosine are mediated by several P1 receptors: A_1-receptor activation stabilizes neuronal membrane potential, inhibits neuronal excitability and glutamate release (8 ,12), and thus prevents initiation of the stroke cascade (66).

Adenosine also hyperpolarizes astrocyte membranes limiting extracellular glutamate and potassium accumulation and modulates local cerebral blood flow and local inflammatory responses, such as platelet aggregation, neutrophil recruitment, and adhesion acting through the A_{2A} receptor (67). A_3-receptor agonists have biphasic effects on cell survival. At nanomolar concentrations, they are neuroprotective and inhibit apoptosis, but at micromolar concentrations they are neurotoxic (31).

mRNA for the $P2X_7$ receptor is up-regulated on microglial cells in the ischemic penumbral region 24 hours after middle cerebral artery occlusion in the rat (49), a finding indicating that cytolytic pore formation and inflammatory cytokine release are associated with neural trauma and neurodegeneration. Antisense to the $P2X_7$ receptor or selective receptor antagonists may represent a novel approach to the treatment of stroke.

Epilepsy

Seizure activity is associated with rapid and marked increases in CNS adenosine concentrations in animals (68), as well as in patients with epilepsy with spontaneous-onset seizures (69). Seizure activity induced by a variety of chemical and electrical stimuli in animal models is reduced by adenosine and related agonists (68) acting through A_1receptors. In electrically kindled seizure models, adenosine agonists reduce seizure severity and duration without significantly altering seizure threshold. These anticonvulsant effects are blocked by doses of methylxanthines that, when given alone, have no observable effect on seizure activity (68), a finding leading to the hypothesis that adenosine functions as an endogenous anticonvulsant.

Neurodegeneration: Alzheimer's Disease and Parkinson's Disease

The nerve cell death that follows excessive glutamate release and changes in calcium homeostasis after ischemia and hypoxia may reflect an acute manifestation of more subtle, long-term changes associated with apoptotic and necrotic cell death in Alzheimer's disease (AD) and Parkinson's disease (PD). Adenosine antagonists including caffeine, theophylline, and BIIP 20 (Fig. 15.4) are potent CNS stimulants (8 ,18), and they can enhance cognition in animal models by blocking the actions of endogenous adenosine. Certain compounds acting by purinergic mechanisms, such as BIIP 20 and propentofylline, have been examined in the clinic for their efficacy in cognitive disorders. Although provocative clinical data have been generated, neither compound showed sufficiently robust efficacy in larger AD trials

to warrant continuation. However, aged patients with rheumatoid arthritis who consume large quantities of antiinflammatory agents such as indomethacin show an inverse correlation for the incidence of AD, a finding highlighting the pivotal role of inflammation in disease origin. Adenosine agonists and AK inhibitors have marked antiinflammatory activity (67), inhibiting free radical production, and thus they may be effective in maintaining cell function in AD, in addition to modulating cytotoxic events.

Trophic factors in nervous tissue act to ensure neuronal viability and regeneration. Withdrawal of nerve growth factor, which exerts a tonic cell death–suppressing signal, leads to neuronal death. Polypeptide growth factors linked to receptor tyrosine kinases, such as fibroblast growth factors, epidermal growth factor, and platelet-derived growth factor, are increased with neural injury (70). ATP can act in combination with various growth factors to stimulate astrocyte proliferation and to contribute to the process of reactive astrogliosis, a hypertrophic-hyperplastic response typically associated with brain trauma, stroke and ischemia, seizures, and various neurodegenerative disorders. In reactive astrogliosis, astrocytes undergo process elongation and express glial fibrillary acidic protein, an astrocyte-specific intermediate filament protein with an increase in astroglial cellular proliferation. ATP increases glial fibrillary acidic protein and activator protein-1 (AP-1) complex formation in astrocytes and mimics the effects of basic fibroblast growth factor (70). Both ATP and guanosine triphosphate induce trophic factor (nerve growth factor, neurotrophin-3, fibroblast growth factor) synthesis in astrocytes and neurons. The effects of guanosine triphosphate are, however, not consistent with any known P2-receptor profile. Nonetheless, these studies have focused research on the hypoxanthine analogue, neotrofin (AIT-082) (Fig. 15.1), which up-regulates neurotrophin production and enhances working memory and restores age-induced memory deficits in mice (71). This compound has shown positive effects in early phase II trials for AD.

In 1974, Fuxe showed that methylxanthines such as caffeine could stimulate rotational behavior and could potentiate the effects of dopamine agonists in rats with unilateral striatal lesions Conversely, adenosine agonists blocked the behavioral effects of dopamine (72). Anatomic links between central dopamine and adenosine systems are well established; adenosine A_{2A} receptors are highly localized in striatum, nucleus accumbens, and olfactory tubercle, brain regions that also have high densities of dopamine D1 and D2 receptors. mRNAs for adenosine A_{2A} receptors and dopamine D2 receptors are co-localized in GABAergic-enkephalin striatopallidal neurons in the basal ganglia (Fig. 15.6) that form an "indirect" pathway from the striatum to the globus pallidus that originates from striatal GABA-enkephalinergic neurons. Through GABAergic relays, this pathway interacts with a glutaminergic pathway from the subthalamic nucleus that can activate the internal segment of the pars reticulata, which, turn, through a pars reticulata–thalamic GABAergic pathway, inhibits the thalamic-cortical glutaminergic pathway. Dysfunction of this pathway may underlie the movement disorders seen in Huntington chorea and PD. A direct pathway originating in striatal GABAergic–substance P–dynorphinergic neurons inhibits the internal segment of the pars reticulata to disinhibit the ascending thalamic glutaminergic pathway and to activate the cortex (Fig. 15.6). The balance between the direct (cortical activating) and indirect (cortical inhibiting) striatal dopaminergic pathways provides a tonic regulation of normal motor activity. These studies indicate that striatal adenosine A_{2A} receptors may play a pivotal role in neurologic disorders involving basal ganglia dysfunction such as PD. The A_{2A} agonist, CGS 21680, given intrastriatally, attenuates the rotational behavior produced by dopamine agonists in unilaterally lesioned rats. Mechanistically, radioligand-binding studies have shown an increased efficacy of CGS 21680 in reducing the binding affinity of supersensitive D2 receptors, a finding supporting the increased sensitivity of animals with supersensitive dopamine receptors to CGS 21680 treatment. Repeated administration of the dopamine antagonist, haloperidol can up-regulate the density of both D2 and A_{2A} receptors in rat striatum.

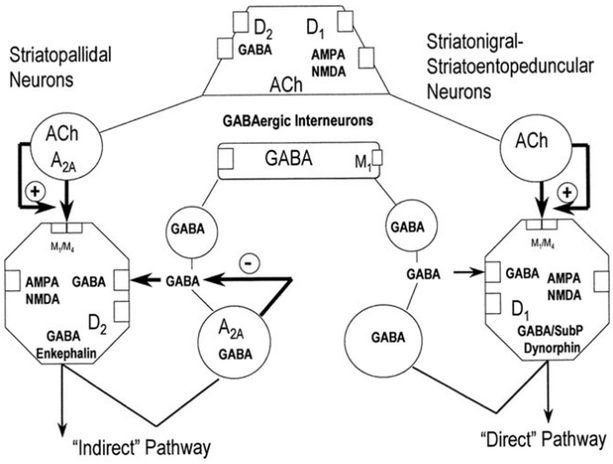

FIGURE 15.6. Dopamine–adenosine (ADO) interactions in the substantia nigra. An indirect pathway dopaminergic pathway arises from the striatal GABA-enkephalinergic dopaminergic neurons on which both dopamine D1 and adenosine A_{2A} receptors are co-localized. Through a GABAergic interneuron originating in the external globus pallidus, the indirect pathway connects to a glutaminergic pathway arising in the subthalamic nucleus. This, in turn, can activate the internal segment of the pars reticulata and, through another GABA pathway, inhibit ascending glutaminegic neurons arising from the thalamus that innervate the cortex. The direct pathway arises from striatal GABA–substance P–dynorphinergic neurons that, through a GABAergic relay, inhibit the internal segment of the pars reticulata to disinhibit the ascending thalamic-cortical glutaminergic pathway. The balance between the direct (activating) and indirect (inhibitory) striatal dopaminergic pathways can then tonically regulate normal motor activity. Dopaminergic inputs arising from the substantia nigra pars compacta can facilitate motor activity, inhibiting the indirect pathway by activation of D2 receptors and activating the direct pathway by D1 receptor activation. (Adapted from Svenningsson P, Le Moine C, Fisone G, et al. Distribution, biochemistry and function of striatal adenosine A_{2A} receptors. *Prog Neurobiol* 1999;59:355–396; and Richardson PJ, Kase H, Jenner PG. Adenosine A_{2A} receptor antagonists as new agents for the treatment of Parkinson's disease. *Trends Pharmacol Sci* 1997;18:338–344.)

Adenosine A_1 receptor activation can reduce the high-affinity state of striatal dopamine D1 receptors, the A_1 receptor agonist, and CPA blocking D1-receptor–mediated locomotor activation in reserpinized mice (72). The nonselective adenosine agonist, NECA, can attenuate the perioral dyskinesias induced by D1-receptor activation in rabbits. Acting through striatal A_{2A} and A_1 receptors, adenosine directly modulates dopamine-receptor–mediated effects on striatal GABA-enkephalinergic neurons and striatal GABA–substance P neurons (Fig. 15.6). These adenosine agonist–mediated effects are independent of G-protein coupling and may involve an intramembrane modulatory mechanism involving receptor heterooligimerization (26).

The dynamic interactions between dopaminergic and purinergic systems in striatum suggest that dopaminergic dysfunction may be indirectly ameliorated by adenosine receptor modulation. Selective adenosine A_{2A} receptor antagonists such as KF 17837 and KW 6002 (Fig. 15.4) have shown positive effects in 1-methyl-4-[henyl-1,2,3,6-tetrahydropyridine–lesioned marmosets and cynomolgus monkeys, well characterized animal models of PD, enhancing the effects of L-dopa (73 ,74). KW-6002 has successfully completed human phase I trials. More recently, a 30-year longitudinal study of 8,004 Japanese-American man enrolled in the Honolulu Heart Program showed an inverse association of the incidence of PD with caffeinated coffee consumption. In men who drank no coffee, the incidence of PD was 10.4 per 10,000 person-years, and it was 1.9 per 10,000 person-years in men drinking at least 28 oz of coffee per day (75).

Adenosine agonists can mimic the biochemical and behavioral

actions of dopamine antagonists in animal models by activation of A_{2A} receptors (9 ,72), a process that inhibits dopamine synthesis and attenuates dopamine transductional processes. CGS 21680, like typical and atypical neuroleptics, can reverse apomorphine-induced loss of prepulse inhibition (76). These actions involve a decrease in dopaminergic neurotransmission, with adenosine receptor agonists acting as functional dopamine antagonists. Adenosine agonists have a behavioral profile similar to that of dopamine antagonists in a conditioned avoidance response paradigm (77), in which they potently disrupting avoidance responding without significantly impairing escape behavior. They also produce catalepsy at the same dose levels effective in attenuating conditioned avoidance response, a property shared by typical neuroleptic agents such as haloperidol. CI-936, an A_{2A} agonist (Fig. 15.1), entered clinical trials in the mid 1970s as a novel antipsychotic agent, but its development was discontinued for unstated reasons.

Sleep

The hypnotic and sedative effects of adenosine are well known, as are the central stimulant activities of the various xanthine adenosine antagonists including caffeine (18). Direct adenosine administration into the brain elicits an EEG profile similar to that observed in deep sleep, an increase in rapid eye movement (REM) sleep with a reduction in REM sleep latency resulting in an increase in total sleep. In contrast, caffeine suppresses REM sleep and decreases total sleep time. Microdialysis studies have shown that extracellular adenosine concentrations are increased in basal forebrain in direct proportion to periods of sustained wakefulness and decline during sleep, a finding indicating that adenosine functions as a endogenous sleep regulator (19). Infusion of the A_{2A} agonist, CGS 21680, into the subarachnoid space associated with the ventral surface of the rostral basal forebrain, an area designated the prostaglandin D_2–sensitive sleep-promoting zone, increased slow-wave and paradoxical sleep, effects that were blocked by the A_{2A} antagonist, KF 17837 (78). The A_1-selective agonist, CHA, suppressed slow-wave and paradoxical sleep before eliciting an increase in low-wave sleep.

Pain

The role of purines in pain perception is well established (79 ,80 and 81), and both P1 agonists and P2X antagonists may represent novel approaches to nociception. ATP application to sensory afferents results in neuronal hyperexcitability and the perception of intense pain (79). These pronociceptive effects are mediated by $P2X_3$ and $P2X_{2/3}$ receptors present on sensory afferents and in the spinal cord. The nucleotide also induces nociceptive responses at local sites of administration and can facilitate nociceptive responses to other noxious stimuli, such as substance P. P2 receptor antagonists such as suramin and PPADS, even though they are limited in their *in vivo* effects, reduce nociceptive responses in animal models of acute and persistent pain (1 ,79). ATP is released from certain cell types (e.g., sympathetic nerves, endothelial cells, visceral smooth muscle) in response to trauma (1 ,8 ,79), and $P2X_3$-receptor expression is up-regulated in sensory afferents and spinal cord after damage to peripheral sensory fibers. $P2X_3$-receptor knockout mice have reduced nociceptive responses (61). The effects of adenosine are opposite effects to those of ATP (80), a finding suggesting that the nociceptive effects of ATP can be autoregulated by adenosine production from the nucleotide. Adenosine, adenosine-receptor agonists, and AK inhibitors inhibit nociceptive processes in the brain and spinal cord. When given intrathecally, these agents have analgesic activity in a broad spectrum of animal models (e.g., mouse hot plate, mouse tail flick, rat formalin, mouse abdominal constriction, rat neuropathic pain models), effects that are blocked by systemic or intrathecal administration of adenosine antagonists. Adenosine A_1-receptor agonists modulate acutely evoked and inflammation-evoked responses of spinal cord dorsal horn nociceptive neurons and can also inhibit pain behaviors elicited by spinal injection of substance P and the glutamate agonist, *N*-methyl-D-aspartate (NMDA). Glutamate is a key mediator of the abnormal hyperexcitability of spinal cord dorsal horn neurons (central sensitization) associated with clinical pain states. A_1 agonists can inhibit the spinal cord release of glutamate and can also reduce cerebrospinal fluid levels of substance P in rat, another key mediator of nociceptive responses. Adenosine has both presynaptic and postsynaptic effects on transmission from primary afferent fibers to neurons of the substantia gelatinosa of the spinal dorsal horn (12 ,80 ,81), and it involves both peripheral and supraspinal mechanisms. Adenosine agonists such as CHA and NECA, were 10- to 1,000-fold more potent in inhibiting acetylcholine-induced writhing in mice when these agents were administered intracerebroventricularly than orally, a finding indicating a supraspinal site of action. The ability of adenosine to inhibit peripheral neurotransmitter (12), and inflammatory processes (67), may block peripheral sensitization, a key feature of the pain resulting from tissue injury and inflammation.

Adenosine agonists are also active in human pain states (81). Spinal administration of the A_1 agonist, R-PIA, relieved allodynia in a patient with neuropathic pain without affecting normal sensory perception, whereas adenosine infusion at doses without effect on the cardiovascular system improved pain symptoms and reduced spontaneous pain and ongoing hyperalgesia and allodynia in patients with neuropathic pain. Low-dose infusion of adenosine during surgical procedures reduced the requirement for volatile anesthetic and also for postoperative opioid analgesia (82). AK inhibitors, such as CP 3269 and ABT-702 (Fig. 15.1), are effective analgesic agents in animal pain models by effects that can be blocked by xanthine adenosine antagonists.

CHALLENGES IN THE DEVELOPMENT OF CNS-SELECTIVE THERAPEUTIC AGENTS

Part of "15 - Purinergic Neurotransmission "

The field of purinergic molecular biology and pharmacology has exploded as more is learned about the cellular targets through which ATP, ADP, AMP, and adenosine (and UTP) produce their effects on mammalian tissues. A clear historical delineation between the P1 and P2 fields is that in the former, more than 20 years of pharmacology and medicinal chemistry resulted in the identification of receptor selective ligands before the receptors were cloned. In contrast, definitive evidence for the existence of the P2-receptor family resulted from both pharmacologic and cloning studies. The latter have resulted in the identification of a remarkable diversity of receptors responsive to ATP, unfortunately in the absence of selective, bioavailable ligands, especially antagonists, that will allow a clearer understanding of P2-receptor

function in normal and pathologic states. Evidence of the oligomerization of GPCRs and the emerging data on P2X heteromers both within the P2-receptor family and with other LGICs, such as nAChRs, suggest that the dynamics and the actual composition of systems targeted by purinergic receptors are potentially very complex (83).

Early efforts to develop therapeutics based on the modulation of P1-receptor–mediated processes met with limited success. Only adenosine has been approved for use as a cardiac imaging agent and for the treatment of supraventricular tachycardia, acute systemic uses that avoid some of the side effects seen with long-acting adenosine agonists. Similarly, the unexpected *in vivo* effects of AK inhibitors suggest that this is not a viable approach to the discovery of new drugs. The use of the adenosine antagonist theophylline for the treatment of asthma and the widespread use of caffeine as a CNS stimulant represent other P1-targeted therapeutics. The evaluation of A_{2A} antagonists as indirect dopamine agonists for use in PD (73 ,74 and 75) is an intriguing and novel approach to treating this neurodegenerative disorder, although the side effect liabilities are unknown at present.

In contrast, the highly discrete localization of $P2X_3$ receptors to sensory nociceptive neurons (79) has led to an intensive effort to identify $P2X_3$ antagonists as novel analgesic agents. Similarly, the discrete localization of other P2 receptors and evidence from mouse knockout studies suggest that selective agonists and antagonists for these receptor subtypes may represent very novel therapeutic agents as well as research tools to understand target function.

A caveat in the drug discovery process, as in all life's endeavors, is that the less that is known regarding the functional liabilities of a molecular target, the more attractive it is as drug target. In the area of purinergic medications, the identification of new ligands in combination with a broader-based evaluation of compound efficacy and side effect liability will greatly assist in the prioritization of therapeutic targets that are amenable to modulation by purinergic ligands (57). Finally, the renewed interest in mitochondria as cellular organelles that have function beyond energy production (56) represents an additional level of molecular targeting for P1- and P2-receptor ligands that may have benefit in treating human disease states, especially those involving apoptosis (55).

Neurotrophic Factors and Intracellular Signal Transduction Pathways

David S. Russell

Ronald S. Duman

David S. Russell and Ronald S. Duman: Laboratory of Molecular Psychiatry, Departments of Psychiatry and Pharmacology, Yale University School of Medicine, Connecticut Mental Health Center, New Haven, Connecticut.

A clear limitation of treating diseases of the central nervous system arises from the loss of regenerative potential of the brain at a very early age. Improper development of neural circuits or injury of neurons appears to be permanently fixed in the adult, with seemingly little hope of restorative therapy. This is most clearly true of the spectrum of neurologic diseases, such as neurodegenerative diseases (e.g., Alzheimer's or Parkinson's disease and stroke) and inflammatory disease (e.g., multiple sclerosis). In addition, breakthrough disorders such as epilepsy or myoclonus reflect inappropriate “wiring” or lack of appropriate feedback control of neuronal activity. It has also become apparent that some psychiatric diseases represent similar fixed deficits or lack of appropriate functional adaptation. Neurochemical and neuroanatomic deficits have been documented in affective diseases, schizophrenia, and anxiety disorders. Methods to recreate the early restorative potential of the brain would have great potential for significantly, and possibly permanently, reversing the often debilitating features of these neurologic and psychiatric diseases.

Over the last several years, of body of literature has delineated the important roles of neurotrophic factors in guiding the development of the nervous system. The first identified neurotrophic factor, nerve growth factor (NGF), was identified and characterized in the pivotal studies of Levi-Montalcini (1). The general properties of NGF now essentially define what neuroscientists consider a *neurotrophic factor*. A neurotrophic factor is capable of supporting the survival of at least one population of neurons in culture. It is secreted by a target tissue (either neuronal or nonneuronal) and acts on the neurons that innervate that tissue to support their survival or differentiation. Finally, a neurotrophic factor is expressed in the appropriate region and at the appropriate time in development to support the survival of a particular neuronal population. Although several variations and extensions of these principles have been delineated, the basics of defining a neurotrophic factor remain the same.

An exciting development in the neurosciences has been the realization that neurotrophic factors play important roles in the adult brain. The time course of neurotrophic factor expression is intriguing and indicates important function in the adult nervous system, as well as during development (2 ,3 and 4). The expression of these factors usually is very high during early development, a time of substantial growth, differentiation, and modeling of the nervous system. Later the levels generally drop, but they do not subside completely. In fact, in most cases in which it has been explored, the continued presence of these factors is substantial and is critical throughout adulthood (e.g., see refs. 5 ,6 and 7). Neuronal populations continue to depend on these factors for survival and optimal functioning.

More intriguing, although perhaps not surprising, studies have clearly shown that after development, these factors participate in the ongoing remodeling of neuronal function that underlies the adaptability or plasticity of neurons. In some cases, specific neurotrophic factors have been found to be necessary and sufficient for these changes to occur, from hippocampal plasticity and long-term potentiation (8 ,9 ,10 and 11) to the acquisition of new songs by songbirds (12 ,13 and 14). Models of neuronal now often incorporate components of neurotrophic factor signaling to explain synaptic alterations or strengthening. Contrary to the original models, these signaling events have been found not only to be retrograde signals from target neurons or other tissues, but also to be anterograde or autocrine signals. Furthermore, numerous studies have demonstrated that the expression of at least some of these factors can be rapidly regulated in the adult, a finding supporting a dynamic role in mediating responses to the environment.

Ongoing work in the neurotrophic factor field has been

devoted to characterizing the pathways that underlie the intracellular signaling of these factors. This information may then be used to treat many different neurologic and psychiatric disorders, given the apparent critical roles of neurotrophic factors in the normal functioning and adaptability of the brain, as well as their potential to recapitulate early developmental processes to restore damaged or maladaptive neural systems. This review focuses on the neurobiology of these factors, their interactions with classical neurotransmitter systems, and their potential roles in the origin and possible treatment of psychiatric illnesses.

NEUROTROPHINS

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

The number of neurotrophic factors has now been expanded in to the dozens, each with unique a specificity in terms of biological activity, regional and temporal expression, and target specificity. Some factors previously known for their effects in other systems, such as insulin-like growth factors or tumor-derived factors, have now clearly been found also to be neurotrophic factors. These have been grouped into different families largely based on homology at the level of nucleotide sequence and therefore evolutionary relatedness. Perhaps the best understood and most widely expressed in the brain of these families are the *neurotrophins* (NTs) (2 ,15). NGF is the prototype of the NT family, which also now includes brain-derived neurotrophic factor (BDNF), NT-3, and NT-4 (or NT-4/5). NGF has the most restricted specificity among these. NGF in the brain acts specifically on cholinergic neurons. In the rest of the nervous system, it also acts on sympathetic and sensory neurons. BDNF and NT-3 are widely and highly expressed, particularly in cortical and neocortical structures. NT-4 is also widely expressed, although generally at lower levels in the adult than are the others. The NTs are small, secreted proteins of about 12 kd that contain characteristic intramolecular disulfide bonds. These then form active noncovalent homodimers. They are found stored in vesicles clustered near the membrane. Each has been cloned and expressed in active recombinant forms.

TRK RECEPTORS

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

Generally better conserved than their ligands, the neurotrophic factor receptors also form families of related proteins (16 ,17). These receptors can be found in many different forms, from single, active proteins to large heteromeric complexes. Common to these are an extracellular ligand-binding portion, a mechanism to transduce this signal across the membrane, and at least one intracellular signaling apparatus. These may be contained in single proteins or distributed among several interacting proteins. Most, if not all, of the neurotrophic factor receptor complexes include a protein tyrosine kinase. Although phosphorylation on tyrosine residues represents a relatively small proportion of all protein phosphorylation in the cell, it seems to be a critical part of neurotrophic factor signal transduction and function.

The NTs act through receptors known as *Trk receptors*. Given their name from a troponin/receptor kinase gene fusion identified from colon carcinoma, it has now been found that in their normal (protooncogene) forms, each Trk receptor contains a ligand-binding domain, a single transmembrane domain, and an intrinsic, intracellular tyrosine kinase domain (16 ,17). Each receptor, when transfected into a cell line, is capable of transducing the appropriate NT signals independently of other receptor proteins (18). There is specificity among the Trk receptors at physiologic NT concentrations. TrkA is a receptor for NGF, whereas TrkC is preferentially bound by NT-3. TrkB serves as a receptor for both BDNF and NT-4. The expression patterns of these receptors correlate with known sensitivity of those neurons to specific NTs. Several studies, particularly in mice with engineered deletions of NTs or their receptors, have shown significant complexity to these interactions. A review of this work falls beyond the scope of this review.

TRK DOCKING PROTEINS

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

On binding of an NT, the Trk receptor tyrosine kinase becomes activated. The most critical substrate of this activity appears to be the receptor itself. The receptor becomes rapidly autophosphorylated, and this is critical to receptor function. The receptor autophosphorylation sites form *docking sites* for the interaction of downstream signaling molecules (Fig. 16.1). Many signaling proteins contain domains that specifically bind to tyrosine residues when they are phosphorylated. Further binding specificity is mediated by the amino acids surrounding the autophosphorylated tyrosine. The domains of the signaling molecules that are used to bind the tyrosine residues seem to fall into a small number of conserved motifs (19).

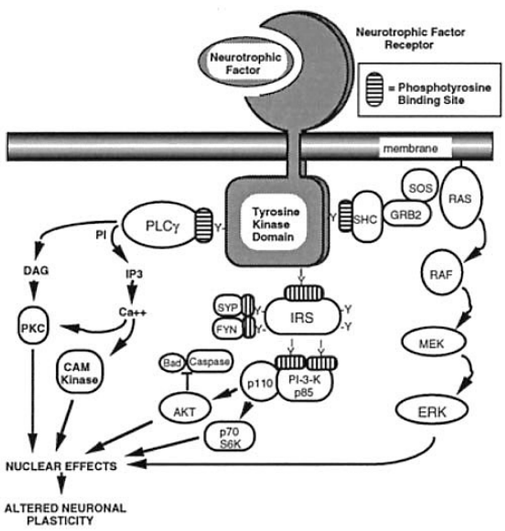

FIGURE 16.1. Neurotrophin intracellular signal transduction pathways. This schematic represents the three major signaling pathways emanating from a Trk-like tyrosine kinase receptor. The ligand, here a neurotrophin dimer, binds to its receptor and activates the tyrosine kinase activity. This results in autophosphorylation and phosphorylation of substrates. A complex forms in which docking proteins bind to the autophosphorylated receptor and are activated. These docking proteins bind to the receptor phosphorylation sites by SH2 domains (PLC-γ) or PTB domains (IRS and Shc). The three pathways shown here are as follows: (1) The PLC-γ pathway leads to the production of diacylglycerol and intracellular calcium. This results in activation of CAM kinases and PKC. (2) PI-3-Kinase (PI-3-K), comprising an 85-kd regulatory subunit and a 100-kd catalytic subunit, generally becomes activated by binding to an insulin receptor substrate (IRS)–like adaptor protein, which interacts with the receptor and then activates signaling proteins. IRS proteins also bind other signaling molecules such as Fyn and Syp. The PI-3-K then activates AKT and p70 S6-kinase (p70 S6K). AKT has an antiapoptotic effect through actions on Bad and caspaces. (3) Ras becomes activated through the stimulation of the GDP/GTP exchange activity of SOS, which is in a complex with Shc and Grb2. Activated Ras then turns on the cascade of kinases including Raf, MEK, and erks (also known as MAP kinases). Erks stimulate many known effectors. Each of these pathways then exerts a number of nuclear and nonnuclear actions with short- and long-term consequences for the cells.

Most proteins that bind to phosphorylated tyrosines fall into one of two groups. The most common phosphotyrosine binding motif is the *src-homology domain 2, or SH-2 domain*. SH-2 domains are typically identified based on their homology to other SH-2 domain–containing proteins. Some of these have been shown directly to possess specificity for phosphorylated tyrosines in the appropriate amino acid context. The SH-2 domain–containing proteins also often contain, or interact with proteins containing, an *src-homology domain 3, or SH-3* (20). The other, unrelated conserved motif that directs a separate type of specific protein–protein interaction has been termed, appropriately, a *phosphotyrosine binding domain, or PTB domain*. Proteins containing a PTB domain bind to a distinct set of phosphorylated tyrosine residues from those with SH-2 domains (21).

After these signaling proteins bind to the activated, autophosphorylated

receptor, they become activated. The mechanisms by which they are activated are not entirely clear. Often they, too, become phosphorylated on tyrosine residues. In addition, their recruitment to the membrane or into signaling complexes plays a role in the initiation of their activity (22 ,23). Activation of each of these NT-signaling proteins triggers distinct downstream cascades of target enzymes and other biological effects. Although there is great diversity of neurotrophic factor receptors, they seem to trigger only a few well-conserved types of downstream signaling pathways. Among the best characterized of the pathways include the Ras/extracellular signal regulated kinase (ERK) pathway, the phosphotidylinositol-3′-OH-kinase (PI-3-K) pathway, and the phospholipase C-γ (PLC-γ) pathway (24). In addition, specific tyrosine phosphatases are activated that modulate these responses and may contain pathway-activating properties of their own.

NEUROTROPHIC FACTOR INTRACELLULAR SIGNALING PATHWAYS: RAS/ERK (MAPK) CASCADE

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

The Ras/ERK pathway is regulated by the activity of the Ras proteins. Ras is a small, membrane-associated protein that serves as a transducer of signal from tyrosine kinase activity to ERK proteins, among other activities (25). The activity of Ras depends on the type of the guanine nucleotide it is bound to. Hence, Ras is a G protein, although distinct from the heterotrimeric G proteins coupled to many neurotransmitter receptors. Ras is active when binding guanosine triphosphate (GTP), but at rest it is inactive and bound to guanosine diphosphate (GDP). Activation of Trk receptor tyrosine kinases leads to the binding of an adapter protein in the Shc family. Shc becomes tyrosine phosphorylated and binds a Grb protein, such as Grb2. Shc contains a PTB domain and an SH-2 domain, whereas Grb2 contains two SH-2 domains and a SH-3 domain. This complex then activates a GDP-GTP exchange factor, such as SOS, which, in turn, activates Ras through GTP binding.

Once activated, Ras recruits a serine kinase of the Raf family to the membrane, where it is activated. This initiates a cascade in which Raf activates MEK (from *M*APK or *E*RK *k*inase), and then MEK phosphorylates and activates ERKs (26). ERKs, also known as mitogen-activated protein kinase (MAPKs), are abundant, multifunctional, intracellular kinases with many different cellular activities. ERKs have been shown to phosphorylate such diverse proteins as tyrosine hydroxylase, transcription factors, regulators of protein translation, microtubule proteins, and many others (27 ,28). In cells *in vitro*, ERKs have been shown to mediate neuron survival, neuritic process elongation (29), and levels of specific neuronal enzymes and ion channels, among other effects (30). ERKs have been shown to be important in hippocampal long-term potentiation in brain slices (31). Some effects of ERK activation are very rapid, whereas others are delayed and persistent.

PLC-γ CASCADE

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

A second NT-signaling pathway involves PLC-γ activation (32 ,33). Like the better-understood PLC-ß, PLC-γ cleaves phosphatidylinositol phosphates into diacylglycerol and inositol phosphates. Diacylglycerol can activate protein kinase C (PKC), whereas inositol-1,4,5-tris phosphate releases intracellular stores of calcium. Intracellular calcium can exert numerous effects from the activation of Ca^{2+}/calmodulin–dependent

protein kinases to the production of cyclic adenosine monophosphate through some adenylyl cyclases. All these are known to have powerful effects on neurons. Unlike PLC-ß, which is regulated by heterotrimeric G-protein–coupled receptors, PLC-γ is regulated by tyrosine phosphorylation (34). PLC-γ contains SH-2 and SH-3 domains. When bound to tyrosine phosphorylated receptors, it is recruited to the membrane and becomes phosphorylated, which activates its PLC activity. Virtually nothing is known about the role of PLC-γ in the intact brain, although it is likely to exert important effects on neuronal function.

PI-3-K CASCADE

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

Somewhat less well understood is the PI-3-K pathway (35 ,36 and 37). Several types of PI-3-Ks have been identified. Type 1 PI-3-Ks are regulated by tyrosine kinase activity. They are heterodimers of a catalytic α subunit and a regulatory ß subunit. The ß subunit contains SH-2 and SH-3 domains. When bound to phosphorylated tyrosines, the ß subunit activates the catalytic activity of the α subunit. This phosphorylates phosphatidylinositol on the 3′-hydroxl group (distinct from the 4′,5′ phosphorylated forms mentioned earlier). Furthermore, PI-3-K has been shown to possess protein kinase activity and can bind Ras (38). The PI-3-K lipid product, phosphotidylinositol-3′-phosphate, activates at least two protein kinases, AKT and S6-kinase. AKT is best known for its powerful ability to oppose programmed cell death (i.e., antiapoptotic effects), although it has other metabolic actions as well. S6-kinase is named for its ability to phosphorylate the ribosomal subunit S6 (although not to be confused with ribosomal S6-kinase RSK), and it has numerous other cellular effects as well. Currently, these effects are less well elucidated than those of the ERKs. Within neurons, PI-3-K has been shown to mediate cell survival, initiation of neuritic process outgrowth, and acquisition of sensitivity to glutamate excitotoxicity (39), among other actions. Again, little is known about its role in intact brain.

Although PI-3-K possesses some ability to bind phosphorylated receptors itself, it seems largely to be activated by receptors through docking proteins. Important PI-3-K docking proteins are the insulin receptor substrate (IRS) family of proteins (40). IRS1, IRS2, and IRS4 are expressed in brain (41). More distantly related PI-3-K docking proteins are the GAB family of proteins. All these bind to the receptors through PTB domains and become phosphorylated on numerous tyrosines. Most of these tyrosines are then bound by PI-3-K, leading to a substantial amplification of PI-3-K signaling. IRS proteins can be bound by other signaling molecules such as protein tyrosine phosphatases and also possess numerous serine and threonine phosphorylation sites. Therefore, it is likely that the IRS proteins are important sites of convergence of numerous types of signaling pathways.

INTERACTION OF NEUROTROPHIN SIGNALING CASCADES

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

Numerous levels of complexity have been found in the downstream signaling pathways of the NT receptors. PI-3-K has been shown to contribute to ERK activation by Ras-dependent and Ras-independent process pathways (36 ,38 ,42). Ras can contribute to activation of AKT, and both SHC and IRS can bind to the same phosphorylated tyrosine site, although with differing affinities (43). PLC-γ can activate ERK in neurons and can theoretically terminate PI-3-K signaling by cleaving phosphotidylinositol-3′-phosphate. In addition, most of these proteins exist in multiple isoforms arising either from different genes or differential splicing of the same gene. These isoforms are differentially expressed during development and in different brain regions, although there is also a great deal of overlap. The complement of signaling proteins and adaptors would be expected to determine the effects of the NT on particular populations of neurons. Regulation of these proteins may influence plasticity or other neuronal responses. Furthermore, this complexity of expression and cross-talk allows tremendous opportunity for potential sites of therapeutic intervention.

REGULATION OF NEUROTROPHIN SIGNALING BY ACTIVATION OF G-PROTEIN–COUPLED RECEPTORS

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

There is also evidence of cross-talk between G-protein–coupled receptor signaling pathways and the NT cascades. Many different types of interactions occur between the G-protein receptor–coupled second messenger-dependent pathways and the Trk signaling pathways. Only a few are discussed here, to demonstrate the complexity and possible types of interactions.

Activation of Trk Docking Proteins and the Ras/ERK Pathway by G-Protein–Coupled Receptors

G-protein–coupled receptors are reported to activate the Ras/ERK by a pathway that is independent of their respective second messenger systems (44). This alternate pathway is dependent on internalization of the receptor and recruitment of a soluble tryosine kinase that directly phosphorylates the adaptor proteins (Shc and Gab) that lead to activation of Ras and subsequently the Ras/ERK pathway. For example, internalization of the ß-adrenergic receptor (ßAR) leads to binding of ß-arrestin, which inhibits activation of the receptor. Studies demonstrated that ß-arrestin also functions as an adaptor protein that binds both ßAR and a soluble tyrosine kinase, Src. Studies demonstrated that 5-hydroxytryptamine (5-HT_{1A}) receptors activate the Ras/ERK pathway, possibly through this mechanism (45). Regulation

of the Ras/ERK pathway by internalization of G-protein–coupled receptors is not observed in all cases (e.g., 5-HT_{2A} receptor), a finding indicating receptor or cellular specificity in the control of this pathway.

Numerous other potential mechanisms of cross-talk between G protein and neurotrophic factor signaling pathways have been identified. For instance, several other forms of PI-3-Ks have been elucidated, some of which are activated by G-protein–coupled receptors, but presumably they lead to at least some similar downstream signaling effects through the production of similar phosphorylated inositol lipids (35 ,36 and 37). Similarly, PLC-ß, the G-protein–coupled form of PLC, would be expected to produce at least some of the same effects as PLC-γ by activation of PKCs and mobilization of calcium. Furthermore, both PKC and levels of cyclic adenosine monophosphate modulate the activity of Raf and hence the ERK pathway (46 ,47 ,48 and 49). Calcium mobilization can activate ERKs through the intracellular tyrosine kinase, Pyk2 (50). Obviously, the potential for cross-talk with G-protein–coupled systems is great, and sorting out the mechanisms relevant in various brain regions and mechanisms of plasticity is an important area for investigation.

SOME OTHER CLASSES OF NEUROTROPHIC FACTORS AND THEIR SIGNALING SYSTEMS

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

Although this review focuses on the NT family of neurotrophic factors, several others have generated significant interest (Fig. 16.2). For example, the glial cell line–derived neurotrophic factor (GDNF) family of proteins has been found to have profound effects on dopaminergic and motor neurons, as well as enteric neurons (51 ,52 and 53). Thus far, this family includes GDNF, artemin, persephin, and neurturin. This family, distantly related to the transforming growth factor-ß (TGF-ß) family, signals through a heteromeric signaling complex (54). A common component of all the GDNF receptor complexes identified is the Ret protein. Ret spans the membrane and contains an intracellular tyrosine kinase domain. This domain, which is less well characterized than for the Trk receptor, can nonetheless signal at least some of the same intracellular signaling pathways, including the Ras/ERK pathway and PI-3-K (55). Ret associates with various receptor-binding proteins (GFR-α subunits 1 through 4). These subunits do not span the membrane, but are linked to the extracellular surface through a glycosyl-phosphatidylinositol moiety. The GFR-α subunits provide specificity for ligand binding and participate in the activation of the Ret tyrosine kinase. Furthermore, evidence indicates that they can stimulate activation of src-like tyrosine kinases independent of Ret. The known activities of the GDNF family of proteins has spurred interest in its role in the pathogenesis and possible treatment of diseases such as Parkinson's disease, addiction, and amyotrophic lateral sclerosis (52 ,53).

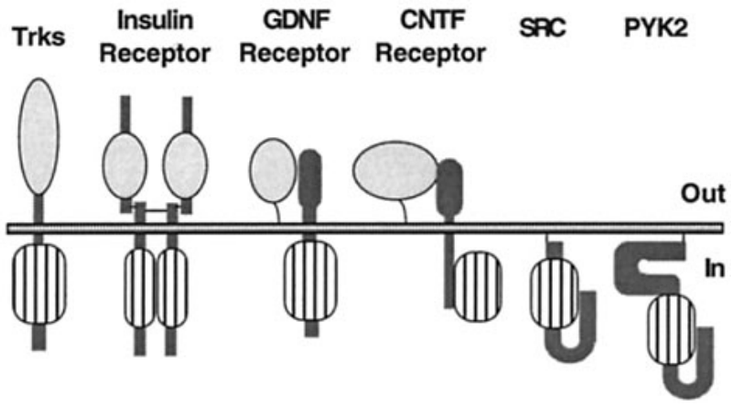

FIGURE 16.2. Other neurotrophic factor signaling cascades. This cartoon illustrates the general motifs used by neurotrophic factor receptors to transduce a signal across the membrane and to couple with the intracellular signaling pathways. The *light gray ovals* represent extracellular (Out) ligand-binding domains. The *vertical striped* intracellular (In) ovals are tyrosine kinase domains. The Trk receptors, like EGF receptors, are single polypeptide chains that span the membrane. These contain intrinsic extracellular ligand binding domains and intracellular tyrosine kinase activity. The insulin and IGF receptors are derived from the cleavage and subsequent disulfide linking of two identical chains. These receptors also contain intrinsic binding and kinase activities. The GDNF receptor is a heteromeric complex in which the ligand-binding specificity resides within a separate phosphatidylinositolglycan-linked subunit (GFR-α). The signal from the ligand–GFR-α complex is then transduced across the membrane by Ret, which contains an intracellular tyrosine kinase domain. The CNTF receptor is typical of the cytokine receptors, which contain separate binding and transmembrane subunits, and then couple to a soluble intracellular tyrosine kinase (a JAK). Other systems couple to the tyrosine kinase intracellular signaling pathway by interacting with one of several membrane-associated intracellular tyrosine kinases. Some G proteins, for instance, act through src-like proteins, whereas intracellular calcium can activate Pyk2, an intracellular tyrosine kinase in the focal adhesion kinase family.

Another large class of receptors couples to an intracellular tyrosine kinase known as the Janus kinase, or JAK (56 ,57). These receptor kinases include extracellular binding components, one of which spans the membrane but does not have intrinsic kinase activity. Instead, they bind to and activate specific members of the JAK family of kinases. The JAKs then activate certain intracellular effector molecules, including IRS proteins, SHC, and others. Moreover, they interact with a unique group of proteins called STATs. STAT proteins bind to JAK. After tyrosine phosphorylation, they are released and translocated to the nucleus, where they function directly as DNA-binding transcriptional activators. Many neurotrophic factors activate the JAK/STAT pathway, including ciliary neurotrophic factor, growth hormone, leptin, and many cytokines. Characterization of the role of STAT-mediated transcription in brain lags behind that of other earlier identified transcription factors, but it is an area of intensive study.

Even factors known for their hormone functions or peripheral

effects have been found to have substantial activity in the central nervous system. Insulin and insulin-like growth factor 1 (IGF-1), and their respective transmembrane receptor tyrosine kinases, are expressed widely in brain and play roles in development and behavior (58 ,59). Furthermore, epidermal growth factor (EGF) and EGF-like ligands in the TGF-α family are expressed in brain along with their receptor, the EGF receptor. Evidence is accumulating for roles for these factors in the adult central nervous system as well (60). Although not discussed in detail, these serve as further examples of the complexity of neurotrophic factor signaling at many levels in the brain. These receptors also share coupling to the same modules of signaling pathway proteins as the Trks and Ret. Apparently, there is a tremendous diversity of neurotrophic ligands and ligand-binding domains within their receptors that allows fine anatomic and temporal specificity of action, along with the potential for synergistic or counterregulatory mechanisms. However, the relatively smaller number of conserved signaling pathways to which they couple suggests that they share common mechanisms of action to shape neuronal responses.

ROLE OF NEUROTROPHIC FACTORS IN THE ACTIONS OF PSYCHOTROPIC DRUGS

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

As investigations of the psychotropic drugs have been extended, it has become clear that these agents also influence the expression of neurotrophic factors and their signal transduction systems. Regulation of neurotrophic factor signaling could thereby contribute to the desired actions of therapeutic of agents, as well as the negative effects of other drugs. These possibilities are illustrated briefly in this section.

Regulation of Neurotrophin Systems by Stress and Antidepressant Treatment

Preclinical and clinical studies have reported an atrophy or loss of neurons in limbic brain structures that could be related to dysfunction of neurotrophic factor systems. Chronic physical or social stress can result in atrophy or death of stress-vulnerable neurons in the hippocampus of rodents and nonhuman primates (61 ,62). More recently, investigators conducting brain imaging studies reported that the volume of the hippocampus is reduced in patients suffering from depression of posttraumatic stress disorder (63). Postmortem studies also demonstrate that the numbers of neurons and glia in prefrontal cortex are reduced in patients with depression (63). The expression of BDNF in hippocampus is decreased by exposure of animals to stress (64). This effect could contribute to the atrophy and death of hippocampal neurons, although it is also likely that other pathways are involved in this effect (61 ,62).

In contrast to the actions of stress, antidepressant treatment increases the expression of BDNF, as well as its receptor TrkB, in hippocampus (65 ,66). Up-regulation of BDNF is dependent on long-term antidepressant treatment, consistent with the time course for the therapeutic action of these agents. Both norepinephrine and serotonin-selective reuptake inhibitor antidepressants increase BDNF expression, a finding suggesting that this NT system may be a common postreceptor target of these monoamines and antidepressant treatment. In addition, nonantidepressant psychotropic drugs do not increase BDNF expression in hippocampus, a finding indicating that this effect is specific to antidepressants. The possibility that BDNF contributes to the therapeutic actions of antidepressants is supported by behavioral studies. Infusion of BDNF into midbrain or hippocampus produces antidepressant-like effects in behavioral models of depression, the forced swim test, and learned helplessness paradigms (67 ,68). Additional studies will be required to elucidate further the role of BDNF, as well as other neurotrophic factors, in the pathogenesis and treatment of depression. However, these findings have contributed to an exciting new hypothesis of depression.

Role of Neurotrophic Factors in the Actions of Drugs of Abuse

A picture is emerging that neurotrophic factors and their signaling pathways play important roles in mediating acute and chronic changes in synaptic connectivity, neuronal physiology, and gene expression. A powerful and important model of environmentally induced acute and persistent alterations in brain function is the effect of chronic exposure to drugs of abuse (69 ,70). Within laboratory animals, exposure to any of several diverse addicting drugs leads a set of alterations in neuronal biochemistry, electrophysiology, and morphology in specific brain regions implicated in addictive behaviors. Concomitantly, these animals display alterations in behavior including tolerance, dependence, sensitization, craving, and drug-seeking behaviors reminiscent of the behaviors seen in humans suffering from drug addiction. Specifically, alterations in the dopaminergic nucleus, the ventral tegmental area (VTA), are reminiscent of the changes seen with neurotrophic factor withdrawal in cell culture: the cells become smaller with less prominent neuritic processes, they have decreased neurofilament expression and axoplasmic transport, and they have decreased expression and accumulation of tyrosine hydroxylase, the rate-limiting enzyme in dopamine syntheses and a critical neuron type-specific protein. Infusing NTs such as BDNF or GDNF into the VTA can restore most, or all, of these features to normal (71 ,72). Additional studies have also implicated endogenous NT-3 in the drug-induced changes (73). Furthermore, the role of ERK signaling in this system has been established. ERK activity is increased in the VTA by chronic morphine exposure (74). Infusion of a specific antisense oligonucleotide against ERK1 into the VTA again blocks the morphine-induced biochemical changes (75).

Dissecting the mechanisms of signaling protein regulation within specific brain nuclei in the intact animal poses special challenges. However, using tools from *in vitro* studies, headway is now starting to be made. For instance, the mechanism of this ERK up-regulation is unclear, but it has been shown that PLC-γ, which is capable of activating ERK, is up-regulated in VTA after chronic morphine exposure (76). Although levels of the neurotrophic factors themselves have not been found to be significantly altered in VTA by chronic drug exposure, they may be regulated indirectly by modulation of their signaling systems.

CONCLUSIONS

Part of "16 - Neurotrophic Factors and Intracellular Signal Transduction Pathways "

The neurotrophic factors and their signal transduction cascades represent a complex array of pathways that influence many aspects of neuronal function and survival during development as well as in the adult central nervous system. The characterization of these pathways has provided many new target sites for the development of novel agents that could be used to treat a variety of neurologic and psychiatric illnesses. There is currently a tremendous amount of interest in this area, and agents are already available for selective blockade of certain components of the Ras/ERK pathway. Moreover, characterization of the roles these pathways play in the normal nervous system may lead to identification of abnormal conditions that underlie pathologic states. The opening of the field of growth factor action into the neurosciences opens opportunities that may be as rich or as powerful, if not more, as those that have been presented with the more traditional neurotransmitter systems.

Regulation of Gene Expression

Eric J. Nestler

Steven E. Hyman

Eric J. Nestler: Department of Psychiatry, The University of Texas Southwestern Medical Center, Dallas, Texas.

Steven E. Hyman: National Institute of Mental Health, Bethesda, Maryland.

For all living cells, regulation of gene expression by extracellular signals is a fundamental mechanism of development, homeostasis, and adaptation to the environment. Indeed, the ultimate step in many signal transduction pathways is the modification of transcription factors that can alter the expression of specific genes. Thus, neurotransmitters, growth factors, and drugs are all capable of altering the patterns of gene expression in a cell. Such transcriptional regulation plays many important roles in nervous system functioning, including the formation of long-term memories. For many drugs, which require prolonged administration for their clinical effects (e.g., antidepressants, antipsychotics), the altered pattern of gene expression represents therapeutic adaptations to the initial acute action of the drug.

Mechanisms that underlie the control of gene expression are becoming increasingly well understood. Every conceivable step in the process is subject to dynamic regulation in the cell. This includes structural changes in the chromatin to make a particular gene accessible for transcription, transcription of DNA into RNA, splicing of RNA into mRNA, editing and other covalent modifications of the mRNA, translation of mRNA into protein, and, finally, post-translational modification of the protein into its mature, functional form.

Molecular details of each of these regulatory steps are becoming increasingly available. In this chapter, we focus on the regulation of gene expression by transcription factors because their role in mediating the ability of extracellular signals to alter gene expression remains the best characterized.

OVERVIEW OF TRANSCRIPTIONAL CONTROL MECHANISMS

Part of "17 - Regulation of Gene Expression "

Regulation of Gene Expression by the Structure of Chromatin

In eukaryotic cells, DNA is contained within a discrete organelle called the nucleus, which is the site of DNA replication and transcription. Within the nucleus, chromosomes—which are extremely long molecules of DNA—are wrapped around histone proteins to form nucleosomes, the major subunits of chromatin (1 ,2 and 3). To fit within the nucleus, much of the DNA is tightly packed into a “coiled coil.” Compared with transcriptionally quiescent regions, actively transcribed regions of DNA may be more than 1,000-fold further extended. Chromatin does not just serve a structural role, however; in eukaryotes, chromatin plays a critical role in transcriptional regulation. Chromatin can inhibit access of transcription factors to the DNA and can thereby repress gene expression. In eukaryotic organisms, with their very large number of genes (approximately 40×10^3 in mammals), this means that the ground state of gene expression is for genes to be turned off. Activation of gene expression requires that cells alleviate nucleosome-mediated repression of an appropriate subset of genes. This is accomplished by means of activator proteins that modify chromatin structure. The activation process, which involves transcription factors, along with histones and cofactors, displaces or remodels chromatin, and opens up regions of the DNA, including the core promoters (see later) of genes, for the binding of regulatory proteins.

Transcription occurs when particular activator proteins displace nucleosomes. This permits a complex of proteins (described later) called *general transcription factors*, to bind DNA at a particular type of element, called a *core promoter*, and to recruit RNA polymerase. The construction of this protein complex at the transcription start site and the synthesis of the first phosphodiester bond between nucleotides are referred to as *transcription initiation* (3). The RNA polymerase must successfully transcribe an appropriate length of RNA without premature termination *(elongation)*. Premature

termination appears to be a regulated mechanism that controls expression of a small number of genes. Transcription of the RNA must also terminate appropriately *(termination)*.

Transcription Initiation: A Critical Biological Control Point

As described in the preceding section, transcription can be divided into three discrete steps: initiation, mRNA chain elongation, and chain termination. Although biologically significant regulation may occur at any step in the process, transcription initiation appears to be one of the most significant control points that gates the flow of information out of the genome. Certainly, as far as we know now, transcription initiation is the step in gene expression that is most highly regulated by extracellular signals (3).

Transcription initiation involves two critical processes: positioning of the appropriate RNA polymerase at the correct start sites of transcription and controlling the efficiency of initiations to produce the appropriate transcriptional rate for the circumstances of the cell. These control functions depend on regulatory elements that recruit appropriate transcription factors to the DNA (Fig. 17.1). Many transcription factors bind DNA directly; others interact indirectly through protein–protein interactions with factors that do bind DNA themselves. Those regulatory elements that set the transcription start sites of a gene are called the *basal or core promoters*. Other regulatory elements tether additional activator and repressor proteins to the DNA.

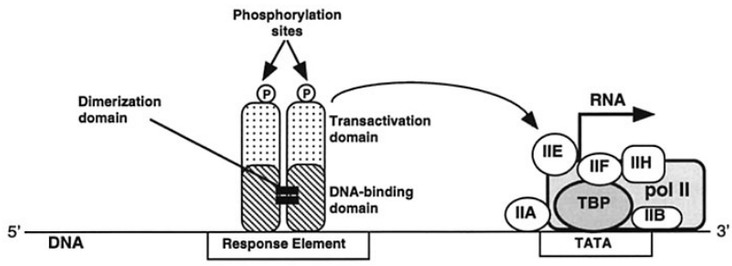

FIGURE 17.1. Scheme of a generalized polymerase II promoter. The figure shows two regulatory elements *(open rectangles)* along the stretch of DNA *(thin black line)*. These include the TATA element and a hypothetic activator or response element. The TATA element is shown binding the TATA-binding protein, TBP. Multiple general transcription factors and RNA polymerase II (pol II) associate with TBP. The general transcription factors are referred to with the nomenclature of TFII(x), for transcription factors of a pol II promoter. Shown are general factors, TFIIA, B, E, F, and H. Each of these transcription "factors" is actually composed of multiple individual proteins complexed together. TBP and its associated proteins are collectively called TFIID. This basal transcription apparatus recruits RNA polymerase II. It also forms the substrate for interactions with various activator proteins that bind to activator elements such as the one shown. Typical activator proteins contain DNA-binding domains, dimerization domains, and transcription activation domains. The latter interact with the basal transcription apparatus and may be modified by phosphorylation. Adapted from reference 14.

Core Promoters: Setting the Start Site and Direction of Transcription

In eukaryotes, transcription is carried out by three distinct RNA polymerases: RNA polymerases I, II, and III (4). These three polymerases interact with different classes of genes, each of which contains distinct promoter elements. Polymerase I (pol I) promoters are used by genes that encode large rRNAs (ribosomal RNAs). Polymerase II (pol II) promoters are used by genes that are transcribed to yield mRNAs and hence proteins. Pol II promoters are also used by a subset of the genes that encode snRNAs that are involved in RNA splicing. Polymerase III (pol III) promoters are used by genes that encode other small RNAs, including the remaining snRNAs, small rRNAs, and tRNAs (transfer RNAs).

None of the RNA polymerases bind DNA directly; rather, the polymerases are recruited to the DNA by other proteins. The core promoters for each of the three polymerases contain distinct elements on which different types of basal transcription complexes are assembled, each using different transcription factors. Because the main focus of this chapter is regulated expression of protein-encoding genes, only transcription by pol II is described.

The core promoters of genes transcribed by pol II are surprisingly diverse, but they share certain key features. By far the most common core promoter element for pol II promoters is the *TATA box* (Fig. 17.1), a sequence rich in the nucleotides A and T located between 25 and 30 bases upstream of the transcription start site. In TATA box–containing genes, mutation of this sequence can inhibit transcription

initiation or make it inaccurate. In addition to setting the start site of transcription, the TATA box sets the orientation of the basal transcription complex and therefore the 5′ to 3′ direction in which pol II synthesizes the RNA. Many pol II promoters (including those for many neurally expressed genes) lack a TATA box; in these cases, a poorly conserved core promoter element called an *initiator* is found.

The TATA-binding protein (TBP) initiates the formation of the basal transcription complex along with multiple TBP-associated proteins (TAFs) and multiple additional general transcription factors (Fig. 17.1). Each of the transcription factors represented in Fig. 17.1 was originally identified as a chromatographic fraction derived from cell nuclei, and it is a mixture of proteins. Thus, TBP together with its TAFs was originally identified as a fraction called TFIID, where TFII is a nomenclature identifying general transcription factors associated with pol II, and the final letter designates the fraction. TFIID, but not TBP by itself, is required to build a basal transcription complex from TATA-less promoters.

Transcription Factors: Key Regulators of Gene Expression

The basal transcription apparatus is not adequate to initiate more than low levels of transcription. To achieve significant levels of transcription, this multiprotein assembly requires help from additional transcriptional activators that recognize and bind to regulatory elements found elsewhere within the gene. Because they are tethered to DNA—by their binding to specific recognition sequences in the DNA—such proteins can be described as sequence-specific transcription factors (5 ,6 and 7).

Functional regulatory elements are generally found within several hundred bases of the start site of the gene to which they are linked, but they can occasionally be found many thousands of base pairs (bp) away, either upstream or downstream of the start site. Regulatory elements that exert control near the core promoter itself have been called *promoter elements*, and those that act at a distance have been called *enhancer elements*, but the distinction between promoter and enhancer elements is artificial from a mechanistic point of view. Both are generally composed of small, modular elements (generally 7 to 12 bp in length), each of which is a specific binding site for one or more transcription factors. The fundamental logic of transcriptional regulation in eukaryotes is that it is combinatorial: each gene has a particular combination of regulatory elements, the nature, number, and spatial arrangement of which determines the gene's unique pattern of expression. These promoter or enhancer elements control the cell types in which the gene is expressed, the times during development in which it is expressed, and the level at which it is expressed in adults both basally and in response to physiologic and environmental signals (7).

Sequence-specific transcription factors typically contain several physically distinct functional domains (these are shown in Fig. 17.1): (a) the DNA-binding domain recognizes and binds to a specific nucleotide sequence (i.e., response element); (b) the transcription activation domain interacts with coactivators or with general transcription factors (i.e., components of the pol II complex) to form a mature or fully active transcription complex; and (c) the multimerization domain permits the formation of homomultimers and heteromultimers with other transcription factors. The modularity of these proteins is emphasized by the finding that particular binding domains, activation domains, and interaction domains are used in different combinations in many naturally occurring proteins. Experimentally, domains can be swapped from different activators to produce novel hybrid proteins that are functionally active.

Many transcription factors are active only as dimers or higher-order complexes. Multimerization domains are diverse and include so-called leucine zippers (described later), Src homology (SH-2) domains, and certain helical motifs (8 ,9 and 10). Within transcription factor dimers, whether they are homodimers or heterodimers, both partners commonly contribute jointly to both the DNA binding domain and to the activation domain. In some cases, dimerization can be a mechanism of negative control of transcription. This is illustrated by the CREB (cyclic adenosine monophosphate [cAMP]–response element binding protein) family of transcription factors discussed later.

Regulation of transcription factors by the formation of heterodimers is not an “all or none” proposition, however. Within the Fos family of transcription factors (described later), some family members, such as c-Fos, are strong activators when dimerized with a partner from the Jun family, such as c-Jun. Other Fos-related proteins, such as Fra1 (Fos-related antigen-1), bind DNA as heterodimers with c-Jun, and they may still activate transcription, but at lower levels than c-Fos (11). Overall, the ability of transcription factors to form heterodimers and other multimers increases the diversity of transcription factor complexes that can form in cells and, as a result, increases the types of specific regulatory information that can be exerted on gene expression.

Sequence-specific transcriptional activator and repressor proteins may contact several proteins within the basal transcription complex directly. In other cases, they interact with the basal transcription apparatus through the mediation of coactivator or adapter proteins. In either of these situations, transcription factors that bind at a distance from the core promoter can still interact with the basal transcription apparatus, because the DNA forms loops that bring distant regions in contact with each other.

Many activator proteins become involved only in the assembly of the mature transcription apparatus after modification, most commonly phosphorylation, that occurs in response

to extracellular signals. An important effect of many phosphorylation events is to alter the ability of the phosphoprotein to interact with other proteins. This is illustrated by CREB, which can activate transcription only when phosphorylated on a particular serine residue (ser133) (12). As seen later, phosphorylation of ser133 permits CREB to interact with an adapter protein, CBP (CREB-binding protein), which, in turn, contacts and activates the basal transcription apparatus (13).

REGULATION OF GENE EXPRESSION BY EXTRACELLULAR SIGNALS

Part of "17 - Regulation of Gene Expression "

Transcription Factors: Targets of Signaling Pathways

Most genes probably contain response elements that confer responsiveness to physiologic signals. Response elements work by binding transcription factors that are activated (or inhibited) by specific physiologic signals, of which the most common is *phosphorylation*. Two general mechanisms of transcriptional regulation by extracellular signals are illustrated Fig. 17.2 (14). In one mechanism, transcription factors that are present at significant levels in cells under basal conditions are rapidly activated by signaling cascades to activate or repress transcription of responsive target genes. In the other major mechanism, transcription factors that are expressed at very low levels under basal conditions are themselves induced by a physiologic signal, after which they can regulate expression of a series of additional genes.

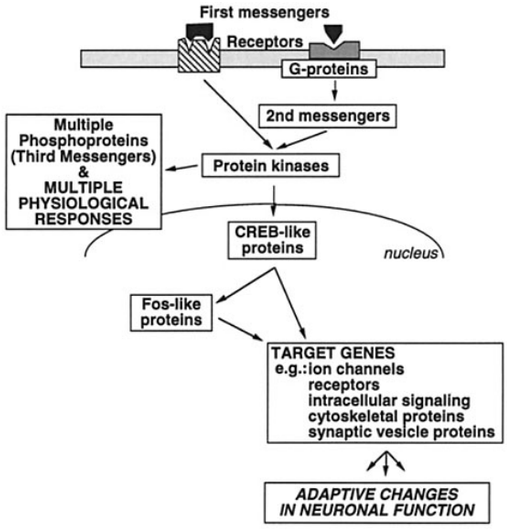

FIGURE 17.2. Scheme of intracellular pathways underlying regulation of gene expression. Activation of neurotransmitter, hormone, or neurotrophic factor receptors leads to the activation of specific second messenger and protein phosphorylation pathways, which produce multiple effects on neuronal function through the phosphorylation of numerous proteins. Among the effects of these intracellular pathways on neuronal function is the regulation of gene expression. This can be accomplished by two basic types of mechanisms. In one case, transcription factors, already in the nucleus, are phosphorylated by protein kinases; this alters their transcriptional activity and leads to alterations in the expression of specific target genes. CREB is an example of a transcription factor that functions in this manner. Among the target genes for CREB family transcription factors are those for other transcription factors, for example, Fos and Jun family proteins. Increased expression of Fos and Jun then leads to alterations in the expression of additional target genes.

A critical step in extracellular regulation of gene expression is the transduction of signals from the cell membrane to the nucleus; this can be accomplished by several different types of mechanisms. Some transcription factors themselves translocate to the nucleus on activation. One example is provided by the steroid hormone receptor transcription factors, discussed at length later. Another example is the transcription factor nuclear factor-κB (NF-κB) (15). This transcription factor is retained in the cytoplasm by its binding protein, IκB, which masks the nuclear localization signal within NF-κB. Signal-regulated phosphorylation of IκB by protein kinase C leads to dissociation of NF-κB, which permits it to enter the nucleus, where it can bind DNA; IκB is then proteolyzed within the cytoplasm.

Other transcription factors must be directly phosphorylated or dephosphorylated to bind DNA. For example, phosphorylation of STATs (signal transducers and activators of transcription) by protein tyrosine kinases in the cytoplasm permits their multimerization, which, in turn, permits nuclear translocation and construction of an effective DNA binding site within the multimer (16).

Still other transcription factors are already bound to their cognate *cis*-regulatory elements in the nucleus under basal conditions and are converted into transcriptional activators by phosphorylation. CREB, for example, is bound to DNA elements termed cAMP-response elements (CREs) (Fig. 17.3) before cell stimulation. The critical nuclear translocation step in CREB activation involves not the transcription factor itself, but activated protein kinases (cAMP-dependent protein kinase; also called protein kinase A) that, on entering the nucleus, phosphorylate CREB. Alternatively, CREB activation can involve the nuclear translocation of second messengers, such as Ca^{2+} bound to calmodulin, which, on entering the nucleus activate protein kinases that then phosphorylate CREB (Fig. 17.3). As stated earlier, phosphorylation converts CREB into a transcriptional activator by permitting it to recruit CBP into the transcription complex.

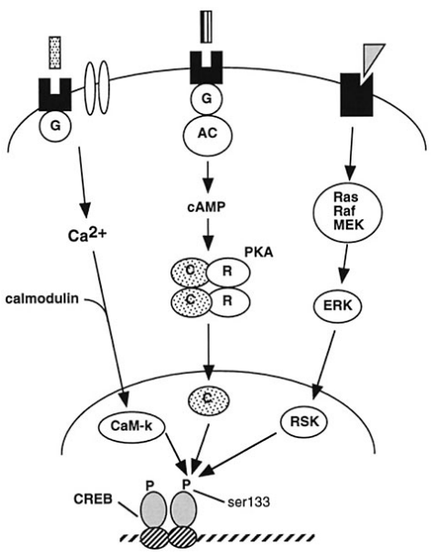

FIGURE 17.3. Scheme of the regulation of CREB phosphorylation by several signaling pathways. The figure illustrates how several signaling pathways converge on the phosphorylation of CREB at a single serine residue, ser133. Neurotransmitters that stimulate adenylyl cyclase would increase CREB phosphorylation by the activation of protein kinase A (PKA). On activation, free PKA catalytic subunits would translocate to the nucleus, where they would phosphorylate ser133 of CREB. Neurotransmitters that inhibit adenylyl cyclase would cause the opposite cascade and inhibit CREB phosphorylation. Any of several signals that increase cellular Ca^{2+} levels (e.g., certain inotropic or G-protein–coupled receptors, voltage-gated Ca^{2+} channels) would also increase CREB phosphorylation. Here, it appears that a wave of increased Ca^{2+} would permeate the nucleus, where it would activate certain Ca^{2+}/calmodulin-dependent protein kinases (CaM kinases), particularly CaM-K IV, which phosphorylates ser133 of CREB. In addition, growth factor regulated pathways lead to CREB phosphorylation, although the details are not as well established. One possibility, shown in the figure, is that activation of Ras-Raf-MEK pathways would lead to activation of ERK (a type of MAP kinase), which would translocate to the nucleus and phosphorylate and activate RSK (ribosomal S6 kinase). RSK would then phosphorylate ser133 of CREB. MEK, MAP kinase and ERK kinase; ERK, extracellular signal regulated kinase; RSK, ribosomal S6 kinase.

The remainder of this chapter provides a more in-depth discussion of several transcription factor families that have received a great deal of attention as mediators of neural and behavioral plasticity in the adult.

CREB Family of Transcription Factors

CREs were the first second messenger response element to be well characterized (12 ,17 ,18). As the name suggests, CREs confer activation by cAMP on genes to which it is linked. Subsequently, it was found that the same element confers response to Ca^{2+} and to the Ras pathway as well. CREs have been identified in many genes expressed in the nervous system, including those encoding neuropeptides (e.g., somatostatin, proenkephalin, vasoactive intestinal polypeptide), neurotransmitter synthetic enzymes (e.g., tyrosine hydroxylase), signaling proteins (e.g., adenylyl cyclase type VIII), and transcription factors (e.g., c-Fos and CREB itself) (12 ,17 ,18).

The idealized or “consensus” CRE sequence is TGACGTCA, although the actual CREs present in various genes differ slightly. The consensus CRE sequence illustrates an important principle, the palindromic nature of many transcription factor–binding sites. Examining the sequence TGACGTCA, it can be readily observed that the sequence on the two complementary DNA strands, which run in opposite directions, is identical. Many regulatory elements are perfect or approximate palindromes because many transcription factors bind DNA as dimers, with each member of the dimer recognizing one of the half-sites. The major protein that binds to CREs is CREB. CREB binds to a CRE as a homodimer, with a higher affinity for palindromic than for asymmetric CREs.

When bound to a CRE, CREB activates transcription only when it is phosphorylated on its critical ser133. It does so, as described earlier, because phosphorylated CREB, but not dephosphorylated CREB, can recruit the adapter protein, CBP, into the transcription complex. CBP, in turn, interacts with the basal transcription complex.

Regulation by cAMP, Ca^{2+}, and Growth Factors

As discussed in previous sections, the regulation of CREB activation by phosphorylation illustrates the requirement for nuclear translocation of protein kinases or second messengers when transcription factors are already found in the nucleus under basal conditions and the role of phosphorylation in regulating protein–protein interactions. An additional important principle illustrated by CREB is the convergence of signaling pathways. CREB is activated in response to activation of the cAMP or Ca^{2+} pathways. This occurs because the same serine residue (ser133) is phosphorylated both by protein kinase A and by Ca^{2+}/calmodulin–dependent protein kinases (CaM kinases) (Fig. 17.3). CaM kinase IV appears to be the most important form of the enzyme that mediates this phosphorylation (19 ,20). CREB also appears to be phosphorylated on ser133 by a growth factor–activated kinase, RSK—ribosomal S6 kinase—that is phosphorylated and activated by mitogenactivated protein (MAP) kinases (21).

Thus, diverse types of signaling pathways converge on the phosphorylation and activation of CREB. If each individual signal is relatively weak, convergence may be a critical mechanism for achieving significant gene regulation, with some genes activated only when multiple pathways are stimulated. Furthermore, some genes that contain CREs are known to be induced in a synergistic fashion by the interaction of cAMP and Ca^{2+} signaling pathways. In addition

to ser133, CREB contains other sites for phosphorylation by a variety of protein kinases, which may fine tune the regulation of CREB-mediated transcription. For example, CaM kinase II phosphorylates a distinct serine residue in CREB, which diminishes the ability of other kinases to phosphorylate ser133. Activation of CaM kinase II would therefore appear to mediate a dampening of the CREB signal (19 ,20).

Role in Neural Plasticity

The convergent activation of a single transcription factor by multiple signaling pathways is particularly important in the nervous system, because this is an important candidate mechanism for long-term neural adaptations, including those underlying long-term memory, drug addiction, and fear conditioning. As discussed elsewhere in this volume, it is reasonably well established that some forms of long-term memory require new gene expression. Furthermore, associative memory depends on the temporally coordinated arrival of two different signals, which must then be integrated within target neurons and their circuits. Activation of CREB is therefore a plausible candidate for playing an important role in long-term memory and related phenomena. Consistent with this prediction, *Drosophila* in which CREB was inactivated by a dominant negative transgene, and mice in which CREB was inactivated by homologous recombination (i.e., knockout), show deficits in long-term memory (22 ,23 ,24 and 25). Manipulation of CREB also influences long-term potentiation in the hippocampus (23 ,24 and 25) and aspects of drug addiction (26 ,27 ,28 and 29). Although much work remains to understand the precise role of CREB in these various phenomena, it does appear that CREB, which is regulated by several major neural signaling pathways, is a critical mediator of many types of plasticity.

CREB-like Proteins

CREB illustrates yet another important principle of transcriptional regulation: CREB is a member of a larger family of related proteins. Many transcription factors are members of families. CREB is closely related to proteins called the *activating transcription factors* (ATFs) and the *CRE modulators* (CREMs), each generated by distinct genes. In addition, several alternative splice forms are known for CREB, certain of the ATFs, and CREMs (30 ,31).

All these proteins bind CREs as dimers, and many can heterodimerize with CREB itself. ATF1 appears to be very similar to CREB; it can be activated by both the cAMP and Ca^{2+} signaling pathways (30 ,31). Many of the other ATF proteins and CREM isoforms also appear to activate transcription. However, certain CREMs (e.g., ICER—inducible cAMP element repressor) act to repress it (30). These CREM isoforms lack the glutamine-rich transcriptional activation domain found in CREB-ATF family proteins that are transcriptional activators. Thus, CREB-ICER heterodimers may occupy CREs, but fail to activate transcription. Like CREB, many of the ATF proteins are constitutively made in cells, but ATF3 and certain CREM isoforms (e.g., ICER) are inducible.

Leucine Zipper Dimerization Motif

The dimerization domain used by the CREB-ATF proteins and several other families of transcription factors is called a *leucine zipper* (8 ,9). This domain was first identified in the transcription factor C/EBP (CAATT-enhancing binding protein) (32), and it is also used by the AP-1 proteins, as described in detail later. The so-called leucine zipper actually forms a coiled coil. The dimerization motif is an α helix in which every seventh residue is a leucine; based on the periodicity of α helices, the leucines line up along one face of the α helix two turns apart. The aligned leucines of the two dimerization partners interact hydrophobically to stabilize the dimer. In CREB, C/EBP, and many AP-1 proteins, the leucine zipper is at the C-terminus of the protein. There is a region of highly basic amino acid residues just upstream of the leucine zipper that forms the DNA binding domain. Dimerization by the leucine zipper juxtaposes the adjacent basic regions of each of the partners; these juxtaposed basic regions undergo a conformational change when they bind DNA, which results in what has been described as a “scissors grip.” This combination of motifs has led this superfamily of proteins to be described as the basic-leucine zipper proteins or the bZIP proteins.

AP-1 Family of Transcription Factors

Another group of bZIP transcription factors that plays an important role in the regulation of neural gene expression by extracellular signals comprises the activator protein-1 (AP-1) proteins. The name AP-1 was originally applied to a transcriptional activity stimulated by protein kinase C activation (33). This activity was found to be composed of multiple proteins, which bind as heterodimers (and a few as homodimers) to the DNA sequence TGACTCA, the AP-1 sequence. The consensus AP-1 sequence is a heptamer that forms a palindrome flanking a central C or G, and differs from the CRE sequence by only a single base. Yet this one base difference strongly biases protein binding away from CREB (which requires an intact CGTCA motif) to the AP-1 family of proteins and means that, under most circumstances, this sequence will not confer cAMP responsiveness on a gene.

Many genes expressed in the nervous system contain AP-1 sites within their regulatory regions (34 ,35 and 36). Examples include genes encoding neuropeptides (neurotensin and substance P), neurotransmitter receptors (D1 dopamine, NR1 NMDA, and GluR2 AMPA glutamate receptor subunits), neurotransmitter synthetic enzymes (tyrosine hydroxylase),

and cytoskeletal proteins (neurofilament proteins), to name a few. In some cases, it has been possible to demonstrate a role for these sites in regulation of gene promoter activity *in vitro*, although it has been very difficult to identify with certainty those genes that are regulated by AP-1 transcription factors in the brain *in vivo* (35).

As alluded to earlier, the AP-1 sequence was described initially as a TPA-response element (TRE) because the phorbol ester, 12-O-tetradecanoyl-phorbol-13-acetate (TPA), which activates protein kinase C, can induce gene expression through AP-1 proteins (33). In addition, it is now thought that a major role of the AP-1 sequence is to confer responsiveness to growth factor–stimulated signaling pathways such as the Ras/MAP-kinase pathways. This occurs by phosphorylation of specific AP-1 proteins by certain MAP kinases.

AP-1 proteins generally bind DNA as heterodimers composed of one Fos family member and one Jun family member (34). Both families are bZIP proteins: they form dimers through their leucine zipper domains. The known members of the Fos family are c-Fos, Fra1, Fra2, and FosB and its alternatively spliced variant ΔFosB. The known members of the Jun family are c-Jun, JunB, and JunD. Unlike Fos proteins, c-Jun and JunD (but not JunB) can form homodimers that bind to AP-1 sites, albeit with far lower affinity than Fos-Jun heterodimers. The potential complexity of transcriptional regulation is greater still because some AP-1 proteins can heterodimerize through the leucine zipper with members of the CREB-ATF family, such as ATF2 with c-Jun. AP-1 proteins can also form higher-order complexes with apparently unrelated families of transcription factors. For example, AP-1 proteins can complex with and thereby apparently inhibit the transcriptional activity of steroid hormone receptors (see later).

Among Fos and Jun proteins, only JunD is expressed constitutively at high levels in many cell types. The other AP-1 proteins tend to be expressed at low or even undetectable levels under basal conditions, but, with stimulation, they may be induced to high levels of expression. Thus, unlike regulation by constitutively expressed transcription factors such as CREB, regulation by Fos-Jun heterodimers requires new transcription and translation of the transcription factors themselves (Fig. 17.2).

Cellular Immediate Early Genes

Genes that are transcriptionally activated by synaptic activity, drugs, or growth factors have often been classified roughly into two groups. *Immediate early genes* (IEGs), such as the c-*fos* gene itself, are activated rapidly (within minutes) and transiently and do not require new protein synthesis. *Late-response genes*, in contrast, are induced or repressed more slowly (over hours) and are dependent on new protein synthesis. The term IEG was applied initially to describe viral genes that are activated "immediately" on infection of eukaryotic cells, by commandeering host cell transcription factors for their expression. Viral IEGs generally encode transcription factors needed to activate viral "late" gene expression. This terminology has been extended to cellular (i.e., nonviral) genes, although this has created some confusion.

The terminology is problematic because there are many cellular genes induced independently of protein synthesis, but with a time course intermediate between "classic" IEGs and late-response genes. In fact, some genes may be regulated with different time courses or requirements for protein synthesis in response to different extracellular signals. Moreover, many cellular genes regulated as IEGs encode proteins that are not transcription factors: for example, any gene induced by CREB could potentially show temporal features of induction of an IEG. Despite these caveats, the concept of IEG-encoded transcription factors in the nervous system has proved useful in thinking about the complexities of gene regulation. In addition, because of their rapid induction from low basal levels in response to neuronal depolarization (the critical signal being Ca^{2+} entry) as well as various second messenger and growth factor pathways, several IEGs have been used as cellular markers of neural activation, and this has permitted novel approaches to functional neuroanatomy (37).

The protein products of those cellular IEGs that function as transcription factors bind to regulatory elements contained within a subset of late response genes to activate or repress them. IEGs such as c-fos have therefore been termed "third messengers" in signal transduction cascades, with neurotransmitters designated intercellular first messengers and small intracellular molecules, such as cAMP and Ca^{2+}, second messengers (34). There have, however, been misunderstandings among some neurobiologists that IEGs are a necessary step in the signal-induced expression of most neural genes involved in the differentiated function of neurons. In fact, as stated earlier, many genes involved in differentiated neural functions, including genes encoding certain neuropeptides and neurotrophic factors, to name a few, are activated in response to neuronal depolarization or cAMP through phosphorylation of CREB rather than through IEG third messengers.

Activation by Multiple Signaling Pathways

The most studied cellular immediate early gene is c-*fos*. The c-*fos* gene contains three binding sites for CREB (the strongest of which is shown in Fig. 17.4). As a result, it is not surprising that the gene can be activated rapidly by neurotransmitters or drugs that stimulate the cAMP or Ca^{2+} pathways (38).

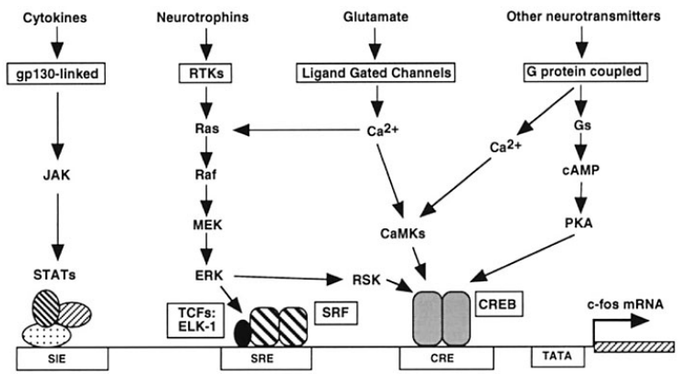

FIGURE 17.4. Scheme of the regulatory region of the c-*fos* gene. The figure shows only three of the many known transcription factor binding sites within this gene. These sites are as follows: a CRE (cAMP-response element), which binds CREB; a serum-response element (SRE), which binds serum response factor (SRF) and Elk-1 (also called the ternary complex factor or TCF); and an SIF-inducible element (SIE), which binds STAT proteins (signal transducers and activators of transcription). Proteins binding at each of these sites are constitutively present in cells and are activated by phosphorylation. CREB can be activated by protein kinase A, CaM kinases (CaM-Ks), or RSKs (ribosomal S6 kinases) (Fig. 17.3); Elk-1 can be activated by the MAP kinases ERK1 and ERK2 (extracellular signal regulated kinases 1 and 2); and the STAT proteins can be activated by the JAK protein tyrosine kinases. Thus, activation of the c-*fos* gene—by any of multiple signaling pathways—depends only on signal-induced phosphorylation rather than on new protein synthesis. This explains the rapidity of its induction by a wide array of stimuli. MEK, MAP kinase and ERK kinase; PKA, protein kinase A; RTKs, receptor tyrosine kinases. Adapted from reference 14.

The c-*fos* gene also can be induced by the Ras/MAP-kinase pathway (39 ,40). Neurotrophins, such as nerve growth factor, bind a family of *receptor tyrosine kinases* (called Trks) that activate Ras. Ras then triggers a cascade

of protein kinases, which results in the phosphorylation and activation of certain MAP kinases called *extracellular signal regulated kinases* (ERKs). These ERKs can phosphorylate and activate additional protein kinases, such as RSK, which, among its other substrates, can phosphorylate ser133 of CREB, as described earlier. However, an additional mechanism exists whereby ERK can induce the c-*fos* gene, and this mechanism appears to predominate in many cell types (41). Here, the ERKs translocate into the nucleus where they phosphorylate the transcription factor Elk-1 (also called the ternary complex factor or TCF). Elk-1 then complexes with the serum response factor (SRF) to bind to and activate the serum response element (SRE) within the c-*fos* gene (Fig. 17.4). SREs are present within many other growth factor-inducible genes as well. In comparison with cAMP- or Ca^{2+}-dependent phosphorylation of CREB, the Ras/MAP kinase pathway depends on a complex chain of phosphorylation events. Nonetheless, these events can occur very rapidly to induce gene expression.

Still another mechanism exists for c-*fos* induction: cytokine-activated signaling pathways that act through STATs (42). As stated earlier, STATs are activated on their phosphorylation by certain protein tyrosine kinases. This permits STATs to form multimeric complexes, translocate to the nucleus, and bind to their specific DNA response elements, generally now described at STAT sites. However, the STAT site in c-*fos* had already been named the SIE or SIF-inducible element (SIF itself is an acronym for sis-inducible factor, i.e., a factor induced by the oncogene v-*sis*, which activated c-*fos* though this site). STATs are activated by the class of cytokines that interact with gp130-linked receptors, which include ciliary neurotrophic factor, LIF (leukemia inhibitory factor), interleukin-6, leptin, and prolactin, to name a few (16 ,43). These receptors activate a cytoplasmic protein tyrosine kinase called JAK (Janus kinase), which then phosphorylates the STATs. As shown in Fig. 17.4 , the c-*fos* gene contains an SIE, which binds STAT proteins and mediates the induction of c-Fos by cytokines.

Most other Fos and Jun family proteins are also induced rapidly in response to diverse acute stimuli and, presumably, many of the same mechanisms operate for the genes encoding these proteins. However, the response elements within these genes are not as well characterized as are those for c-*fos*, and further research is needed to understand their regulation.

Regulation by Phosphorylation

Several AP-1 proteins are regulated at the post-translational level by phosphorylation. The best-established example is

the phosphorylation of c-Jun, which provides a critical mechanism of regulation of AP-1-mediated signaling (44 ,45). c-Jun phosphorylation occurs in response to activation of a MAP kinase–related signaling pathway that is activated by many forms of cellular stress. In this pathway, a Ras-like G protein is activated by any of several insults (e.g., ultraviolet radiation, osmotic stress, toxins, certain cytokines); this triggers a cascade of protein kinases analogous to that triggered by Ras and the neurotrophins outlined earlier. The culmination of this pathway is the phosphorylation and activation of certain MAP kinases called SAP kinases (stress-activated protein kinases) or alternatively JNKs (for Jun N-terminal kinases). JNKs phosphorylate c-Jun on serines 63 and 73 in its transcriptional activation domain and increase the ability of c-Jun to activate transcription. Phosphorylation and activation of c-Jun have been implicated in the regulation of apoptosis (programmed cell death) pathways (45).

Generation of Unique AP-1 Complexes by Repeated Stimulation

After acute stimulation of cells, different members of the Fos family are induced with varying time courses of expression, which leads to a progression of distinct AP-1 complexes over time (46). Thus, under resting conditions, c-*fos* mRNA and protein are barely detectable in most neurons, but c-*fos* expression can be induced dramatically in response to numerous stimuli. As just one example, experimental induction of a grand mal seizure causes marked increases in levels of c-*fos* mRNA in brain within 30 minutes and induces substantial levels of c-Fos protein within 2 hours. c-Fos is highly unstable and is degraded back to low, basal levels within 4 to 6 hours (46). Administration of cocaine or amphetamine causes a similar pattern of c-*fos* expression in striatum (47 ,48). In either of these stimulus paradigms, other Fos-like proteins are also induced, but with a longer temporal latency than c-Fos; their peak levels of expression lag behind c-Fos by approximately 1 to 2 hours. Moreover, expression of these proteins persists a bit longer than c-Fos, but it still returns to basal levels within 8 to 12 hours.

With repeated stimulation, however, the c-*fos* gene, and to an extent the genes for other Fos-like proteins, become refractory to further activation (i.e., their expression becomes desensitized) (49 ,50). Instead, other Fos-like proteins continue to be expressed. These proteins, originally termed chronic Fras (51 ,52 and 53), are now known to be biochemically modified isoforms of ΔFosB, which exhibit very long half-lives in brain (54 ,55 and 56). As a result, these proteins accumulate in specific neurons in response to repeated perturbations and persist long after cessation of these perturbations (Fig. 17.5). Although the precise physiologic significance of these stable ΔFosB isoforms remains unknown, there is now direct evidence that ΔFosB plays an important role in aspects of drug addiction (57) and in mediating various types of striatal-based movement disorders (e.g., see refs. 58 ,59 and 60). More generally, ΔFosB may function as a sustained molecular switch that gradually converts an acute response to a long-lived adaptation in the brain (61).

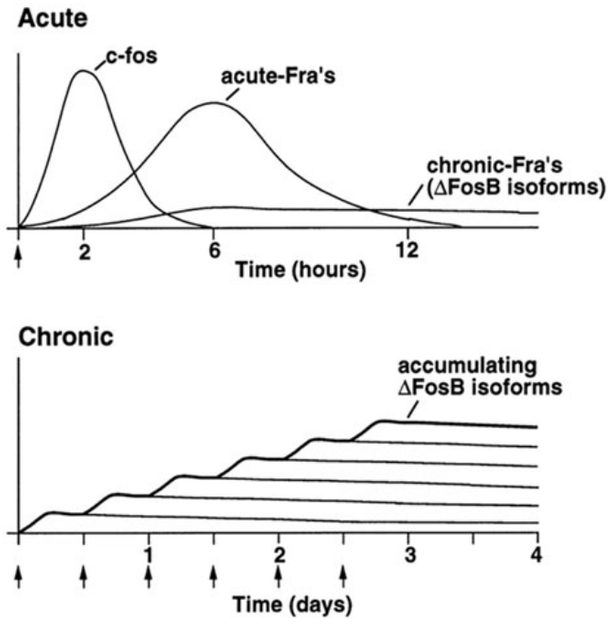

FIGURE 17.5. Scheme showing the composition of AP-1 complexes changing over time. **Top:** There are several waves of Fras (Fos-related antigens) induced by many acute stimuli in neurons. C-Fos is induced rapidly and degraded within several hours of the acute stimulus, whereas other "acute Fras" (e.g., FosB, ΔFosB, Fra1, Fra2) are induced somewhat later and persist somewhat longer than c-Fos. The "chronic Fras" are biochemically modified isoforms of ΔFosB; they, too, are induced (although at low levels) after a single acute stimulus but persist in brain because of their enhanced stability. In complexes with Jun family proteins, these waves of Fras form AP-1 binding complexes with shifting composition over time. **Bottom:** With repeated stimulation, each acute stimulus induces a low level of ΔFosB isoforms. This is indicated by the lower set of overlapping lines, which indicate ΔFosB-induced by each acute stimulus. The result is a gradual increase in the total levels of ΔFosB with repeated stimuli during a course of long-term treatment. This is indicated by the increasing *stepped line* in the graph. The increasing levels of ΔFosB with repeated stimulation would result in the gradual induction of significant levels of a long-lasting AP-1 complex, which could underlie persisting forms of neural plasticity in the brain. (Adapted from reference 53.)

Steroid Hormone Receptor (or Nuclear Receptor) Superfamily

The steroid hormones (e.g., glucocorticoids, gonadal steroids such as estrogen and testosterone, and mineralocorticoids), retinoids, thyroid hormones, and vitamin D_3 are small, lipid-soluble ligands that diffuse readily across cell

membranes. Unlike amino acid–derived neurotransmitters and neuropeptides, their receptors are cytoplasmic, rather than localized to the cell membrane. On ligand binding, these receptors translocate to the nucleus, whereupon they bind to specific hormone-response elements (HREs) located in the regulatory regions of specific genes and thereby regulate expression of those genes. These receptors are referred to as the *steroid hormone receptor, or nuclear receptor, superfamily* (62 ,63 and 64).

The glucocorticoid receptor (GR) exemplifies general mechanisms utilized by this superfamily (62 ,63 ,64 and 65). Under basal conditions, the GR is retained in the cytoplasm by a large multiprotein complex of chaperone proteins, including the heat shock protein Hsp90 and the immunophilin Hsp56. When bound by glucocorticoid, the GR dissociates from its chaperones and translocates to the nucleus. The first activity of the GR to be identified was its function as a ligand-regulated transcription factor, as stated earlier, by binding to glucocorticoid response elements (GREs). GREs are typically 15 bases in length; they consist of two palindromic half-sites of six bases each separated by a 3-bp spacer. As described earlier for other transcription factors, this palindromic organization of the GRE suggests that the GR binds as a dimer. Like many other transcription factors, the nuclear receptor superfamily has a modular structure. The GR has three domains: an N-terminal transcriptional activation domain, a C-terminal ligand binding domain, and an intervening DNA binding domain. The DNA-binding domain of the GR is characterized by a zinc finger motif, in which multiple cysteines are organized around a central zinc ion. This type of DNA binding domain is used by many other transcription factors, including the immediate early gene zif268/egr1 (see later). The DNA binding domain also contains a region that permits dimer formation after GR monomers bind GRE half-sites.

GREs can confer either positive or negative regulation on genes to which they are linked, depending on the particular GRE involved (62 ,63 ,64 and 65). One of the first positive GREs characterized is that within the metallothionein IIA gene, which encodes a protein that chelates heavy metals. A well-characterized negative GRE is found within the proopiomelanocortin *(POMC)* gene. This negative GRE permits glucocorticoids to repress the gene that encodes adrenocorticotropic hormone and is therefore an important mechanism of feedback inhibition on further glucocorticoid synthesis.

GRs have many important physiologic actions that do not appear to be mediated by DNA binding. GRs can interfere with transcriptional activity mediated by other transcription factors, particularly AP-1 and NF-κB. Although the mechanisms are not fully understood, GRs appear to interact directly with AP-1 and NF-κB proteins to block their ability to activate transcription (62 ,63 ,64 and 65). An alternative mechanism by which glucocorticoids may interfere with NF-κB activity is by inducing expression of IκB, the protein that holds NF-κB in the cytoplasm.

Other Transcription Factors in Neural Signaling

The CREB, AP-1, STATs, and steroid hormone receptor families are just a few of the literally hundreds, perhaps thousands, of transcription factors that are expressed in neurons and glia. Most of these other factors are best understood with respect to their roles in nonnervous tissues, although more recent work implicates them in neural signaling as well. Examples of these other transcription factors have already been mentioned. NF-κB is activated by protein kinase C and immunologic signals and likely plays an important role in the regulation of neural gene expression (15). C/EBP and its several family members are known to mediate some of the effects of the cAMP pathway on gene expression and have been implicated in neural plasticity (32 ,66). Specific protein-1 (SP-1), which binds to GC rich regions of promoters, is often thought of as a general transcription factor, that is, a regulator of the basal rate of transcription. However, more recent research has shown that certain SP-1 family members are subject to dynamic regulation and could mediate transcriptional changes induced by extracellular signals (5). AP-2 (activator protein-2) binding sites are present in many neural-expressed genes, although we still know very little about its physiologic role (5). Zif268 (also called Egr-1) and related Egr family members are zinc finger transcription factors that, like c-Fos, are induced rapidly and transiently in brain by many stimuli with temporal features of IEGs. Induction of Egr family proteins has been correlated with induction of hippocampal long-term potentiation; however, their specific target genes remain poorly characterized (67).

CONCLUSIONS

Part of "17 - Regulation of Gene Expression "

Our discussion of nuclear signaling mechanisms highlights several important points. The first is that the potential number of mechanisms by which the expression of a gene can be controlled is vast. This highlights the exquisite control over gene expression that is required both for the generation of a diversity of cell types during development and for adaptation of cells to the environment throughout life.

We devoted most attention to nuclear transcription factors, because these provide the best-understood mechanisms of how cells adapt to external cues with alterations in gene expression. However, even the complexity of mechanisms discussed represents the tip of the iceberg. Regulatory regions of genes are often far longer than the coding regions of genes. Regulatory information is contained not only within the 5′ promoter regions of genes, but throughout intronic (and sometimes exonic) sequences as well as 3′ untranscribed regions. Within the 5′ regions, we focused on relatively small response elements, such as CRE and AP-1 sites. It is extraordinary, indeed, that the difference of 1

nucleotide (e.g., from a CRE to an AP-1 site) in a sequence of literally thousands can confer specificity on a gene with respect to its regulation. Nonetheless, we know that any given gene likely contains many regulatory sites. Moreover, these sites do not function in isolation, but they influence one another. As a result, the rate of expression of a given gene represents the temporal and spatial synthesis of multiple signaling pathways. Unraveling these layers of complexity is a daunting task, particularly *in vivo*, but it could hold important clues for understanding neural and behavioral plasticity.

Emerging Methods in Molecular Biology and Genetics - Introduction

When the American College of Neuropsychopharmacology was founded in the mid-1950s, molecular biology and genetics were in their infancy and had little to offer neuropsychopharmacology. By 1967, when the first volume in this series was published, it still had not become apparent how greatly our field would be influenced by research on genes and on DNA. Of more than a hundred papers in that volume--*Psychopharmacology: A Review of Progress 1957-1967*--only a few used tools of molecular biology. None of those papers, including my own, envisioned the central role that such tools have now come to play.

This central role, which is documented in this section, is the result of the development of two types of new technologies. One of them, the automated sequencing of the nucleotides in DNA, facilitated the decoding of the structure of all genes, including those that make up the human genome. The other consists of ways to manipulate the structure of individual genes in isolated cells or in intact organisms, and to measure their levels of expression. This made it possible to directly study the biological actions of particular genes, and the effects of changes in their regulatory regions and coding regions.

These technologic advances are now being applied to a variety of problems in neuropsychopharmacology. For example, measurements of the levels of expression of large numbers of genes in various brain regions and nerve cells are providing information about the molecular basis of normal brain functions, and the effects of drugs on these functions. The same technologies are also being used to learn about the molecular pathogenesis of mental disorders. As work on the human genome continues it will lead to the identification of gene variants that influence susceptibility to mental disorders, as well as of gene variants that influence the alternative ways that individuals respond to particular psychiatric drugs. It will also provide new targets for the creation of better drugs, with greater efficacy and specificity.

The six chapters in this section provide a sampling of the molecular and genetic tools that are being used to advance neuropsychopharmacology. Because these tools are changing so rapidly, the authors provide overviews rather than extensive details. In this way they hope to make these tools comprehensible to the nonspecialist, and to invite their further application.

As you read these overviews you will become increasingly familiar with a series of new terms--from *gene chip*, *knockouts*, and *viral vectors*, to *genome scans* and *pharmacogenetics*. These terms are becoming commonplace, and are already scattered throughout this book. By the time the next volume in this series appears, it is likely that the methods that they refer to will be so widely used in our field that a separate section about them will no longer be needed.

18

Using Human Genomics to Advance Neuropsychopharmacology

L. Alison Mcinnes

Nelson B. Freimer

L. A. McInnes and Nelson B. Freimer: Department of Psychiatry and Neurogenetics Laboratory, University of California–San Francisco, San Francisco, California 94143.

Genomics, the study of genomes, includes gene mapping, sequencing, and investigation of gene functions. This field will advance neuropsychopharmacology in two complementary ways. First, it is hoped that application of genomics technologies to pedigree and population samples of patients with psychiatric disorders will allow the identification of genes contributing to the etiology and pathogenesis of these diseases and provide a rational basis for new drug development. Second, variations in the sequence of known genes whose products are the targets of current psychotropic drugs may influence the likelihood that an individual patient will have a therapeutic response to these drugs or experience a side effect. Identification and functional characterization of these sequence variants in large populations of patients of various ethnicities constitutes the discipline of pharmacogenomics. The scope of psychopharmacogenomics, however, is currently restricted by our limited knowledge of the genes that contribute to psychiatric disorders and the neural pathways altered by psychotropic agents. Fortunately, data and technologies provided by the U.S. Human Genome Project (HGP), including provision of the complete sequence of the human genome, will greatly facilitate identification of such genes (1 ,2). This chapter describes how technologic advances in genomics will shape the future of psychiatric genetics and psychopharmacogenomics, fields that may establish an objective basis for the restructuring of the nosology, diagnosis, and treatment of psychiatric disorders. The results of genetic studies of particular psychiatric disorders and of responses to specific drugs are considered in other parts of this book.

IDENTIFYING GENES FOR PSYCHIATRIC DISORDERS

Part of "18 - Using Human Genomics to Advance Neuropsychopharmacology "

Rational strategies for the advancement of psychopharmacology are dependent on furthering our currently sparse knowledge of the pathophysiologic basis of psychiatric disorders. To this end, human genetic approaches offer a promising alternative to traditional biochemical and neurophysiologic investigations as twin, family, and adoption studies all support the heritability of many psychiatric syndromes. Unfortunately, attempts to first map (i.e., localize a unique region of DNA shared by patients with a particular disorder) and then identify genes predisposing to psychiatric disorders have been frustrated by the complexity of the genetic mechanisms underlying behavioral phenotypes.

A phenotype is the observable physical manifestation of genetic variation at a particular site or locus in the DNA, whereas a genotype refers to the actual DNA sequence, at the responsible genetic locus. With single gene disorders (also referred to as mendelian disorders) there is a simple, direct relationship between variation in a single gene and the phenotype that results. Thus, all patients with a given mendelian disorder, such as cystic fibrosis, will carry abnormal genotypes at a single disease locus. In contrast, the relationship between phenotype and genotype is not straightforward for complex genetic traits. In this setting, multiple different susceptibility genes and environmental factors interact in varying combinations within individuals who appear to have clinically indistinguishable phenotypes. This means that in any given sample of patients diagnosed with a particular psychiatric disorder, the number of individuals actually sharing a disease gene or genes in common might be very small such that the “effective” sample size does not provide enough power to detect the responsible genes.

Fortunately, there are strategies for finding genes contributing to complex traits that have been successfully applied to the genetic dissection of other nonpsychiatric, genetically

heterogeneous disorders. One approach is to try to reduce genetic heterogeneity in the patient sample by studying genetically isolated populations or by narrowing the affected phenotype under study based on criteria of severity or the presence of a biological marker for the disease. Another approach is to greatly expand the sample size and number of DNA markers used in genetic association studies to increase the power to detect multiple possible genes contributing to disease in subsets of the sample. In either case, both pedigree and population-based genetic mapping studies are expected to yield more promising results in the future due in part to the extensive characterization of the human genome provided by the HGP. The HGP, begun in 1990, is a joint effort coordinated by the U.S. Department of Energy and the National Institutes of Health, with the cooperation in recent years of international entities such as the Wellcome Trust in Great Britain (3). One of the HGP's main goals is to finish the complete human genome sequence by the end of 2003 while concomitantly identifying all the estimated 100,000 genes in human DNA and creating the most dense and accurate genetic maps for genome screening studies. The next subsection describes how innovations in genetic maps and the structure of genetic mapping studies may eventually lead us to identify the as yet elusive genes for psychiatric disorders.

Genetic Maps

At the time of this writing, commonly used genetic maps consist mostly of microsatellite DNA markers (usually repeats of two, three, or four nucleotides that vary in length among individuals) that occur with fairly even spacing across the entire genome. These maps contain several thousand markers spaced at roughly 1 to 5 centimorgans (cM); 1 cM is a unit of genetic distance equivalent to a recombination frequency between two loci of 1%, i.e., one recombination would occur per hundred meioses. Much denser maps are under construction now, however, as part of the HGP. In fact, a major goal of the HGP is to characterize the extent of genetic variation that exists among humans in order to create a map of several hundred thousand markers to enable high-density genome screening studies of complex traits (4). Differences in single bases of DNA known as single nucleotide polymorphisms (SNPs) are thought to constitute roughly 90% of sequence variation in humans. Occurring at an average spacing of 1 SNP per 1,000 base pairs (1 kilobase, kb), they will thus constitute the majority of the markers in the planned high-density map. To facilitate identification of these SNPs, the National Institutes of Health (NIH) recently assembled cell lines and DNA from a collection of 450 anonymous, unrelated individuals representing the major ethnic groups of the United States; this collection is known as the DNA Polymorphism Discovery Resource (DPDR) (5). The DPDR is available to investigators to facilitate detection of population genetic variation in their loci of interest, with the expectation that they will share this information with the scientific community. For instance, SNP variants in the coding or regulatory regions of genes (cSNPs) may cause functional differences in gene expression. With such variants catalogued in advance, it will be relatively straightforward to test multiple candidate genes for association with a disease phenotype or a pharmacogenetic effect. The enormous task of identifying and scoring SNPs in large samples, or performing the projected high-density genome screening studies, has necessitated the development of high-throughput technologies such as DNA chips (6), which are discussed elsewhere in this volume.

Principles of Genetic Mapping: The Search for Identity by Descent

Genetic mapping methods are based on the expectation that a proportion of patients in a study population, whether members of an extended pedigree or more remotely related descendants of a common ancestor, will share segments of DNA identically by descent (IBD) in the vicinity of the disease gene under study. The principle behind this expectation is best illustrated by considering genetically isolated or founder populations (7 ,8). A founder population descends from a small number of ancestral individuals and grows in relative isolation with little admixture, so it is genetically homogeneous. The premise is that a disease mutation is introduced into a population on a particular “founder” chromosome, which is then transmitted to patients descended from a common ancestor carrying this mutation. Over subsequent generations, recombination will reduce the size of the segment of DNA that patients share around the disease gene. The shared segment includes the markers that flank the disease gene. These markers are said to be linked to the gene since, because of their close physical proximity, they seldom recombine with each other and hence are transmitted as a unit or segment. Detection of linkage is the goal of pedigree-based genetic studies. Alternatively, if alleles at markers co-occur more frequently than expected given the known allele frequencies and recombination fraction between the markers, they are said to be in linkage disequilibrium (LD). Evidence of LD between markers also indicates that they are probably close to each other. If LD is observed between the same markers over a region greater than occurs at random in a sample of patients, it may indicate that they share this segment of DNA IBD and that it harbors a disease gene. Detection of LD is a goal of population-based genetic studies.

The length of the IBD segment around a disease gene is inversely proportional to the number of generations by which patients are separated from a common ancestor (Fig. 18.1), and thus genomic screening strategies to detect such a segment will depend on the “age” of the study population (9). For example, a sample of affected individuals separated by roughly 15 generations from their common ancestors

might be expected to share segments around a disease gene detectable in genome screens using current microsatellite maps with markers spaced at 3 to 5 cM. In contrast, the Finnish population is a founder population in which present-day individuals are separated from their common ancestors by up to 100 generations. In this case, shared DNA segments harboring a particular disease gene may be so small that one would have to screen the genome with a much denser marker map (e.g., markers every 0.1 cM) to find them. Such screening studies in a nonhomogeneous population such as that of the United States, wherein common ancestors must be located in the very remote past, will require use of the planned SNP map of around several hundred thousand markers in order to detect regions of LD, which, it has been hypothesized, may be as small as 3 kb (10).

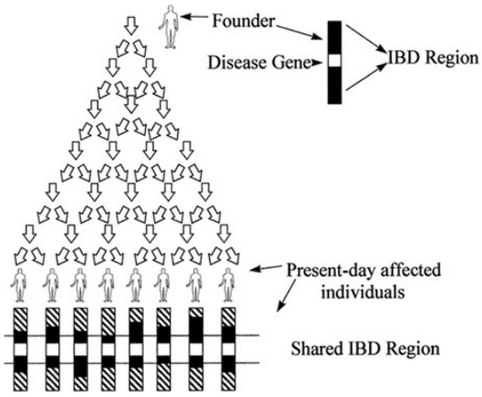

FIGURE 18.1. Genetic mapping studies in isolated populations take advantage of the fact that many recombination events separate affected individuals in the present day from a common disease ancestor. As a result, the majority of patients should share a segment of DNA around the disease gene that is longer than any other DNA segment they might share by chance, but still small enough for positional cloning purposes.

Alternatively, identification of much larger chromosomal regions that are IBD among a sample of patients may also be carried out in extended pedigrees wherein the small number of meioses separating affected individuals leads to a greater length of IBD sharing around the disease gene. Such regions may be easier to detect in pedigrees with genome screens using markers spaced at broader genetic intervals (on the order of 5 to 10 cM). It can be difficult, however, to find recombinant individuals that will allow refinement of the candidate interval to a sufficiently small region to facilitate positional cloning. We review the relative strengths and weaknesses of pedigree- and population-based genetic studies below.

Pedigree-Based Mapping Studies: Problems and Solutions

Linkage analysis of pedigree data has been a very successful method of mapping genes for rare single gene disorders with distinct phenotypes such as cystic fibrosis (11). There are many limitations on the use of linkage analysis for complex traits, however. Linkage analysis is a statistical means of quantifying the likelihood that the observed segregation of marker alleles within a family supports the hypothesis of linkage versus nonlinkage to a disease gene. Traditional linkage analysis is model-based or parametric, meaning that it requires specification of disease inheritance parameters that are not easily estimated for psychiatric disorders, such as the frequency of the disease allele, the genotype specific penetrance, or even the number of genes likely involved. The lack of knowledge of these parameters means that data must be analyzed under a number of different models. This process of multiple testing diminishes the strength of statistical conclusions such that it may be nearly impossible to distinguish between background “noise” and true but weak signals coming from multiple genes of small effect (12). However, several strategies have been successfully implemented to increase the power of linkage analysis for complex nonpsychiatric illnesses by attempting to reduce genetic heterogeneity in the patient sample or by using methods of statistical analysis that do not require specification of genetic model parameters.

Solution 1: Reduce Genetic Heterogeneity in the Sample

Strategies for reducing genetic heterogeneity include studying a small number of large, multiply affected pedigrees ascertained, if possible, from a founder population and narrowly defining the phenotype understudy. The premise in the former case is that the number of genes contributing to a particular disease phenotype within one or a few large families may be less than in many small families or the population at large. This premise is also more likely to hold if the number of disease loci in the population as a whole is limited, as may be the case for founder populations (7 ,8). Furthermore, a multiply affected family may indicate that the gene or genes involved are highly penetrant (penetrance refers to the likelihood that a person who has a disease gene will manifest the disease phenotype) and may be easier to find.

For nonpsychiatric complex traits, refinement of the affected phenotype can be accomplished in several ways. For instance, limiting the affected phenotype to include only the most extreme or distinct form of the illness under study has also been critical to the success of mapping studies for complex traits, as such phenotypes are expected to reflect a more homogeneous genetic etiology than more broadly defined phenotypes (13 ,14). Illustrating these points, a gene

for a severe form of Alzheimer's disease (AD) characterized by early age of onset was detected in a few large multiply affected pedigrees ascertained from a genetically isolated population of German descent (15 ,16). Although such a gene may not contribute significantly to AD in the general population, it may still provide clues as to relevant biological pathways that might suggest candidate genes for other mapping studies.

Another way to refine an affected phenotype is to require the presence of an objective measure associated with the disorder such as elevated immunoglobulin E (IgE) levels in patients with asthma (17). However, we still have no comparable biological markers for psychiatric disorders at least when these disorders are defined by current nosology. Hence, investigators are attempting to find endophenotypes or subcomponents within psychiatric syndromes that may be objectively measured and inherited in a more straightforward fashion than the constellation of symptoms that constitute the full psychiatric syndrome (18 ,19 and 20). What differentiates this strategy from other attempts to refine traditional psychiatric phenotypes is that family members who have not received a psychiatric diagnosis may still be segregating the trait of interest and may display an endophenotype that allows them to be considered “affected” for genetic study.

Many of the efforts to investigate familial transmission of endophenotypes have focused on schizophrenia. For example, investigators have hypothesized that abnormalities of sensory gating are biological markers for attentional dysfunction, which seems to be a core phenotypic characteristic of schizophrenia or psychosis. Abnormal ocular movements and failure to suppress evoked responses to auditory stimuli after a cue (the P50 response) are both thought to be transmitted within families of schizophrenic probands whether or not family members have a psychiatric diagnosis (21 ,22 ,23 ,24 and 25). Two studies have examined the same set of families for linkage to either an abnormal P50 response alone or in combination with abnormal oculomotor movements (26 ,27). Evidence for linkage to each phenotype implicated different loci (the α_7-nicotinic acetylcholine receptor subunit gene and a region in chromosome 22q11-12, respectively) and was stronger than evidence for linkage of the schizophrenia phenotype alone.

Few endophenotypes have been characterized so far for mood disorders; however, a possible endophenotype is that of suicide (28). Roy et al. (29) studied the monozygotic and dizygotic co-twins of twin suicide victims and found that significantly more monozygotic co-twins than dizygotic co-twins also attempted suicide, possibly arguing for a genetic component to this behavior. Investigators are continuing to develop brain banks of suicide victims for postmortem studies including genetic screens and searching for relevant biochemical markers (30).

Solution 2: Alternative Analytic Models

As an alternative to model-based methods, nonparametric or “model-free” methods can be utilized to detect linkage and may be more robust when the true mode of inheritance is unknown. These methods were originally developed for samples of affected sibling pairs but have now been modified for analysis of other types of relative pairs or whole pedigrees. Simply stated, nonparametric methods are designed to calculate the amount of IBD sharing of marker alleles among affected relatives where the null hypothesis is that transmission of alleles is independent of transmission of disease. For any pair of affected relatives, the probability that the pair will share zero, one, or two alleles IBD can be calculated based on their degree of relationship. Linkage is detected if the sharing of marker alleles among affected relatives is increased over the sharing expected given their relationship.

Demonstration that patients share a series of alleles over multiple markers on the same chromosome, also known as haplotypes, can definitively establish that a segment of DNA has been inherited IBD and thus likely harbors a disease gene. Methods that can quantitate the significance of haplotype sharing among affected individuals are thus particularly useful tools for determining candidate gene intervals in both pedigree and population samples, although the inheritance patterns within extended pedigrees need to be fully characterized to avoid misinterpretation of the allele sharing data.

In addition to the problems with statistical detection of linkage, another major shortcoming of pedigree and affected relative pair studies is that investigators may detect a disease gene but be able to localize it only to a very broad genetic interval. The extent to which a genetic interval containing the disease locus can be narrowed to a small-enough interval for positional cloning purposes depends on the number of opportunities for recombination of the disease haplotype in affected persons; in pedigrees where individuals are separated by only two or three generations, opportunities for recombination of the disease haplotype are limited. Although affected relative pairs are usually much easier to collect than multiply affected pedigrees, very large numbers are required to detect linkage, and the accuracy of gene localization is usually much less than that provided by pedigrees.

Finally, when studying complex traits it is very likely that some individuals will be phenocopies, which means that they exhibit the phenotype under study but due to different genetic or environmental factors. In this case, one may be misled by apparent recombination events even in a single individual, and may therefore incorrectly delineate the candidate interval for a disease gene in a region.

All of these factors can seriously impede localization and positional cloning efforts for disease genes in pedigree samples.

Population-Based Mapping Studies

Given the limitations on pedigree studies described above, analysis of a population-based sample is frequently a preferred strategy for high-resolution mapping of disease loci (31). One reason for this is that many meioses (and therefore opportunities for recombination) have occurred since the patients in such a sample were separated from their common ancestor, so there is a better chance to narrowly define a candidate gene interval (Fig. 18.1). Risch and Merikangas (32) also proposed that population mapping strategies might be a more efficient means of initially localizing disease genes (given a sufficient sample size and an appropriately dense marker map), particularly for loci of relatively small effect, as the sample sizes needed for affected relative pair strategies may be huge and thus not feasible.

Association studies are designed to be case-control or family based (see ref. 33 for review). In case-control association studies, allele frequencies at a particular marker are compared between a sample of patients and a sample of controls matched as closely as possible to cases in terms of ethnicity, age, gender, and other relevant socioeconomic variables. Unfortunately, perfect matching can never be guaranteed, and unknown population stratification can occur if many of the cases or controls share an uninvestigated variable. In this setting, the alleles of cases might appear to differ markedly from controls at a particular genetic locus because of such an unknown variable and not because of the presence of the disease phenotype; this could lead to a false-positive result. Such stratification can occur even within distinct ethnic groups. For example, an association study of type 2 diabetes mellitus in a Native-American tribe seemed to indicate that a particular allele of the immunoglobulin complex was protective against diabetes (34). However, after extensive genealogic examination of Native Americans with this allele, it appeared that they all had distant Caucasian relatives. As the allegedly associated allele was common in Caucasians, and diabetes was less common in Caucasians than in the tribe studied, overrepresentation of this allele in nondiabetic Native Americans reflected only the presence of Caucasian admixture and not a true protective effect from diabetes.

Alternatively, affected individuals and their parents are ascertained for family-based studies that utilize the alleles on the nontransmitted chromosomes of parents as controls for the patients' alleles to prevent ethnic mismatching. One commonly used approach to analyzing such family data is the transmission disequilibrium test (TDT) (35). In this test each allele of a heterozygous parent is measured to see if it is transmitted to an affected offspring significantly more often than the expected 50% by chance. In this case, the implicated allele would be both associated and linked to the disorder, obviating the possibility that the allele is falsely associated through population stratification. Other approaches for analyzing family-based association data use nontransmitted parental alleles as controls, but do not evaluate actual transmission of these alleles to the patient and do not exclude data from homozygous parents. One such approach is the likelihood-based method of Terwilleger (36). A disadvantage of family-based LD methods is that it can often be difficult to sample parents of affected individuals, especially for adult-onset disease.

The LD tests described above are often used to examine the association at single markers individually, which can also be problematic because a very large number of markers must be used for LD genome screening studies, even in isolated populations, and statistical correction for multiple testing is necessary. Interpreting the significance of single-point association tests in this setting becomes extremely difficult (37). Fortunately, the development of multipoint statistical methods for quantifying the significance of haplotypes shared over multiple markers could help to increase the power to detect even weak LD signals coming from a subset of the sample. Such approaches are inherently more powerful than single-point tests of association and will be essential for the evaluation of data generated from SNP maps.

One promising LD method, termed ancestral haplotype reconstruction (AHR), assesses the likelihood that a sample of patient haplotypes have descended from a common mutation-bearing founder haplotype (38). This method is currently being modified so that it will be useful both for genome screening and subsequent fine-mapping studies. At the genome screening stage, markers are generally spaced at sufficient distances such that they can be considered to be in linkage equilibrium with each other in distantly related affected persons. Detecting LD between two or more markers in this setting should thus point to the candidate gene interval as long as the underlying assumption is met that the markers tested are not in LD with each other independent of the disease phenotype (so-called background or random LD); it is still not certain how such background LD is distributed within the genome and between different populations. Once a candidate region has been identified by LD analysis, the next step is to type as many markers as closely spaced as possible within the area to determine the minimal interval of maximal IBD sharing that should contain the disease gene. Although this step can be accomplished in some cases just by observation (39), a statistical method that can assign some level of significance to the observed data would be very useful, especially if the disease haplotype is relatively common and a large sample is required to detect its contribution to the phenotype. However, multipoint analysis of markers typed at high density for fine mapping (or for genome screens with dense SNP maps) is complicated because, since the markers are so closely spaced, one cannot assume that these markers are not in LD with each other independent of the disease phenotype. Multipoint LD methods such as AHR will need to take into account the possibility that significant background LD could occur between

closely spaced markers in order to distinguish this background LD from what may be a very subtle increment of LD surrounding the true disease locus.

In summary, the ability to localize disease genes using LD methods in a given population sample depends on the amount and extent of LD present, the number of disease predisposing alleles at a given locus (allelic complexity), the degree to which the disease locus increases the likelihood of manifesting the affected phenotype, and the power of current statistical methods to measure existing LD. For an excellent review of the strengths and weaknesses of current statistical approaches for analyzing LD, see ref. 40 .

Identification of a Disease Gene

Should psychiatric geneticists overcome the many obstacles facing them and succeed in mapping a disease locus to a specific interval, the next step would be to identify the disease gene within it, a process termed *positional cloning* or, given the completion of genome sequencing, the *positional candidate approach* (41). Positional cloning in its purest sense is the process of identifying a disease gene based only on knowledge of its chromosomal location as determined by linkage analysis or LD mapping, without any knowledge of the gene's function. This process involves laborious efforts to build a physical map and sequence the region. Physical maps are made by isolating and linking together yeast and/or bacterial artificial chromosomes (YACs, BACs) containing fragments of human DNA from the region. These fragments are then sequenced and ordered so that the genomic DNA sequence across the candidate gene region is known. Then comes the arduous process of identifying all the genes in the interval and performing mutation detection. Advances in physical mapping and gene-finding technologies arising from the HGP have greatly speeded up this process, however. For instance, near-complete genomic sequence data for the region of interest may already have been deposited in the public databases, obviating the need for extensive genomic sequencing. Next, an investigator may explore large databases of partial complementary DNA (cDNA) sequences also known as “expressed sequence tags” (ESTs) to find most or all of the genes mapping within the area. In addition, there are already a multitude of Web-based sequence analysis programs that provide a host of information such as exon and promotor prediction, open reading frames, and protein homologies for translated sequence. This computer exercise is part of the positional candidate approach. Once all the ESTs have been identified, the complete sequence of the corresponding genes (including definition of intron/exon boundaries and the promotor, if possible) are elucidated and mutation detection begins. If the causative mutation is not detected in coding sequence, however, it can be very difficult to detect disease-causing mutations in the surrounding noncoding DNA or introns, as these regions are large and likely to display more natural variation than highly conserved coding sequence. One possible strategy in this situation is to search for an orthologous (similar) gene in a model organism such as the mouse. Comparison of these sequences may highlight strongly conserved regions of DNA outside of coding sequence that may be functionally relevant and important to examine closely for disease predisposing variants (42). Provision of the complete sequences of the genomes of model organisms amenable to genetic manipulations such as flies, mice, roundworms, and yeast by the HGP could speed understanding of comparable gene structure and function in humans and serve as a molecular confirmation and/or supplement to current gene prediction programs (43 ,44).

PHARMACOGENOMICS

Part of "18 - Using Human Genomics to Advance Neuropsychopharmacology "

As genes contributing to the development of psychiatric disorders are discovered, they will be added to the known array of neurotransmitters, receptors, and transporters that are already considered candidate genes for pharmacogenetic analysis. Pharmacogenetics is the study of the genetic mechanisms determining an individual's responsiveness to drugs (45). In this approach, genes involved in drug metabolic pathways and sites of action, or disease processes if known, are examined for naturally occurring variants or polymorphisms, which may then be shown to affect the expression of that gene. This effect on gene function may then be linked to the efficacy of the drug and/or a predisposition to particular side effects in individuals with that genotype. For example, the apolipoprotein (apo) E4 allele at the apo E locus has been shown to be associated with late-onset AD, as well as to a poor response to cholinesterase inhibitor treatment of AD (46). The downside of this strategy is that it is limited by the paucity of candidate genes with proven association to psychiatric phenotypes. Fortunately, investigators in the emergent field of pharmacogenomics are seeking to identify previously unsuspected genetic markers of drug responsiveness by using a variety of high-throughput genomics technologies to examine drug-induced changes of gene expression in different tissues throughout the body. We provide here a brief overview of the principles of pharmacogenetics and pharmacogenomics (see ref 47 . for review), focusing on how these approaches are being applied in an effort to provide a more rational basis for pharmacotherapy of psychiatric disorders than the trial-and-error approach we currently employ.

The impact of genetic variation on drug response is characterized broadly by changes in pharmacokinetic and pharmacodynamic parameters. Pharmacokinetic studies assess the processes of absorption, distribution, first-pass and general metabolism, and elimination of drugs. Transport processes in renal, intestinal, and hepatic epithelia and drug metabolizing enzymes exhibit genetic variability, which will in many cases be likely to influence the pharmokinetics of

relevant drugs. In the latter situation, the cytochrome P-450 system has been best studied (48) beginning with the classic example of the poor metabolism of the antihypertensive drug debrisoquine due to several mutant alleles of the polymorphic CYP2D6 gene also known as debrisoquine/sparteine hydroxylase. This enzyme is responsible for the metabolism of roughly a quarter of all drugs including most antipsychotics and antidepressants (49). This enzyme is also inhibited potently by fluoxetine. About 7% of Caucasians and an even greater percentage of Asians are poor metabolizers of such drugs due to polymorphisms in this enzyme. On the other hand, some persons carry different alleles and/or multiple copies of this gene, which predispose to more rapid metabolism; up to 13 copies have been documented in a single individual. A study of nortriptyline metabolism in these individuals clearly demonstrated that clearance of nortriptyline was proportional to the number of copies of the *CYP2D6* gene, especially the CYP2D6*2 allelic form (50 ,51). Knowledge that a person has a genotype predisposing to unusually slow or rapid metabolism could guide appropriate drug choice and dosing regimen. Unfortunately, despite intensive study, no definitive relationship between polymorphisms in cytochrome P-450 enzymes and drug efficacy or predisposition to side effects of antidepressant drugs has yet been discovered (52).

Pharmacodynamics concerns the relationship between the concentration of a drug and response at its site of action, for example at receptors and transporters for neurotransmitters. Pharmacodynamic effects may also vary temporally, and so both the acute and chronic nature of response to the drug must be considered. In the acute phase of responsiveness, receptor polymorphisms could alter any of the myriad steps in a pathway from receptor-drug binding through the cascade of signals that result; such variants may determine who is more prone to immediate drug reactions, for example the malignant hyperthermia that may occur in response to antipsychotics. Genetic variation could also play a role in the drug-induced neural plasticity that occurs as a result of the chronic treatment required for alleviation of psychiatric symptomatology as well as chronic use of addictive substances. Adaptive responses to drugs will vary among individuals, and genetic factors may predict such phenomena as waning of drug response over time, and proneness to side effects such as tardive dyskinesia induced by antipsychotics (53).

From a pharmacogenetic perspective, one of the most obvious candidates for studying psychiatric drug responsiveness identified to date is the serotonin (5-hydroxytryptamine, 5-HT) transporter (5-HTT) (52). This transporter plays a critical role in the termination of serotoninergic transmission and is the target of the most widely prescribed family of antidepressants, known collectively as the selective serotonin reuptake inhibitors (SSRIs). Heils et al. (54) identified in 1996 a variant of 5-HTT with a 44–base pair (bp) insertion within the promoter region, which is commonly referred to now as the long (versus the short) allele. Lesch et al. (55) then demonstrated that baseline levels of transcription of the long variant were more than double that of the short variant in transfected cells and that this difference was reflected in altered 5-HTT expression and 5-HT reuptake). Since then, investigators have studied depressed patients to see if they can correlate SSRI response with alleles at the 5-HTT promoter. Smeraldi et al. (56) presented data suggesting that patients with delusional depression responded better to fluvoxamine if they were homozygous for the long allele of the 5-HTT promoter. Other investigators have obtained similar findings in a samples of depressed patients treated with paroxetine (57), although in this study rapidity of response was improved in persons homozygous for the long allele, while overall outcome at 12 weeks was the same for all genotypes.

Besides the serotonin transporter, there are several thousand other genes for neuromodulatory molecules that have been cloned and expressed in some type of cellular system and that are viable candidates for drug targets (58). Pharmacogenomic technologies may aid in prioritizing these candidates for examination, or identifying yet more candidates, by determining those genes that are activated or deactivated in tissues during an acute psychiatric episode and in response to treatment. One approach to evaluating gene expression involves hybridization of fluorescent or radioactively labeled messenger RNA (mRNA) samples taken from the relevant cell population to cDNA arrays. Changes in gene expression (up, down, or none) can then be compared between different samples at a single time point or within a sample overtime. This technique is known as serial analysis of gene expression (SAGE) (59). However, if the changes in gene activation induced by disease or by drugs are localized to a specific population of cells in inaccessible tissues such as that of the brain, rather than, say, in fibroblasts from skin biopsies, the SAGE technique will not be helpful. Alternatively, large-scale analysis of proteins within clinical samples is also predicted by some to become a useful means of identifying biological markers indicative of a response to drugs (60). Again, any changes in protein expression would need to be detectable in easily obtainable fluids such as blood or urine to be of use in the evaluation of psychiatric disorders, and the process of informed consent for such experimentation would need to be reviewed thoroughly.

SUMMARY

Part of "18 - Using Human Genomics to Advance Neuropsychopharmacology "

Genomics has great potential to advance the field of psychiatry in general and neuropsychopharmacology in particular. This will occur through the identification of genes involved in the etiology of psychiatric disorders and the identification and characterization of genes involved in the response to psychotropic agents. Although we have not made much headway as of yet in either of these fields, impressive advances

in our knowledge of the genomes of human and model organisms as well as access to the technologies developed to provide this information are likely to stimulate swift progress. Success in these endeavors will lead to more efficient identification and development of drug targets, the provision of an objective basis for choice of drug, “custom drugs” based on an individuals genotype, improved diagnosis of disease, and earlier detection of genetic predispositions to disease.

Gene Targeting and Transgenic Technologies

Laurence H. Tecott

David S. Johnson

Laurence H. Tecott and David S. Johnson: Department of Psychiatry, Langley Porter Psychiatric Institute, University of California–San Francisco, San Francisco, California 94143-0984.

Recent progress in the development of molecular genetic methods enables the manipulation of genes in intact mammalian organisms. The power of such techniques to elucidate complex biological systems was initially recognized and exploited by developmental biologists and immunologists. More recently, the utility of these approaches for examining neural gene function in the context of the intact organism has led to their use in neuropsychopharmacology. Since the publication of the previous edition of this book, there has been an explosion in the application of molecular genetic technologies to study the regulation of complex behavior and its modulation by psychoactive drugs.

For several decades, the ability to manipulate genes in organisms such as yeast, fruit flies, and nematodes has produced important insights into the regulation of a wide variety of complex biological processes. Limitations in the use of such organisms for research in neuropsychopharmacology arise from the marked organizational differences between the mammalian brain and the systems that govern behavior in these organisms. By contrast, a substantial degree of homology exists in the organization of the central nervous system (CNS) and in the complement of genes expressed across mammalian species. Currently, the mouse genome is by far the most accessible mammalian genome to manipulation. Procedures exist in the mouse for introducing new genes, expressing elevated levels of endogenous genes, and eliminating or altering the function of identified target genes.

Mutant mouse models may be used for a number of purposes relevant to neuropsychopharmacologic research. For example, the impact of genetic mutations on the behavior of mutant mice may be examined, providing insights into the functional significance of particular gene products. In some cases, the manifestations (phenotypes) of these mutations may resemble features of human neuropsychiatric diseases, providing animal models for studying neural processes relevant to such disorders. Furthermore, as genes that confer susceptibility to human diseases are identified, it will be possible to introduce corresponding mutations into the mouse genome, generating useful models for studying disease pathophysiology and treatment. Finally, genetic models will be useful for investigating mechanisms through which nonselective drugs influence neural function and behavior. For example, the contribution of a particular receptor subtype to the actions of a nonselective drug may be examined by studying its actions in animals with targeted loss-of-function mutations of that receptor gene.

This chapter provides an overview of the transgenic and gene targeting approaches used to manipulate the mammalian genome. We have divided these techniques into three categories: (a) transgenic technologies, in which exogenous gene sequences are inserted into the mouse genome; (b) gene targeting technologies, in which mutations are targeted to inactivate or otherwise modify an endogenous gene of interest; and (c) conditional genetic manipulations, in which mutations are restricted to particular stages of development or to particular regions of the CNS. In addition to a brief description of these technologies, examples of their application to neuropsychopharmacology are provided, as well as discussions of the benefits and limitations of each approach.

TRANSGENIC PROCEDURES

Part of "19 - Gene Targeting and Transgenic Technologies "

The ability to insert an exogenous (or foreign) gene into the mouse genome by direct injection into the pronuclei of zygotes was achieved just two decades ago (1) . The term *transgenic* was applied to mice expressing exogenous DNA that had been produced using this technique (2) . With this method, the gene of interest is inserted into a random locus in the mouse genome, and is expressed “in trans,” i.e., not in its usual genetic locus. The techniques required for introducing

transgenes into the mouse genome have been highly refined, permitting their widespread use. Since the development of this technique, many thousands of lines of transgenic mice have been generated, and it has been the most widely utilized technique of genetic manipulation in mice.

Methods of Production of Transgenic Mice

Techniques for producing transgenic mice involve the microinjection of DNA constructs into fertilized mouse eggs (Fig. 19.1) . DNA constructs used for the generation of transgenic mice typically consist of a gene of interest located 3′ to promoter sequences selected to produce a desired distribution of gene expression. The maximum length of the DNA sequence that may be successfully incorporated into the mouse genome is not known, and up to 70 kilobase (kb) DNA fragments have been successfully integrated. The transgene is linearized and purified from prokaryotic vector sequences. For optimal integration efficiency, about 1 to 2 picoliter (pL) of DNA at a concentration of 1 to 2 ng/μL (corresponding to a few hundred molecules of a 5-kb DNA fragment) is microinjected into the male pronucleus of a fertilized mouse egg. Although labor intensive, direct injection of DNA into the pronucleus results in much higher rates of integration of transgenes than other known methods of transformation. After microinjection, the embryos are surgically transferred into the oviduct of pseudopregnant mice. Pseudopregnant females are generated by matings with vasectomized males. The act of copulation initiates the endocrine changes of pregnancy, providing a suitable uterine environment for the survival and implantation of the transferred embyros. The foster mothers give birth 19 to 21 days after oviduct transfer. For genotyping, DNA is typically isolated from mouse tail biopsies and screened for the presence of the transgene by Southern blotting or polymerase chain reaction (PCR). Typically, about 20% to 40% of the mice that develop to term possess the transgene. In the majority of cases, integration of the transgene occurs during the one-cell stage, so that the transgene is present in every cell of the transgenic mouse. Integration usually occurs at a single random chromosomal location, and, for reasons that are not fully understood, there are usually multiple copies of the transgene inserted as head-to-tail concatamers. Mice identified to possess the integrated transgene are referred to as *founders*. The founders are typically used in a breeding strategy to produce animals that are homozygous for the transgene insertion.

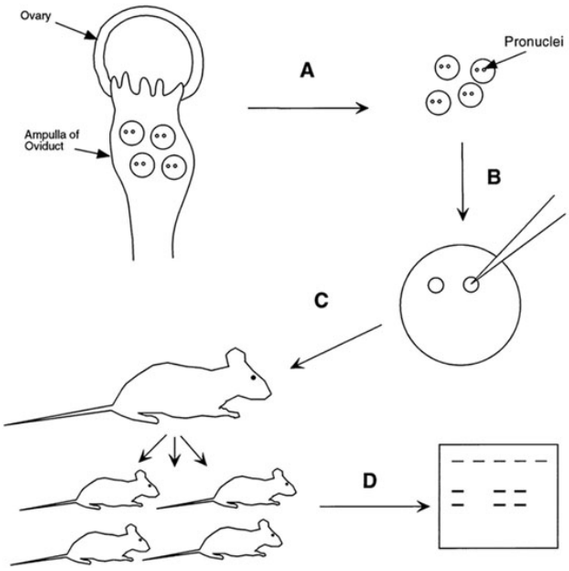

FIGURE 19.1. Procedure for production of transgenic mice. **A:** One-celled fertilized zygotes located in the oviduct ampullae of pregnant donor mice are surgically harvested. **B:** DNA encoding the gene of interest is microinjected directly into the pronucleus of the zygotes. **C:** Injected zygotes are surgically transferred into the oviducts of pseudopregnant female mice. **D:** DNA from the progeny can be analyzed by Southern blot or polymerase chain reaction (PCR) for the presence of the transgene.

Uses of Transgenic Mice

Because transgenic mice often possess multiple copies of the transgene, this method can be used to produce animals with increased levels of expression of particular genes, i.e., mice that “overexpress” genes of interest. In addition, it can be used to express altered forms of a gene product in the distribution of the endogenous gene. One example is a transgenic line bearing a transgene composed of the Ca^{2+}/calmodulin-dependent protein kinase α subunit (CaMKIIα) promoter driving expression of a mutant form of CaMKIIα that conferred Ca^{2+}-independent activation. These mice exhibited an increased stimulation threshold for the induction of synaptic plasticity in the hippocampus, as well as deficits in spatial memory (3, 4) . Studies of these animals led to an enhanced understanding of the role of CaMKIIα in synaptic plasticity and spatial memory acquisition.

In many cases, it is desirable to express a gene with an anatomic distribution that does not mirror its native expression pattern in the mouse. Such ectopic expression of a gene may be achieved using a transgenic construct in which the gene of interest is preceded by promoter elements that direct expression in an anatomic distribution characteristic of another gene. An example of this approach is a transgenic line in which the D1 dopamine receptor promoter was used to drive expression of a cholera toxin subunit (which constitutively activates G_s) in cells that express D1 dopamine receptors (5) . Studies of these animals revealed that chronic overstimulation (by constitutively activated G_s) of forebrain neurons expressing D1 receptors results in an abnormal behavioral phenotype that was likened to human compulsive

behaviors. For most genes, the promoter elements necessary to reproduce the native patterns of expression are not well defined. A useful approach for identifying important promoter elements for genes of interest involves the generation of transgenic mice in which putative promoter sequences are used to direct expression of *reporter genes*, whose expression is readily determined in brain tissue. Comparisons may then be made between the pattern of reporter gene expression and that of the gene of interest (6, 7 and 8) .

It is also possible use transgenic approaches to reduce the expression of a particular gene product. This may be achieved using “dominant-negative” mutations, mutations that induce loss of function of a gene product when expressed in the heterozygous state. For example, transgenic constructs may be designed to express antisense RNAs that hybridize to native messenger RNA (mRNA) sequences, thus decreasing production of the gene product of interest (9, 10 and 11) . Alternatively, the function of gene products that aggregate into multimeric complexes may be disrupted by dominant-negative mutations that produce dysfunctional subunits of the complex. The most prevalent approach used to generate loss of function mutations, gene targeting, is described in the next section.

Considerations in the Interpretation of Transgenic Mouse Phenotypes

An important factor that frequently complicates the interpretation of studies with transgenic mice is the difficulty that may be encountered in achieving a desired anatomic distribution of transgene expression. Promoter elements are often quite large, and additional regulatory elements may at times be located great distances from the gene of interest. In addition, the site of integration often affects the pattern and level of transgene expression, so that founder mice generated with a common targeting construct may display different expression patterns. It may therefore be difficult to accurately duplicate a promoter's endogenous pattern of gene expression in the setting of a transgenic mouse. Commonly, expression patterns are assessed in multiple founders, and those with the most appropriate transgene expression would then be selected for a particular experiment.

Several additional considerations in the interpretation of phenotypes in transgenic mice warrant mention. For example, the number of copies of the transgene incorporated into the genome varies between founder mice. In some cases, concatamers can be unstable and susceptible to deletion of one or more copies of the transgene. In addition, the integration of the transgene may occasionally disrupt an endogenous gene. This could lead to the development of a phenotypic abnormality unrelated to the function of the transgene—this is estimated to occur in 5% to 10% of transgenic mice (12) . This possibility may be assessed by determining whether similar phenotypes are present in animals derived independently from different founders, because the likelihood of two founders possessing the same transgene integration site is minimal.

GENE TARGETING PROCEDURES

Part of "19 - Gene Targeting and Transgenic Technologies "

A mutational approach has proved to be invaluable to investigators examining the roles of gene products in complex biological processes within prokaryotic and cultured eukaryotic cells. Recently it has become possible to apply this approach to a mammalian system. Gene targeting procedures enable the precise (site-specific) introduction of a mutation to one of the estimated 100,000 murine genes. Typically, mutations have been designed to eliminate gene function, resulting in the generation of “knockout” or “null mutant” mice. The introduction of mutations that produce more subtle alterations in gene function has also been achieved. Two major developments have made gene targeting experiments feasible: (a) the generation of totipotent embryonic stem (ES) cells, and (b) the elucidation of techniques to achieve homologous recombination in mammalian cells.

Gene Targeting Methods

ES cells are derived from 3.5-day-old mouse embryos, at the blastocyst stage of development (Fig. 19.2) . Blastocysts are cultured individually under conditions that permit the proliferation of the inner-cell mass cells, which are those cells that would normally become the fetus. These cells are then disaggregated, and individual ES cells clones are grown. Under optimal conditions, ES cells retain the ability to contribute to all of the tissues of the developing fetus. The derivation of ES cells was pioneered using embryos derived from the 129/Sv strain of mice, a strain that has been most commonly used in studies of early embryonic development. Although this mouse strain is not ideal for the study of behavior (see below), most ES cell lines in current use are 129/Sv-derived.

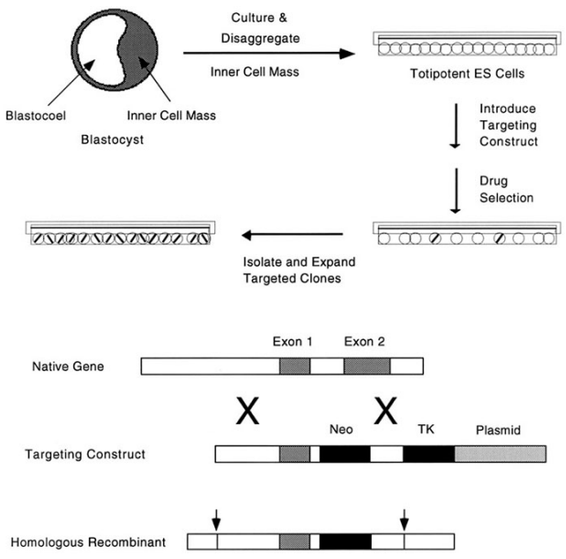

FIGURE 19.2. Gene targeting in embryonic stem (ES) cells. **A:** ES cells are derived from the blastocyst inner cell mass. A targeting construct is introduced into ES cells by electroporation. Cells are subjected to drug selection to enrich for homologous recombinant clones (*striped cells*). Homologous recombinant clones are isolated for blastocyst injection. **B:** A targeting construct is produced in which the second exon of the gene of interest is replaced by a neomycin resistance cassette (Neo). A thymidine kinase (TK) cassette is included for negative selection. Homologous recombination results in the incorporation of engineered mutation into endogenous gene locus. *Arrows* indicate the junction of construct sequences and native locus.

Homologous recombination is the process by which a mutation is targeted to a precise location in the genome. A targeting construct is generated that typically consists of a target gene sequence into which a loss-of-function mutation has been engineered (Fig. 19.2) . Most targeting constructs are designed to achieve homologous recombination events in which recombination at the target locus results in replacement of native target sequences with construct sequences. In mammalian cells, fragments of DNA preferentially integrate into the genome at random locations, at rates that greatly exceed homologous recombination. Therefore, targeting constructs are designed for use in selection strategies that enrich for ES clones in which homologous recombination has occurred. In the commonly used positive-negative selection strategy (13), a portion of a protein-coding exon is replaced by sequences that confer resistance to the drug neomycin. This mutation serves two purposes: (a) to inactivate

the gene product, and (b) to provide a marker that enables the selection of cells that have integrated the construct. This exogenous DNA fragment is flanked by regions of DNA that are homologous to the native gene. Adjacent to one of these homologous regions is a gene encoding thymidine kinase. Treatment with the drug ganciclovir will kill cells that express this gene.

The targeting construct is typically introduced into ES cells by electroporation. In this step, cells are subjected to an electric current that facilitates the internalization of the DNA construct. Those cells that failed to incorporate the targeting construct are killed by the addition of neomycin to the culture medium (positive selection). The majority of the remaining cells have incorporated the entire DNA construct (including the thymidine kinase gene) at random sites throughout the genome. By contrast, during homologous recombination, nonhomologous regions of the construct that are not flanked by homologous sequences are excluded from the integration event. Therefore, homologous recombinant clones will not contain the thymidine kinase gene. Thus, the addition of a second drug, ganciclovir, will selectively kill cells that have randomly incorporated the construct (negative selection), thereby enriching for targeted clones. ES cell clones that survive this double drug selection are then screened for homologous recombination by PCR or Southern blot analysis. The homologous recombinant clones, which are heterozygous for the introduced mutation, are then used to generate chimeric mice.

Following the isolation of homologous recombinant ES cell clones, these cells are microinjected into the fluid-filled blastocoele cavity of 3.5-day-old embryos at the blastocyst stage (Fig. 19.3) . The injected embryos are then surgically transferred into the uterus of pseudopregnant females. These animals will then give birth to chimeric mice, which are derived partly from the injected ES cells and partly from the host embryo. For example, ES cells derived from a brown strain of mice are often injected into embryos derived from black C57BL/6 mice, resulting in chimeras with coats

containing black and brown patches. The extent to which the ES cells have colonized the animal may be roughly approximated by the extent of the brown contribution to the coat. It is most important that ES cell derivatives colonize the germ cells of the chimera, so that the targeted mutation can be propagated to subsequent generations. If chimeras are mated with C57BL/6 mice, then the germ line transmission of ES cell–derived genetic material is indicated by the generation of brown offspring. Half of these brown mice will be heterozygous for the targeted mutation. These heterozygous mice are then bred to produce homozygous mutant mice that completely lack the normal gene product.

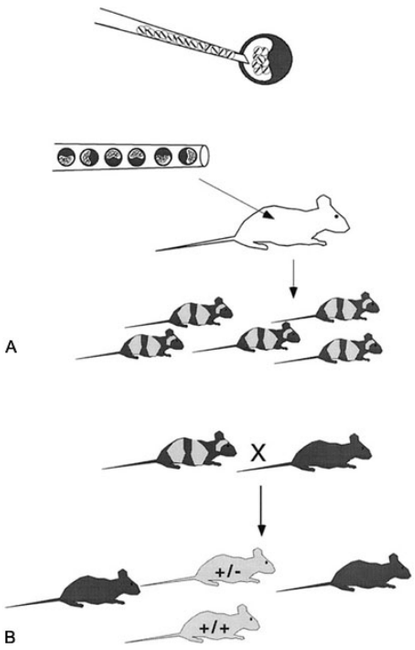

FIGURE 19.3. Generation of gene targeted mice. **A:** Homologous recombinant ES cells are injected into the blastocoele cavity. **B:** Injected blastocysts are surgically transferred into the uterus of pseudopregnant female mice for the production of chimeric mice. **C:** In this example, chimeric mice are bred with C57BL/6 animals. Germ-line transmission is indicated by coat color. One-half of animals with the coat color indicative of the ES cell line will be heterozygous for the targeted mutation and the other half wild type. Heterozygous animals may be bred for the production of homozygous mutant mice.

Uses of Gene Targeted Mice

Studies of null mutant mice provide novel insights into the functional roles of neural genes and, in some cases, animal models relevant to human neuropsychiatric disorders. An illustrative example is a recent study of mice lacking the hypothalamic neuropeptide orexin (14) . Observations of homozygous mutant mice revealed an unanticipated phenotypic abnormality. The mutants displayed frequent episodes of inactivity characterized by the sudden collapse of the head and buckling of the extremities. Subsequent electroencephalogram (EEG) analysis revealed these episodes to be similar to narcoleptic attacks observed in humans and in a strain of narcoleptic dogs. Moreover, a mutation of an orexin receptor gene was found to underlie the canine syndrome (15) . Thus, the null mutant phenotype revealed a novel role for orexin in sleep regulation. In addition, this line of mice represents an important animal model for examining the pathophysiology and treatment of narcolepsy.

Another example illustrates the potential utility of null mutant mice to uncover mechanisms underlying the behavioral effects of psychoactive drugs. The nonselective serotonin (5-hydroxytryptamine, 5-HT) receptor agonist m-chlorophenylpiperazine (mCPP) interacts with several subtypes of 5-HT receptors. Although this compound typically reduces locomotor activity in rodents, it produced a paradoxical hyperlocomotor response in a line of 5-HT_{2C} receptor null mutant mice (16) . This response to mCPP was blocked by pretreatment with a 5-HT_{1B} receptor antagonist, indicating that the absence of 5-HT_{2C} receptors unmasked a hyperlocomotor effect of mCPP on 5-HT_{1B} receptors in mutant mice. These results provide a model whereby genetic endowment may contribute to the development of a paradoxical drug response. When a compound alters the function of multiple gene products with opposing influences on behavior, then mutations or allelic variation of these genes may lead to paradoxical effects.

Although gene targeting techniques are most commonly used to generate animals with null mutations, subtle mutations may also be introduced that alter, but do not eliminate, function. The benefits of such an approach are highlighted by a mutation of a gene encoding the α_1 subunit of the γ-aminobutyric acid A ($GABA_A$) receptor (17) . The mutation produced a single amino acid change, rendering the α_1 subunit–containing subpopulation of $GABA_A$ receptors insensitive to benzodiazepines, without affecting their responsiveness to GABA. The resulting animals exhibited reduced sensitivity to the sedative and amnestic effects of diazepam, but no change in sensitivity to the anxiolytic-like effects of this drug. These results indicate that benzodiazepine site ligands devoid of activity at α_1 subunit–containing $GABA_A$ receptors may act as anxiolytics devoid of some of the side effects typically associated with benzodiazepines, a prediction borne out by a recent report of the behavioral effects

of such a compound (18) . These insights would not have been obtained using a conventional gene targeting approach, because a null mutation of the α_1 subunit gene would profoundly perturb brain GABA signaling.

Considerations in the Interpretation of Targeted Mutant Phenotypes

In interpreting behavioral phenotypes, attention must be paid to the effects of genetic background. The phenotypic consequences of many targeted mutations may be influenced by modifying genes that differ among various inbred strains (19) . In some cases, phenotypic abnormalities have been lost when mutations were bred to a new genetic background (20) . It may therefore be useful to examine the persistence of mutant phenotypes in the context of several genetic backgrounds. In one example, three groups independently generated lines of mice with null mutations of the 5-HT_{1A} receptor subtype (21, 22 and 23) . Interestingly, although each group placed this mutation on a different genetic background, all observed enhanced anxiogenic-like behaviors in the mutant lines. Thus, particularly strong evidence is provided for a contribution of the 5-HT_{1A} receptor to the regulation of anxiety.

Another potential problem arises from the common use of ES cells derived from 129/Sv mice. Mice of this strain are susceptible to structural abnormalities of the CNS, such as agenesis of the corpus callosum, and are impaired in several behavioral assays (19, 24) . This potential problem may be addressed through breeding programs to place targeted mutations on different inbred backgrounds, and by the generation of ES cell lines derived from other inbred strains. It has been recommended that the C57BL/6 and DBA strains be used as standards, due to the extensive body of data relating to the behavioral characterization of these strains (19) .

In addition to the above strain considerations, the standard application of gene targeting technology has several inherent limitations. The null mutations engineered into knockout mice are typically constitutive, i.e., they are present throughout embryonic and postnatal development. Therefore, the potential for developmental perturbations is a major caveat to the interpretation of mutant phenotypes in adult animals. It may be difficult to determine whether a mutant phenotype reflects a normal adult role for the targeted gene or an indirect effect of the mutation attributable to perturbed development. Such an effect may lead to an overestimation of the functional significance of the gene product in the adult animal. Conversely, if significant compensation for the loss of a gene product occurs during development, then the severity of the mutant phenotype may underestimate the functional significance of the gene product. The nature of such compensatory mechanisms and the extent to which they exist may be difficult to determine. The above considerations also pertain to the analysis of transgenic mice carrying constitutive mutations.

Another limitation of the standard gene targeting technology is that the mutations are ubiquitous, present in all of the cells of the animal. Thus, if a neural gene of interest is also expressed in peripheral tissues, then the absence of the gene product peripherally could lead to a lethal or altered phenotype, independent of its neural role. Moreover, for genes that are widely expressed in the CNS, it may also be difficult to anatomically localize the brain region(s) that underlie the mutant phenotypes. New techniques to overcome these problems by achieving region-specificity and inducibility of targeted mutations are under development, and are described in the next section.

PROCEDURES FOR ENGINEERING CONDITIONAL MUTATIONS

Part of "19 - Gene Targeting and Transgenic Technologies "

New technologies are under development for circumventing the limitations of standard gene targeting approaches by creating mutations that may be induced in adult animals and/or restricted to particular brain regions. Although these strategies are not yet in widespread use, it is likely that rapid advances in this area will lead to an exponential increase in the generation of such “conditional mutations” over the next several years.

Cell Type–Specific Mutation Strategies

When a null mutation of a gene results in a mutant phenotype, limitations in the interpretation of that phenotype can arise because the gene is inactivated in every cell in which it was expressed in the mouse in the wild-type (WT) state. Therefore, the observed abnormal phenotype may arise from the absence of the functioning gene product in a peripheral organ system, the peripheral nervous system, or the CNS—i.e., in any of those regions in which the gene is normally expressed. It is possible that the absence of a gene product in the periphery may lead to embryonic lethality, precluding use of the mutant for the studies of neural function. For genes that are widely expressed within the CNS, it may be difficult to identify neural circuits through which mutations produce behavioral perturbations. The ability to inactivate genes in restricted subpopulations of the cells that normally express them will be a valuable asset in studies to uncover the neural mechanisms underlying neural phenotypes.

Recent efforts have focused on a mutational strategy developed to exert spatial control over the pattern of expression of genetic changes introduced into mice. This approach utilizes somatic cell recombination rather than germ cell (or embryonic stem cell) recombination to inactivate a gene in restricted populations of cells or tissues. In this approach, a tissue-specific promoter is used to direct expression of one

of the site-specific recombinases (25) to limit gene inactivation to only those cells expressing the recombinase. The two recombinase systems that have been utilized for genetic manipulation in mice have been the Flp-frt system from yeast (26), and the Cre-lox system from bacteriophage P1 (27, 28 and 29), with the large majority of reports using this technique utilizing the Cre-lox system.

Cre (cyclization of recombination) recombinase is a 38-kd protein from bacteriophage P1, which recognizes and catalyzes reciprocal DNA recombination between two loxP (locus of crossing over of P1) sites. The loxP site is the 34–base pair (bp) recognition sequence for Cre composed of a palindromic 13-bp sequence separated by a unique 8-bp core sequence (Fig. 19.4A) . A gene or gene segment with flanking loxP ("floxed") sites will be excised by homologous recombination in the presence of Cre, leaving a single loxP site marking the point of excision and re-ligation of upstream and downstream DNA (Fig. 19.4B) . This approach, then, involves generating two independent lines of mice—a line bearing loxP sites, and a transgenic line in which Cre expression is driven by a tissue-specific promoter. Animals with a gene or gene region of interest flanked by loxP sites (floxed) are generated by gene targeting. Because the loxP sites are relatively small and placed in intronic regions, they do not typically interfere with normal gene transcription. Of course, WT patterns and levels of expression need to be documented in these floxed mouse lines, because inadvertent placement of lox sites into promoter elements or RNA splice sites could disrupt gene expression. The Cre mice are most commonly generated by creating a transgenic line of mice in which Cre expression is driven by a tissue-specific promoter. As discussed above in the section on transgenic mice, variability in transgenic expression patterns requires several lines of Cre mice that need to be generated and assayed for patterns of Cre expression. An alternative strategy is to use gene targeting procedures to place Cre under the control of an endogenous promoter (30) . The advantage of this approach is that Cre expression should closely approximate the WT expression pattern of the gene it is replacing because the original gene's promoter remains in its endogenous location. A potential disadvantage is that Cre may disrupt expression of the gene into which it has integrated. Once a line exhibiting the desired pattern of Cre expression is identified, it is crossed with an appropriate floxed line to commence a breeding strategy resulting in the generation of animals with a restricted pattern of gene inactivation (Fig. 19.4C) .

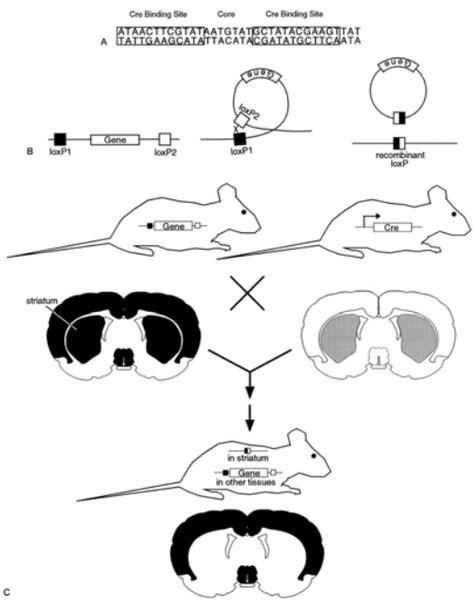

FIGURE 19.4. Strategy for cell-type–selective mutations using Cre-mediated recombination. **A:** The loxP DNA sequence indicating the core region and the inverted repeats that constitute Cre binding sites. **B:** In the presence of Cre, a gene flanked by tandomly oriented loxP sites (floxed gene) will be excised by homologous recombination. The recombination occurs in the core region of the loxP site, leaving a single recombinant loxP site in the genome after Cre excision. **C:** Use of the Cre-lox system to generate cell-type–specific gene inactivation in mice. A "floxed mouse" is generated by gene targeting to introduce loxP sites flanking a gene of interest. The wild-type expression pattern of this gene is shown (*black*) in the coronal section beneath the floxed mouse. In this example, there is expression of the gene in the cortex (ctx), striatum (str), and hypothalamus (hypothal). This floxed mouse can be crossed to a transgenic mouse expressing Cre in a distribution dictated by the promoter used in the transgene construct. In this example, Cre expression is shown (*gray*) and is limited to the striatum. A breeding program is pursued to produce animals in which expression of the floxed gene is normal except in the striatum, where the expression of Cre results in the excision of the floxed gene.

Several lines of Cre mice have been reported in which expression is restricted to subpopulations of cells within the CNS (31, 32, 33, 34 and 35) . The first example of this approach was the inactivation of the glutamate receptor subunit NMDAR1 in CA1 pyramidal neurons of the hippocampus, with expression in other brain areas mostly intact (31) . NMDAR1 is the predominant *N*-methyl-D-aspartate (NMDA) receptor subunit and is widely expressed in most CNS neurons. It had been previously demonstrated that widespread gene inactivation in NMDAR1 null mutants resulted in perinatal lethality (36, 37) . When the mutation was restricted to hippocampal CA1 neurons, animals were viable and exhibited impaired spatial learning and impaired plasticity at CA1 synapses (31) . Thus, spatial restriction of neural mutations can be used to uncover particular brain regions or cell type through which gene inactivation alters behavior.

The utility of this approach for producing cell-type–specific inactivation of genes is enhanced by the fact that the components of the system produced in one laboratory can be "mixed and matched" with components from another laboratory. That is, Cre lines generated for use with a particular floxed gene may also be used with other floxed genes when a similar pattern of gene inactivation is desired. Collaborative efforts to generate databases of Cre and floxed lines will speed and simplify the production of animals with restricted patterns of gene inactivation.

Inducible Mutation Strategies

As described above, the absence of a gene product throughout development complicates the interpretation of mutant phenotypes. Efforts are currently under way to overcome this limitation through the use of gene expression systems that may be induced in the adult animal. Strategies are under exploration for achieving this goal using a variety of compounds, such as tetracycline, steroid receptor antagonists, and ecdysone to induce gene expression. Although these approaches have yet to be optimized for general use, this development is likely to be close at hand. The tetracycline system has been the most utilized and best developed approach to inducible gene regulation.

Since the introduction of the Tet system by the Bujard laboratory in 1992, many laboratories have validated the utility of this approach to inducible gene regulation, and many refinements/improvements in the system have been introduced (38) . This system is based on the regulatory elements of a tetracycline resistance operon of *Escherichia coli*, in which the transcription of tetracycline resistance genes is negatively regulated by the tetracycline repressor (tetR) (Fig. 19.5) . When tetracycline is present, tetR binds the tetracycline and loses its capacity to bind to the operator sequences (tetO) located within the promoter of the tetracycline resistance operon, and transcription is permitted. By creating a fusion protein composed of the tetR and a potent transcriptional activator, VP16, a tetracycline-dependent transactivating factor (tTA) was produced that retained the DNA binding and activation specificity of the tetR. The desired regulatable gene of interest is placed under tetO plus a minimal promoter (P_{min}), that contains the basic promoter elements required for transcription in all cell types. Activation of this system requires the binding of the tTA to the tetO operator sequence (39) . The presence of tetracycline,

or other suitable ligand such as doxycycline, prevents tTA from binding to tetO and activating transcription of the gene of interest. This is referred to as the *tet-off* system—that is, when tetracycline is present, transcription is off. A *tet-on* system has also been developed, in which tetracycline induces transcription of the gene of interest. It utilizes a reverse tetracycline transcriptional activator (rtTA), designed so that it would bind to tetO and activate transcription only in the presence of tetracycline-related compounds (38) . Doxycycline is most frequently used because it is a potent regulator in both the tet-off and tet-on systems (38), and can be easily supplied to mice through their water or food supply (40, 41) .

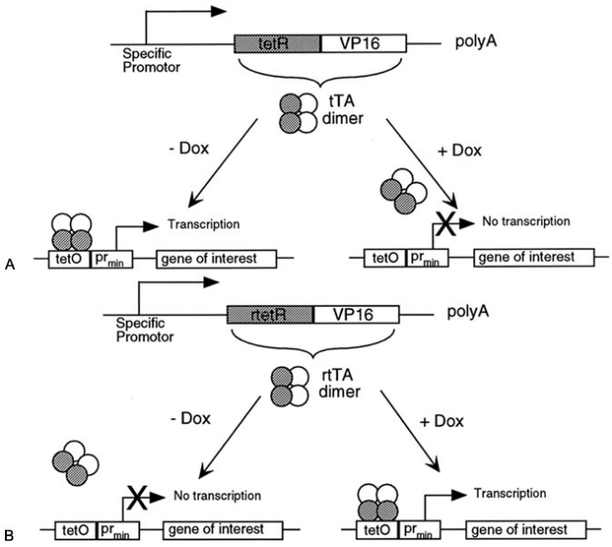

FIGURE 19.5. Tetracycline-regulated expression systems. **A:** Tet-off system. The tetracycline-controlled transactivator, tTA, is a fusion protein consisting of the tetracycline repressor (tetR) domain and a transcriptional activation domain (VP16). tTA homodimerizes, and in the absence of tetracycline (or the tetracycline analogue doxycycline) activates transcription of the gene of interest that has been placed downstream from tetO and a minimal promoter. Binding of doxycycline (Dox) to the tTA dimer prevents the binding of tTA to tetO, and transcription of the gene is prevented. Therefore, the tTA system has been called the Tet-off system, because in the presence of doxycycline, transcription is prevented. **B:** Tet-on system. In the Tet-on system, the tetracycline-controlled activator has been mutated to reverse the action of doxycycline on the transactivator. By contrast with tTA, doxycycline binding to rtTA enables the complex to bind to tetO and activate gene transcription. In the absence of doxycycline, rtTA is unable to bind to tetO and cannot activate transcription. Therefore, the rtTA system is also called the Tet-on system, because doxycycline activates transcription of the regulated gene.

The tet-off and tet-on systems are binary systems—i.e., they require two genetic elements to be introduced into mice. First, a tissue-specific promoter can be used to express tTA or rtTA in a region or cell-type specific manner; then the gene of interest is inserted behind tetO and a minimal promoter. This can be achieved by creating two separate transgenic lines of mice and then cross-breeding to produce bigenic lines. In these lines, expression of the gene of interest may be induced by doxycycline (tet-on) or by the discontinuation of doxycycline treatment (tet-off). For example, the tet-off system has been used to investigate the effects of the transcription factor ΔFosB on psychostimulant responses. A line of mice was generated in which expression of a ΔFosB transgene was suppressed by continuous doxycycline treatment throughout development. Discontinuation of treatment in adult animals led to overexpression of the transgene in the nucleus accumbens and to augmentation of the rewarding and locomotor stimulant properties of cocaine (42) . The utility of the tet-on system has also been demonstrated. For example, a line of mice was developed to examine the role of the Ca^{2+}-activated protein phosphatase calcineurin in synaptic plasticity. Treatment of these animals with doxycycline induced calcineurin overexpression in restricted forebrain regions, associated with deficits of neuronal plasticity and spatial learning (41) .

Rather than generating regulatable gain of function mutants with the Tet system, regulatable loss of function mutants can also be generated by combining the Tet system with the Cre-lox system (43, 44) . In this arrangement, a cell-type–specific promoter drives rtTA expression and Cre is linked to tetO and a minimal promoter. In the presence of doxycycline, Cre is expressed in the cell type specified by the promoter used to drive rtTA expression, and somatic

cell recombination excises floxed DNA fragments in those cells—achieving an inducible cell-type–specific knockout. This inducible knockout approach may be utilized to circumvent concerns discussed above in the interpretation of gene knockout phenotypes.

In these inducible knockout mice it must be remembered that although the excision of the floxed gene can be induced relatively quickly, the appearance of any phenotype resulting from the absence of the gene product will occur gradually, depending on the degradation rate of the relevant mRNA and the half-life of the protein. Another important limitation of strategies utilizing the Tet system relates to the inherent “leakiness” of the tetO operator; i.e., low levels of unwanted gene expression may occur during periods in which gene expression is expected to be turned off. This may be problematic when the inducible transgene is toxic or has significant effects even when expressed at very low levels. Recent findings with tetracycline controlled transcriptional silencers indicate that it may be possible to modify the tet system to substantially reduce unwanted gene expression (45) . In addition, work has begun on alternative inducible gene expression systems with low levels of basal expression. One such system utilizes the insect hormone ecdysone as an induction signal.

SUMMARY

Part of "19 - Gene Targeting and Transgenic Technologies "

The development of transgenic and gene targeting technologies is significantly enhancing understanding of cellular and molecular functions of genes and their contributions to neural processes relevant to clinical disorders. In some instances, novel roles for receptor subtypes have been revealed by the observation of unexpected phenotypic abnormalities in mutant animals. Mutant strains are also providing models for studying the pathophysiology and treatment of particular neuropsychiatric diseases. In addition, some mutant mouse models are useful for investigating the mechanisms of action of psychoactive drugs. Although mutant mouse models represent powerful tools in neuropsychopharmacology, they do not replace older methods of investigation. These models may be best used as components of integrated multidisciplinary research efforts spanning multiple levels of analysis.

This chapter briefly surveyed the most common strategies used for manipulating the mouse genome, and cited the advantages and limitations of each approach. Progress in the development of conditional mutagenesis strategies will address many of the current limitations, and facilitate uncovering the neural mechanisms through which mutations alter neural systems to impact behavior. Although this field is still in its infancy, an exponential increase in the application of molecular genetic technologies is anticipated to contribute substantially to our understanding of brain function in health and disease.

Gene Delivery into the Brain Using Viral Vectors

Rachael L. Neve

William A. Carlezon Jr.

Rachel L. Neve and William A. Carlezon, Jr.: Department of Psychiatry, Harvard Medical School and McLean Hospital, Belmont, Massachusetts 02478.

The delivery of recombinant genes into the brain is becoming an increasingly important strategy for answering questions about the molecular mechanisms of brain function. Answers to these questions may be applied to many of the disorders that affect the brain. For example, an understanding of the mechanisms by which repeated exposure to drugs of abuse increases their stimulant and rewarding properties in animal models will almost certainly lead to new ways of treating addiction in humans. If we are able to decipher the molecular events underlying long-term changes in neurotransmitter release, we will find new approaches to diseases such as the epilepsies, in which neurotransmitter release is altered. Knowledge of the molecular means by which neurotransmitters shape neuronal development and plasticity, or how trophic factors regulate neuronal health, will lead to insights into how defects in these pathways cause specific psychiatric and neurodegenerative diseases.

Unfortunately, the brain does not yield easily to genetic intervention. The terminally differentiated state of most neurons in the brain precludes the use of vectors, such as conventional retroviruses, that are dependent on cell replication for stable maintenance in the cell. In addition, the molecular mechanisms of specific brain disorders may be restricted to subsets of neurons at specific times during development and maturity. Therefore, strategies for manipulating gene expression in the brain must utilize vectors that persist stably in postmitotic cells and that can be targeted both spatially and temporally in the nervous system. A number of such gene delivery systems have been developed over the last decade. Rather than giving a superficial overview of the field, this chapter highlights the use of herpes simplex virus (HSV) as a vector for gene transfer into neurons, with emphasis not only on its potential but also on its flaws; compares and contrasts HSV-mediated genetic intervention in neurons with that mediated by other viral vectors; and gives detailed examples of the practical uses of this technology by describing the use of HSV vectors to study the molecular basis for drug addiction.

HERPES SIMPLEX VIRUS: THE PROTOTYPIC VECTOR

Part of "20 - Gene Delivery into the Brain Using Viral Vectors "

HSV possesses multiple features that make it an ideal vector for delivery of genes into the nervous system. In particular, it accepts large molecules of exogenous DNA; it infects nondividing cells from a wide range of hosts with high efficiency; it enables strong expression of foreign genes; it is episomal, and thereby does not cause integration effects; its infection of postmitotic cells is persistent; and HSV-1 particles can be concentrated to relatively high titers. Because of these characteristics of HSV-1, and because it is neurotropic, it is currently one of the best viral vectors available for functional analysis of genes in the nervous system.

Amplicon vs. Genomic HSV-1 Vectors

There are two types of replication-deficient HSV vectors: those in which the foreign DNA of interest is cloned into the viral genome itself (genomic vectors), and those that are composed of a plasmid carrying minimal HSV sequences that allow it to be packaged into virus particles with the aid of a helper virus (amplicon vectors). A number of genes within the wild-type HSV genome are dispensable for its growth in cells *in vitro*. This knowledge was used to create “crippled” recombinant HSV-1 viruses that could be used as vectors for gene transfer into cells (1) . This type of genetically engineered genomic vector has been used by a number of investigators and is described in detail by Fink et al. (2) .

The idea of the amplicon vector originated with the discovery of defective HSV-1 particles (3, 4) that appeared in and interfered with HSV-1 stocks that were passaged at high multiplicities of infection (MOIs). Examination of the

genomes of these defective HSV-1 particles revealed that they carried only a minimal subset of DNA sequences from the wild type genome (3, 4 and 5) . These sequences included an origin of DNA replication and a cleavage/packaging site (the “a” site). It was found that incorporation of these two sequences into a plasmid (the “amplicon”) gave the plasmid the ability to be replicated and packaged into virus particles when it was introduced into a cell that was superinfected with wild-type virus (which supplied HSV replication and virion assembly functions in trans). The plasmid sequences that were packaged into virus particles consisted primarily of 150-kilobase (kb) concatamers of the original plasmid (3, 4, 5 and 6) .

The chief advantage of this amplicon type of vector, which is now packaged with replication-defective helper viruses, is that cloning manipulations are relatively easy due to the small size (5 to 10 kb) of the plasmid. One disadvantage is that production of amplicon vectors requires a co-propagated HSV helper virus, resulting in viral stocks that are a mixture of helper and amplicon viruses. In the past, cytotoxic effects of these stocks limited the amount of vector that could be used to infect cells. Even though the replication-incompetent helper viruses could not cause lytic infections in normal cells, cytopathic effects resulted both from proteins present in the HSV-1 particles and from expression of HSV-1 immediate-early (IE) genes (7) . Occasionally, wild-type HSV-1 revertants appeared during the amplicon packaging process, exacerbating the cytotoxicity of the virus preparations (7, 8) . However, recent improvements in the amplicon packaging procedure, which are discussed in the following section, have largely overcome these problems. The development of a helper virus–free packaging system for the HSV vector (9) has virtually eliminated any lingering cytotoxicity in the preparations, although the helper-free system yields relatively low titers of virus and still needs improvement in that area.

Present-Day Amplicon Vectors: Advantages and Disadvantages

Genomic and plasmid defective HSV-1 vectors have been used to manipulate neuronal physiology both *in vitro* and *in vivo*. These studies have been promising, but they have also revealed limitations of the current HSV vector systems. Because HSV is too fragile to purify on cesium chloride gradients, it could not be concentrated in the same way that encapsulated viruses such as adenovirus were concentrated. Moreover, as noted above, nonspecific cytopathic effects of the defective vectors restricted the number of viral particles that could be used to infect neurons. Finally, lack of persistence of high expression levels from the viral recombinants has hampered long-term *in vivo* studies and has limited the usefulness of the vectors for both experimentation and gene therapy.

Recent improvements in the amplicon packaging procedure (Table 20.1) have corrected some of the limitations listed above. The most widely used second-generation helper virus was HSV-1 tsK, with a temperature-sensitive single-base mutation in the *ICP4* (*IE3*) gene. Because revertants of this mutant arose at a finite frequency during the packaging procedure, lytic virus was present in some preparations (7, 8) . The frequency of revertants was decreased with the development of an efficient packaging system using a deletion mutant of *IE3* (8) as helper virus. However, occasional lytic virus particles continued to appear, albeit at a greatly reduced frequency, presumably as a result of recombination between the helper virus and the sequences flanking both sides of the *IE3*-containing fragment present in the permissive host.

A key breakthrough was made by Lim et al. (10) when they compared three replication-defective HSV-1 mutants [KOS strain 5dl1.2, deleted in the *ICP27* (*IE2*) gene; and strain 17 D30EBA and KOS strain dl120, both deleted in the *ICP4* (*IE3*) gene] for their usefulness as helper virus for packaging an amplicon vector. Historically, *IE3* mutants have been preferred because they express fewer HSV-1 genes under nonpermissive conditions than do ICP27 mutants. However, Lim et al. found that use of the *IE2* mutant 5dl1.2 yielded higher vector titers than did use of the *IE3* mutants, with no increase in cytotoxicity. In addition, wild-type lytic virus was virtually absent in stocks made using 5dl1.2 in conjunction with the permissive host 2-2 cells, likely due to the fact that 5dl1.2 is a more complete deletion than D30EBA, sharing little sequence with the *IE2*-containing fragment present in the permissive host.

To achieve a favorable ratio of recombinant vector to helper virus, the stocks derived from transfection of the packaging cells followed by superinfection with helper virus are passaged three times on the permissive host. The recombinant vector is packaged as long concatamers, which contain multiple origins of replication, conferring a selective replicative advantage on the vector-containing virus relative

to the helper virus. Therefore, the efficiency of the initial transfection of vector DNA into the packaging line is critical to the success of the packaging. Lim et al. (10) showed that the transfection of the vector DNA at the start of the packaging procedure was significantly more efficient using Lipofectamine (Life Technologies) than using calcium phosphate, and thereby achieved a favorable ratio (≥1) of vector to helper. Since then, we have achieved vector/helper ratios greater than 100.

For a viral vector to have utility for gene therapy, cytopathic effects of the virus must not outweigh the beneficial effects of the transgene. Unfortunately, in the past, investigators have had difficulty generating nontoxic HSV-based replication-defective vectors. They often were toxic to neurons *in vitro* (7) . Significant necrosis, often accompanied by inflammation and gliosis, was identified at injection sites with some genetically engineered HSV-1 vectors used for *in vivo* studies (see, e.g., ref. 11) . However, the achievement of a more favorable ratio of vector to helper, and the virtual elimination of wild-type virus in the vector preparations (10) has greatly reduced the cytotoxicity of present-day defective HSV-1 amplicon vectors (see, e.g., refs. 12, 13 and 14) . An additional improvement to the packaging procedure, the banding of the virus on a sucrose step gradient, followed by a high-speed centrifugation to pellet the virus, has reduced further the cytotoxicity of the virus preparations. It simultaneously removes toxic factors present in the crude cell lysates, and enables concentration of the vector to titers exceeding 10^8/mL.

A troubling problem that has not yet been resolved for any viral vector used in the brain, except perhaps for the lentiviral vector (see below), is that of persistence of expression. Numerous investigators have had the experiences reported by During et al. (15) and Lim et al. (10), in which an initial peak in expression of an HSV transgene *in vivo* or *in vitro*, respectively, has been followed by loss of the bulk of the expression by 1 to 2 weeks postinfection. Interestingly, superinfection with helper virus 5dl1.2 1 week postinfection rescued expression of a transgene expressed under the control of the IE 4/5 promoter (10) . Apparently, transactivating factors provided by the helper virus reactivated transcription of the transgene.

Two recent developments suggest that the problem of persistence of expression is not insoluble. Use of a 9-kb fragment of the tyrosine hydroxylase promoter to drive reporter gene expression in an HSV-1 amplicon vector resulted in prolonged gene expression *in vivo* (16), suggesting that neuronal, unlike viral, promoters in HSV-1 vectors have the potential to produce stable gene expression. Additionally, the development of hybrid amplicons that incorporate elements that allow autonomous replication of the episome (17) or that incorporate adeno-associated virus (AAV) elements for genomic integration of the amplicon (18, 19 and 20) have resulted in vectors that support long-term gene expression both *in vitro* and *in vivo*.

An improvement in gene transfer methods in general has been the incorporation of the gene for the green fluorescent protein (GFP) into many vectors. Coexpression of GFP allows the investigator to detect cells infected by the vector with a fluorescence microscope, whether they are fixed or alive. There are at least three ways to “mark” vector-infected cells with GFP (Fig. 20.1) . In the example shown, the objective is to coexpress GFP with the AMPA receptor GluR1. They can be expressed on a single transcript (HSV-IRES/GFP) by putting an internal ribosome entry site (IRES) between the two genes, which are then transcribed from the same promoter. The IRES enables independent translation of the two coding sequences even though they are present on the same messenger RNA (mRNA). In theory, the two coding sequences should be expressed at similar levels, but in practice the translation of one of the two coding sequences on the mRNA often occurs at the expense of the other. Alternatively, they can be expressed from two independent transcriptional units, in a bicistronic vector. The addition of an extra transcriptional cassette to the vector makes it larger and more unwieldy to use; and the level of transcription from one promoter is independent of the level of transcription from the other, so that the transgenes may be expressed at very different levels. Third, the GFP can be fused to the transgene product, so that they are expressed

as a single protein. This is a trickier construction, since the two coding sequences must be placed in frame with each other. However, the added benefit of being able to track the subcellular location of the transgene product makes this the option of choice in many instances.

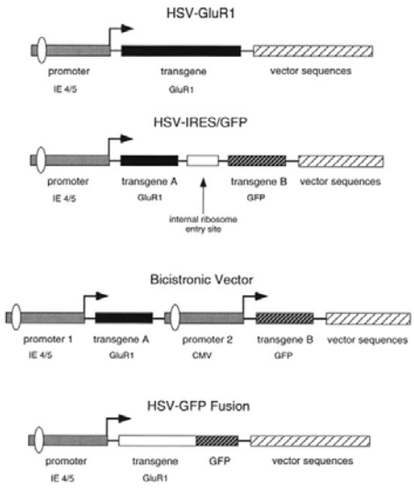

FIGURE 20.1. Different vector constructions for coexpressing two genes from a viral vector. Glutamate receptor GluR1 and green fluorescent protein (GFP) are used as examples.

COMPARISON OF HSV-1 WITH ALTERNATIVE VECTORS FOR GENE TRANSFER INTO NEURONS

Part of "20 - Gene Delivery into the Brain Using Viral Vectors "

Despite the problems that remain with the HSV-1 vector, it is a gene delivery system that has come of age. In addition, numerous alternative and increasingly user-friendly means of gene transfer into the brain are now available (Table 20.2) . Adenovirus vectors, like HSV-1 vectors, infect postmitotic cells and can enter a broad range of mammalian cell types. They have the additional advantages that they can be concentrated to very high titers (≥10^{10}/mL). However, the use of adenovirus vectors continues to be restricted by the robust host immune response that they elicit (21, 22) .

TABLE 20.1. CHRONOLOGY OF IMPROVEMENTS IN AMPLICON VECTOR PACKAGING SYSTEM

1985—Use of wild-type HSV-1 as helper virus and first amplicon plasmid (5)
1988—Use of HSV-1 *tsK* IE3 mutant as helper virus (64)
1990—Use of D30EBA IE3 deletion mutant and M64A complementing cell line (8)
1996—Use of 5*dl*1.2 IE2 deletion mutant and 2-2 complementing cell line (10)
1996—Improvements in transfection procedure and development of methods to purify and concentrate the virus result in amplicon/helper ratios of up to 100:1 (previously 1:100) and titers of up to 2×10^8 infectious units/mL
1997—Helper-free packaging by transient transfection of HSV cosmids (19)

HSV, herpes simplex virus.

TABLE 20.2. COMPARISON OF VIRUSES USED TO MANIPULATE GENE EXPRESSION IN THE BRAIN

Advantages	Disadvantages
Herpesvirus vectors	
Broad host and cell type range	Occasional cytotoxicity
Episomal (no possibility of insertional activation of host genes)	Lack of persistence of expression
Can accommodate up to 15 kb of foreign DNA	
High level of expression of foreign genes within hours	
Can be concentrated to high titers	
Helper virus–free stocks possible	
Adenovirus vectors	
Broad mammalian host and cell type range	Elicits host immune response
Episomal (no possibility of insertional activation of host genes)	
Growth to high titers (~10^{10}/mL)	Accommodates <10 kb of foreign DNA
High level of expression of foreign genes	
Expression is relatively persistent	Genetic manipulation is unwieldy
Adeno-associated vectors	
Broad mammalian host and cell type range	Can accommodate only 4.7 kb of foreign DNA
Nonpathogenic	
Helper virus–free stocks possible	
Expression is relatively persistent	
Lentivirus vectors	
Integrates into host chromosome	Can accommodate only 6–8 kb of foreign DNA
Expression is persistent	Low titers
	Potent human pathogen

kb, kilobase.

At present, HSV amplicon vectors can accommodate larger pieces of foreign DNA, on the order of 15 kb, than can the adenovirus vectors, which can only contain a maximum of 6 to 8 kb (although the new "gutless" adenovirus vectors can take up to 37 kb of foreign DNA). Foreign genes are cloned into easy-to-manipulate amplicon vectors that can be packaged directly into viral particles as head-to-tail repeats in the presence of the helper virus, with no intermediate recombination step required. This enables rapid construction of a large number of recombinant vectors simultaneously, and is particularly useful for those who are doing mutation analysis, and who wish to work with multiple genes. Such ease of cloning is not possible with the genomic HSV and adenovirus vectors.

Direct *in vivo* transfer of genes into the brain has been achieved using not only herpes virus and adenovirus vectors, but also adeno-associated virus vectors (see refs. 23, 24 for review) and lentivirus vectors (see ref. 25 for review). In contrast to other viral vectors, adeno-associated virus vectors do not cause an immune response or toxicity. Interestingly, the ability of adeno-associated virus vectors to transduce and express transgenes is not equivalent in all regions of the brain (26, 27) . Only in some regions will neurons bind and internalize the virus, with resultant long-term expression. Stability of expression of lentivirus vectors in the brain is their greatest advantage. Long-term expression of B-galactosidase and GFP was observed in rat neurons for at least 9 months following intracerebral injection of the vectors, with no sign of tissue pathology or immune response (28, 29) . Progress has been made in achieving biosafety with these vectors, by eliminating viral sequences nonessential for transduction.

GENE DELIVERY INTO THE BRAIN AS A TOOL FOR NEUROPSYCHIATRIC RESEARCH: DRUG ADDICTION

Part of "20 - Gene Delivery into the Brain Using Viral Vectors "

Overview

The bulk of the published work on gene transfer technologies has focused on their use for gene therapy (see ref. 30 for an excellent review). To date, the delivery of recombinant genes into the brain as a strategy for answering questions about the molecular mechanisms of brain function has utilized primarily HSV vectors. One of the most successful uses of this strategy has been in the field of addiction research. Exposure to drugs of abuse causes many changes in gene expression within the brain. A major challenge in addiction research is to determine which of these changes have a direct influence on behavior. Viral vectors offer the ability to study individual changes in gene expression in

discrete brain regions. In the case of addiction, it is thus possible to mimic certain aspects of the drug-exposed state without ever administering the drugs themselves. The ultimate goal of such studies is to understand the “biobehavioral” mechanisms of addiction, that is, to establish direct, causal relationships between drug-induced changes in biology and drug-induced changes in behavior. Examples of behavioral changes in addiction that may result from drug-induced alterations in biology (gene expression) are compulsive drug use (drug-taking) and craving (drug-seeking).

Biobehavioral Studies of Addiction

Addiction Circuitry

Much research on the neuronal circuitry involved in drug addiction has focused on the mesolimbic dopamine (DA) system. The dopaminergic projection from the ventral tegmental area (VTA) of the midbrain to the nucleus accumbens (NAc) of the forebrain has been implicated in the habit-forming (rewarding) effects of many types of abused drugs, including stimulants (cocaine, amphetamine) and opiates (heroin, morphine) (31, 32) . However, the neural events that mediate the acute rewarding effects of abused drugs are not understood, nor are the neuroadaptations that presumably underlie the transition from occasional drug use to compulsive drug use. In rats, repeated exposure to drugs of abuse appears to cause increases in sensitivity (“sensitization”) to the rewarding effects of drugs (33, 34 and 35), a phenomenon that may contribute to the addiction process (36) . This altered sensitivity is presumably a consequence of altered gene expression, and the VTA-NAc circuitry is a logical starting point for biobehavioral studies. Because several robust and reliable drug-induced neuroadaptations have been discovered within this circuitry (37), it has been the focus of gene transfer studies in which the behavioral significance of altered gene expression has been assessed. To date, the biobehavioral significance of three specific, drug-induced changes in gene expression have been studied using viral-mediated gene transfer—the ability of drugs (cocaine, morphine) (a) to increase expression of the AMPA (glutamate) receptor subunit GluR1 in VTA, (b) to alter expression of GluRs in the NAc, and (c) to increase the activity of the transcription factor CREB (cAMP response element binding protein) in the NAc.

GluRs in the VTA

AMPA receptors are made up of various combinations of the subunits GluR1, GluR2, GluR3, and GluR4 (collectively called GluRs) (38, 39) . Repeated intermittent exposure to morphine selectively elevates expression of GluR1 in the VTA (40) . Relative levels of GluR1 and GluR2 expression in the dopamine neuron-rich VTA are important because the subunit composition of AMPA receptors controls their function. High expression of GluR1 favors the formation of Ca^{2+}-permeable (GluR1-homomeric) AMPA receptors (13, 38, 39), which presumably increases sensitivity to the excitatory (depolarizing) effects of glutamate (12) . Conversely, high expression of GluR2 favors the formation of Ca^{2+}-impermeable (heteromeric) AMPA receptors, since this subunit contains a motif that blocks Ca^{2+} conductance (38) . Because repeated drug exposure is known to selectively increase the electrophysiologic responsiveness of VTA dopamine neurons to AMPA receptor agonists (41), it is possible that drug-induced alterations in GluR1 expression in this region contribute to drug-induced behavioral changes, such as sensitization. However, this question is difficult to address using traditional methods. For example, AMPA agonists and antagonists cannot be used to study the relationship between GluR1 expression and sensitized drug responses because they affect AMPA receptor function generally and thus do not mimic morphine's selective effects. This biochemistry-behavior relationship could be studied by performing intra-VTA microinjections of HSV-GluR1, which caused ˜75% increases in GluR1 expression within this region (13) .

It was first necessary to determine if viral-mediated elevations in GluR1 expression within the VTA would increase sensitivity to the locomotor-stimulating effects of morphine, a hallmark of behavioral sensitization (36, 42) . Low doses of morphine induced significantly more activity in rats with viral-mediated elevations in GluR1 expression within the VTA. Furthermore, increased activity in rats given HSV-GluR1 was seen only in response to morphine, and was not evident after saline. The transient nature of the HSV-mediated elevations in transgene expression allowed the behavioral adaptations to be correlated with the time course of GluR1 expression: when morphine was given only on days 7 and 8 after microinjection—when elevations in GluR1 expression had dissipated—the rats that were given HSV-GluR1 were no longer more sensitive to the stimulant effects of morphine. When some rats given HSV-GluR1 were tested with morphine on days 3 to 4 and on days 7 to 8, significant increases in sensitivity to the locomotor-stimulating effects of the persisted in rats given HSV-GluR1, despite the fact that GluR1 labeling in the VTA had dissipated. Thus when morphine is given while GluR1 expression in the VTA is elevated, increased sensitivity to morphine outlasts viral-induced increases in GluR1 expression. These data suggest that altered expression of GluR1 in the VTA underlies, at least in part, the development and expression of sensitized behavioral responses to morphine.

The effect of elevated GluR1 expression in the VTA on the rewarding effects of morphine was examined using place conditioning, a classic conditioning procedure in which rats learn to associate the rewarding effects of a drug with a distinctive environment. Rats given HSV-GluR1 into the rostral (anterior) portion VTA spent more time in morphine-associated environments than did control rats, indicating

an increase in morphine reward (13, 43) . Since prior treatment with morphine intensifies its rewarding actions in the place-conditioning paradigm (33), these data suggest that the behavioral consequences of morphine preexposure are mimicked by HSV-mediated expression of GluR1 in the VTA.

Together, these data demonstrate that specific changes in motivational states can result from altered expression of a single, localized gene product. Drug-related increases in GluR1 expression in the VTA, a region known to be involved in the induction of sensitization (42, 44), may themselves be sufficient to explain sensitization (13, 41), or they may lead to Ca^{2+}-dependent adaptations (45) that also contribute to changes in drug sensitivity (Fig. 20.2) . Thus these studies have added strength to the hypothesized association between the VTA and sensitization, and identified biobehavioral relevance for the drug-induced regulation of the GluR1 protein in the VTA.

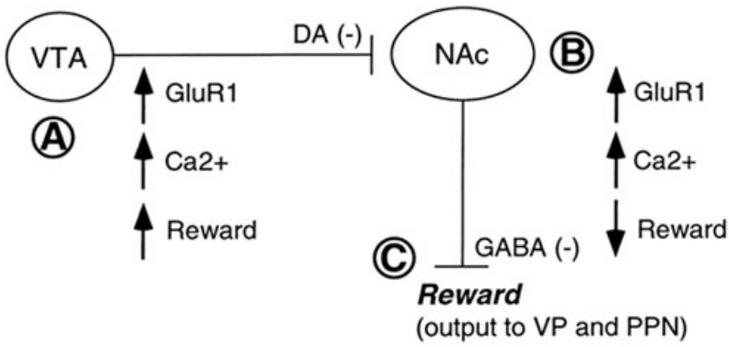

FIGURE 20.2. Simplified schematic of putative reward circuitry; see ref. 39 for detailed discussion. Treatments that increase excitation in the ventral tegmental area (VTA) (**A**) are rewarding, presumably because they promote the inhibitory actions of dopamine (a D2-like receptors) in the nucleus accumbens (NAc) (**B**). Inhibition of NAc GABAergic output neurons, in turn, decrease inhibitory influences on reward processes in other areas of brain reward circuitry (**C**), including the ventral pallidum (VP) and peduncular pontine nucleus (PPN) (63). Elevations in GluR1 expression in the VTA (**A**) increase drug reward, presumably because the accompanying changes in Ca^{2+} flux increase the excitability and/or neuronal function of VTA dopaminergic neurons (as in ref. 49). Conversely, elevations in GluR1 in the NAc decrease drug reward (**B**), presumably because the accompanying changes in Ca^{2+} flux increase the excitability of NAc GABAergic neurons that normally inhibit reward processes in distal regions (C). (Based on refs. 13, 43, and 55.)

GluRs in the NAc

There are two important reasons for interest in how altered expression of GluRs in the NAc affects the actions of drugs of abuse. First, GluR2 is a target gene of ΔFosB, a stable and long-lasting variant of the fos family of transcription factors that is regulated in the Nac by drugs of abuse (46) . Second, GluR1 expression is elevated the NAc in cocaine-sensitized rats during long-term drug withdrawal (47) .

Exposure to cocaine and other drugs of abuse causes the rapid and transient expression of the immediate-early gene c-*fos* in the striatum (including the NAc) (48, 49) . Repeated drug exposure decreases expression of the transient forms of c-*fos*, but increases expression of a more stable and long-lasting form of the transcription factor, ΔFosB (50, 51) . The accumulation and sustained transcriptional activity of ΔFosB in the NAc could mediate long-lasting neural and behavioral adaptations that accompany repeated drug exposure (37) . Consistent with this notion, inducible transgenic mice that express ΔFosB spontaneously (i.e., without prior drug treatment) in the NAc during adulthood have increased sensitivity to the locomotor-stimulating and rewarding effects of cocaine (46) . The proximal cause of the increase in drug sensitivity is presumably not increased expression of ΔFosB per se, but rather increased expression of a target gene (or genes) whose transcription is regulated by this factor. The ΔFosB-overexpressing mice also had large increases in GluR2 expression in the NAc, implicating this AMPA receptor subunit in the increased drug sensitivity. To examine whether elevated GluR2 expression in the NAc was sufficient to cause increases in sensitivity to the rewarding effects of cocaine, rats were tested in the place-conditioning paradigm after microinjections of HSV-GluR2 into this region (46) . This treatment dramatically increased sensitivity to the rewarding effects of cocaine, mimicking the effects of increased expression of ΔFosB. Together, these findings provide strong evidence that the increase in cocaine sensitivity seen in ΔFosB transgenic mice is attributable, at least in part, to elevated expression of GluR2 in the NAc.

For comparison, rats were given microinjections of vectors expressing other GluRs into the NAc, and tested with cocaine in the place-conditioning paradigm. Rats given microinjections of HSV-GluR1 into the NAc spent dramatically less time than control rats in the cocaine-associated environments, suggesting that elevated expression of this AMPA receptor subunit in this region increases sensitivity to the aversive effects of the drug. Additionally, some rats were tested after intra-NAc microinjections of HSV-GluR2Q, which expresses unedited GluR2. This form of GluR2 lacks the final transcriptional edit (Q → R) that produces the motif that blocks Ca^{2+} flux (38, 39) . Use of this construct showed that the ability of GluR2 to increase cocaine reward appears to be directly related to diminished Ca^{2+} permeability, because overexpression of GluR2Q does not increase cocaine reward, but rather causes effects that more closely resemble those of increased GluR1 expression (as would be expected).

There are many possible explanations for how altered Ca^{2+} flux in the NAc might influence drug reward, considering the role of Ca^{2+} in cellular functions including membrane depolarization, neurotransmitter release, signal transduction, and plasticity (52, 53) . Certainly, cocaine-induced changes in the excitability of NAc neurons have been reported:

repeated exposure to cocaine makes neurons in this region significantly less excitable than normal at short (3-day) withdrawal periods (54) . Studies with ΔFosB (46) suggest that these electrophysiologic adaptations are associated with increases in the rewarding efficacy of cocaine, because elevations in GluR2 expression (which would be expected to minimize Ca^{2+} flux and/or neuronal excitability) increase cocaine reward, whereas elevations in GluR1 (which would be expected to increase Ca^{2+} flux and/or neuronal excitability) decrease (or oppose) cocaine reward.

Together, these data support the working hypothesis (55) that altered Ca^{2+} flux and/or neuronal excitability in the NAc has important consequences on motivated behaviors (Fig. 20.2) . Moreover, they suggest that altered GluR1 expression in this region seen during long-term (3-week) cocaine withdrawal (47) might also be associated with important changes in the rewarding efficacy of the drug. Regardless, the use of HSV vectors has identified biobehavioral relevance for the drug-induced regulation of GluRs in the Nac.

CREB in the NAc

Chronic cocaine exposure increases 3′,5′-cyclic adenosine monophosphate (cAMP) formation and protein kinase A (PKA) activity in the NAc (37) . Direct stimulation of PKA in the NAc counteracts the rewarding properties of cocaine (56), suggesting that drug-induced up-regulation of the cAMP system is a neural mechanism of drug tolerance. Increased PKA activity leads to increased CREB phosphorylation, which activates CREB-mediated gene transcription and could be an important step in producing long-lasting neuroadaptations. To determine the functional role of CREB and its transcriptional consequences in the NAc, its expression in this region was increased directly by microinjecting HSV-CREB (57) . In other rats, a dominant negative mutant CREB (mCREB) was overexpressed, which is transcriptionally inactive and competes with endogenous CREB for cAMP response element binding sites (CREs) (58) .

The effects of elevated CREB expression in the NAc on cocaine reward was studied with place conditioning. Although the effects of a low (threshold) dose of cocaine were not altered by control treatments, this dose established dramatic conditioned place preferences in rats given bilateral microinjections of HSV-mCREB (which acts as a CREB antagonist) into this region. This rewarding effect was “inversed” to aversion in rats with elevated expression of CREB in the NAc; rats given HSV-CREB avoided drug-associated environments, suggesting that this dose of cocaine was made aversive by gene transfer. When cocaine was administered a week (rather than 3 days) after microinjections of the HSV vectors into the NAc, cocaine was devoid of rewarding or aversive effects. This finding confirms that the behavioral consequences of HSV viral vectors are transient and reversible, and have a time course of efficacy that parallels that of transgene expression.

Dose-response analyses revealed that microinjections of HSV-mCREB and HSV-CREB in the NAc were producing, respectively, approximately parallel leftward (more rewarding) and rightward (less rewarding) shifts in the effects of cocaine. At a high dose of cocaine, there were no differences in the preferences for the drug-associated environment between rats given HSV-mCREB and those given vehicle, consistent with observations that there is an upper limit to the magnitude of place preferences that can be established (59) . Treatment with high doses of cocaine established place preferences in some rats given HSV-CREB, suggesting that the aversive consequences of increased levels of CREB in the NAc can be counteracted by more drug.

One explanation for these findings is that elevated CREB expression in the NAc increases local dynorphin function. Dynorphin is the endogenous ligand for κ opioid receptors (60), and κ opioid agonists have aversive actions in the nucleus accumbens shell (NASh) (61) . To determine if dynorphin is involved in the cocaine aversion caused by HSV-CREB, brain receptors for dynorphin were blocked with the long-lasting κ receptor antagonist norBNI. Treatment with norBNI [intracerebroventricular (ICV)] before cocaine place conditioning blocked the aversive effects associated with cocaine in animals given HSV-CREB into the NAc, but not in rats given microinjections of vehicle or HSV-mCREB. The fact that only the aversive properties of cocaine are altered significantly by *nor*-Binaltorphimine (norBNI) suggests that microinjections of HSV-CREB into the NAc enhance the aversive aspects of cocaine via increased stimulation of κ opioid receptors by dynorphin.

These results suggest that drug-induced increases in CREB activity (62) is a homeostatic change that opposes drug reward. Mimicking increases in CREB activity by increasing levels with HSV-CREB or by stimulating PKA-induced phosphorylation (56) decreases the rewarding effects of cocaine. Moreover, these data implicate κ opioid receptors in the valence (reward versus aversion) of cocaine action, and suggest that CREB-mediated transcription in the NAc is a “drug reward rheostat” (Fig. 20.3), in part via effects on dynorphin expression. These data also suggest a sequence of D1 receptor–mediated intracellular events, culminating with altered gene transcription, through which exposure to cocaine influences subsequent responsiveness to the drug. Augmented release of dynorphin could inhibit local DA release through actions at κ opioid receptors on terminals of mesolimbic DA neurons that innervate the NAc (61) . Diminished release of dopamine in the NAc may itself be aversive, or it may unmask other actions of cocaine that are aversive or that oppose drug reward. Regardless, these viral vector studies have identified biobehavioral relevance for alterations in CREB function in the NAc.

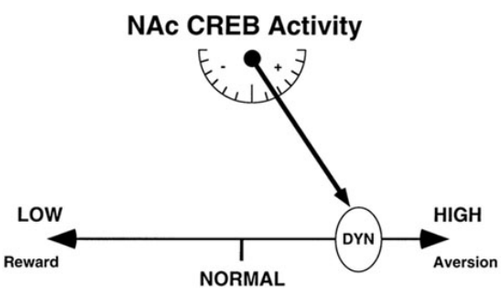

FIGURE 20.3. Schematic depiction of CREB activity in the NAc functioning as a cocaine “reward rheostat.” Elevated expression of CREB increases CREB-mediated transcription of dynorphin (a measure of CREB activity). Elevated dynorphin, in turn, decreases cocaine reward at high doses of drug, and makes cocaine aversive at low doses of drug. Conversely, disruption of CREB activity by overexpression of dominant-negative CREB (mCREB) decreases dynorphin transcription, which increases cocaine reward. (Based on ref. 57.)

Conclusions

The use of viral-mediated gene transfer in addiction research is leading to an understanding of where certain changes in gene expression occur within the cascade of molecular events that lead to the addicted phenotype. This approach complements and extends the predominantly pharmacologic approaches that previously have been used in addiction research, and in fact can be thought of as “genetic pharmacology.” Understanding the molecular basis of addiction will facilitate the development of effective pharmacologic treatments that specifically target proteins, enzymes, or transcription factors within the addiction cascade. These therapeutics may be the prototypes for a new generation of “smart” pharmacotherapies that are designed to negate or even reverse changes in the molecular structure of the brain that characterize specific brain disorders.

GENE DELIVERY INTO THE BRAIN AS A MEANS FOR GENE THERAPY

Part of "20 - Gene Delivery into the Brain Using Viral Vectors "

The recent rapid advancements in gene transfer technologies have raised hopes that central nervous system (CNS) gene therapy, the introduction of genes into the brain to ameliorate neuropsychiatric diseases, is closer to reality. However, a number of major methodologic advances must be made before it can become a reality. First, and most important, stability of transgene expression must be achieved. Second, not only stability but also inducibility and regulatibility of transgene expression are a priority, since the level of transgene product is often critical. Third, the transgene capacity of most vectors must be increased, so that not only the gene(s) of interest but also appropriate regulators or inducible promoters can be delivered to the brain. Fourth, because of the small volume of material that can be delivered stereotactically, it will be necessary to increase both the viral titers and the transduction efficiencies for all the known vectors. Fifth, a high degree of cell specificity of gene transfer must be achieved, by the use of targeted vectors that selectively infect particular cell types, cell-specific promoters, and routing via normal neuronal projections in the brain. Finally, nontoxic vectors that do not induce an immune response must be developed.

The development of gene therapy for neuropsychiatric diseases suffers, in addition, from many of the same problems that drug therapeutics research on these disease does. Neurodegenerative disorders such as Alzheimer's disease pose particular problems for gene therapy because neurons in the CNS cannot undergo regeneration. Therefore, gene therapeutic approaches must target the remaining brain cells, provide suitable replacements for the dying cells, or enable regeneration of CNS neurons. Another set of hurdles arises from the complex etiology of most neuropsychiatric disease. It is not clear that a single gene product will cure any of these diseases. In addition, the molecular mechanisms of different neuropsychiatric diseases may be restricted to subsets of neurons at specific times during development and maturity. Consequently, as noted above, optimal strategies for gene therapy must utilize vectors that persist stably in postmitotic cells and that can be targeted both spatially and temporally in the nervous system. Present-day viral vectors have come of age for use in basic research, but vectors useful for gene therapy in the brain are still a work in progress.

Neuropsychopharmacology of Worms and Flies

William R. Schafer

William R. Schafer: Division of Biology, University of California–San Diego, La Jolla, California 92093-0349.

Pharmacologic agents often biochemically interact with multiple receptor or channel proteins, and induce multiple changes in cellular physiology and signal transduction. Thus, identifying the biologically relevant targets and effectors of a given neuroactive substance can be a challenging problem. This chapter describes how genetic analysis in simple model organisms, primarily worms or flies, has been used to identify molecules that mediate drug responses in the nervous system.

Essentially all the studies described here rely on the same general strategy. The drug of interest is tested for its ability to affect worm or fly behavior. Once a behavioral response is defined for wild-type animals, it is then used as a behavioral assay to identify mutant worms/flies that exhibit abnormal drug responses and thus define genes whose products are involved in the drug's mechanism of action. Once these genes are identified and cloned, human homologues can be identified based on sequence similarity, and tested for involvement in human drug responses. This sort of approach has a number of potential advantages. For one, phenotype-driven genetic screens essentially make no prior assumptions about the types of molecules involved in the process being studied; any gene that is not essential for life and affects the behavioral response to a drug is in principle equally likely to be identified in a mutant hunt. Thus, this approach is well suited for identifying previously unknown receptors or signal transduction molecules that participate in drug responses. Furthermore, modern molecular genetics provides the ability to manipulate specific gene products in an intact animal, often in a cell-type–specific manner. By making it possible to assess a particular protein function within the context of an intact nervous system, this approach can provide a most compelling demonstration of *in vivo* function.

Among organisms with nervous systems, two are particularly amenable to genetic analysis: the nematode *Caenorhabditis elegans*, and the fruit fly *Drosophila melanogaster*. These organisms share a number of advantages that make them especially well suited for classic and molecular genetics. For example, both have short generation times (2 weeks for *Drosophila*, 3 days for *C. elegans*), can be maintained easily and in large numbers in the laboratory, and are amenable to germline transformation. In addition, detailed genetic maps of both organisms are available, and the genome sequences of both organisms are now virtually complete. Although both organisms contain relatively simple nervous systems, they differ significantly in scale and level of characterization. The *C. elegans* nervous system consists of exactly 302 neurons, whose precise position, cell lineage, and anatomic connectivity are known (1, 2 and 3) . Consequently, it is possible to identify the roles of specific neurons and muscle cells in behavior using techniques such as single-cell laser ablation, and to thereby understand in a precise manner how the action of a particular gene product in a defined set of neurons influences the whole animal's behavior (4) . *C. elegans* is particularly suitable for genetic analysis of basic intracellular processes in neurons because the worm's nervous system is nearly dispensable for growth in the laboratory. Thus, even mutants with defects in basic neuronal functions such as neurotransmitter release are often viable and fertile (5) . The *Drosophila* nervous system is somewhat more complex, and contains approximately 10^5 neurons. Consequently, it is somewhat less well characterized at the cellular level than the *C. elegans* nervous system; however, the increased behavioral complexity afforded by this bigger nervous system also makes it perhaps better suited for investigating more complex forms of behavior and learning (6) .

STUDIES OF DRUG MECHANISMS IN MODEL ORGANISMS

Part of "21 - Neuropsychopharmacology of Worms and Flies "

Genetic pharmacology has historically been a powerful approach for neurobiological studies in *C. elegans* and *Drosophila*. Many studies of drug-resistant flies or worms have made use of pesticides or antihelminthic drugs that target

the insect or nematode nervous system. For example, screens for *C. elegans* mutants resistant to the pesticide (and cholinesterase inhibitor) aldicarb have been used with notable success to identify genes involved in synaptic function; molecules first studied in this way include the vesicular acetylcholine transporter and the synaptic proteins UNC-13 and UNC-18 (7, 8) . Likewise, studies of *C. elegans* mutants resistant to the anthelminthic ivermectin have provided insight into the functions of the invertebrate-specific family of glutamate-gated chloride channels (9) . More recently, attention has turned to the possibility of using genetic pharmacology to study the mechanisms of action for psychotropic drugs, including therapeutic agents and drugs of abuse. The following sections describe some examples of drugs whose mechanism of action has been studied in worms and/or flies, and the information that these studies have provided so far.

Therapeutic Agents

Lithium

Lithium salts are widely used for the treatment of bipolar affective disorder (manic-depressive illness). Lithium remains among the most effective treatments for acute mania, and it is also an effective mood-stabilizing agent for the prevention of both manic and depressive episodes. However, lithium has a number of side effects; for example, it is a known teratogen in vertebrate embryos, and can mimic the action of insulin in inducing synthesis of glycogen (9a) . However, although lithium has been shown to affect a number of molecular and cellular processes in neurons and other cells, the mechanisms through which it exerts its therapeutic effects on mood are not well understood.

One of the most prevalent theories for lithium's mechanism of action, first proposed by Berridge et al. (10) , is the inositol depletion hypothesis. According to this model, the critical functional consequence of lithium treatment is to reduce the intracellular concentrations of inositol, a key component of the phosphoinositide signal transduction cycle that mediates the effects of many neuromodulators, including serotonin (11) . Lithium ions are uncompetitive inhibitors of both inositol monophosphatase (IMPase), the enzyme that catalyzes the conversion of inositol monophosphates (IMPs) to inositol, and inositol polyphosphatase (IPP), the enzyme that converts inositol 1,4-bisphosphate to inositol 4-monophosphate (Fig. 21.1) . Inositol is required for the generation of phosphatidyl 4,5-inositol bisphosphate (PIP_2), whose cleavage by phospholipase C yields the calcium mobilizing agent inositol 1,4,5-trisphosphate (IP_3) and the protein kinase C activator diacylglycerol (DAG). Since both of these phosphoinositide-derived second messengers are critical signal transduction molecules that mediate the effects of diverse neurotransmitters and neuromodulators, a severe depletion of intracellular inositol would be expected to dramatically alter neuronal function. Thus, it has been proposed that lithium exerts its psychoactive effects by depleting intracellular inositol pools and thereby attenuating phosphoinositide signaling in neurons and other cells. However, experiments in rats suggest that while clinically effective concentrations of lithium are sufficient to inhibit IMP activity in the brain, they result in only a modest decrease in inositol levels (12) . Thus, it is not clear that inositol depletion can account for the psychotropic effects of lithium.

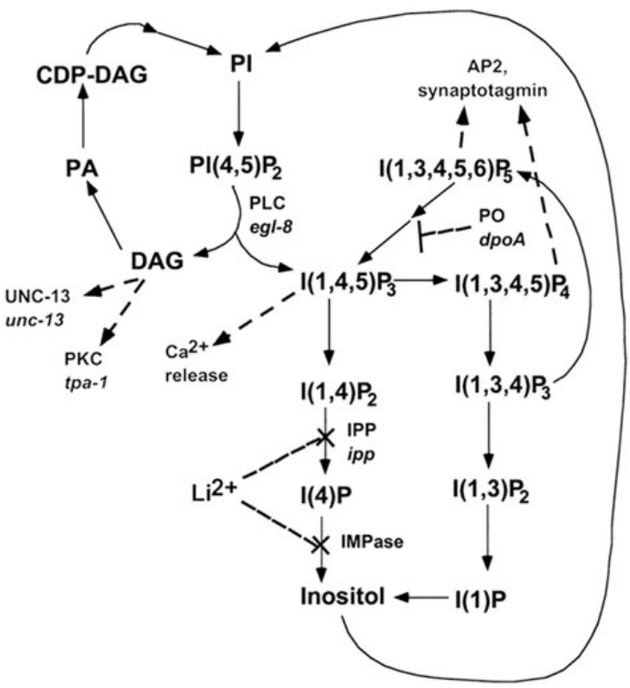

FIGURE 21.1. The phosphoinositide signaling pathway.

Recent genetic studies using simple eukaryotes has provided two plausible alternative hypotheses for lithium's mechanism of action. Interestingly, many of the key genetic findings on lithium response mechanisms have come from studies of a unicellular eukaryote that lacks a nervous system altogether, the slime mold *Dictyostelium discoideum*. Despite its considerable evolutionary divergence from the metazoa, many of the signal transduction mechanisms in *Dictyostelium* show remarkable conservation with those in human neurons. *Dictyostelium* usually exists as a free-living amoeba; however, during times of nutrient deprivation, these amoebae aggregate into a multicellular mass, or slug, which then develops into a fruiting body consisting of differentiated stalk and spore cells. Lithium has two effects on *Dictyostelium* development (13) . At high concentrations, lithium blocks the aggregation of amoebae. In contrast, low concentrations of lithium permit aggregation, but block spore cell differentiation, causing cells that normally would form the spore head to instead form stalk cells. This latter effect of

lithium on spore differentiation is mimicked by a mutation in the gene *gskA* (14) , which encodes a homologue of the signaling molecule glucogen synthase kinase 3 (GSK-3). GSK-3 molecules are conserved signaling molecules originally identified as negative regulators of glycogen synthesis, and subsequently implicated in the regulation of gene expression and cell movement. Since lithium's effects on both *Dictyostelium* development and glycogen synthesis were identical to those caused by inhibition of GSK-3, Klein and Melton (15) investigated whether lithium might affect GSK-3 signaling. They subsequently demonstrated that vertebrate GSK-3 is directly inhibited by lithium in *Xenopus* oocytes, and that GSK-3, but not IMPase, is responsible for the teratogenic effects of lithium on the embryo. Thus, at least some of the side effects of lithium, such as its teratogenic and insulin-mimetic effects, are almost certainly phosphoinositide-independent and instead mediated through the GSK-3 pathway. Because GSK-3 molecules are abundant in the brain, it is also possible that this pathway might also mediate some of lithium's therapeutic effects on mood.

However, other studies in both *Dictyostelium* and *Drosophila* support a link between the phosphoinositide pathway and the mood-altering effects of lithium. One such study concerned the mechanism of lithium's aggregation-inhibiting action in *Dictyostelium*, an effect that is independent of the *gskA* gene. A number of genes required for this high-concentration response to lithium were identified in genetic screens. One of these genes, *dpoA*, was shown to encode a proline oligopeptidase (PO), an enzyme involved in the degradation of bioactive peptides (16) . Interestingly, *dpoA* appeared to act via the phosphoinositide signaling pathway, since both mutations in *dpoA* and treatment with PO inhibitors elevated the levels of intracellular IP_3, but had no effect on GSK-3 activity. The elevation of IP_3 in *dpoA* mutants was a consequence of increased dephosphorylation of IP_5 (inositol 1, 3, 4, 5, 6-pentaphosphate), an alternate source of IP_3 utilized by both *Dictyostelium* and animal cells. Thus, inhibition of PO compensated for the decrease in PIP_2 levels induced by lithium by activating an alternative pathway for the production of IP_3 (and by extension inositol). Interestingly, abnormalities in PO activity have been observed in patients with both bipolar and unipolar depression (17, 18) . Thus, these results in *Dictyostelium* raise the possibility that PO may be linked to depression and mania through its effect on inositol signaling, and that lithium's efficacy in the treatment of depression may result from its ability to exert compensatory effects elsewhere in the inositol pathway.

However, the mechanism by which lithium-induced changes in the inositol pathway affect neuronal function may not involve inositiol depletion per se. This conclusion rests in part on a study of mutant flies defective in the enzyme IPP, a lithium-sensitive enzyme in the inositol pathway involved in the conversion of IP_3 to inositol (19) . ipp mutants were shown to be completely defective in the IPP activity, since they were unable to degrade I(1, 4) P_2, the IPP substrate. However, contrary to the prediction of the inositol depletion model, the phosphoinositol signaling pathway (which is necessary for *Drosophila* phototransduction) remained fully functional in photoreceptor neurons of the ipp mutant. Similar effects were seen when photoreceptor neurons were treated with lithium; IPP activity was inhibited, yet the inositol-dependent phototransduction cascade was still functional. Thus, neither genetic nor pharmacologic inhibition of IPP resulted in a depletion of inositol pools sufficient to interfere with the phosphoinositide signaling cascade. The ability to maintain high levels of inositol in the absence of IPP was apparently due to an alternate pathway involving synthesis and dephosphorylation of inositol 1,3,4,5-tetrakisphosphate (Fig. 21.1) . However, although ipp mutations and lithium treatment did not affect phosphoinositide signal transduction, they had unexpected and dramatic effects on synaptic function. Specifically, in ipp mutant and lithium-treated wild-type photoreceptor neurons, the probability of vesicular release was greatly increased, and affected neurons were unable to maintain a synaptic response to a prolonged tetanic stimulus. A variety of molecules involved in synaptic fusion and vesicular traffic, including synaptotagmin and adaptor protein 2 (AP2), are regulated through specific physical interactions with inositol polyphosphates (e.g., IP_4, IP_5, and IP_6) (20) . Thus, the effects of lithium on neuronal function in *Drosophila* as well as in humans may stem not from defects in inositol signaling per se, but from defects in synaptic function and plasticity due to alterations in inositol polyphosphate pools.

In summary, lithium provides a good example of the power of genetic neuropsychopharmacology in simple model systems. Studies in *Dictyostelium* were instrumental in identifying the GSK-3 pathway as a possible mediator of lithium's deleterious side effects, and have also provided insight into a possible link between neuroactive peptides and depression. Work in *Drosophila* has provided an important lead into discovering how lithium's effects on phosphoinositide signaling affect neuronal function. Future studies in both organisms have the potential to provide further insight into lithium's mechanism of action, in particular to address more precisely how lithium-induced changes in inositol lipid content alter synaptic transmission and plasticity in neurons.

Fluoxetine and Other Antidepressants

Another group of drugs that have been the subject of research in simple eukaryotes are those used in the treatment of unipolar depression. Such drugs include the monoamine oxidase (MAO) inhibitors, the tricyclic antidepressants (e.g., imipramine and clomipramine), and the selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine). A common property of many of these molecules is their ability

to potentiate serotoninergic neurotransmission, either by interfering with reuptake of serotonin from the synapse (tricyclics and SSRIs) or by blocking enzymatic degradation of serotonin (MAO inhibitors). Thus, the therapeutic actions of all of these molecules are usually explained in terms of a model for depression known as the serotonin hypothesis. According to this model in its simplest form, levels of serotoninergic neurotransmission in the forebrain are a key determinant of mood, with high activity leading to euphoria and low activity to dysphoria. Thus the chronic dysphoria experienced by depressed patients could be a consequence of chronically low serotoninergic transmission, which could be compensated for by interfering with serotonin degradation. This serotonin hypothesis, or variations thereof, represents the most widely accepted explanation for antidepressant action (21, 22) .

However, the serotonin hypothesis, at least in its simplest form, fails to account for a number of observations about antidepressants. For one, a direct correlation between the level of serotoninergic transmission and mood has not been demonstrated; normal individuals treated with serotonin reuptake blockers do not typically experience euphoria, nor does dietary serotonin depletion induce depression in individuals not already prone to depression (23) . Moreover, the mood-altering effects of serotonin reuptake blockers in depressed patients occur on a different time scale from their effects on serotoninergic transmission; whereas SSRIs and most tricyclics elevate synaptic serotonin levels within hours, their effects on mood are not apparent for 2 to 6 weeks. Finally, a number of effective antidepressants appear to function independently from serotonin, including selective norepinephrine reuptake inhibitors (SNRIs) such as desipramine, MK869, which antagonizes substance P receptors, and bupropion, whose target is unknown (24, 25) . Because of these observations, many current models hypothesize that SSRIs are effective against depression not because of their acute effects on serotoninergic transmission, but because of long-term adaptive changes in monoamine neurotransmission that arise from chronic inhibition of serotonin reuptake (21) . An appealing feature of this type of model is that long-term activation of different direct targets by different classes of antidepressants (the serotonin transporter by SSRIs, other targets by atypical antidepressants) could in principle lead to a common set of adaptive responses in the brain. Alternatively, it is possible that antidepressants might act, at least in part, at serotonin-independent direct targets.

Studies in *C. elegans* have provided insight into potential serotonin-dependent and -independent activities of antidepressants. Nearly all antidepressants have at least two clear effects on *C. elegans* behavior: stimulation of egg laying and hypercontraction of muscles in the nose. Whereas the stimulation of egg laying by antidepressants is primarily due to potentiation of serotoninergic transmission (see below), the effect of antidepressants on the nose muscles appears to be independent of serotonin, since serotonin itself does not cause nose contraction, whereas antidepressants still contract the noses of serotonin-deficient mutants. Mutations conferring resistance to the induction of nose contraction by fluoxetine have been identified in seven genes, designated *Nrf* genes, for *n*ose *r*esistant to *f*luoxetine (26) . All the *Nrf* mutations are recessive and confer resistance to several chemically disparate antidepressants in addition to fluoxetine; thus, the products of the *Nrf* genes might potentially represent common, serotonin-independent antidepressant targets. So far, two *Nrf* genes have been cloned, *nrf-6* and *ndg-4*. These two genes define the first members of a novel gene family, and encode predicted multipass integral membrane proteins that are expressed in the nasal epidermis and the intestine. *nrf-6* and *ndg-4* have been shown to be defective in the transport of yolk proteins across the intestinal membrane, suggesting that NRF-6 and NDG-4 may be components of a complex that transports molecules across epithelial membranes. Based on this result, it is reasonable to suppose that the fluoxetine resistance of *nrf-6* and *ndg-4* mutants might reflect a defect in drug uptake rather than the absence of a functional drug target in the neuromuscular system. However, while NRF-6 and NDG-4 (and by extension their yet unidentified vertebrate homologues) may not represent antidepressant targets per se, they might represent molecules that function in transport of antidepressants across the blood–brain barrier.

Another *C. elegans* molecule that clearly represents a serotonin-independent antidepressant target is encoded by the gene *egl-2*. *egl-2* was originally defined by the dominant gain of function mutations that impaired the activity of the vulval muscles (which mediate egg laying) and enteric muscles (which mediate defecation) (27, 28) . Both of these defects in muscle activation could be relieved by treatment with the tricyclic antidepressant imipramine, though not by serotonin or fluoxetine. Thus, imipramine appeared to act through a serotonin-independent target to suppress the *egl-2* muscle activation phenotype (29) . The nature of this target was revealed when *egl-2* was cloned and shown to encode a potassium channel homologous to the *Drosophila* ether-a-go-go (eag) channel (30) . Studies on EGL-2 channels expressed in *Xenopus* oocytes demonstrated that the imipramine-suppressible dominant alleles of *egl-2* encoded mutant channels that opened inappropriately at low voltages. Remarkably, imipramine was shown to function as a specific antagonist of both the *EGL-2* channel and its mammalian homologue MEAG. Thus, this class of calcium channels appears to represent a conserved target of tricyclic antidepressants in both worms and humans. Interestingly, an important side effect of tricyclic antidepressants is a type of cardiac arrhythmia called long QT syndrome, a disorder which has also been linked to mutations in potassium channel genes (29a, 29b) . Thus, the blockade of eag-related potassium channels by tricyclics provides a likely explanation for this clinically important side effect of tricyclics.

Studies in *C. elegans* may also provide insight into the serotonin-dependent mechanisms of antidepressant action.

The ability of antidepressants (other than tricyclics) to stimulate egg laying in *C. elegans* depends on their ability to potentiate serotoninergic neurotransmission (29) , and can be mimicked by exogenous serotonin itself (31) . Serotonin is released from egg-laying motor neurons called HSNs (27) , and appears to function as a neuromodulator that modifies the functional state of the egg-laying muscles to potentiate contraction (32) . Serotonin also inhibits locomotion, apparently by inhibiting neurotransmitter release from excitatory motor neurons (32, 33) . The signal transduction mechanisms that mediate both of these actions of serotonin have been analyzed genetically, and in both cases the phospholipase C (PLC) homologue *egl-8* is required for serotonin response. In the egg-laying muscles, the effects of PLC appear to be mediated through the protein kinase C homologue tpa-1, whereas in the motor neurons the most important mediator appears to be the diacylglycerol-binding synaptic protein UNC-13. The involvement of the phosphoinositide signaling pathway in serotonin signal transduction in both the egg-laying muscles and the motor neurons of *C. elegans* has an interesting parallel in mammals, since a number of mammalian serotonin receptor subtypes also signal through activation of PLC.

The apparent conservation between the signaling pathways mediating serotonin response in *C. elegans* and humans raises the possibility that the long-term effects of elevated serotoninergic transmission might also be accessible to genetic analysis in *C. elegans*. As noted previously, the alleviation of depression by serotonin-potentiating antidepressants is thought to involve adaptive signaling pathways that are activated by prolonged elevation of serotoninergic neurotransmission. In *C. elegans*, prolonged exposure to serotonin has been shown to lead to adaptive down-regulation of egg-laying behavior and recovery from serotonin-induced paralysis (34) . Genes encoding possible components of serotonin adaptation pathways have been identified on the basis of serotonin hypersensitive or adaptation-defective phenotypes (35) ; however, at present little is known about how these or other genes affect long-term responses to serotonin. Future analysis of serotonin adaptation genes may provide insight into the molecular mechanisms underlying long-term responses to elevated serotonin transmission that may be important for the therapeutic action of antidepressants.

Volatile Anesthetics

A variety of volatile molecules, including diethyl ether, halothane, and isoflurane, are capable of inducing general anesthesia, a behavioral state involving loss of consciousness, analgesia, amnesia, and loss of motor activity. Although these agents have been widely used in surgery for over a century, their mechanism of action remains poorly understood. General anesthesia appears to result from defects in synaptic transmission rather than axonal firing; however, it is not clear whether anesthesia results from potentiation of inhibitory synapses, inhibition of excitatory synapses, or both. The potency of a given volatile anesthetic shows a very strong correlation to its lipid solubility; this observation, known as the Meyer–Overton rule, has led to the hypothesis that volatile anesthetics act by disrupting hydrophobic interactions between proteins and/or lipids in neurons. However, the biologically relevant targets for volatile anesthetics have not been conclusively identified. In principle, this problem appears ideally suited to attack by a phenotype-driven genetic approach; by identifying mutants that are resistant or hypersensitive to anesthetics and cloning and sequencing the mutant genes, it should be possible to identify anesthetic targets that are essential for anesthesia *in vivo*. In fact, such screens have been conducted in both *Drosophila* and *C. elegans*, and a variety of genes affecting sensitivity have been identified (36) . At present, none of the *Drosophila* anesthetic response genes have been cloned; thus, molecular information about their gene products is not available. However, the recent cloning of several *C. elegans* genes with quantitatively large effects on anesthetic sensitivity raises the possibility that they might define conserved molecular targets important for anesthetic action.

C. elegans has two distinct responses to volatile anesthetics. At lower concentrations (similar to the alveolar concentrations used in human anesthesia), volatile anesthetics rapidly induce abnormalities in the pattern of locomotion (37) . Although this effect is behaviorally quite dissimilar from anesthesia, it is similar to the effect of many mutations that affect synaptic transmission in *C. elegans*. In fact, treatment with volatile anesthetics confers resistance to the behavioral effects of cholinesterase inhibitors (38) , a hallmark of defective neurotransmitter release (7) . Thus, at these concentrations, volatile anesthetics appear to act presynaptically to interfere with synaptic transmission in *C. elegans*. A number of mutants with altered sensitivity to these low-concentration effects of volatile anesthetics have been identified. Potentially the most informative with respect to anesthetic mechanisms contain mutations in genes encoding components of the SNARE complex, the presynaptic machinery that mediates synaptic vesicle fusion. Recessive mutations in at least three SNARE genes, *unc-64* [encoding *C. elegans* syntaxin (39)], *snb-1* [encoding VAMP/synaptobrevin (40)], and *ric-4* (encoding SNAP-25), confer significant hypersensitivity on the effects of both halothane and isoflurane on coordinated movement. Furthermore, a novel mutation in *unc-64*, which affects a spice receptor site and consequently leads to the production of truncated syntaxin peptides, confers strong resistance to the effects of volatile anesthetics on both coordinated movement and cholinesterase sensitivity (38) . These results suggest that volatile anesthetics interfere with synaptic transmission through direct interaction with one or more members of the SNARE complex.

At approximately 10-fold higher concentrations, volatile anesthetics induce reversible paralysis in *C. elegans*, a behavioral

effect qualitatively reminiscent of anesthesia. Interestingly, none of the synaptic mutations affecting the low-concentration effects on coordinated movements affect this high-concentration paralytic response. However, a different, nonoverlapping group of genes has been identified that confers resistance or hypersensitivity to paralysis by anesthetics in *C. elegans*. Several of these genes have been cloned, including *unc-1*, which encodes a homologue of stomatin (41) , and *unc-8*, which encodes a subunit of the degenerin/ENaC family of passive sodium channels (42, 43) . Both *unc-1* and *unc-8* are expressed in neurons, and both genes can be mutated to confer either resistance or hypersensitivity to halothane (44) . Allele-specific genetic interactions between *unc-1*, *unc-8*, and the yet uncloned *unc-79* and *unc-80* genes suggest that their products may physically interact in a multimeric channel complex specifically involved in anesthetic responses. Since stomatin has been shown to function as a negative regulator of cation channels in erythrocytes, a reasonable hypothesis is that UNC-1/stomatin may modulate influx through UNC-8 degenerin channels in neurons that respond to anesthetics. Homologues of both stomatins and ENaC channels have been identified in mammals, and are known to be expressed in the central nervous system; thus, in principle stomatin-regulated ENaC channels could also affect anesthetic responses in humans.

In summary, there are two distinct sets of genes that affect responses to volatile anesthetics in *C. elegans*, which affect different behavioral responses to different concentrations of anesthetics. At present, it is not clear which of the two (or whether both) might encode homologues of biologically relevant human anesthetic targets. Although the genes involved in synaptic function alter anesthetic responses at clinically relevant concentrations, the behavioral responses they affect are qualitatively quite different from general anesthesia. Conversely, although the stomatin/degenerin genes affect a paralytic response that closely resembles anesthesia, the response also has a relatively long time delay and occurs at concentrations well above those clinically relevant in humans. Given the effective drug concentrations for these two behavioral responses, it is possible that the synaptic genes might encode targets relevant to anesthesia, while the stomatin/degenerin genes might encode targets relevant for side effects of anesthetics. Alternatively, it is possible that genes affecting high-concentration anesthetic responses do define molecules involved in anesthesia, especially since the nematode cuticle is relatively impermeant and presents a significant barrier for the entry of many drugs. Since well-defined mammalian homologues exist for both classes of anesthetic response genes, it should be possible in the future to examine these issues directly in mammalian systems.

Drugs of Abuse

Ethanol

Unlike many neuroactive substances, ethanol is not believed to have a single molecular target in neurons; rather, a number of receptors and channels, including the *N*-methyl-D-aspartate (NMDA), serotonin, and γ-aminobutyric acid (GABA) receptors and various voltage-gated ion channels, appear to be modulated by the presence of ethanol (45) . Very little information exists concerning the relative importance of each of these putative direct targets for the psychoactive effects of ethanol; however, a variety of experiments in cultured cells suggest that a critical short-term effect of ethanol is to enhance receptor-mediated synthesis of the second messenger 3′,5′-cyclic adenosine monophosphate (cAMP). Conversely, long-term ethanol exposure appears to decrease intracellular cAMP levels. Both the acute and chronic effects of ethanol have also been linked to changes in dopaminergic neurotransmission (46) . In particular, ethanol has been shown to promote release of dopamine in the mesolimbic pathways of the brain, in particular the so-called reward pathway synapses between the ventral tegmental area (VTA) and the nucleus accumbens (NAc). At present, the *in vivo* significance of these findings with respect to the psychoactive effects of ethanol in mammals remains to be determined. Moreover, although sensitivity to both the acute and chronic effects of ethanol are clearly affected by genetic factors, the nature of the genes affecting human ethanol sensitivity are not known.

Recent work in *Drosophila* has provided support for both the dopamine and cAMP hypotheses of ethanol action. Ethanol vapor has a number of effects on *Drosophila* behavior, including hyperactivity, disorientation, uncoordination, and ultimately immobilization. Using an instrument called an inebriometer (47) , lines of mutant flies have been identified that exhibit abnormal sensitivity to volatilized ethanol. Among the mutants showing significant hypersensitivity to ethanol were those containing a mutation in the learning gene amnesiac, which encodes a homologue of the mammalian pituitary adenylyl cyclase activating peptide (PACAP) (48, 49) . Consistent with the implications of this homology, the effects of amnesiac on ethanol response appeared to involve the adenylyl cyclase pathway, since the adenylyl cyclase activator foskolin blocks the ethanol sensitivity associated with amnesiac loss-of-function mutations. Moreover, several other loss-of-function mutations affecting cAMP pathway components, including the adenylyl cyclase gene rutabaga and the cAMP-dependent protein kinase gene *DCO*, also conferred ethanol sensitivity. Although one might suppose based on these results that the response to ethanol is simply a function of the level of cAMP signaling in the relevant neuronal targets (with increased ethanol response corresponding to low cAMP signaling), a variety of data are inconsistent with this simple model. For example, genetic or pharmacologic activation of the cAMP pathway does not lead to ethanol resistance. Nonetheless, these genetic data provide the first conclusive link between the activity of the cAMP pathway and the behavioral effects of ethanol in an intact organism; the precise nature of that link remains to be determined, but should be accessible to further genetic analysis.

Some of the behavioral effects of ethanol on *Drosophila* have also been shown to be dependent on dopamine (50) . Ethanol has varying effects on fly locomotion depending on the duration of exposure. During the first 7 to 10 minutes of ethanol treatment, animals become hyperactive and move at a greatly increased rate; subsequently, they become increasingly uncoordinated and eventually become completely immobile. When flies are depleted of dopamine through ingestion of a tyrosine hydroxylase inhibitor, they become significantly less susceptible to this stimulation of motor activity by ethanol. However, these dopamine-depleted flies exhibited no abnormalities in their sensitivities to ethanol-induced uncoordination or immobilization. Thus, the stimulation of motor activity by ethanol may involve ethanol-induced enhancement of dopaminergic transmission in brain areas controlling locomotion, whereas the other behavioral effects of ethanol are likely to involve other neurotransmitter systems.

The genetic analysis of ethanol response mechanisms in *Drosophila* is still in its early stages. However, it is already clear that mutants with altered responses to ethanol can be identified in straightforward genetic screens, and at least in some cases analyzed in the context of well-defined neuronal signaling cascades. Perhaps the greatest promise for future studies is the possibility that novel ethanol response genes, possibly including the direct molecular targets of ethanol, can be identified in ethanol-resistant or ethanol-hypersensitive screens.

Nicotine

Tobacco has been implicated in more deaths than any other addictive substance (51) , yet the biochemical basis for compulsive tobacco use remains poorly understood. The substance most responsible for the addictive properties of tobacco is nicotine, a potent stimulant and cholinergic agonist. Long-term exposure to nicotine is known to cause adaptive changes in the activity and number of nicotinic receptors in the brain, which are thought to be important for nicotine addiction (52) . For example, nicotinic receptors exist in multiple functional states, some of which are relatively refractory to channel opening though they retain affinity for agonists. Chronic exposure to nicotine or other agonists results in an increased fraction of receptors adopting the lower activity states, leading to an attenuation of the overall nicotine response (53) . Long-term nicotine treatment also causes a long-lasting functional inactivation of some nicotinic receptors (54) , which has a slower time course and is much longer lasting than the rapid, receptor-intrinsic desensitization induced by acute agonist exposure. Depending on the receptor and cell type, long-term nicotine treatment can also either increase or decrease the number of nicotinic receptors on the cell surface, effects that appear to be mediated at the level of protein turnover (55, 56) . The cellular pathways that promote these changes are not well understood; for example, little is known about the cellular pathways that regulate receptor turnover, or the molecular mechanisms that regulate the switching between different nicotinic acetylcholine receptor (nAChR) states.

Genetic analysis in *C. elegans* may provide insight into the mechanisms underlying long-term responses to nicotine. Both acute and chronic nicotine treatment have striking effects on the behavior of *C. elegans*, including hypercontraction of body wall muscles, stimulation of egg laying, and increased pharyngeal pumping. The effects of nicotine on the body and egg-laying muscles are mediated through a nicotinic receptor known as the levamisole receptor (57, 58) . The antihelminthic drug [and ganglionic nAChR agonist (59)] levamisole is a potent agonist of this receptor; like nicotine, levamisole causes body muscle hypercontraction and (at high doses) spastic paralysis. Although the levamisole receptor is found on nematode muscle, its pharmacologic profile generally resembles that of ganglionic nicotinic receptors of vertebrates. By screening for levamisole-resistant mutants, it has been possible to identify genes affecting the function of the levamisole receptor (60) . Mutations conferring strong resistance to levamisole have been identified in six genes. Three of these genes, *unc-38*, *unc-29*, and *lev-1*, encode nicotinic receptor subunits (61, 62) . The UNC-38 protein is most similar to the insect α-like subunits ALS and SAD (49% amino acid identity); among vertebrate receptor subunits, the closest similarity is to neuronal α subunits (61) . UNC-29 and LEV-1 are closely related proteins whose closest homologues in vertebrates are neuronal non-α subunits (approximately 55% sequence similarity). Three additional genes conferring strong levamisole resistance, *unc-50*, *unc-74*, and *unc-63*, have not been cloned, but have been shown to be required for assembly of a functional levamisole receptor as assayed *in vitro* (63) . In addition to conferring resistance to levamisole (and other nicotinic agonists), mutations in these genes cause defects in the coordination of body movement (60) . Mutations in three additional genes (*lev-8*, *lev-9*, and *lev-10*) confer weaker resistance to levamisole, do not cause defects in locomotion, and have no detectable effect on the biochemical properties of the receptor as assayed *in vitro* (60, 63) . Thus, the proteins encoded by these genes have been hypothesized to regulate the activity of the receptor indirectly.

Long treatments with nicotine and other nicotinic receptor agonists lead to adaptation (57) . Animals treated with exogenous nicotine initially hypercontract to the point of spastic paralysis; however, after several hours in the presence of nicotine, they recover their ability to move and regain much of their body length. In some *C. elegans* strains (for example, strains with weakly crippled nAChRs), long-term nicotine treatment eventually leads to almost complete inactivation of the response to nicotine. Moreover, when nicotine-adapted animals are removed from nicotine, their locomotive behavior becomes uncoordinated and resembles that of mutants with strong defects in the levamisole receptor (i.e. an *unc-29* or *unc-38* null mutant). Thus, long treatments with nicotine cause nicotine dependence in addition

to nicotine tolerance in the *C. elegans* body muscle. Long-term nicotine treatment also down-regulates levamisole receptors in the egg-laying muscles. Overnight treatment with nicotine leads to an almost complete attenuation of levamisole sensitivity with respect to egg laying, and this attenuation of levamisole response persists for up to 24 hours after removal from nicotine. This loss of levamisole responsiveness is accompanied by a corresponding decrease in the abundance of UNC-29–containing receptors in the vulval muscles, an effect that may be mediated at the level of protein turnover (64) . Interestingly, the nicotine-dependent decrease in UNC-29 receptor abundance requires the activity of TPA-1, a vulval muscle-expressed PKC isoform. Since UNC-29 and other nicotinic receptor subunits contain consensus sequences for PKC phosphorylation, this raises the possibility that direct phosphorylation of nicotinic receptors might represent a signal for increased turnover. In the future, it should be possible to test this hypothesis, as well as identify other genes required for long-term responses to nicotine in *C. elegans*.

Another set of genes, the weak levamisole-resistance genes *lev-8* and *lev-9*, appear to represent positive regulators of nicotinic receptor activity. Mutations in these genes confer partial resistance to levamisole and nicotine with respect to body muscle contraction and strong resistance with respect to egg laying (65) . However, *lev-8* and *lev-9* mutations do not affect the assembly of levamisole-binding nicotinic receptors as assayed *in vitro* (58) , and the abundance of UNC-29 receptors in the vulval muscles is not significantly reduced by mutations in these genes (65) . *lev-8* and *lev-9* may therefore encode regulatory proteins that stimulate the activity of nicotinic receptors *in vivo*, but are not subunits or essential accessory proteins. In principle, the inhibition of the *lev-8* or *lev-9* gene products might represent a plausible mechanism for functional inactivation of nicotinic receptors. Once *lev-8* and *lev-9* are cloned, it will be interesting to determine whether mammalian homologues exist for these molecules, and if so, whether they are involved in regulating the functional activity of nicotinic receptors in human neurons.

Cocaine

Cocaine is a potent psychostimulant, and among the most widespread addictive drugs of abuse. The psychoactive effects of cocaine are thought to result largely from its ability to potentiate aminergic neurotransmission in the limbic pathways of the brain. Cocaine inhibits the reuptake transporters for dopamine, serotonin, and norepinephrine, which leads to accumulation of monoamine transmitters at the synapse. The dopaminergic synapses of the nucleus accumbens are thought to be particularly important for cocaine addiction, since pharmacologic inhibition or surgical lesioning of these areas confers significant resistance to both the short-term and long-term effects of cocaine in rodents (46) . However, dopamine is probably not the only neurotransmitter involved in cocaine addiction, since mice lacking the vesicular dopamine transporter will still self-administer cocaine after repeated administration of the drug (66, 67) . Although dopaminergic transmission in the limbic reward pathways has been implicated in the reinforcing properties of a wide range of addictive substances in addition to cocaine, the molecular and cellular mechanisms that lead to addiction in these neurons are not well understood.

Recent work in *Drosophila* suggests that the mechanisms of cocaine action may be accessible to genetic analysis. When flies are exposed to volatized free-base cocaine, they exhibit dose-dependent stereotypical behaviors that are surprisingly reminiscent of cocaine's psychostimulant effects in mammals (68) . For example, at low doses treated flies become hyperactive and exhibit compulsive, continuous grooming behavior. At intermediate doses animals move more slowly and display stereotyped locomotive behaviors such as circling. Finally, at high doses animals undergo tremors, spastic paralysis, and finally death. Repeated treatment of flies with low doses of cocaine results in an increased behavioral response, a phenomenon known as sensitization; cocaine sensitization also occurs in mammals and is thought to underlie some aspects of addiction in humans. Interestingly, male flies are more sensitive to cocaine than females, a sexual dimorphism that also holds true in mammals (69) . Thus, cocaine has both short-term and long-term effects on fly behavior that are remarkably analogous to its effects on mammals.

These behavioral similarities between cocaine's action on flies and mammals raise the possibility that they might share a common functional basis as well. In fact, recent evidence indicates that cocaine's actions on fly behavior also involve effects on aminergic neurotransmission. Insects contain cocaine sensitive reuptake transporters for dopamine, serotonin, and octopamine (an invertebrate neurotransmitter chemically similar to norepinephrine); thus, cocaine at least in principle could increase synaptic levels of multiple monoamine neurotransmitters in the fly brain (70, 71 and 72) . The monoamine most convincingly implicated in cocaine's acute effects on flies is dopamine. Dopamine receptor antagonists have effects on grooming and locomotive behaviors that are the converse of the effects of cocaine, and these antagonists can also block the effects of cocaine and cocaethylene on these behaviors in decapitated *Drosophila* preparations (Fig. 21.2) (69, 73) . Moreover, when flies are depleted of endogenous dopamine using tyrosine hydroxylase inhibitors, they acquire resistance to the acute effects of cocaine treatment (50) . Paradoxically, however, transgenic animals in which dopamine and serotonin release is blocked by ectopic tetanus toxin expression are actually hypersensitive to cocaine (74) . Thus, although dopaminergic neurotransmission is clearly involved in behavioral responses to cocaine in *Drosophila*, the specific role that it plays in these responses is not completely clear.

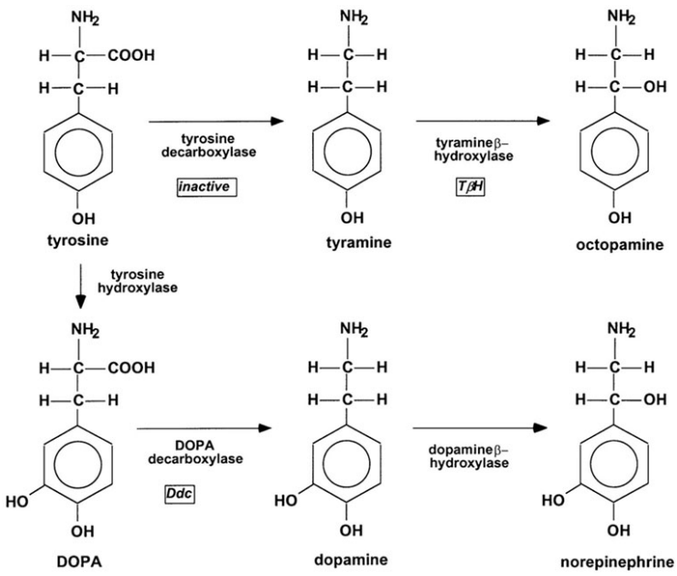

FIGURE 21.2. Biogenic amines and their biosynthesis.

Surprisingly, cocaine sensitization in *Drosophila* has been linked to a different biogenic amine—tyramine. Tyramine is present only in trace quantities in mammalian nervous systems; however, in insects it is a somewhat more abundant molecule and also serves as a precursor for the important neuromodulator octopamine (Fig. 21.3) . Mutants with defects in this biosynthetic pathway have been identified in *Drosophila* behavioral screens. For example, inactive mutants have low levels of the enzyme tyrosine decarboxylase, and consequently fail to efficiently synthesize both tyramine and octopamine; in contrast, TβH mutants are defective in the tyramine ß-hydroxylase enzyme, and thus synthesize tyramine but not octopamine. Interestingly, while inactive mutants display an essentially normal acute response to cocaine, they are strongly defective in sensitization (75) . This sensitization defect can be rescued by feeding the mutant flies tyramine but not octopamine; moreover, TβH mutants (which lack octopamine but not tyramine) and Ddc mutants (which fail to synthesize dopamine) show normal cocaine sensitization. Furthermore, cocaine actually increases the levels of tyrosine decarboxylase activity in treated flies, suggesting that cocaine sensitization may actually occur at least in part through induction of tyramine synthesis. Remarkably, both the induction of tyrosine hydroxylase activity by cocaine and cocaine sensitization itself require the activities of the period, clock, and double-time genes, three members of the conserved signal transduction pathway that controls circadian rhythms in animals and fungi (76) .

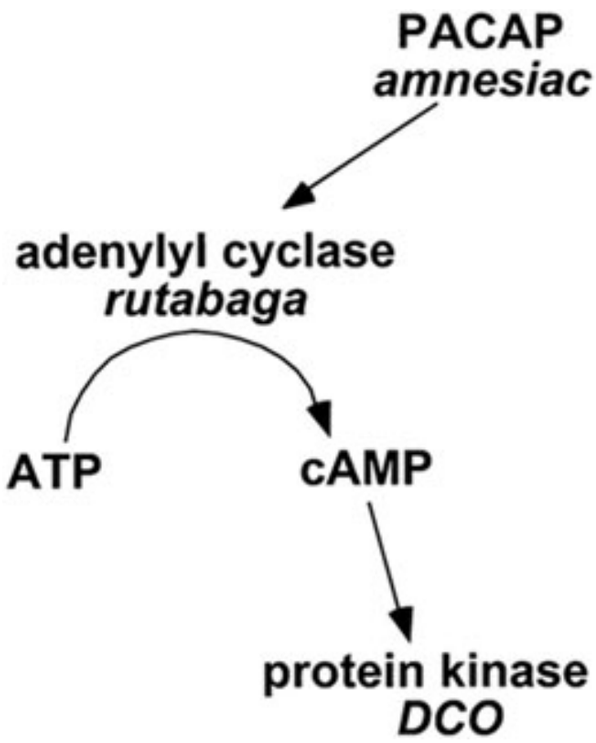

FIGURE 21.3. The adenylyl cyclase signaling pathway.

How might tyramine mediate cocaine sensitization in flies, and does it play a similar role in mammals? At present, these questions are difficult to answer. Although the function of tyramine in insect nervous systems has not been clearly established, putative tyramine receptors have recently been identified in both *Drosophila* and the honeybee (77) . Possibly cocaine might act in a period-dependent manner to facilitate tyramine release from nerve terminals, which could then induce plasticity in other monoamine pathways in the brain. Future studies will be needed to identify the specific tyramine receptors that might mediate such responses and to understand the neural basis for their effects on behavior. In vertebrates, tyramine receptors have not been identified; thus, it remains an open question whether tyramine plays a role in human sensitization to cocaine that parallels its role in *Drosophila*. However, the involvement in *Drosophila* of the circadian clock pathway, which is highly conserved between insects and humans, suggests that at least some components of the molecular mechanisms underlying this process may be shared between these widely divergent organisms.

QUESTIONS AND FUTURE PROSPECTS

Part of "21 - Neuropsychopharmacology of Worms and Flies "

Perhaps the major potential pitfall of using worm or fly genetics to investigate drug mechanisms is that there is no guarantee that those mechanisms will be conserved across the evolutionary gulf separating these disparate animals. Certainly at the anatomic level, the brains of humans, flies, and worms are vastly different organs. Nonetheless, for most pharmacologic studies, the critical issue is conservation at the molecular level, and with the worm and fly genomes essentially complete, it is clear that at the molecular level the *C. elegans* and *Drosophila* nervous systems are quite similar to their human counterpart. For example, the *C. elegans* and *Drosophila* genomes contain homologues of each of the basic types of potassium channels, calcium channels, and G proteins, as well as putative receptors for most human neurotransmitters (78, 79) . To be sure, there are a small number of nervous system molecules found in vertebrates and flies but not nematodes (e.g., voltage-gated Na channels), as well as molecules found in nematodes and flies but not vertebrates (e.g., the ivermectin-sensitive glutamate-gated Cl channel). However, on the whole the nematode,

fly, and vertebrate nervous systems appear to be remarkably similar at the molecular level given their vast differences in scale and functionality.

What are the prospects for model organism neuropsychopharmacology in the postgenomic future? The availability of substantial portions of the worm and fly genomes has already made the rate-limiting step of classic forward genetics—cloning a mutant gene—significantly easier and more straightforward. This cloning process will become easier still as high-resolution, single-nucleotide polymorphism maps of the worm and fly genomes become available. The imminent completion of the human genome will also provide great benefits to model organism studies, since it will allow rapid identification of human homologues for worm or fly genes and more reliable distinction of genuine mammalian orthologues from other members of a gene family. The great advantage of worm and fly studies for the elucidation of drug mechanisms is the ability to conduct unbiased, phenotype-driven mutant screens to identify unknown gene products involved in drug response. Since ethical considerations will always preclude such approaches in humans, and since time, space, and cost considerations make them inefficient even in simpler vertebrates, *C. elegans* and *Drosophila* are likely to serve as workhorses for basic neuroscience research for many years to come.

The origins of the modern concept of receptors can be traced to the beginnings of the 20th century (1). Almost two decades passed until the first neurotransmitter, acetylcholine, was identified from classic physiologic studies on the vagus nerve performed by Otto Loewi in 1921. Since these seminal discoveries the pace of advance has increased enormously. A revolution in the field began in the 1950s, with the discovery that neurotransmitter receptors are targets of clinically relevant psychotropic drugs and the development of radioligand binding techniques (2 ,3). Radioligand binding methodologies remain a mainstay of modern neuropsychopharmacology, and have facilitated the identification of receptor subtypes as well as the discovery of novel receptors that mediate the actions of important drugs.

The application of recombinant DNA methodologies sparked a second revolution in neuropsychopharmacology. These methods facilitated the cloning of complementary DNAs (cDNAs) encoding distinct receptors, the identification of large families of homologous receptors, and unprecedented insight into subtype diversity within individual receptor families (4 ,5).

Important families of receptors include steroid hormone receptors, receptor tyrosine kinases, ligand-gated ion channels, and G-protein–coupled receptors (GPCRs). GPCRs comprise the largest class of signal-transducing receptors, with well over 1,000 members identified in humans. In some organisms, genes encoding GPCRs comprise 1% of the genome (6). GPCRs mediate the actions of the majority of neurotransmitters and neuromodulators, as well as other important biological ligands. These receptors are also critically important drug targets. Indeed, the majority of psychopharmaceuticals presently in use either bind directly to specific GPCRs (e.g., antipsychotics) or indirectly influence GPCR function by modulating the availability of endogenous ligands (e.g., selective serotonin reuptake inhibitors, SSRIs). Therefore elucidating mechanisms of GPCR function and regulation is of central importance to understanding the actions of clinically relevant drugs.

During the past several years there has been a great deal of progress in elucidating specific mechanisms of GPCR function and regulation. Much of this progress can be attributed to the application of newer molecular and cell biological techniques, which have complemented previously developed pharmacologic approaches for probing receptor function. This chapter discusses some of these molecular and cell biological approaches for isolating and studying cloned receptors, focusing specifically on GPCRs expressed in a variety of systems. Although we restrict our scope in this chapter to representative approaches applied to GPCRs, these methods have broad potential application and have been used to study other important receptor families.

ISOLATION AND IDENTIFICATION OF RECEPTORS

Part of "22 - Beyond Binding: Molecular and Cell Biological Approaches to Studying G-Protein–Coupled Receptors "

The identification of GPCRs by biochemical purification is a challenging task because of the generally low abundance of these proteins in cells and tissues, and because GPCRs are highly hydrophobic molecules that are easily denatured when solubilized in detergent solutions. Molecular cloning techniques have greatly facilitated the identification of GPCRs. Molecular cloning takes advantage of the ability to generate and screen “libraries” containing cDNAs corresponding to the messenger RNAs (mRNAs) that encode cellular proteins.

A detailed discussion of molecular cloning techniques is beyond the scope of the present review and has been described elsewhere (7). In general, a cDNA library is generated from a specific tissue and animal source (such as rat brain) by purifying mRNA from the tissue, using the enzyme reverse transcriptase to generate a strand of DNA complementary to each mRNA present in this mixture, and then using a DNA polymerase to generate double-stranded DNA from this sequence that is suitable for insertion into an appropriate plasmid or phage vector that facilitates faithful replication of the sequences and allows selection of individual clones corresponding to a single cDNA. The main challenge in receptor cloning is to isolate or "screen" for the appropriate receptor-encoding cDNA from a library. Several different approaches to library screening have been used successfully for cloning cDNAs encoding GPCRs.

Receptor Cloning from Protein Sequence

Early isolation and cloning of receptors relied on purifying sufficient quantities of receptor and then microsequencing peptide fragments. The hamster $ß_2$-adrenergic receptor was cloned using partial sequence information derived from protein purified from hamster lung (8). The sequence of amino acids present in a GPCR fragment allows one to predict the sequence of the corresponding region of the mRNA sequence by "back-translation" from the genetic code. This nucleic acid sequence can be searched for in the cDNA library by virtue of the ability of complementary strands of DNA to anneal together with extremely high specificity. Because of the degeneracy of the genetic code, many amino acids can be encoded by more than one nucleic acid codon. Therefore, nucleic acid "probes" used to screen cDNA libraries often contain mixtures of sequences representing multiple potential "spellings" of the known peptide fragment. cDNA clones encoding the sequence of interest can be isolated by hybridization of a labeled probe or by polymerase chain reaction (PCR)-mediated amplification from a cDNA mixture.

Receptor Cloning by Sequence Homology

Sequence homology within the GPCR superfamily of receptors enables the use of DNA sequence from a previously cloned receptor to probe libraries for other related receptors. Cloning of the dopamine D2 receptor is an example of where sequence homology was used to clone other members of the GPCR superfamily of receptors. Olivier Civelli's group (9) used the hamster $ß_2$-adrenergic receptor gene as a hybridization probe to isolate cDNA encoding the rat D2 dopamine receptor. The authors used two major criteria to determine that the cDNA isolated encoded a functionally relevant dopamine receptor. First, they demonstrated that mRNA corresponding to their cDNA sequence was expressed in tissues that had been previously shown by radioligand binding to express functional D2 receptors. They accomplished this by Northern blotting, a procedure by which RNAs isolated from cells or tissues is resolved by gel electrophoresis and the specific RNAs homologous to a particular sequence is detected by hybridization of a specifically labeled probe. Second, the authors demonstrated that the cDNA isolated from their library encoded a functional D2-class dopamine receptor. This was accomplished by applying conventional radioligand binding and receptor signaling assays to detect functional D2 receptor activity in fibroblast cells that do not normally express dopamine receptors and that were transfected with the cDNA isolated from library screening.

Receptor Cloning by Functional Expression

GPCRs can also be cloned based on their functional properties. The cloning of the serotonin (5-hydroxytryptamine) 5-HT_{1C} receptor used this approach (10). Taking advantage of the high expression level of the 5-HT_{1C} receptor in the choroid plexus, the authors isolated mRNA from this source and injected this preparation into *Xenopus* oocytes, which allows both injected mRNA and cDNA to be translated and expressed. The activation of the 5-HT_{1C} receptor by its ligand leads to an increase in intracellular calcium through the inositol phosphate signaling pathway. This rise in intracellular calcium leads to the opening of Ca^{2+}-dependent chloride channels that was detected by means of highly sensitive electrophysiologic techniques. Similar results could be obtained by injecting cDNAs produced from the mRNAs. Pools containing progressively smaller numbers of cDNAs were then analyzed until a single cDNA encoding a functional serotonin receptor was isolated.

The cloning of the delta opioid receptor (11 ,12) was also achieved by a functional assay. A cDNA library prepared from cells that endogenously express the delta opioid receptor was expressed in cultured fibroblast-like cells that do not normally express opioid receptors. Cells expressing opioid receptors were identified by binding of a radiolabeled opioid peptide. cDNA isolated from the selected cell was isolated and retransfected, to allow multiple rounds of purification until a single cDNA encoding the delta opioid receptor was isolated. The isolated cDNA was confirmed to encode a delta opioid receptor by analysis of radioligand binding properties and ligand-induced signal transduction in transfected cells.

Identification of Receptor Subtypes (Fig. 22.1)

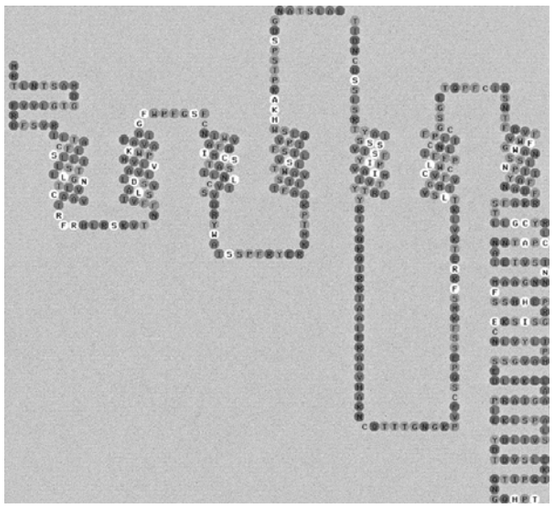

FIGURE 22.1. Dopamine D1 receptor two-dimensional (2D) snake diagram downloaded from the G-protein–coupled receptor database (GCRDb), http://gcrdb.uthscsa.edu/index.html, which is a very useful site for researchers working on GPCRs (13,14). This diagram shows the seven-transmembrane structure of GPCRs and the long carboxy terminus tail characteristic of D1-like dopamine receptors. In the GCRDb, amino acid mutations found in the receptor are listed in *white* in the 2D snake diagram and hyperlinked to the GRAP mutant database. [http://tinygrap.uit.no/]. (Used by permission of the GCRDb.) See color version of figure.

A general principle in molecular pharmacology is that multiple receptors exist that can recognize the same ligand. This "one ligand, multiple receptors" principle has led to great interest in the identification of multiple receptor subtypes.

For example, radioligand binding techniques and assays of receptor-mediated signal transduction originally defined two classes of dopamine receptor: D1 receptors that stimulate adenylyl cyclase, and D2 receptors that inhibit this enzyme. Molecular biological techniques confirmed that these receptors represent distinct gene products and led to the discovery of additional, structurally homologous subtypes of receptor protein. These subtypes of dopamine receptors would have been impossible to identify definitively using classic pharmacologic approaches, as their pharmacologic properties are quite similar and some subtypes are expressed at very low levels in native tissues. For example, the D4 dopamine receptor is a member of the “D2-class” of dopamine receptors that was cloned by sequence homology to the cloned D2 receptor (15). D4 receptors are of great interest because they bind the atypical antipsychotic clozapine with approximately 10-fold higher affinity than cloned D2 receptors (16).

Molecular biological methods also led to the discovery of additional diversity among closely related GPCRs encoded by genetic variants or by modification of the receptor gene after transcription. For example, multiple variants of D4 receptor, which differ only in the structure of the third cytoplasmic loop of the receptor protein, are encoded by closely related genes that are inherited in a mendelian manner ((17)). Two variants of the D2 dopamine receptor are

generated from the same gene by alternative splicing, which occurs during posttranscriptional processing of the RNA. Another interesting example of such receptor diversity is the 5-HT_{2C} receptor, which exists in variant forms determined by a posttranscriptional process called RNA editing (18). In many cases the functional significance of such variation among GPCRs is not known. However in some cases, such as RNA editing of the 5-HT_{2C} receptor, individual receptor variants have significantly different functional properties.

As a further extension of the “one ligand, multiple receptors” concept, molecular biological methods led to the discovery that a specific neurotransmitter can often bind to more than one class of receptor protein. The first example of this can be found in the acetylcholine receptors (AChRs). The idea that distinct muscarinic and nicotinic AChRs exist was first indicated by pharmacologic studies. Molecular cloning of the corresponding receptor cDNAs confirmed this idea and revealed very precisely the differences between these classes of AChR: muscarinic-type AChRs are GPCRs, whereas nicotinic-type AChRs are members of the structurally distinct family of ligand-gated ion channels (LGICs). There are now several examples of this type of diversity, including the existence of distinct GPCRs and LGICs for serotonin, glutamate, and γ-aminobutyric acid (GABA).

Discovery of Orphan Receptors

Orphanin FQ and Its Receptor

In addition to identification of receptor subtypes, the cloning approaches discussed above have also enabled the isolation of GPCRs before the identification of any known ligands. Putative receptors for which a ligand is not known, called orphan receptors, hinge on sequence similarity with other GPCRs. The cloning of an opioid-like GPCR, known as ORL1 or the orphanin receptor, was accomplished by several groups looking for additional members of the opioid receptor family by cloning structurally homologous cDNAs (19 ,20). Expression of the ORL1 cDNA revealed that this putative receptor did not bind any of the typical mu, delta, or kappa ligands with high affinity, despite having particularly high sequence homology to the kappa receptor. In addition, there are large differences in anatomic distribution of ORL1 mRNA compared to the known distribution of opioid receptors. Later, elegant studies led to the isolation of an endogenously expressed peptide ligand for this receptor, nociceptin or orphanin FQ, allowing the ORL1 gene product to be clearly established as a *bona fide* GPCR (21).

Orexins and Their Receptors

Many other cDNAs encoding candidate orphan receptors have been identified by DNA sequence analysis. Current estimates suggest that there are ˜100–200 such orphan GPCRs encoded in the human genome (not including predicted olfactory receptors). The isolation of so many candidate orphan receptors has led some groups to attempt systematic approaches to identifying their endogenous ligands. Identification of orexin and the orexin/hypocretin receptor was accomplished by using a cell-based detection system using cells transfected with a large number of candidate orphan receptor cDNAs (22). A cDNA (HFGAN72) was identified that was capable of causing an elevation in cytoplasmic free calcium in response to a crude peptide-containing extract prepared from brain. A specific peptide ligand was isolated from this mixture according to its ability to activate this orphan GPCR. This peptide is expressed highly in the lateral hypothalamus and influenced feeding behavior when introduced into rat brain, and is called orexin (from the Greek *orexis* meaning appetite). The receptor encoded by HFGAN72 was named the orexin receptor. Recently, a canine narcolepsy gene was identified by positional cloning as belonging to a subtype of orexin receptor (23). Thus the identification of orphan GPCRs can lead to powerful new insights relevant to diverse areas of neuropsychopharmacology.

EXPRESSION AND PURIFICATION OF CLONED GPCRS

Part of "22 - Beyond Binding: Molecular and Cell Biological Approaches to Studying G-Protein–Coupled Receptors "

Expression

The ability to express cloned cDNAs in various cell types has provided powerful tools for studying the functional properties of defined GPCRs. In many cases, receptors expressed in heterologous cell systems have remarkably similar functional properties to those in their native tissue of origin, although this is not always the case. For example, D2 dopamine receptors differ in their properties in pituitary GH4C1 cells and Ltk-fibroblasts. In the pituitary cells, D2 receptors fail to elicit phosphoinositide hydrolysis and induce a decrease of intracellular calcium. In contrast, in the fibroblast cells, the D2 receptor induced a rapid stimulation of inositol 1,4,5-trisphosphate and an increase of intracellular Ca^{2+} (24). Therefore it is important to compare results obtained from studies of cloned receptors in heterologous systems to the properties of receptors in native tissues.

In addition to facilitating functional studies, heterologous expression can also be used to produce large amounts of receptor protein, which is necessary for certain biophysical and structural studies. Mammalian cells are typically used for functional studies of expressed GPCRs; however, it is sometimes preferable to use nonmammalian cells (such as insect cells or yeast cells) for large-scale expression of GPCRs because these cells can be grown economically in very large amount. Prokaryotic expression systems (such as *Escherichia coli*) have potential advantages for large-scale production but have not been used widely in GPCR research because, in general, it has been difficult to obtain functional activity of GPCRs using these systems.

Purification

The ability to express cloned receptors makes it possible to modify the receptor protein to facilitate purification and detection. There are many strategies that have developed from this capability. For example, one useful approach is to insert an antigenic epitope into the GPCR, which can facilitate detection and purification by standard immunochemical procedures using well-characterized antibodies (see ref. 25 for review). This approach obviates the sometimes laborious path of generating antibodies that recognize the native receptor. Epitope tags are typically short sequences (˜10 residues) that bind tightly to a highly specific antibody. In many cases, epitopes chosen for this purpose are either synthetic (not derived from any known biological sequence) or derived from nonmammalian sources, in an attempt to reduce the probability of cross-reaction with endogenous antigens. Popular epitopes include a region from the hemagglutinin molecule of influenza virus (“HA” epitope) or the “Flag” epitope, a synthetic sequence recognized by a series of well-characterized antibodies. The use of such epitopes allows the purification of tagged proteins using commercially available reagents. Tagged receptors can be isolated from extracts prepared from cultured cells by immunoaffinity chromatography. A column can be made by immobilizing an antibody onto a solid support that will bind to tagged receptors as the extracts are passed over the column. Elution of the specifically bound receptor can be accomplished by changing either the salt concentration or the pH to disrupt the antigen-antibody interaction. An example of this approach is found in the high-level production of the human ß-adrenergic receptor (26).

MECHANISMS OF LIGAND BINDING AND ACTIVATION

Part of "22 - Beyond Binding: Molecular and Cell Biological Approaches to Studying G-Protein–Coupled Receptors "

Use of Site-Directed Mutagenesis

The availability of cDNAs encoding specific GPCRs and the development of various cellular expression systems provide powerful tools for examining the specificity of ligand binding to receptors. In particular, site-directed mutagenesis can be used to alter residues in the GPCR structure, and then the functional consequences of these modifications on ligand binding can be examined. Many techniques have been developed for introducing specific mutations into the receptor cDNA, as discussed in detail elsewhere (27). Selected examples of the use of these techniques for understanding the structural basis of ligand binding and receptor activation are outlined below.

Point Mutagenesis

Point mutations refer to modifications of the cDNA that result in the substitution of a single amino acid residue in the expressed receptor protein with another amino acid. Point mutagenesis can be used to dramatically change the physicochemical properties of a specific residue (e.g., substitution of a basic residue with an acidic one); or cause a subtle change in residue structure (such as substitution of a serine residue with cysteine, which results in a change of a single atom in the protein structure). Point mutations are extremely useful because they often do not cause global perturbations of receptor structure and therefore allow highly specific analysis of the function of defined receptor residues. For example, point mutations have been used to define important determinants of receptor-ligand interaction with considerable precision (28).

Point mutations can identify essential features in the receptor structure. Mutation of a single aspartic acid residue present in the predicted third transmembrane domain of catecholamine receptors abrogates high-affinity binding of catecholamines to the $ß_2$-adrenergic receptor. Since an aspartic acid residue is present at the corresponding position in other catecholamine receptors as well, this residue is said to be “conserved” in the structure of multiple receptors. Point mutagenesis applied to these receptors indicates that this aspartic acid is required for ligand binding to a number of receptors, apparently by serving a conserved function as a counter-ion for the positively charged amine moiety of catecholamine ligands (28 ,29). Like the aspartic acid residue discussed above, other amino acids that serve a specific function in the receptor generally are found to be conserved between receptors with similar properties.

Point mutations can identify nonconserved residues that determine the specificity with which drugs bind to structurally homologous receptors. Nonconserved residues present in the receptor sequence may play a pharmacologically important role in determining unique properties of individual receptor subtypes. Nonconserved residues can be essential for determining the specificity with which a drug binds to closely related subtypes of G-protein–coupled receptors. Point mutation analysis combined with appropriate pharmacologic assays can be used to identify such divergent receptor residues that are critical for drug binding, thus providing insight into the structural basis of ligand binding specificity that is useful for drug design.

Point mutations can provide insight into species- and population-specific differences in receptor pharmacology. For the very reason that nonconserved residues are often not essential for basic receptor function, these residues are often not conserved across species. Thus the pharmacology of many subtype-specific drugs can be highly dependent on the species of animal studied. For example, three homologous genes encoding distinct subtypes of α_2-adrenergic receptor are expressed in various mammalian species. However, the pharmacology with which subtype-selective drugs bind to receptor subtypes encoded by mouse or rat receptor genes can differ substantially from the pharmacology characteristic of the corresponding human receptor (30). This

has led to considerable confusion in the correspondence between pharmacologic and molecular biological definitions of specific receptor subtypes across species, and has important implications for the use of animal models for the development of subtype-specific drugs for humans. Furthermore, nonconserved residues involved in subtype-specific drug binding can also differ within the human population, as a result of random mutation and genetic drift. This concept has not yet been extensively explored but may be an important direction for the use of pharmacogenomics in clinical medicine.

Deletion Mutagenesis

Another mutational approach useful for probing receptor structure and function is removal of certain residues from the receptor structure entirely. Deletions of multiple residues in certain parts of the receptor protein (e.g., transmembrane helices) can be difficult to interpret because they often lead to massive disruption of receptor structure. However, deletion of limited regions in extracellular or cytoplasmic domains are often well tolerated and have been quite informative. For example, deletion of residues located in the amino-terminal extracellular domain of polypeptide receptors [such as the follicle-stimulating hormone (FSH) receptor] and the calcium receptor implicate this domain in ligand interaction. Deletion of residues located in the third cytoplasmic loop of various receptors, such as the muscarinic acetylcholine receptors, implicated this domain in functional coupling to heterotrimeric G proteins (27).

Substitution or Chimeric Mutagenesis

A very powerful approach to site-directed mutagenesis is to substitute entire series of residues from one receptor with the corresponding residues of another. This approach is based on the idea that receptors are composed of modular structural domains, and takes advantage of the fact that receptor domains that mediate similar functions often have conserved amino acid sequence. Chimeric substitutions are often less disruptive than deletions to the overall structure of the receptor protein. For example, chimeric mutagenesis has been useful for defining transmembrane residues that mediate subtype-specific and species-specific differences in ligand binding to adrenergic receptors. Receptor chimeras between α_2- and $ß_2$-adrenergic receptors defined multiple cytoplasmic domains that contribute to the specificity of receptor interaction with their cognate heterotrimeric G proteins (4).

Use of Random Mutagenesis

In contrast to site-directed mutagenesis, random mutagenesis is an unbiased approach that can examine a much broader range of modifications of the receptor protein. Random mutagenesis, therefore, has the potential to reveal unanticipated features of receptor structure and function. Random mutagenesis typically requires functional assay of a much larger number of mutant receptors than analyzed using site-directed mutation. The relatively low throughput inherent to traditional methods of receptor characterization have limited the practical utility of random mutagenesis of mammalian GPCRs. This limitation has become less significant with the recent development of higher throughput functional assays and the successful expression of mammalian GPCRs in more genetically tractable organisms. For example, the budding yeast *Saccharomyces cerevisiae* has been used recently for studying the functional properties of a large number of mutant chemokine receptors in which selected regions of the receptor protein were mutagenized in a nonbiased manner. Analysis of these data identified residues in the receptor protein essential for ligand binding and activation. In addition, this nonbiased screening approach yielded unanticipated information, including the identification of mutations that constitutively activate receptors and the identification of functional mutant receptors predicted to contain fewer than seven transmembrane domains (31).

Use of Biophysical Approaches

Biophysical techniques are essential for detailed examination of protein structure and conformational change. One reason these methodologies have had limited application in the study of GPCRs is that they typically require milligram quantities of receptor, a quantity difficult to acquire from native tissue sources. For many years rhodopsin, purified from retina, was the only GPCR that could be generated in sufficient quantity for biophysical study. Indeed, much of what we know about GPCR structure and conformational change has been elucidated from elegant biophysical studies of rhodopsin. Recently, the development of improved expression and purification strategies have made it possible to obtain other GPCRs in sufficient quantity and purity for biophysical study. Thus it is likely that biophysical approaches will play an increasingly important role in future studies of GPCR structure and activation.

Structural Studies of Rhodopsin

High-resolution structural information can be provided by x-ray diffraction methodologies applied to ordered three-dimensional crystals of pure protein. Rhodopsin, a GPCR mediating phototransduction in the retina, has been a favorite for such studies because it can be purified in sufficient amount and purity to facilitate crystalization. Previous studies using electron diffraction of two-dimensional crystals of rhodopsin obtained structural information to a resolution of approximately 7.5 Å (angstroms; 1 angstrom = 10^{-10}m), revealing the relative orientation of the transmembrane helices in the lipid bilayer (32). Recently x-ray diffraction has

been used to solve the structure of three dimensional crystals of rhodopsin to a resolution of 2.8 Å. This accomplishment is truly a major milestone in the field, revealing for the first time the atomic structure of any GPCR and providing detailed information about specific interactions between this GPCR and retinal, its physiological ligand (33).

Molecular Modeling of GPCR Structure

As the hydrophobic domains predicted to form transmembrane helices are extensively conserved among all GPCRs, it is believed that the general features of rhodopsin's transmembrane structure are relevant to other GPCRs. This has motivated the use of rhodopsin's structure as a "template" on which to predict the stucture of other GPCRs, via computational approaches that identify homologous residues and infer thermodynamically stable conformations of extracellular and cytoplasmic loops. It remains to be determined the degree to which specific features of diverse GPCRs are actually conserved at the level of atomic resolution. Indeed, based on well established differences in the pharmacology of individual GPCRs, one might expect there to be significant limitations of such homology-based predictive methods, at least with respect to structural features involved in drug binding. Nevertheless, the available experimental data leave little doubt that this approach is an important starting point for mechanistic studies and for rational drug development (34).

Biophysical Studies of Conformational Dynamics Involved in GPCR Activation

While crystallographic methods have the potential to provide detailed information regarding the relative positions of all residues of the receptor protein, these methods are inherently limited to reporting on a static structure. Thus additional methods are required to examine dynamic conformational transitions that mediate ligand-dependent signal transduction via GPCRs. Several biophysical approaches have been utilized for this purpose. Classic studies of rhodopsin measured the optical absorbance properties of this photoprotein that are highly sensitive to changes in protein conformation. Sophisticated studies using optical spectroscopy indicate that rhodopsin cycles rapidly through a series of distinct conformational states following photon-induced activation. Many other types of biophysical techniques have been applied to examine specific features of light-induced conformational changes of rhodopsin, as well as to examine ligand-induced conformational changes of other GPCRs (35). Specific residues in the receptor protein can be labeled with a chemical probe, typically using a combination of site-directed mutagenesis and organic chemistry techniques. Spectroscopic methods can then be used to detect conformational changes involving the labeled residue, by measuring changes in the local environment or mobility of the chemical probe. Approaches of this type have been applied to several GPCRs, and have begun to yield interesting new information about the dynamic effects of clinically relevant drugs on GPCR structure (29).

Potential for Rational Drug Design

The availability of increasingly detailed mutational and biophysical data and the development of sophisticated molecular models suggest that it may be possible in the future to design new classes of therapeutically useful drugs based on this information. A precedent for such an approach is the structure-based design of the angiotensin-converting enzyme inhibitor captopril, the first drug on the market that was designed based on its interactions with its target (36). Inferences about the structure of GPCR-ligand interaction are currently used in a limited manner to guide the modification of existing drugs. However, an important goal is to design completely new drugs de novo based on the structural basis of GPCR activation. A clue that this may be possible comes from recent studies of mutant GPCRs, in which histidine residues have been introduced at defined positions in the receptor structure that can be coordinated by certain metal ions. Addition of the metal ion to the receptor, by coordinating histidine residues introduced within specific transmembrane helices, influences the receptor conformation to either activate or inactivate the receptor (37). Thus the metal ion can serve either as an "engineered" agonist or antagonist for certain mutant receptors. While it is unlikely that this strategy will directly yield clinically useful drugs, these exciting studies serve as a proof of the principle motivating further studies of GPCR structure and conformational change.

REGULATION OF RECEPTOR SIGNALING

Part of "22 - Beyond Binding: Molecular and Cell Biological Approaches to Studying G-Protein–Coupled Receptors "

Methods to Examine Regulation of Receptors by Posttranslational Modification: GPCR Phosphorylation

Many different types of posttranslational modification have been implicated in the regulation in of GPCR function, localization or stability. A detailed discussion of this large area of research is beyond the scope of this chapter. Instead, we illustrate the use of specific methods by discussing some aspects of protein phosphorylation, the most extensively characterized type of posttranslational modification that regulates GPCRs.

Work by Edwin G. Krebs and his collaborators in the 1950s demonstrated that enzyme-catalyzed protein phosphorylation and dephosphorylation reactions were involved in the regulation of glycogen phosphorylase and suggested the notion of the phosphate group as a "covalently bound allosteric ligand" (38). Since these seminal studies, phosphorylation has been shown to play a critical role in the

regulation of a wide variety of cellular proteins, including many GPCRs. Phosphorylation of mammalian proteins typically occurs on serine, threonine, or tyrosine residues. Serine/threonine phosphorylation is widely recognized to regulate GPCRs. Tyrosine phosphorylation, a more recently discovered modification that is well established to mediate signaling via non-GPCR growth factor receptors (39), may also play a role in regulating certain GPCRs (40).

A family of enzymes called G-protein–coupled receptor kinases (GRKs) are well known to attenuate GPCR signal transduction and promote the endocytosis of certain GPCRs by clathrin-coated pits. Other kinases, such as the 3′,5′-cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA) and protein kinase C can also regulate GPCRs by phosphorylating distinct cytoplasmic serine/threonine residues (41 ,42 ,43 and 44). Certain kinases (such as PKA) typically phosphorylate residues located within a well-defined “consensus sequence,” making it possible to predict potential sites of regulatory phosphorylation simply by examination of the primary structure (polypeptide sequence) of the cytoplasmic domains of the receptor. Residues phosphorylated by other kinases, such as GRKs, are more difficult to predict because they do not conform to a rigidly defined consensus sequence. However, even in the case of enzymes with relatively well-understood substrate specificity *in vitro*, there are major limitations to the use of sequence analysis for predicting phosphorylation sites *in vivo*. Residues conforming to a specific consensus sequence are not always phosphorylated under physiologic conditions, and, conversely, in some cases residues that do not conform to a well-defined consensus sequence can be phosphorylated in the intact cell. Thus it is important to determine the phosphorylation of GPCRs when expressed in the appropriate mammalian cells.

Analysis and Identification of Phosphorylated Proteins In Vivo

There are many ways of detecting phosphorylated proteins. A starting point for many of these methods is resolution of phosphorylated proteins by electrophoresis in sodium dodecyl sulfate polyacrylamide gels (SDS-PAGE). In SDS-PAGE, proteins dissolved in SDS are loaded onto one end of a porous gel and exposed to an electric field, which causes the SDS-coated proteins to move as “bands” in the gel according to differences in relative molecular mass. By using appropriate radiolabeled compounds (such as inorganic phosphate added to the culture medium), it is possible to apply the technique of autoradiography to specifically detect radioactive, phosphorylated proteins resolved by SDS-PAGE. It is also possible to use gel electrophoresis to separate proteins according to relative charge, a property that is modified predictably by certain modifications such as phosphorylation. These types of separation can be combined in the use of two-dimensional gel electrophoresis, which allows high resolution of proteins as “spots” differing in relative size and charge.

Proteins resolved by gel electrophoresis can be transferred to a membrane composed of nitrocellulose or polyvinyl difluoride (PVDF). This allows many manipulations to be performed, such as detection of a specific protein from a complex mixture by the ability of the protein to be bound by a specific antibody. This procedure, called immunoblotting or “Western” blotting, can be used with commercially available antibodies recognizing phosphorylated peptide sequences or phosphorylated amino acids.

GPCRs resolved by gel electrophoresis can also be analyzed by chemical sequencing, typically by a process called Edman degradation, which sequentially cleaves residues from the amino-terminal end of the protein. Phosphorylated residues can be distinguished from their nonphosphorylated counterparts by chromatography or by incorporation of radioactive phosphate, allowing the identification of specific phosphorylated residues in a polypeptide sequence by the order of appearance in the eluate collected after multiple cycles of Edman degradation. A very powerful method for determining amino acid sequence and detecting posttranslational modifications of proteins is via mass spectrometric analysis. For example, with tandem mass spectrometry it is possible to measure the mass of specific protein fragments with an accuracy of one part in 10,000 up to 12,000 daltons and one part in 1,000 up to 25 kd (45). The impressive accuracy of this method makes it possible to detect phosphorylation as well as many other posttranslational modifications, even those that cause subtle changes in the protein size or charge.

Chromatography, which refers to any separation based on differential behavior of a molecule between a stationary phase and a moving phase, offers many ways of identifying protein modifications. High-performance liquid chromatography (HPLC) using reverse-phase (e.g., C18) columns allows the precise separation of peptides derived from proteolytic or chemical fragmentation of GPCRs. By comparing the pattern of peptide fragments derived from the native protein and the modified protein, one can identify specific polypeptide fragments containing the modification of interest. Subsequently, these fragments can be isolated and further analyzed by methods such as Edman degradation or mass spectrometry.

Methods to Examine Regulation of Receptors by Localization and Trafficking

It has been appreciated for many years that a critical parameter that can regulate the strength of functional signal transduction via GPCRs is the actual number of receptors present in target tissues and, in particular, the number of receptors present in the plasma membrane of individual cells. Indeed, disturbances in the regulation of receptor number and/or distribution may be of primary importance in the pathophysiology

of certain neuropsychiatric disorders. For example, long-term administration of dopamine receptor antagonists can induce upregulation of specific receptors, which may contribute to the apparent supersensitivity of dopamine receptors associated with tardive dyskinesia (46). In contrast, prolonged stimulation of certain GPCRs with agonist ligands can lead to a decrease in the number of binding sites available on the cell surface. This phenomenon is termed receptor “down-regulation” and may contribute to the effects of certain antidepressant drugs (47). Studies using radioligand binding and subcellular fractionation techniques provided early evidence that multiple mechanisms are capable of mediating changes in the number of GPCRs present at the cell surface (48). More recently developed molecular and cell biological approaches provide powerful tools for directly visualizing the subcellular localization of GPCRs and for performing biochemical studies of specific receptor trafficking mechanisms.

Immunochemical Methods to Visualize the Subcellular Localization of Receptors

GPCRs can be detected *in situ* in cell or tissue preparations using immunochemical techniques and receptor-specific antibodies. Antibodies that recognize the native receptor protein can be used to examine the localization of endogenously expressed receptors, whereas epitope-tagging methods (see above) can be used to detect mutated versions of the receptor protein or as a means to detect recombinant receptors for which antibodies recognizing the native receptor are not available. In either case the general scheme is as follows: Cells or tissues expressing the receptor of interest are fixed using standard histologic methods. The fixed cells or tissue can be “permeabilized” with a nonionic detergent, to facilitate biochemical access to receptors situated in intracellular membranes, and then specimens are incubated with antibodies recognizing the receptor of interest. After sufficient time has elapsed to allow antibodies to bind to their respective epitopes in the specimen (typically several hours), the specimens are washed extensively to remove nonspecifically associated antibodies. Antibodies bound to the receptor are then detected by incubation of specimens with a “secondary” antibody that binds specifically to the “primary” antibody (the antibody bound initially to the receptor). The secondary antibody is typically coupled to a fluorochrome (such as fluorescein), a recognizable particle (such as colloidal gold), or an enzyme that can produce a localized reaction product (such as horseradish peroxidase) to facilitate direct visualization of the receptor-containing immune complex using various light or electron microscopic techniques (Fig. 22.2).

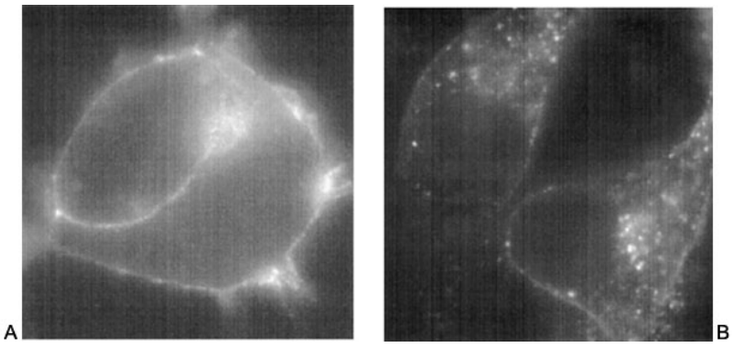

FIGURE 22.2. Visualization of HA epitope-tagged dopamine D1 receptors in transfected cells, using a fluorochrome-labeled secondary antibody and fluorescence microscopy. The ability of this receptor to undergo regulated internalization is indicated by the dopamine-induced redistribution of immunoreactive receptors from the plasma membrane (visualized as linear staining at the cell periphery) to endocytic vesicles (visualized as punctate structures located throughout the cytoplasm). **A:** Untreated cells (no ligand). **B:** Treated with 10 μM dopamine. Biochemical Methods to Assay Specific Receptor Trafficking Processes

Whereas microscopic imaging can readily provide a great deal of qualitative information about GPCR localization and trafficking, it can be quite challenging to quantitiate

from these data the precise amount of receptor present in a specific subcellular localization or to measure accurately the rate or extent of specific trafficking processes. The importance of these processes has motivated the development of biochemical methods for examining GPCR trafficking. In addition to their utility for receptor localization, antibodies specifically recognizing GPCRs facilitate biochemical studies of GPCR trafficking using techniques adapted from other areas of cell and molecular biology. For example, one method that has been extremely useful for quantitative studies of GPCR endocytosis is cell-surface biotinylation coupled with immunoprecipitation of receptors. Proteins present in the plasma membrane of cells can be specifically labeled by incubating intact cells in the presence of biotin coupled to an activated ester, which is membrane-impermeant and therefore forms a covalent bond only with exposed amine moieties present in plasma membrane proteins. In general, biotinylation in this manner does not adversely affect GPCR function, allowing biotinylation to be used as a chemical tag for surface receptors. The biotin moiety is extremely useful for subsequent detection or purification of surface-tagged proteins because it binds with extremely high affinity (K_a ~10^{15} M^{-1}) to the proteins avidin or strepatavidin. Using variations of this basic biochemistry, it is possible to measure a wide variety of membrane trafficking processes. For example, internalization of GPCRs has been measured by the inaccessibility of biotinylated receptors to a membrane-impermeant reducing agent that “cleaves” the biotin moiety away from tagged proteins (49), and surface biotinylation has been used to measure the rate and extent of proteolytic degradation of receptors after endocytosis (50 ,51).

Methods for Examining Specific Protein Interactions Involved in GPCR Function and Regulation

A salient lesson emerging from recent cell biological studies is that GPCR signal transduction can be viewed, in essence, as a dynamically regulated network of protein–protein interactions that occur in specific subcellular locations. Therefore, an important goal of current and future research is to define these critical protein interactions and elucidate their temporal and spatial regulation in intact cells and tissues. A great deal of effort is presently going into developing and applying novel methods for the study of protein–protein interactions both *in vitro* and *in vivo*, as illustrated by the following examples.

Coimmunoprecipitation Techniques to Examine Defined Protein Interactions with GPCRs in Intact Cells

As discussed above, it is possible to rapidly purify GPCRs from cell or tissue extracts using receptor-specific antibodies or epitope tagging methods. In addition to being extremely useful for examining posttranslational modifications of GPCRs, in some cases it is possible to use these techniques to isolate receptor-containing complexes that presumably reflect protein interactions occurring in the intact cell. The basic idea is to immunopurify a specific GPCR from cell or tissue extracts (or from a partially purified subcellular fraction prepared from a cell or tissue lysate) using an antibody recognizing the native receptor or an engineered epitope tag, and then to analyze proteins specifically associated with this complex using a different antibody. In general, this is accomplished by immunoprecipitation of the receptor followed by analysis of associated proteins in the complex by immunoblotting with the appropriate additional antibody. In some cases, the protein complexes are sufficiently stable that they remain associated through the initial immunopurification of the receptor. In other cases this is not true, and the complexes dissociate before the receptor can be purified from the extract. In this case, various chemical agents can be added prior to cell lysis to physically “cross-link” closely associated proteins with one another by forming covalent bonds that prevent dissociation of the complex. Coimmunoprecipitation has been used to assay GPCR interaction with heterotrimeric G proteins (52) and with ß-arrestins (53), and to examine the regulation of these protein interactions by ligand-induced activation of the receptor.

Use of Coimmunoprecipitation to Examine Oligomerization of GPCRs

The idea that GPCRs may function *in vivo* as higher-order molecular complexes has been suspected for many years. Recent studies provide strong support for this idea and, specifically, provide evidence for homo- and heterodimerization of individual GPCRs *in vivo*. This principle is perhaps best established for receptor tyrosine kinases, where it is well established that oligomerization of receptors is required for appropriate ligand-dependent signal transduction (54). A relatively early hint that GPCRs may also undergo oligomerization came from studies of the $ß_2$-adrenergic receptor using epitope-tagging techniques, where it was observed that receptors tagged with one epitope could specifically coimmunoprecipitate receptors tagged with a distinct epitope (55). Early evidence suggesting a functional role of oligomerization in GPCR signaling came from mutational studies in which structural domains present in distinct, functionally inactive mutant receptors could “complement” one another when coexpressed in cells, suggesting the formation of a functional “hybrid” oligomeric receptor protein (56). More recently, evidence for oligomerization of many GPCRs has been reported. A particularly compelling example of this is the recent observation that distinct subtypes of GABA-B receptor hetero-oligomerize in cells, and that oligomerization is essential for the formation of recombinant receptors possessing the functional properties characteristic

of native GABA-B receptors observed *in vivo* (57 ,58). Recent studies using epitope-tagging and coimmunoprecipitation have demonstrated the formation of homo- and heterodimers of opioid receptors, and suggest that receptor oligomerization may contribute to the remarkable diversity of pharmacologic properties observed in natively expressed opioid receptors (59). There is also emerging evidence that certain GPCRs may associate *in vivo* with completely different classes of receptor protein, such as the dopamine D5 receptor (a GPCR) and the GABA-A receptor (a ligand-gated ion channel). In a recently published study (60), glutathione S-transferase (GST)-fusion proteins encoding the C-terminal tail of the D5 receptor were shown to interact with the GABA-A receptor present in rat hippocampal extracts. Additionally, using an antibody recognizing the dopamine D5 receptor, it was possible to coimmunoprecipitate the GABA-A receptor from cell extracts. Interestingly, this coimmunoprecipitation was detected only when both receptors were stimulated by their respective ligands, suggesting that this heterotypic interaction is regulated in a ligand-dependent manner.

Identification of Novel Protein Interactions with GPCRs

In addition to known proteins that mediate and regulate GPCR signaling (heterotrimeric G proteins, GRKs, arrestins), which were originally identified by functional assays using biochemical purification, cDNA cloning methods have facilitated the identification of additional protein interactions with GPCRs that were completely unanticipated (61). These novel protein interactions, while their functional relevance remains unclear in many cases, are of great interest and potential therapeutic importance as drug targets.

Of the many techniques for identifying novel protein–protein interactions developed over the last 10 years, interaction cloning methods such as the yeast two-hybrid system (62) have been particularly useful for studies of GPCRs. In the yeast two-hybrid system, protein interactions are detected by their ability to reconstitute the activity of a “split” transcriptional activator complex. A transcription factor such as GAL4 can be divided into two domains: a DNA binding domain and a transcriptional activation domain. For the transcription factor to be active, these two domains must be in close proximity to one another, so that the DNA binding domain can bind the promoter sequence in a “reporter” gene and the activation domain can promote gene transcription. A polypeptide sequence for which one wishes to identify putative interacting proteins (such as a sequence derived from a cytoplasmic domain of a GPCR) is cloned into a vector coding for the isolated DNA binding domain from the GAL4 transcription factor, thereby producing a fusion protein containing the GPCR-derived sequence as “bait” with which to search for potential protein interactions. A cDNA library prepared from a tissue of interest is cloned into a cDNA encoding an isolated transcriptional activation domain, producing a large number of fusion proteins containing tissue-derived polypeptide sequences as potential “prey” for protein interaction with the GPCR-derived fusion protein. Both the bait and prey plasmids are transformed into a strain of yeast harboring a “reporter” gene that can be transcribed only in the presence of an “intact” GAL4 transcription factor. Either “half” of the transcription factor is not sufficient to promote efficient transcription of the reporter gene. However, if the fused bait and prey polypeptides form a sufficiently stable protein–protein interaction, they bring their corresponding DNA binding and transcriptional activation domains into close proximity, thus reconstituting transcriptional activation of the reporter gene. Transformed yeast cells containing plasmids encoding the corresponding interacting protein domains can be identified by screening techniques based on GAL4-dependent transcription of reporter genes conferring antibiotic resistance or other selectable metabolic activities, or encoding enzymes that can be detected using colorimetric assays. Assays using the *E. coli*–derived *lacZ* gene, for example, can be used to screen for a characteristic blue reaction product when exposed to 5-bromo-4-chloro-3-indolyl α-D-galactoside.

Protein interactions suggested to occur by the yeast two-hybrid system can be examined using various *in vitro* biochemical techniques, such as affinity chromatography facilitated by GST-fusion proteins. In addition to serving as an independent assay for previously defined candidate interacting proteins, this method can be used to identify novel protein interactions with GPCRs *de novo* (63). In this method a DNA encoding a polypeptide sequence of interest is fused to GST using standard cDNA cloning techniques and expressed as a recombinant protein in *E. coli*. The GST portion of the fusion protein allows the efficient immobilization of the protein by binding to agarose beads covalently derivatized with glutathione. Proteins from a cell or tissue extract that bind to the fusion protein then can be isolated as an immobilized protein complex by affinity chromatography. As an example of the use of these methods, it was shown recently (64) that the third cytoplasmic loop of the dopamine D2 receptor binds specifically to spinophilin, a large cytoskeleton-associated protein that also binds to protein phosphatase-1. This binding was initially identified through use of the yeast two-hybrid system, and then the identification of the specific domains that mediate this protein interaction was accomplished by affinity chromatography using GST-fusion proteins.

Methods for Examining Candidate Protein Interactions in Intact Cells

A major question regarding novel protein interactions with GPCRs, such as those identified using interaction cloning

or protein affinity chromatography, is whether or not they actually occur in an intact cell. Immunocytochemical techniques can provide some insight into this question by determining whether candidate interacting proteins “colocalize” in cells with the appropriate GPCR, as expected if the proteins physically interact *in vivo*. However, even in the event that extensive colocalization is observed, immunocytochemical techniques of this sort do not provide direct evidence for a physical interaction between candidate proteins. Coimmunoprecipitation techniques, as discussed above, provide a useful method for addressing this question. However, demonstrating that a specific protein association can occur *in vivo* is only the first step in the process of assessing the potential physiologic relevance of a novel protein interaction, as this method generally does not provide any information regarding the possible functional activity of a candidate protein interaction. Addressing this question can be a challenging task that involves creative application of diverse techniques and functional assays. Examples of novel protein interactions with GPCRs for which compelling functional data exist include the aforementioned interaction of the D2 dopamine receptor with ABP280 (65) and interaction of the ß$_2$-adrenergic receptor with NHERF/EBP50-family proteins (51 ,63).

EMERGING HORIZONS

Part of "22 - Beyond Binding: Molecular and Cell Biological Approaches to Studying G-Protein–Coupled Receptors "

Unexpected Signaling, Cross-Talk, and Transactivation Involving GPCRs (Fig. 22.3)

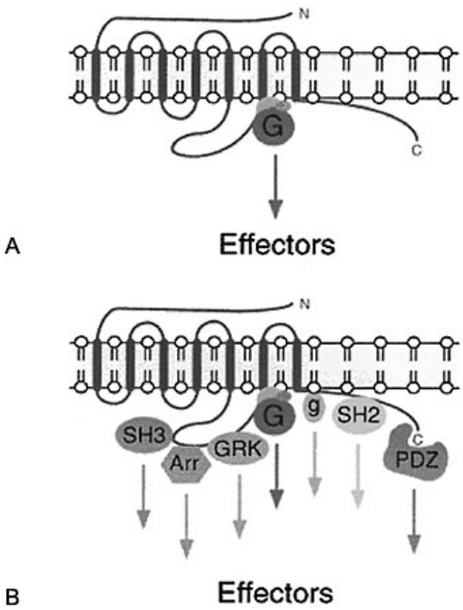

FIGURE 22.3. Schematic diagram of G-protein–coupled receptor (GPCR) signaling. **A:** The G-protein paradigm. Following agonist binding, GPCRs activate heterotrimeric G proteins (G), which then regulate the activity of specific cellular effectors. **B:** Beyond the G-protein paradigm. Following agonist binding, GPCRs can associate with members of diverse families of intracellular proteins, including heterotrimeric G proteins (G), polyproline-binding proteins such as those containing SH3 domains (SH3), arrestins (Arr), G-protein–coupled receptor kinases (GRK), small guanosine triphosphate (GTP)-binding proteins (g), SH2 domain–containing proteins (SH2), and PDZ domain–containing proteins (PDZ). These interactions allow GPCRs to initiate multiple intracellular signaling pathways, with each subtype of receptor likely coupled to a relatively unique set of effectors. (From Hall RA, Premont RT, Lefkowitz RJ. Heptahelical receptor signaling: beyond the G protein paradigm. *J Cell Biol* 1999;145:927–932, with permission.) See color version of figure.

Another line of evidence suggesting the existence of functionally relevant, novel protein interactions involving GPCRs comes from recent work by several labs suggesting that unanticipated functional interactions can occur between GPCRs and receptor tyrosine kinases (RTKs), a distinct family of single-transmembrane receptors involved in growth, differentiation, and oncogenesis (66). The RTK family includes the epidermal growth factor receptor (EGFR), the first receptor shown to have intrinsic tyrosine kinase activity (67 ,68). Whereas the classic pathway for RTK-mediated signaling is initiated by binding of polypeptide growth factors (such as EGF) to the extracellular domain of the RTK, it has been observed recently that certain GPCRs can initiate signaling cascades traditionally thought to be controlled by RTKs. In this situation, the primary signal appears to be through the GPCR, which in turn “transactivates” the RTK. For example, several GPCRs can mediate transactivation of coexpressed EGFRs, thus stimulating mitogenesis by a similar downstream pathway as that initiated by binding of EGF directly to the EGFR (69). One mechanism of GPCR-mediated transactivation involves the activation of a membrane-associated metalloproteinase, which cleaves the EGF precursor protein to generate increased amounts of ligand for the EGFR (70). Another mechanism of cross-talk involves the formation of heteromeric signaling complexes, which include components of both “classical” GPCR and RTK signaling cascades. For example, recent studies suggest that the nonreceptor tyrosine kinase c-Src can associate with the ß$_2$-adrenergic receptor and the ß-arrestin in endocytic membranes, thus mediating mitogenic kinase activation either by a c-Src-mediated phosphorylation of downstream effectors (71) or by c-Src-mediated phosphorylation of co-endocytosed EGFR (72).

Visualization of Protein Localization and Interaction in Living Cells

As discussed above, immunochemical methods are useful for examining the localization of proteins in intact cells.

However, these methods are typically applied to fixed cells because they require disruption of the cell membrane and prolonged incubation of specimens with antibodies used to detect the receptor of interest. The discovery of proteins from certain marine animals that have high levels of intrinsic fluorescence has fostered a revolution in the ability to localize proteins in living cells. These proteins, such as the green fluorescent protein (GFP) isolated from the jellyfish *Aequorea victoria*, are brightly fluorescent molecules that can fold properly in many environments and do not require any additional chromophore for their fluorescence (73 ,74). This allows them to be used to “tag” GPCRs and other important signaling proteins in intact cells. This is accomplished by using site-directed mutagenesis to create a fusion between the GPCR polypeptide sequence and the sequence encoding the GFP tag, analogous to the introduction of an antigenic epitope tag. The localization of the fusion protein can be examined in intact cells using fluorescence microscopy. Examples of this methodology include the visualization of ligand-induced endocytosis of a GFP-tagged $ß_2$-adrenergic receptor in living cells and visualizing the dynamic recruitment of GFP-tagged ß-arrestin from the cytoplasm to the plasma membrane induced by activation of various GPCRs (75 ,76).

While GFP has facilitated the localization of proteins in living cells, localization by itself does not necessarily indicate the occurrence of a physical interaction of a GPCR with a specific protein. The development of mutant versions of GFP, which differ in their excitation and emission spectra, has made it feasible to examine *in vivo* protein interactions using the process of fluorescence resonance energy transfer (FRET) (77). FRET occurs when two suitable fluorophores are present in extremely close proximity so that light produced from one fluorophore can be “transferred” efficiently into exciting the other. FRET can be detected in living cells using sophisticated microscopy, making it possible in principle to detect specific protein interactions with GPCRs and study their localization in real time. FRET imaging has not yet been used extensively for GPCR research but holds great promise for future study of the spatial and temporal dynamics of protein interactions with GPCRs in intact cells and tissues.

SUMMARY AND CONCLUSIONS

Part of "22 - Beyond Binding: Molecular and Cell Biological Approaches to Studying G-Protein–Coupled Receptors "

We have discussed a subset of experimental approaches that have provided powerful new tools for studying GPCR function and regulation. These approaches are responsible, in large part, for the vast explosion of new information about specific mechanisms of GPCR biology that has emerged over the past several years. In many cases these developments have extended directly from seminal observations made originally through classic pharmacologic approaches, which remain of central importance to understanding GPCR function and regulation. Indeed, we view newer molecular and cell biological approaches as complementing, rather than replacing, the sophisticated pharmacologic methods that have been developed over the years since the discovery of receptors as important drug targets.

Molecular cloning techniques have allowed the isolation of cDNAs encoding many G-protein–coupled receptors. The isolation of receptor cDNAs has provided insight into the remarkable structural homology among GPCRs, revealed an unanticipated level of molecular diversity in the GPCR superfamily, allowed functional characterization of defined receptor subtypes in heterologous systems, and made it practical to produce large amounts of receptor protein for pharmacologic, biochemical and biophysical studies.

Structural, biophysical, and molecular modeling approaches hold great promise for ultimately defining the precise atomic determinants of receptor-ligand interaction and for understanding protein conformational changes involved in receptor activation and regulation. Continued progress in this important area may lead to entirely new concepts and methods relevant to therapeutic drug design. Site-directed mutagenesis techniques complement structural and biophysical approaches and have enabled, in the absence of precise structural information, the empirical identification of residues and receptor domains important for ligand binding and activation. Cell biological methods have elucidated mechanisms of signal transduction and regulation in impressive detail, and have revealed a previously unanticipated level of specificity and complexity of crosstalk between signal transduction systems. Emerging technologies for detecting protein interactions in intact cells are suggesting new insights into cell biological mechanisms of GPCR function and regulation, and are beginning to allow real-time examination of the temporal and spatial dynamics of defined protein interactions in living cells.

Based on the new methodologies available today and current pace of progress in using these methods for elucidating GPCR function and regulation, we anticipate that the next several years will see even greater progress in our understanding of the fundamental biology of GPCRs. Indeed, the field of GPCR research is rapidly moving away from a focus on any one set of experimental techniques and has become a vanguard area of integrative structural, molecular, and cell biology. Further developments of these experimental methods, combined with new *in vivo* imaging and genomics approaches that have appeared on the horizon, are likely to fuel continued rapid progress in the field. This exciting progress is fundamentally and directly relevant to the main mission of neuropsychopharmacology: to develop and provide effective therapies for the complex neuropsychiatric disorders that affect our patients.

Applying Functional Genomics to Neuropsychopharmacology

Michael Brownstein

M. Brownstein: National Institutes of Health, National Institute of Mental Health, Bethesda, Maryland.

> “The time has come,” the Walrus said, “to talk of many things.”
>
> --Lewis Carroll

The time has come indeed. The sequencing of the human genome and the genomes of a number of other species subject to research (1 ,2 ,3 ,4 ,5 and 6) have paved the way for new sorts of studies. Soon researchers will be able to look at the response of every human gene to specific manipulations or developmental events at multiple time points. This will require a new mindset. Researchers will not necessarily be testing specific hypotheses as they have done in the past. Instead, they will rely on the emergence of patterns and systematic features in their data sets (and those of others) to describe the phenomena being examined. Such patterns may hint at functions of collections of genes, the interactions of their products, and their importance in physiologic and pathologic processes. This chapter introduces array technology, discusses the sorts of experiments that can now be done with it, and suggests future advances. Several reviews have already been published on this subject, and the reader should refer to them for additional information (7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 and 15). In addition, university, government, and commercial Web sites are valuable sources of news, background material, reagents, arrays, software, and instrumentation (16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 and 33).

EARLY STUDIES OF GENE EXPRESSION

Part of "23 - Applying Functional Genomics to Neuropsychopharmacology "

The human genome is composed of approximately 3 billion DNA nucleotides encoding more than 100,000 genes (16). Each of these genes must be turned on or off in the right cells at the right time for an individual to develop and prosper. The genes that are ultimately expressed in a particular tissue define it. That is, brain is brain and liver is liver because of the particular collections of transcripts found in their respective cells. Brain, however, is extraordinarily heterogeneous. It has been estimated that nearly half of the genes in the genome are expressed there, distributed among the different neuronal and glial populations.

Genes are made of DNA, a nucleic acid polymer that has deoxyribose as its sugar backbone. Each sugar moiety in the chain has a base (adenine, A; cytosine, C; guanine, G; or thymine, T) attached to it. DNA exists as a double-stranded helix. The two antiparallel strands are bound to one another because their sequences are complementary—that is, the opposing bases are held together by hydrogen bonds, A to T and C to G. Similarly, messenger RNA (mRNA), the transcription product of the coding region of each gene, is complementary to the DNA strand from which it was copied and can bind to it. Northern blotting, the first method developed for detecting single mRNA species in a cellular extract, is based on this phenomenon. In this technique, RNA samples are fractionated by agarose gel electrophoresis, and the RNA bands are transferred (blotted) onto nitrocellulose membranes. Single RNA species can then be detected by hybridizing a radiolabeled DNA to the blot that is complementary to the RNA of interest.

In the past, the responses of cells or organisms to environmental cues were studied on a small scale, one gene or pathway at a time. Initially, Northern blotting was used to examine the abundance of specific mRNA species. Subsequently, other methods were chosen because they were simpler and more sensitive, such as reverse-transcriptase polymerase chain reaction (RT-PCR) (34), or because they were more comprehensive, such as SAGE (serial analysis of gene expression) (35 ,36). These techniques provide useful information, but they are tedious, time-consuming, and expensive to employ.

In the last 5 years, spurred by the availability of large volumes of genomic and cDNA (EST [expressed sequence tag]) sequence data from a variety of organisms, investigators have developed methods to study mRNA profiles in cells and tissues by means of large-scale, high-throughput, parallel methods. In the future, it would be helpful to look at protein and small molecule profiles as well, but the reagents required (panels of antibodies, for example) are difficult to

assemble and utilize. Even though there is not a one-to-one correspondence between the level of a particular transcript in a cell and that of its translation products, a great deal can be learned by performing mRNA expression profiling.

GENE EXPRESSION ARRAYS

Part of "23 - Applying Functional Genomics to Neuropsychopharmacology "

Expression profiling relies on large ordered collections of cDNAs immobilized on glass (microarrays) or synthetic oligonucleotides immobilized on silica wafers or chips (probe arrays). Both of these methods are the conceptual descendants of target nucleic acids immobilized on filters or membranes and detected with complementary radioactive probes. While filter-based systems are commercially available, reasonably priced, and fairly easy to use, it is clear that they will be preempted by glass or chip arrays developed with fluorescent probes. Glass arrays printed on microscope slides are now much cheaper to employ than chips, and many universities and research institutes have already built facilities for printing and probing such arrays. So it is worth discussing the uses to which such arrays have already been put, and the uses to which neuropsychopharmacologists could put them.

Few investigators have used arrays to study brain so far, preferring instead to look at mammalian cell lines and tumors (37 ,38 ,39 ,40 ,41 ,42 ,43 and 44). In addition, many workers have focused on yeast (45 ,46) or prokaryotes (47 ,48) because their genomes are small and have been completely sequenced. Consequently, every protein-encoding gene can be arrayed and examined. This will be true of human and mouse arrays in the not-too-distant future. Meanwhile, experiments can be done with the arrays that are available. These have between a few thousand and a few tens of thousands of elements, and with them we can begin to catalogue genes expressed in regions of the developing and adult nervous system, and to look for alterations in expression patterns associated with pathologic states or physiologic/pharmacologic manipulations (49). Consider, for example, the work that could be done to understand the mechanism(s) of action of selective serotonin reuptake inhibitors (SSRIs) and the reason for their delayed onset of action in depressed patients. As is known, SSRIs increase the availability of serotonin (5-hydroxytryptamine, 5-HT) to presynaptic and postsynaptic receptors, of which there are at least 14 subtypes (50). Among these, 5-HT_{1A} receptors on serotoninergic raphe neurons are thought to play a key role in regulation 5-HT release (51). 5-HT_{1A} agonists, which are used to treat anxiety, inhibit serotonin secretion. Conversely, desensitization of 5-HT_{1A} receptors, which could result from elevated 5-HT levels in the synaptic space following SSRI administration, may have the opposite effect—an increase in 5-HT release by raphe neurons, and chronic stimulation of 5-HT receptors in regions such as the hippocampus, amygdala, and septum. Despite all the research that has been done to date, the identity of the structures and biochemical alterations that are responsible for the antidepressant actions of SSRIs is still moot.

Array experiments will allow investigators to explore the serotoninergic system in a way that is model independent and comprehensive, and the experiments should become easy and cheap enough to perform to permit varying many parameters and comparing many conditions.

Initially, regional responses to a single dose of SSRI at a variety of times in one mouse strain might be examined. Subsequently, mouse strains that differ in their behavioral reactions to SSRIs could be examined; knockout mice known to have altered responses to SSRIs (e.g., 5-HT_{1A} receptor knockouts) could be studied; and drugs that resemble, facilitate, or inhibit the behavioral effects of SSRIs could be investigated. Mice would be better to use for this work than rats as of now because very big mouse arrays are available as are genetically manipulated animals and a variety of well-characterized inbred strains. Unfortunately, mice have small brains, and obtaining samples of minute regions (e.g., raphe nuclei) large enough to make sufficient RNA for labeling is difficult. Help is on the way, though. Better labeling methods, dyes, and detection devices are being developed. In fact, the amount of total RNA needed for an array experiment has already fallen well below 1 µg, and should approach 1 ng shortly.

Each array experiment will let an investigator look simultaneously at thousands of transcripts including those encoding enzymes involved in energy metabolism, receptors, G proteins, second messengers, and ion channels, to name a few. In addition, there will be many species represented on big arrays, the actions of which are unknown. The major task will be to assign them functions (see below).

THE DEVIL IS IN THE DETAILS

Part of "23 - Applying Functional Genomics to Neuropsychopharmacology "

Methods for making and probing arrays and analyzing array data have developed quickly. In spite of this, the supply of arrays has not kept up with demand, and demand should increase dramatically if the goal of using arrays is to compare many conditions and then mine the data systematically for patterns of gene expression. Thus, as stated earlier, costly products are unlikely to gain wide acceptance, and glass slide arrays are likely to be most commonly employed. For this reason, I now discuss their production and use.

Large collections of cDNAs and their sequences are now in the public domain. Some sets of cDNAs have been sequence verified and are ideal to use for preparing arrays; others have not been validated and are less useful. To make arrays, plasmid DNA is prepared from gridded sets of clones to be printed, and (typically) the 3′ end of each cDNA is amplified by PCR. The purified PCR products are then spotted using a robotic arrayer. It is possible to fabricate one's own arrayer (18), but many investigators will prefer

to buy an instrument or obtain arrays from core facilities or commercial vendors. Many thousands of 100-μM spots can be printed on a single glass microscope slide (see ref. 10 for details).

It is important to realize that array experiments do not permit measurement of the amount of each RNA that is present in a sample. This is because the relationship between the amount of transcript in a mixture and the intensity of the fluorescent spot it produces is a complex one—influenced by labeling efficiency, hybridization and wash conditions, and the sequence, quality, and quantity of the printed DNA. Thus, microarrays are typically employed to measure the relative abundances of RNA species in two or more extracts. To achieve this goal, in a two-sample experiment the RNAs are separately labeled with dyes of different colors, and then the products are mixed and hybridized to the arrayed spots (Fig. 23.1). After washing, the slides are scanned with a "reader" or "scanner" and the intensities of the fluorescent signals produced by the two separate dyes are determined spot by spot. Following background subtraction and "normalization" of the signals from the two channels (see below), a ratio of intensities of the two colors is determined for each spot, and the relative abundance of the two input RNAs can then be estimated. Finally, "clustering" methods are used to sort and display the data.

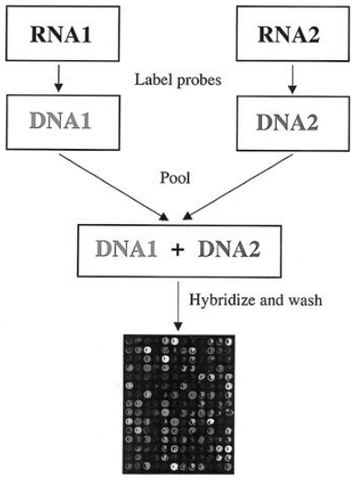

FIGURE 23.1. To perform microarray experiments, RNA is purified from two or more samples of cultured cells or dissected tissues. These RNAs are used to produce labeled probes. In the example given, the dye cy5, which fluoresces red, was used to label probe from sample 1; and the dye cy3, which fluoresces green, was used to label probe from sample 2. The labeled products are mixed and hybridized to the spots on the microarray. Following a wash step, the array is scanned and the signals from the red and green channels are superimposed. If an RNA species is more abundant in sample 1 than 2, the resulting spot will be red; in the reverse case, the spot will be green. When the RNA is equally abundant in the two samples, the spot is yellow. See color version of figure.

Two sorts of experimental paradigms have been defined: type I and type II (42). In the former, two samples are compared to one another; in the latter, multiple samples are compared. To look at multiple samples (e.g., time points, drug doses, developmental ages, brain regions, autopsy specimens), each sample in the set could theoretically be labeled with a different fluorescent dye that could, in turn, be visualized with a different laser. Presently, most commercial readers have only two lasers, but four-color instruments have already appeared on the market. (The number of dyes that it is possible to use for labeling RNA samples is dictated by a reader's ability to resolve the signal from individual dyes and the strength of the signal each dye produces.)

To use a two-color scanner for multiple comparisons, discrete samples must be compared to a reference standard. The ideal standard would have modest amounts of each transcript represented on the array used, because it needs to generate a nonzero denominator for the hybridization ratio. In the case of the mouse, the 17-day embryo and/or the adult brain have been proposed as sources of standard RNA. Pools of cell-line RNAs have been used as standards for human work. It would be useful if a central source of standards existed and if huge batches were prepared.

NORMALIZING RATIOS

Part of "23 - Applying Functional Genomics to Neuropsychopharmacology "

Since it is difficult, if not impossible, to measure the amount of RNA used to produce a labeled probe, normalizing the signals from the source RNAs is essential. To do this, a set of "housekeeping genes" is chosen because their transcription is fairly constant across a range of conditions. The ratio of signals from these genes is set to 1. The housekeeping set needs to be defined empirically, and in looking for candidates to include in such a set, few genes have been found that have constant expression levels. When large arrays are used, this is not a problem; hundreds of genes (or the entire set of genes) can be used for "global normalization" (Fig. 23.2). When small arrays are employed, on the other hand, the size and composition of the gene set used for normalization are very important. Just as a reference standard is urgently needed now, a normalization set supplied by a central site would be quite valuable.

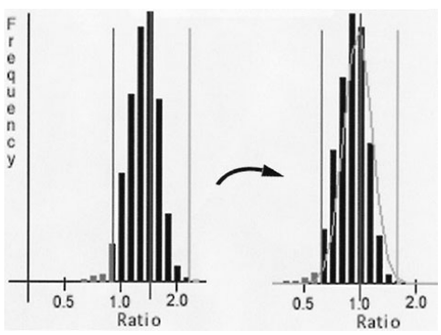

FIGURE 23.2. Normalization. Most genes, especially those with "housekeeping" functions, do not change very much from one experimental condition to another. For this reason, housekeeping genes, or the entire collection of genes on a large array, can be used to set the ratio of signals from the two color channels to 1 as shown here. See color version of figure.

QUALITY CONTROL

Part of "23 - Applying Functional Genomics to Neuropsychopharmacology "

While we have methods to assess the quality of DNA sequence data, for example, there is no generally accepted method for establishing the quality of an array study. In spite of this, there are some controls that can be built into an array. As noted earlier, scientists are arraying DNAs generated by PCR from plasmid templates. It is highly desirable to use sequence-verified cDNA sets. Amplifying these with

specific primers would confirm the identity of each clone, but this is expensive. Assuming we can obtain a reasonably well-validated clone set, the cheapest way to produce the 1.5- to 2.0-kilobase (kb) DNAs for printing is to use vector primers, and to analyze the products on agarose gels. The resulting cDNAs will include T-tails of varying lengths, and repeat sequences. Hybridization of labeled probe to these sequences is prevented by addition of a blocking solution containing oligo (dA) 20-mers, yeast transfer RNA (tRNA), and (for human probes) Cot-1 DNA to the probe solution. To show that the blocking was successful, a number of negative controls should be included among the samples arrayed: spotting buffer, Cot-1 and human genomic DNA, plasmid DNA, oligo (dT), and oligo (dA).

It is useful to array targets for nonmammalian transcripts and to “spike” the samples with the corresponding polyA-tailed RNAs. These RNAs can be added in different concentrations to crude tissue extracts, total RNA samples, or purified polyA-plus RNA to determine extraction efficiencies and detection sensitivities. It would be a mistake to imagine that the added RNA standards can be used to generate figures for absolute amounts of RNA in samples for the reasons given earlier. They should be used exclusively for quality control.

An additional set of spots that have been found useful to array are “landing lights.” These DNAs, which are printed at regular intervals, are used for orientation.

SMALL SAMPLES, FALSE NEGATIVES, AND FALSE POSITIVES

Part of "23 - Applying Functional Genomics to Neuropsychopharmacology "

Failure to detect transcripts or changes in transcripts could result from low-quality arrays or poor labeling methods. Over time, the methods used to make and probe arrays should improve, and false negatives will grow less important. Presently, we can detect RNAs with an abundance of about 1:300,000 in a complex sample. This translates into a few copies per cell if one is studying a homogeneous cell line. Seeing increases in rare transcripts under these circumstances should be simple, but measuring decreases will difficult if not impossible when one can barely detect a weak signal in the first place. Since brain samples are much more heterogeneous than cell lines, the problem of detecting rare mRNAs is even harder. For this reason, it may be necessary to isolate neuronal populations from brain sections by microdissection or to collect single neurons by laser capture methods to enrich and study rare, cell-specific transcripts. To take full advantage of these dissection techniques, methods will have to be developed for isolating and labeling picogram quantities of RNA. (One million cells yield about 5 to 10 µg of total RNA.) It is important to note that labeling methods have to preserve the heterogeneity and relative abundances of the RNAs in the samples to be studied. Care must be taken if PCR is used in the labeling procedure to avoid biasing the sample. Novel labeling methods can be tested using arrays and serially diluted RNA templates.

At present investigators use Northern blotting, the TaqMan system, or *in situ* hybridization histochemistry to weed out false-positive responses of selected mRNAs. When arrays are no longer limiting, this could be accomplished by studying replicate samples, but the argument could be made that one should focus on variations in collections of genes instead of single ones, and that looking at many conditions once may be more powerful than looking at the same condition many times.

BIOINFORMATICS

Part of "23 - Applying Functional Genomics to Neuropsychopharmacology "

Analyzing the earliest, small-scale, array experiments was simply a matter of listing the names of transcripts that appeared to increase or decrease from control levels (Fig. 23.3). As the sizes of arrays increased and labeling methods improved, new algorithms had to be developed that “clustered” the hundreds or even thousands of expression changes found in a typical experiment. Clustering methods permit the classification of genes on the basis of similarities or differences in their patterns of expression across multiple experiments (52 ,53). The output is usually in tabular form. Experimental conditions are listed across the top of a table, and names of genes listed along the side. The response of each gene in each experimental condition is color coded—one color (red) indicating an increase and another (green) a decrease vs. a standard signal (Fig. 23.4). The eye can readily detect patterns in complex images of the sort described, and groups of genes can be identified that parallel one another. Commonly, such genes function in concert.

In the hypothetical SSRI study described above, one group of genes may be increased or decreased in the raphe nuclei following chronic, but not acute, treatment with drug, and a different collection of genes is altered in areas innervated by raphe neurons such as the hippocampus. Different sets of genes might respond to SSRI treatment when behaviorally responsive mouse strains are compared to unresponsive ones, and the pattern of gene expression is different in knockout animals that do not respond to SSRIs as compared with animals that do. Each additional experiment may narrow (or broaden) the list of genes of interest.

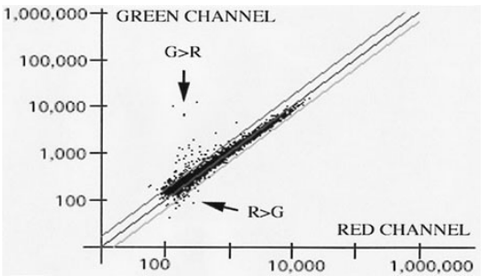

FIGURE 23.3. After normalization, a scatter plot shows that most genes fall in a ratio = 1 space. *Arrows* above and below this space point at genes with altered expression. See color version of figure.

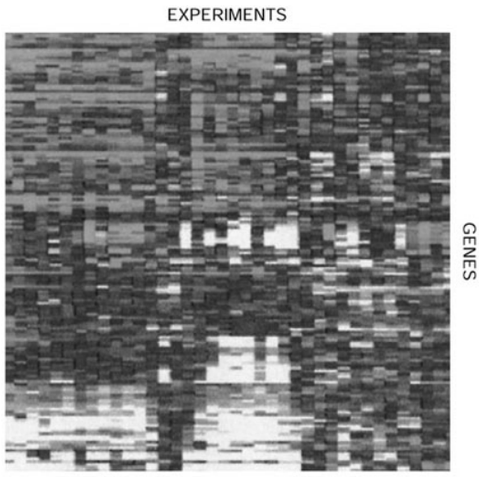

FIGURE 23.4. Clustering. The clustering algorithm has sorted the genes that were studied in a series of experiments according to similarities in their patterns of expression. By convention, red indicates an increase from the standard used, and green a decrease. The collections of genes that are moving up or down in parallel can be readily seen. See color version of figure.

There are ways of evaluating data that are not completely model-independent. Gene responses can be imposed on metabolic charts or on maps of chromosomes. In the former case, increases or decreases in the utilization of certain pathways can be detected; in the latter, deletions or changes in copy number may be recognized, or strong positional candidates identified.

INTERPRETING EXPERIMENTS

Part of "23 - Applying Functional Genomics to Neuropsychopharmacology "

Recent studies of changes in gene expression in yeast associated with nutritional and environmental stresses, the cell cycle, or genetic manipulations are examples of well planned and executed surveys (45 ,46 ,54 ,55 and 56). All of the 6,200 known and predicted protein-coding genes in the yeast genome were arrayed on a single microscope slide, and sufficient numbers of cells were grown to make ample amounts of RNA for labeling. Each experiment gave a richly detailed picture of molecular responses to a physiologic process or perturbation.

Unfortunately, the brain is much more difficult to examine than yeast. It varies with age, and is composed of hundreds of different sorts of cells that express, in aggregate, as many as half of the genes in the genome in a highly regulated manner. To determine the properties of single populations of cells in the context of the intact structure will be difficult, but perhaps not impossible. Initially, it would make sense to identify all the genes expressed in the developing and adult nervous system. This, in fact, is one goal of the Brain Molecular Anatomy Project (BMAP) (57). After this goal is achieved, the regional and cellular localization of “brain genes” will be determined.

In addition to cataloging the transcripts in the brain, it would be helpful to look at the reactions of isolated populations of neurons or glia to specific signals or environmental alterations—e.g., oxidative stress, excitotoxins, neurotransmitters, hormones, and drugs. Some responses may be of a global nature—increases or decreases in energy metabolism or protein biosynthesis—while others may be quite specific to the cell studied or the agent administered.

The availability of transcript maps and collections of “expression motifs” should help us interpret some of the changes observed in human or mouse brain samples. For example, if it were possible to examine the responses of isolated raphe neurons to SSRI treatment *in vitro*, it might be easier to recognize similar responses in tissue samples. Bear in mind, however, that the majority of arrayed genes discovered by sequencing the human genome and large collections of cDNAs are of unknown function. Structural motifs may hint at the function of some gene products (58), but the role of most will remain an enigma. Expression studies may help solve this problem because genes with similar expression profiles often have related jobs. Functional proteomic work will be useful as well. The combination of

two-dimensional gel electrophoresis, ultrasensitive detection methods, and mass spectroscopic analyses will permit researchers to map protein species to specific organelles or macromolecular complexes (59). It is important to remember that most proteins in a cell do not exist or act in isolation. Components of metabolic pathways and regulatory cascades reside in protein communities. Interactions between members of such communities can be detected with yeast two-hybrid methods, and researchers have already begun to examine protein–protein interactions in simple organisms on a genome-wide basis (60 ,61 and 62). Furthermore, yeast "*n*-hybrid" methods have been developed that permit one to look at protein–DNA and protein–RNA interactions (63). Finally, it is worth mentioning that large collections of mice are being produced with random mutations in their genomes. The goal of "saturation mutagenesis" projects is to use multiple screens to identify animals with interesting phenotypes. The goal of investigators who are making insertional mutations in embryonic stem (ES) cell lines, on the other hand, is to determine the insertion site of each cell produced so that knockout animals can be made on demand.

In the future, in analyzing the results of array experiments, the field will benefit from work on animals, proteomics, and earlier expression studies too—but only if everyone adheres to standard formats in archiving and annotating data.

ANNOTATING EXPERIMENTS

Part of "23 - Applying Functional Genomics to Neuropsychopharmacology "

Presently, there are no standards for annotation, but efforts are under way to solve this problem. To create useful and searchable archives, all features of each experiment will have to be described in a standard way using an explicit and unambiguous, "controlled" vocabulary. Some of the required vocabulary already exists. For example, DNAs spotted onto an array can be given and linked to identifiers in public databases. (Unfortunately, different databases sometimes use different identifiers for the same gene. Consequently, the sequence of each DNA on an array should be specified.) Drugs used in array experiments can be referred to by Merck Index number (64), organisms can be described using names in the taxonomy database (65), and mouse strains and mutants can be named according to established rules and guidelines (66). Much of the language needed to describe array experiments has not been standardized, however, and for now databases will have to contain many free-form text fields.

For studies of autopsy samples from psychiatric patients, a good deal of specialized information should be provided. The patient's age at death, gender, diagnosis, genotype (if available), cause of death, postmortem interval, pathology, toxicology screening results, and medication/drug abuse history should be given. The brain region dissected, dissection method used, side of the brain sampled, specimen weight, microdissection procedure and cells selected, RNA extraction method and quality, and labeling method are all essential fields as well. It would be useful to have quality scores for some of these—e.g., the diagnosis and sample condition. Short of a quality score for diagnosis, a detailed description of the key elements of the patient's clinical and laboratory findings should be made available.

Annotating array experiments can be tedious and time-consuming. I am not suggesting that the recommendations above should all be implemented immediately. This would hinder progress. On the other hand, the field would benefit from well-annotated work, and the sooner guidelines are agreed to and implemented, the better. If this chapter serves one useful purpose, it would be to promote this agenda.

Section III
Emerging Imaging Technologies and Their Application to Psychiatric Research

Robert Desimone
Robert Desimone: National Institute of Mental Health, Intramural Research Program, National Institutes of Health, Bethesda, Maryland.

Emerging Imaging Technologies and Their Application to Psychiatric Research - Introduction

In a series of chapters on advances in neuroimaging techniques, it is ironic that images per se of the brain's structures or of neural activity have actually diminished in importance since publication of the American College of Neuropsychopharmacology's Fourth Generation of Progress. The focus of neuroimaging in cognitive neuroscience and psychiatry is widening beyond initial questions of where normal and pathologic functions are localized in the brain, to begin to include questions of how cognitive operations are carried out and why they sometimes fail. For these more mechanistic questions, images become simply measurements for testing hypotheses and are not an end in themselves.

Structural imaging of the brain with magnetic resonance imaging (MRI) is a good example of a field that is no longer restricted to simple localization of pathology in psychiatric disease. Indeed, there are few psychiatric cases that are characterized by clear pathology that is visible in MRI pictures. By contrast, the new analytic approaches to measuring the size of structures in MRI images described by Evans in this section allow one to track small changes in structures over time, which can potentially reveal abnormal patterns of development in either gray or white matter. Recently, for example, these techniques have been used to track the distribution of gray and white matter during development in child-onset schizophrenia, which is characterized by an abnormal time course of gray matter reductions in several different brain systems. These abnormal trajectories suggest possible concomitant abnormalities in synaptic pruning, which is known to take place throughout development. New diffusion-tensor imaging techniques in MRI, described by Makris et al. in this section, add the ability to track major fiber bundles in the white matter, which can give some insight into cortical connectivity. Makris et al. discuss the current limitations with this technique, including the difficulty in following fiber bundles to their termination.

Another evolutionary change in neuroimaging has been the continued shift from positron emission tomography (PET) to MRI-based techniques for indirect measurement of neural activity. However, as described by Fujita and Innis, PET and single photon emission computed tomography (SPECT) remain the only viable techniques for studying ligand binding in the brain, and the resolution of PET is continuing to increase as new detectors are developed. Fujita and Innis review the status of radiotracer development in PET and SPECT and describe new tracers for measuring postreceptor signal transduction and even gene expression. Another relatively new approach to mapping the distribution and concentration of specific molecules in the brain is magnetic resonance spectroscopy (MRS), described by Rothman et al. in this section. The focus of this chapter is on measurements of metabolites involved in neuroenergetics and amino acid neurotransmission, especially the flux through glutamate/glutamine and ɣ-aminobutyric acid (GABA)/glutamine cycles during neural activity. GABA metabolism, in particular, appears to be sensitive to both psychiatric disorders, such as depression, and to pharmacologic treatment.

Some of the biggest advances in functional MRI (fMRI) methodology for the indirect measurement of neural activity have been in the time domain. Bandettini describes new methods for improving the temporal resolution of fMRI, in particular event-related designs. In more traditional blocked-trial designs, the BOLD signal is averaged for many seconds, typically for several trials of a behavioral task. However, with event-related designs, one can measure BOLD changes for events lasting less than 2 seconds, which allows one to distinguish activity changes in one part of a trial from another, e.g., from the encoding to the retrieval phase of a trial in a memory task.

The specific application of both fMRI and brain-lesion analyses to studies of mood and emotion is the focus of the chapter by Davidson. The brain systems important for the regulation and expression of mood and emotion are highly distributed, and thus it is essential to take a systems approach to imaging and lesion data in this field, rather than a “function per brain structure” approach. Davidson also describes how basic behavioral research lays the necessary groundwork for studying mood and anxiety disorders, and he gives specific examples of basic research into fear and anxiety and its implications for understanding disorders such as social phobia.

Despite improvements in the temporal resolution of fMRI, the technique will never approach the temporal resolution of event-related potential (ERP) methods, which is at the millisecond level. As described by Hillyard and Kutas, new analytic techniques have improved the spatial resolution of ERPs, and there has been considerable progress in combining the spatial resolution of fMRI with the temporal resolution of ERPs. Perhaps even more important than these technologic advances, there have been conceptual advances in understanding the functional components of ERP signals through the application of cognitive theory to ERP paradigms. For example, there are characteristic signals found in visual tasks for the arrival of visual information in a cortical region, for the modulation of this signal by attention, and for the decoding of the visual information into semantic information. With the appropriate task design and with the large base of information acquired on the timing of these cognitive operations in normal subjects, one can then begin to ask how these operations differ in schizophrenia, for example.

Finally, the techniques described in the chapters in this section allow one to create and test models of the functional interactions between different brain structures, but they provide no direct evidence of functional connectivity. One new, direct approach to functional connectivity is an analytic technique known as effective connectivity mapping, described by BÜchel and Friston. Here, one makes use of the moment-to-moment relationships between fMRI signals in different brain regions to create structural equations, which can quantify the contribution of activity in one brain structure to the activity in another. An even more direct approach to measuring connectivity is through the combined use of transcranial magnetic stimulation (TMS) and fMRI, described by George and Bohning. They describe studies in which brain structures are directly stimulated with TMS, and the resulting effects on far-removed brain structures, including in the opposite hemisphere, are measured using fMRI.

The chapters in this section describe an impressive armamentarium of techniques now available to brain imaging researchers, and they outline some promising new directions in the application of these techniques to mental illness. Together, the chapters show that the key to progess in brain imaging studies of pathophysiology will be to see beyond the images.

24

Automated 3D Analysis of Large Brain Mri Databases

Alan C. Evans

Alan C. Evans: Department of Neurology, McGill University, Montreal Neurological Institute, Montreal, Quebec, Canada.

In recent years, the study of gross neuroanatomy and its relationship to behavior and brain function has been reenergized by the advent of imaging techniques and the powerful computational tools with which to analyze high-resolution three-dimensional (3D) brain images (10 ,11 ,22 ,52 ,53). However, such high technology tools often demand that scientific questions be restated and made more amenable to quantitative analysis. Questions such as “How much normal variation is there in the size, shape, or location of an individual brain structure?” or “To what extent does functional architecture of the cortex depend on the anatomic boundaries between anatomic regions?” carry with them the assumption that the borders of individual structures can be specified accurately in any brain. In the past, basic questions of functional neuroanatomy were difficult to address in a systematic way in the living brain. We have learned much from anecdotal reporting of individual patients with various forms of brain lesion or from direct cortical stimulation during brain surgery, but the generalization of individual observation to the wider population has been confounded by the normal variation in brain structure itself. There is then a fundamental interest in understanding the nature of anatomic variability in the population, both for its relationship to functional variability and for the potential of using structural abnormality as a measure of development, normal aging, and disease. For instance, in some degenerative diseases like Huntington's disease and Alzheimer's disease, the sulci become more open and the ventricles become enlarged. Magnetic resonance imaging (MRI)-based measurements of these changes can lead to early diagnosis and treatment, but we need to understand the variation among normal brains first.

Although the study of postmortem neuroanatomy is a long-established science, the ability to accumulate the numbers of brains necessary to make statistically meaningful conclusions about cerebral anatomy is a relatively recent phenomenon. It is still difficult to identify reliably in any single brain the anatomic landmarks, boundaries, and other delimiting features necessary for any subsequent analysis. Thus, we face a new problem posed by this newfound technology and its inflexible demand that anatomic questions be posed in numerical rather than descriptive terms. The tools exist to image large numbers of brains noninvasively with MRI, but we are still struggling with how to extract the anatomic measurements necessary to answer the questions posed above. It is relatively easy to identify the precentral gyrus, but few researchers attempt to define its “top” and “bottom.” Where does the inferior frontal sulcus end? Traditional brain atlases identify brain regions only by pointing to the middle of the region or surface feature, leaving the interfaces between regions unspecified. Neuroanatomists debate the exact boundary of even relatively simple structures such as the thalamus or caudate nucleus. With this context, new initiatives at various laboratories are attempting to standardize and codify the partitioning of the human brain into named regions, not without controversy. Traditional neuroanatomists debate among themselves about what parcellation scheme and nomenclature to use. Computer scientists argue among themselves about whether to use hierarchical, relational, object-oriented, or some other form of database structure to organize the brain parcellation. Both groups tend to misunderstand the importance of the other's concerns. Neurobiologists or physicians are not used to thinking in terms of inclusive sets where, for instance, every structure at one level is wholly included within a higher level organization, where all 3D pixels, i.e., voxels, within the brain space *must* be labeled as one of the structures in the partitioning scheme, or that the cerebrospinal fluid (CSF) ventricular spaces may be declared as being outside of “brain.” Computer scientists tend to ignore the realities that many cortical sulcal features do not exist in every brain, and may be fragmented or have multiple occurrences. Some sophisticated analytic approaches for quantifying anatomic variability assume that a particular landmark can be perfectly identified in any brain when the reality is that errors of 5 to 10 mm typically occur, an error that is about

the same magnitude as the true spatial variation being sought.

Despite heroic efforts in the recent past (2 ,29 ,58 ,60 ,62 ,75 ,79 ,80), manual labeling of many individual MRI data sets in 3D is a labor-intensive effort that is not likely to be widely adopted. Fully automated techniques that produce accurate neuroanatomic segmentation in large numbers of MRI data sets are essential if questions of normal cross-sectional variability, normal longitudinal development, and detection of abnormality in single subjects or in groups are to be answered definitively. Many groups are now engaged in the field of MRI-based quantitative neuroanatomy, and an exhaustive review of the field is beyond the scope of this chapter. A representative sampling of activity by other groups in the field, categorized into the four forms of segmentation discussed in the subsequent Methods section, include the following:

- Tissue classification/voxel morphometry: This refers to MRI intensity-based classification of images into tissue classes and voxel-based statistical analysis of the resulting class maps. In normal brain, the tissue classes are typically gray matter, white matter, and CSF, although there is no reason in principle to restrict to these three tissue types. In these approaches, one or more co-registered MRI images of the same neuroanatomy, obtained using different acquisition protocols [e.g., T1-weighted, T2-weighted, proton density (PD), magnetization transfer), provide the input data. At each voxel the MRI intensity for each of the *N* input images provides an *N*-dimensional "feature vector." Ideally, each tissue class is identified by a unique feature vector. In practice, many confounding factors (e.g., tissue heterogeneity, MRI field distortions, partial volume effects, and image noise) blur the feature space and render it difficult to distinguish accurately even three tissue classes. Many different multivariate statistical methods exist to optimize the class labeling and, for most of them, more independent images (features) help to disentangle overlapping class distributions in feature space.

  Mapping the segmented images into stereotaxic space (69 ,70) allows for group analysis across a population of 3D data sets from different individuals. All of the machinery of random field statistical analysis developed for functional imaging then becomes available for structural analysis (1 ,5 ,30 ,31 ,35 ,54 ,56 ,57 ,81 ,82 and 83).

- Regional parcellation/atlas deformation: Delineation of brain regions within each tissue class (e.g., caudate nucleus in the gray matter class) is not possible using only the information available in the MR image(s) since there is not sufficient differentiation among these regions within the feature space. Some form of prior information on neuroanatomic boundaries is needed, usually in the form of a computerized brain atlas, to assist in 3D brain regional labeling. Regions can be identified by vector boundaries or by labeling of all internal voxels. The atlas or parcellation scheme can be used as a guide to manual segmentation or as the basis for automated regional segmentation in which the atlas space is deformed to match each new 3D brain image. The atlas template is matched to the new MRI volume through a variety of nonlinear deformation techniques, the most successful of which use image similarity criteria to deform one image into another.

  Once delineated in their native space it is possible to map the regional labels into stereotaxic space in much the same way as tissue class maps and to conduct voxel morphometry among groups using the random field statistical analysis (3 ,4 ,6 ,12 ,18 ,18 ,21 ,26 ,32 ,34 ,36 ,39 ,40 and 41 ,50 ,68).

- Surface extraction/cortical unfolding: Regional parcellation is generally quite successful at labeling relatively well-defined 3D brain regions, such as the thalamus, but is typically less successful in identifying cortical gyri. Indeed, the cortex as such is sufficiently important to merit special analytic treatment. Techniques have been developed to "extract" the exterior cortical surface automatically by boundary detection of the intensity interface between gray matter and subarachnoid CSF. To overcome partial effects, some groups have targeted the internal cortical margin at the interface between gray and white matter. Obtaining a measure of the two surfaces simultaneously allows for a measure of cortical thickness at each location over the cortical surface.

  Extraction of the cortical surface has prompted some groups to explore the potential of an "unfolded" cortical surface as a means of studying functional neuroanatomy on a two-dimensional (2D) plane. Arguably, this device reduces the variability of functional areas introduced by cortical folding in three dimensions. The mapping from 3D to 2D is a nontrivial task with many issues surrounding the optimal mapping function, with direct analogies to the well-known cartographic dilemmas of preservation of area, direction, distance etc. (7 ,8 ,20 ,27 ,28 ,38 ,49 ,55 ,77 ,78).

- Sulcal extraction/analysis: The cortical sulci have held a historical position of prominence in functional neuroanatomy, in part because of their utility as approximate landmarks to functional areas. Recent interest has centered upon extracting not just the surface trace of the sulcus as a line but rather the depth of the sulcus as a ribbon. The latter approach provides more information on buried cortex and sulcal shape than a simple line trace, which can be related to genetic and developmental considerations (46 ,51 ,59 ,65 ,76).

In the United States, the Human Brain Project has specifically set out to foster the application of computational techniques, hardware, and algorithms to neuroscience at all spatial scales. We are involved in one of these applications operating at the gross morphology level. The International Consortium for Brain Mapping (ICBM) (52), seeks to create a so-called probabilistic human brain atlas (see below).

This chapter provides an overview of the methods developed by the Brain Imaging Centre (BIC) at the Montreal Neurological Institute for fully automated 3D segmentation of the ICBM database and other MRI databases like it, such as those collected for the creation of normal pediatric development and for evaluation of new pharmaceuticals. A key concept underlying this work is that of the analysis "pipeline," which takes 3D MRI volumes from large numbers of subjects and generates 3D statistical maps of adult brain morphology with no manual intervention. The pipeline concept has also been implemented for clinical trial analysis of MRI data from multiple sites. All data sets, across patients, time points, and pulse sequences, are mapped into a standardized 3D coordinate space for automatic segmentation and statistical analysis.

Once the MRI image has been segmented, each voxel in the 3D image space carries an anatomic label and a measure of the confidence in that label. This information can be used in a variety of ways to detect subtle neuroanatomic or neuropathologic changes:

- Single subject vs. group data for detection subtle of structural abnormality (e.g., misshapen corpus callosum)
- Intergroup cross-sectional comparison (e.g., Alzheimer's disease group vs. normal age-matched controls)
- Longitudinal study in a single subject (e.g., tumor growth, progressive atrophy)
- Longitudinal study in a group [e.g., early development and aging in normal populations, multiple sclerosis (MS) disease progression].

Illustrative example applications of some of these capabilities are described at the end of the chapter.

IMAGE SEGMENTATION METHODS

Part of "24 - Automated 3D Analysis of Large Brain Mri Databases "

Within the BIC image analysis pipeline, MRI data are processed using a series of tools that provide measurements of volume, shape, size, and tissue composition of selected brain regions. These are summarized below. To manage the flow of MRI data through the pipeline, we have developed PCS (Production Control System), which allows the rapid implementation and parallel execution of analysis pipelines for processing large MRI databases. Each processing stage in the pipeline is performed by a single command. PCS allows the user to specify this command with its options, input and output files, and dependencies on other stages in the pipeline using a simple script language. Efficient coarse-grain parallelism is achieved by distributing the individual jobs over a network of workstations. PCS monitors the status of each job and submits a new job when the prerequisites for submission have been satisfied (typically the completion of all stages on whose output data the stage depends). The major elements of this environment include (Fig. 24.1):

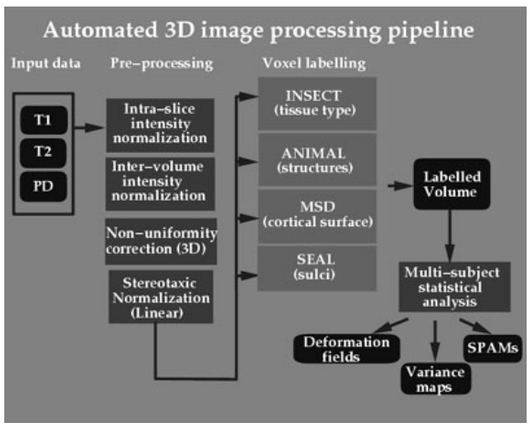

FIGURE 24.1. Brain Imaging Centre (BIC) pipeline environment for magnetic resonance imaging (MRI) processing: major components of pipeline analysis of large ensembles of MRI multispectral data sets. Each multispectral data set yields labeled maps of tissue type, three-dimensional (3D) brain region, and cortical topology.

- Thin-slice MRI data acquisition (typically 1-mm axial sampling, with 1-mm isotropic voxels).
- Multimodal, multidimensional stereotaxic data format (MINC).
- MRI simulator for validation of segmentation algorithms (MRISIM).
- Correction for coil-dependent 3D intensity nonuniformities (N3).
- Within-subject registration of different sequence volumes (MINCTRACC).
- Cross-subject mapping into a standardized "stereotaxic" 3D coordinate space (MRITOTAL).
- Fully automated 3D classification of gray/white/CSF tissue classes (INSECT).
- Fully automated 3D regional segmentation based on prior atlas templates (ANIMAL).
- Fully automated 3D extraction of gray/CSF and gray/white cortical interfaces (MSD, ASP).
- Computer-assisted 3D labeling of individual sulci (SEAL).

Stereotaxic Image Format—MINC

A fundamental aspect of this pipeline environment and its interaction with other sites within ICBM is the MINC image format for intersite data communication. MINC (Medical Image Net CDF), developed at the MNI by Peter Neelin, is a multidimensional, multimodality image file format that supports stereotaxic coordinate representation.

Image volumes can be explored in real time in 3D with continuous update of stereotaxic coordinates. Image files with different native voxel dimensions can be compared directly without regard for the original acquisition sampling grid. This simplifies stereotaxic analysis of MRI data ensembles collected with different voxel dimensions.

MRI Simulation—MRISIM

To assist in the evaluation of these segmentation tools, we created an average MRI data set of a single young normal male, by repeated MRI scanning followed by linear alignment of all volumes. A total of 27 separate MRI scans were collected. The improved signal-to-noise ratio (SNR) in the composite MRI, termed ICBM27, produces a high-definition data set (37), suitable for brain atlas construction, validation of segmentation/mapping algorithms, and MRI simulation. (Note: Since it incorporates the structural idiosyncracies of a single brain, it is not intended for use as a high-definition master data set for stereotaxic normalization.) This data set has been segmented manually to create an accurate digital phantom (17) for use as the source template of an MRI simulator, MRISIM (43).

MRISIM requires as input a set of “fuzzy” structure maps, one for each distinct tissue (or structure) type to be modeled, in which each voxel value is the probability of that voxel containing that tissue (structure) type. Such maps are generated by algorithms like INSECT or ANIMAL (see below) applied to a high-SNR data set. The MRI signal is simulated by solving the Bloch equations for the specified pulse sequence and tissue relaxation characteristics. Noise is modeled from first principles rather than by adding some parametric (e.g., gaussian) noise distribution to the expectation image (42). MRISIM has been used in validation studies for correction of MRI intensity nonuniformity (67) and tissue classification (84). It has been used to create a database of 108 simulate MRI images [3 slice thicknesses × 3 tissue contrasts (T1/T2/PD) × 3 noise levels × 4 levels of radiofrequency (RF) inhomogeneity], available at Web site http://www.bic.mni.mcgill.ca/.

Correction for 3D Intensity Nonuniformity—N3

A major problem for automated MRI image segmentation is the slowly varying change in signal intensity over the image, caused principally by nonuniformities in the radiofrequency field (Fig. 24.2). Apparent signal from any one tissue type is therefore different from one brain area to another, confusing automated segmentation algorithms that assume constant signal for one tissue type. We have developed a fully automated 3D technique for inhomogeneity correction, modeling inhomogeneity as the convolution of the true MRI intensity histogram with a blurring kernel. This effective kernel can be estimated and deconvolved by iterative entropy maximization. The method is applicable to any pulse sequence, field strength, and scanner (66 ,67).

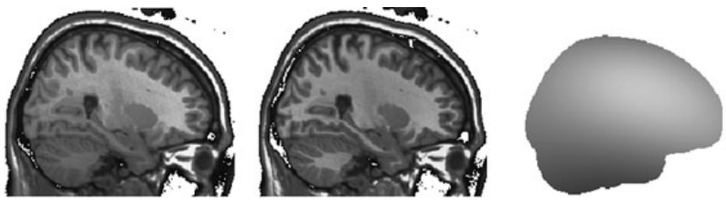

FIGURE 24.2. N3 correction for intensity nonuniformity. MRI image before (*left*) and after (*middle*) correction for nonuniformity field (*right*), estimated using N3. Note the increased uniformity of white matter regions.

Intrasubject Image Alignment—MINCTRACC

Alignment of images from the same subject, either from the same modality at different times in a longitudinal study or from different modalities, is achieved using a linear version of ANIMAL (see below), constrained to a six-parameter (three rotation, three translation) rigid-body transformation (15).

Stereotaxic Transformation—MRITOTAL

Stereotaxic transformation is achieved using a simple nine-parameter linear [three rotation, three translation, three scale, (15)] transformation to match the image volume to a master data set already resident in stereotaxic space. The master data set therefore defines the gross dimensions and orientation of stereotaxic space. We have previously constructed

a composite stereotaxic MRI data set drawn from 305 normal subjects, sampled on a 1-mm voxel grid (24), as that master data set. This mean data set, now termed ICBM305, has been circulated to over 100 international sites and defines the stereotaxic space for the SPM statistical package. That data set was derived from T1-weighted data with 2-mm-thick slice data. More recently, this has been superseded by a composite data set derived from 1-mm-thick data collected within the ICBM project (see below). That latter data set, while exhibiting higher contrast and more anatomic detail than the original ICBM305, was nevertheless mapped into the space of the ICBM305 using the nine-parameter MRITOTAL and is therefore a derivative of that first data set.

Tissue Classification—INSECT

We have developed an algorithm for tissue classification, known as INSECT (Intensity-Normalized Stereotaxic Environment for Classification of Tissue) (25 ,63 ,84). The algorithm operates upon multispectral (typically T1-, T2-, PD-weighted) data sets. In a series of preprocessing steps, each MRI data set is corrected for intensity nonuniformity (67), interslice normalization, and intersubject intensity normalization (Fig. 24.3). Stereotaxic transformation is then performed (15). An artificial neural network (ANN) classifier with one hidden layer is used to assign each voxel to a tissue type (gray/white/CSF) based on its MRI intensity feature space. The algorithm also employs tissue likelihood, based on the spatial location of the voxel in stereotaxic space, as orthogonal prior information to constrain the feature-space assignment. For example, periorbital fat exhibits a similar feature-space signal as white matter and, without consideration of spatial location, would be classified as white matter. Spatial masks expressing the normal distribution of tissue classes in the population (see Fig. 24.8) indicate that the likelihood of finding white matter in the periorbital stereotaxic region is small, and reduce the likelihood of misclassifiation.

INSECT operates on an arbitrary number of input images and generates a user-selected number of output tissue maps.

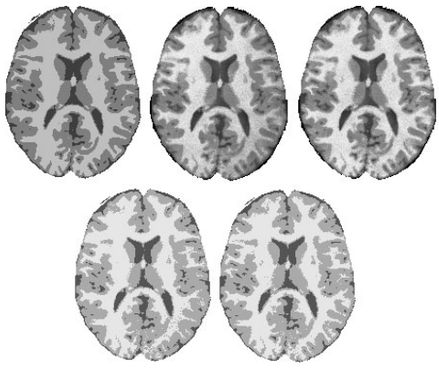

FIGURE 24.3. Classification with and without correction for intensity nonuniformity: tissue classification with INSECT with and without correction for nonuniformity using N3. An idealized 3D digital phantom was created from by segmentation of a high=nsignal-to-noise ratio (SNR) data set (17,37). The initial phantom data (*top left*) contains three classes: cerebrospinal fluid (CSF) (*black*), gray matter (*dark gray*), and white matter (*light gray*). This phantom was used to generate a simulated MRI image with (*top middle*) and without (*top right*) a 20% inhomogeneity running from *top left* to *bottom right* of the image. The INSECT-classified image without prior N3 correction (*bottom left*) exhibits artifactually thicker cortex at *bottom right* and thinner cortex at *top left* of the image, respectively, a consequence of the field inhomogeneity gradient. This artifact is removed in the N3-corrected classification (*bottom right*).

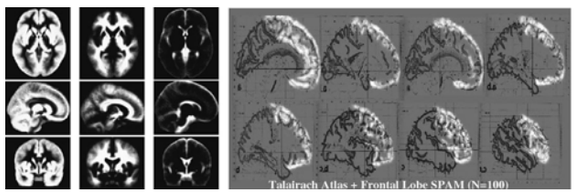

FIGURE 24.8. Tissue probability maps. **Left**: Cuts through INSECT-generated 3D tissue class maps for gray matter, white matter, and cerebrospinal fluid (CSF). **Right**: Serial sagittal sections through Talairach atlas with ANIMAL-generated probabilistic frontal cortex SPAM (statistical probability anatomy map) overlaid. In both cases 100 subjects were used to generate the SPAMs.

Regional Parcellation—ANIMAL

Manual labeling of brain voxels is both time-consuming and subjective. We have previously developed an automated algorithm to perform this labeling in 3D (13). The ANIMAL algorithm (Automated Nonlinear Image Matching and Anatomical Labeling), deforms one MRI volume to match another, previously labeled, MRI volume. It builds up the 3D nonlinear deformation field in a piecewise linear fashion, fitting cubical neighborhoods in sequence using a mutual information residual for parameter optimization (Fig. 24.4). The algorithm is applied iteratively in a multiscale hierarchy. At each step, image volumes are convolved with a 3D gaussian blurring kernel of successively smaller width [32-, 16-, 8-, 4-, and 2-mm full-width at half-maximum (FWHM)]. Anatomic labels are defined in the new volume by interpolation from the original labels, via the spatial mapping of the 3D deformation field. Originally, ANIMAL used 3D gradient magnitude as the image property to be matched. The ridge-tracking Lvv operator is now used to extract additional topologic information on brain shape in each image. Furthermore, the surface trace of major sulci, represented as 3D line segments, can be used as local constraints on image deformation (14 ,16). Both steps increase the correspondence of cortical anatomy across brains.

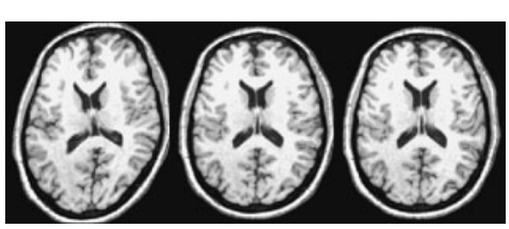

FIGURE 24.4. ANIMAL warping. Slice through a 3D ANIMAL deformation. The *left* image was warped to match the *right*, with the result in the *middle*.

Cortical Surface Segmentation and Unfolding—ASP

We have previously developed a fully automated procedure for unfolding the entire human cortex, using an algorithm that automatically fits a 3D mesh model to the cortical surface extracted from MRI (47). This algorithm, MSD, uses an iterative minimization of a cost function that balances the distance of the deforming surface from (a) the target surface, and (b) the previous iteration surface (Fig. 24.5). Specification of the relative weight of these competing forces allows MSD to range from unconstrained (data-driven) deformation to tightly constrained (model-preserving) deformation. Further shape-preserving constraints to penalize excessive local stretching and bending of the model surface are also employed. The initial mesh surface can be chosen arbitrarily to be a simple geometric object, such as a sphere, an ellipsoid, or two independently fitted hemispheres. The MSD algorithm has formed the basis of cortical analysis at both MNI and UCLA within the ICBM project (71 ,72 and 73). Recently, the algorithm has been extended to allow multiple concentric surfaces to be mapped simultaneously. The new algorithm, Automatic Segmentation

using Proximities (ASP), has the following refinements and capabilities (48), compared with the earlier MSD version:

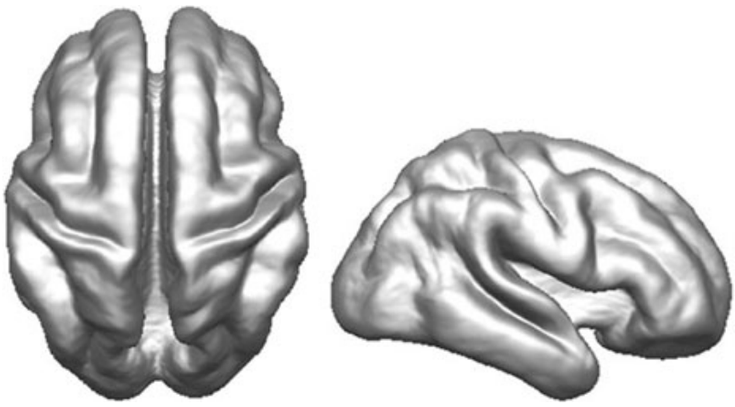

FIGURE 24.5. Average cortical surface. Average of 150 normal cortical surfaces. Note the prominence of the major gyral and sulcal features common to all brains.

- A boundary search along the normal local surface is used to increase the range of attraction of edges.
- The use of proximity constraints with appropriate weights excludes the potential for impossible self-intersecting surface configurations.
- Some arbitrary weights are replaced by more intuitive geometric constraints.
- Multiple surfaces, models, and data sets may be combined into a single objective function.
- Automatic identification of the total cerebral cortical surface from MR images is achieved in a robust way with respect to partial volume effects.
- A preliminary map of cortical gray matter thickness has been produced and related to previous studies.
- A higher resolution average brain surface has been created using the deeper sulcal penetration of ASP compared to earlier versions of this algorithm (47).

As an alternative form of stereotaxy applicable to cortical analysis, ASP also provides a fully automated mapping from 3D to an unfolded surface space. Since ASP iteratively deforms a starting 3D polygonal mesh onto the 3D cortical surface, the inverse mapping projects this fitted surface and topologic feature at each surface vertex back to the model space (47 ,48). Individual anatomic features such as gyral ridges and sulcal valleys are converted to measures of topology, e.g., curvature, mapped on to the model surface. These can be analyzed in terms of 2D variability on the surface of the starting model using a 2D surface coordinate space (Fig. 24.6).

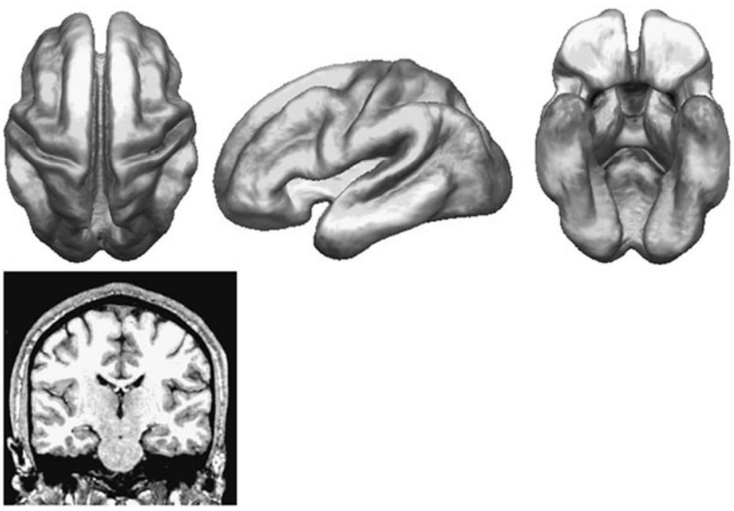

FIGURE 24.6. Cortical thickness. Mean cortical thickness in 150 normal adult brains, color-coded and texture-mapped onto the average cortical surface obtained from the same population.

Sulcal Extraction and Labeling—SEAL

We have implemented an automated sulcal extraction and labeling algorithm (SEAL) (45). At every voxel on the ASP-generated exterior cortical isosurface, SEAL calculates the two principal curvatures: k1, the mean curvature, and k2, the gaussian curvature (g = k1 * k2). Voxels with negative

mean curvature, belonging to sulci, are extracted and pruned to obtain a set of sulcal traces on the cortical surface. SEAL extracts the buried sulcus with an “active ribbon” that evolves in 3D from a superficial trace to the bottom of a sulcus by optimizing an energy function. We have defined a relational graph structure that stores, for each sulcus, its length, depth, and orientation, as well as attributes, e.g., hemisphere, lobe, sulcus type, connecting sulci, etc. Sulcal labeling is performed semiautomatically by tagging a sulcal trace in the 3D graph and selecting from a menu of candidate labels. The menu is restricted to most likely candidates by the use of sulcal probabilistic maps. SEAL identifies the sulci maps that overlap with each selected sulcus with highest likelihood (44 ,45) (Fig. 24.7).

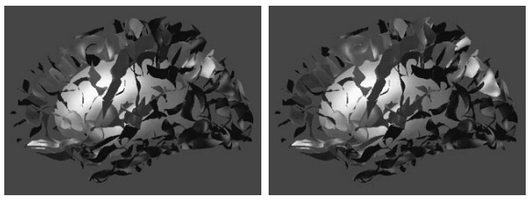

FIGURE 24.7. Use of spatial priors for automatic sulcus labeling within the sulcal extraction and labeling algorithm (SEAL). 3D representation of labeled sulcal folds occurs either automatically with SEAL, using prior probabilities (*left*), or manually labeled by a neuroanatomist (*right*). Different colors represent different sulcal labels, e.g., central sulcus is colored magenta (the smooth object is an average MRI surface, reduced in scale, included only to provide context for the sulcal maps). The automated and manual labeling of the sulci are in broad agreement, although some differences are apparent.

SAMPLE APPLICATIONS

Part of "24 - Automated 3D Analysis of Large Brain Mri Databases "

ICBM: Multicenter Consortium on Statistical Neuroanatomy

The International Consortium for Brain Mapping (ICBM) multicenter initiative was launched in 1993 as part of the Human Brain Project (52). Its overall goal is to create a 3D probabilistic brain atlas, based on MRI volumes from 450 normal adult brains. Within the ICBM project, all scans at all sites were collected with a strictly defined protocol, specifying three MRI volumes per subject (a 1-mm-thick, 1-mm-spaced gradient echo sequence for T1-weighted data and a 2-mm-thick, 1-mm-spaced double-echo sequence for PD and T2-weighted volumes). This database as been segmented using the pipeline environment described above and the variability captured in the form of probability maps as follows. Neuroanatomic variability can be conveniently represented in the form of 3D stereotaxic maps where each voxel expresses the likelihood of finding a particular structure at that location. By labeling one structure, e.g., caudate nucleus, in an ensemble of stereotaxic MRI volumes, a continuous 3D probability field for that structure (0% to 100% at each voxel), termed a statistical probability anatomy map (SPAM), can be constructed and used to test for group difference, e.g., pediatric versus adult brains, or outliers. For visualization purposes, these statistical maps can the thresholded at any level of structural probability to create probability isosurfaces suitable for surface-rendering and 3D display. Example SPAMs are shown for (a) gray/white/CSF tissue classes (INSECT, Fig. 24.8); (b) all major cortical gyri, cerebellum, and deep nuclei (ANIMAL, Fig. 24.8 and Fig. 24.9); and (c) cortical surface (ASP) (23).

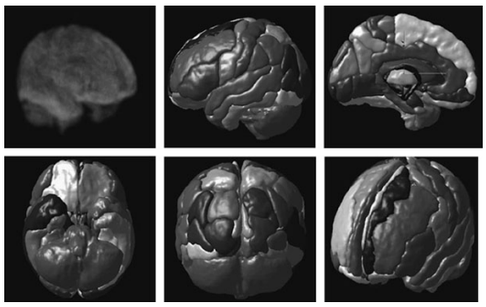

FIGURE 24.9. Rendered probabilistic atlas. Volume rendering (*top left*) and surface renderings (*all others*) of the 3D probabilistic atlas (*N* 100). For the surface renderings, the SPAMs were thresholded at the 40% level to generate regional probability isosurfaces.

Multicenter Clinical Trial Image Analysis

The principles of pipeline analysis described above for large databases of normal brain MRI data are equally applicable for population analysis of neuropathology or for tracking structural change over time, such as the progressive tissue atrophy, which occurs in some degenerative diseases. Indeed, the MRI analysis employed within the ICBM project was originally developed for a multicenter phase III clinical trial of a new pharmaceutical for treatment of multiple sclerosis. In this trial, 14 centers in the U.S. and Canada collected a total of 1,850 data sets, each data set composed of T1, T2, and PD volumes, from 514 subjects. All data collection was coordinated by the BIC clinical trials group, which performed quality control before trial launch and for all data shipped to the BIC for processing. Pipeline analysis of the database was used to generate 3D statistical maps of normal tissues and of MS lesions. In validation studies, the

results obtained with this automated approach for a subset of images were compared with those obtained by totally manual methods at seven established MRI/MS sites in Europe and North America. The results of the comparison indicated no significant differences between the BIC approach and the mean result obtained across the seven sites. They also indicate considerable variability among the sites themselves when analyzing the same data, which emphasizes the importance of the reproducibility of results obtained with a fully automated approach.

After correction for MRI intensity inhomogeneity, interslice and intervolume intensity normalization, and stereotaxic transformation, the multispectral data were tissue classified to identify MS lesion voxels for each patient time point. Figure 24.10 shows a 3D rendering of a probability map for lesion distribution obtained from all data sets. It shows the most likely locations for MS lesions within a population and is a convenient way to distill a large amount of population data into a single entity. Tests of drug effect are reduced to testing for a significant group difference in the overall volume of this distribution above a given threshold when partitioned into drug and placebo groups.

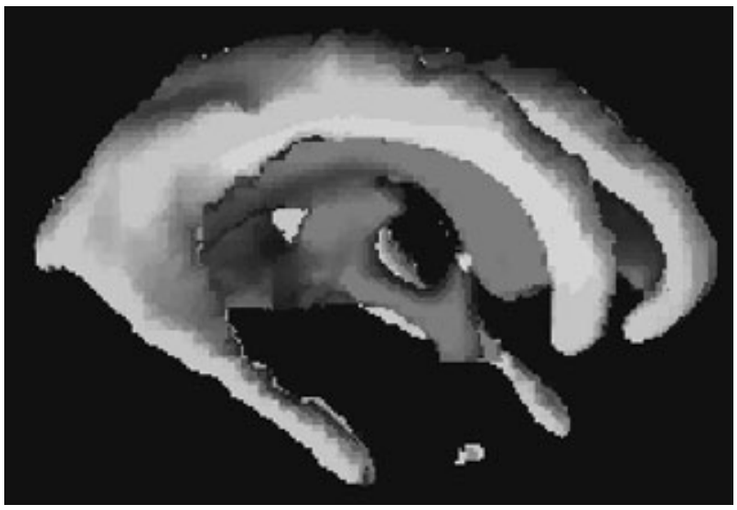

FIGURE 24.10. Multiple sclerosis (MS) lesion probability map. 3D renderings of probability maps for MS lesion (*light region*) and ventricle (*dark region*), obtained from 460 patients.

NIMH Intramural Pediatric Database

As part of an ongoing collaboration with Drs. Jay Giedd and Judy Rapoport at the National Institute of Mental Health (NIMH) Child Psychiatry Branch, the BIC image analysis pipeline has been used to process a large pediatric MRI database collected at the NIMH. Subjects were scanned on a General Electric 1.5 tesla Signa scanner using a 3D SPGR protocol. Approximately 1,800 T1-weighted images with slice thickness of 1.5 to 2.0 mm in the axial plane have

been obtained in approximately 600 children aged 3 to 18 from a number of subgroups:

- Normal development: A subset of this database, 111 normal children aged 4 to 17, was processed using the INSECT algorithm. All data were resampled into stereotaxic space using a simple nine-parameter linear transformation prior to image segmentation. Regression of population mean white matter intensity at each stereotaxic voxel against age yielded a regression map with significant correlation in the left arcuate fasciculus and the bilaterally in the internal capsule (33 ,61). The former tract links the anterior and posterior speech regions, while the latter is part of the corticospinal motor tract. These areas are continuously developing during maturation and it is tempting to interpret the results as increased myelination in these areas during development.

  A subset of the intramural NIMH database has also been analyzed by the ICBM group at UCLA under the direction of Arthur Toga (74). Using MSD-generated surfaces and tensor field analysis, they produced fourdimensional quantitative maps of growth patterns in the developing brain. Serial scanning in children aged 3 to 15 years across time spans of up to 4 years revealed a rostrocaudal wave of growth in the corpus callosum, a fiber system that relays information between brain hemispheres (Fig. 24.11). Peak growth rates, in fibers innervating association and language cortices, were attenuated after puberty, and contrasted sharply with a severe, spatially localized loss of subcortical gray matter. Conversely, at ages 3 to 6 years, the fastest growth rates occurred in frontal networks that regulate the planning of new actions.

- Child-onset schizophrenia: Fifteen patients with childhood-onset schizophrenia and 34 temporally yoked, healthy adolescents, scanned twice with an interval of 4 years, were analyzed using the pipeline (64). Lobar gray and white matter volumes were obtained with INSECT and ANIMAL. A significant decrease in cortical gray matter volume was seen for healthy controls in the frontal (2.6%) and parietal (4.1%) regions. For the childhood-onset schizophrenia group, there was a decrease in volume in these regions (10.9% and 8.5%, respectively) as well as a 7% decrease in volume in the temporal gray matter. Thus, the childhood-onset schizophrenia group showed a distinctive disease-specific pattern, with the frontal and temporal regions showing the greatest between-group differences. Changes in white matter volume did not differ significantly between the two groups. Patients with very early onset schizophrenia exhibit a fourfold greater decrease in cortical gray matter volume during adolescence and a disease-specific pattern of change.
- Attention-deficit/hyperactivity disorder (ADHD): Anatomic studies of boys with ADHD have previously detected volumetric differences in basal ganglia, prefrontal regions, and the cerebellar vermis. This study sought to

replicate those findings in young girls. MRI data from 53 girls with ADHD and 44 healthy matched female controls, ages 5 to 15, were analyzed using ANIMAL. Significantly smaller volumes were observed in prefrontal brain regions, caudate nucleus, globus pallidus, and amygdala bilaterally. The posterior-inferior cerebellar vermis volume and the rostrum of the corpus callosum were also significantly smaller in the ADHD group. Significantly smaller volumes were seen in the same brain regions as previously reported in boys with ADHD. As in boys, ADHD in girls is associated with anatomic deviations in corticostriatal-pallidal-thalamic circuits and in the posterior-inferior cerebellar vermis (9).

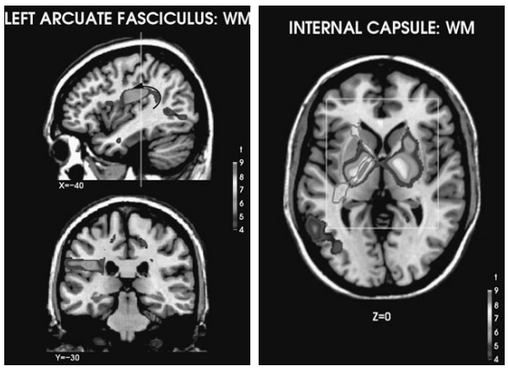

FIGURE 24.11. White matter density changes during pediatric development. Regression maps of white matter density changes over the age range from 4 to 17 (61). These maps show increased white matter density, possibly myelination, in the left arcuate fasciculus (*left*) and internal capsule (*right*), white matter tracts implicated in the development of language and motor skills, respectively.

NIH Extramural Pediatric MRI Database

The NIMH intramural database above has been acquired with only T1-weighted information and sparse behavioral information from a variety of subgroups, including approximately 200 normal children aged 3 to 8. While this database will provide much valuable information on pediatric development, there remains a need to create a more complete database of MRI information from a larger cohort of normal children, well-characterized by behavioral batteries. Therefore, a recent joint initiative by three National Institutes of Health (NIH) agencies (NIMH, NICHD, NINDS) has been launched to create such an MRI database of normal pediatric development in 550 children. This project, drawing upon a clinical trial model, will collect identical imaging and behavioral data at seven U.S. sites. The data will be consolidated into a single database at the BIC for pipeline analysis and eventual dissemination to the community. Each child in the age range of 5 to 18 will be scanned three times over a 6-year period. Behavioral batteries covering the major performance criteria will be collected at each time point. A younger cohort of approximately 100 children, aged 0 to 5, will undergo a more frequent scanning protocol and an age-appropriate behavioral battery. Magnetic resonance spectroscopy (MRS) and diffusion tensor imaging (DTI) information will also be collected at three of the sites to provide information on developmental neurochemistry, myelination, and fiber tract development.

SUMMARY AND FUTURE DIRECTIONS

Part of "24 - Automated 3D Analysis of Large Brain Mri Databases "

This chapter has presented an overview and sample applications of the MRI analysis pipeline environment at the Brain Imaging Centre (BIC) of the Montreal Neurological Institute. The key conceptual elements of this environment are as follows:

1. The use of stereotaxic space for consolidation of large ensembles of MRI data into a common spatial frame for analysis of gross neuroanatomy;
2. Fully automated 3D image preprocessing and segmentation;
3. Statistical analysis using voxel-bases random field theory and general linear models;
4. Incorporation of nonimaging parameters such as behavioral variables, demographic information, and genetic data into the statistical models.

The pipeline is highly modular, allowing for separate development and continued upgrading of the individual elements making up the pipeline. Processing is distributed across the BIC computing infrastructure using the PCS control scripts to optimize the utilization of resources. It has application in a variety of settings from basic neuroscience through clinical research to clinical trials. However, the current environment is focused on gross morphology. Conventional MRI allows us to collect gross anatomic information from a large sample of brains and develop population statistics. Unfortunately, this level of analysis provides no information about the cellular and molecular organization of the brain at a finer scale. A full understanding of functional neuroanatomy links function to macroscopic anatomy via these ultrastructural segregations. High-field MRI offers new possibilities, providing resolution of a few hundred microns over limited volumes. Sectioning, staining, and optical digitization of cadaver brains allow even finer spatial and chemical resolution in limited numbers of brains. A number of sites are bringing together these new acquisition technologies with the concepts of 3D stereotaxic mapping to create probabilistic maps at this finer scale. The advantage of the stereotaxic approach is that information from these many techniques operating at different spatial scales can be consolidated over many years into a systematic description of the whole brain structure and function. Such a rich database of information on both cerebral structure and function, accessible to sophisticated computational and statistical exploration, offers exciting possibilities for future brain research and clinical practice. Quite apart from direct hypothesis testing, such an environment may allow for the detection of hitherto unsuspected patterns of interaction among normal brain elements and the isolation of constellations of measurements that characterize specific disease states.

In the last 5 years there has been a renewed interest in the role of metabolism in supporting brain function. Much of this interest is based on the development of functional positron emission tomography (PET) and magnetic resonance imaging (MRI). Although often incorrectly described as directly mapping neuronal activity, both functional PET and MRI actually measure changes in either glucose metabolism or physiologic parameters coupled to glucose metabolism such as blood flow and volume (1). A major limitation in interpreting functional imaging is that the relationship between neuronal activity and the neuroenergetic processes supported by glucose metabolism is poorly defined (2 ,3). The term *neuronal activity* applies to a spectrum of energy-requiring processes including action potential propagation, neurotransmitter release and uptake, vesicular recycling, and maintenance of membrane potentials (4). All of these processes are involved in short-term neuronal information transfer, and the relative distribution of energy among them remains an open question. There is also uncertainty as to how the different classes of neurons in a region contribute to the overall energy consumption. While an increase in the imaging signal is usually assigned to an increase in neuronal excitation, this interpretation is confounded by both inhibitory and excitatory neuronal function requiring energy. Observation of a regional increase or decrease of the functional imaging signal is not sufficient to distinguish these possibilities. Glia also requires energy, and the relationship between its energy demands and neuronal activity remains to be established. Given these uncertainties about the meaning of the signal at a neuronal level, the validity of functional imaging as a tool for studying mental processes has been largely established based on agreement with prior expectation from psychological paradigms (3 ,5).

An alternative approach for imaging brain function, which has the potential of directly measuring metabolic pathways involved in excitatory and inhibitory neurotransmission, is *in vivo* magnetic resonance spectroscopy (MRS). MRS uses technology similar to that of the more familiar MRI. It differs by allowing the measurement of the concentrations and synthesis rates of individual chemical compounds within precisely defined regions in the brain. The basis of its chemical specificity is that the resonance frequency of an MRS active nucleus depends not only on the local magnetic field strength, but also on its chemical environment, a phenomenon referred to as chemical shift. MRS measurements of the ^{1}H nucleus are the most commonly used for *in vivo* studies due to ^{1}H being the most sensitive nucleus present in biological systems. Metabolites that can be measured by ^{1}H MRS include aspartate, γ-aminobutyric acid (GABA), glucose, glutamate, glutamine, and lactate. These metabolites play critical roles in neuroenergetics, amino acid neurotransmission, and neuromodulation. Another nucleus of importance for *in vivo* MRS studies is the

^{13}C nucleus. The natural abundance of the ^{13}C isotope is 1.1% so that in conjunction with the infusion of ^{13}Cenriched substrates the rates of isotopic incorporation into brain metabolites can be measured. Substrates labeled with the nonradioactive, stable, ^{13}C isotope have been employed *in vivo* to study metabolic flux, enzyme activity, and metabolic regulation in the living brain of animals and humans (6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 ,37 ,38 and 39). Enhanced sensitivity may be achieved by measuring the ^{13}C enrichment of a molecule through indirect detection through ^{1}H MRS. From these measurements the flux through specific metabolic pathways may be calculated (17 ,18).

This chapter covers the recent development of *in vivo* MRS to study neuronal glutamate and GABA metabolism and the relationship of amino acid metabolism to functional neuroenergetics. The brain pools of GABA, glutamate, and glutamine have been shown to be localized within glutamatergic neurons, GABAergic neurons, and glia, respectively (under nonpathologic conditions). Under nonfasting conditions glucose is the almost exclusive source of energy for the brain. By following the flow of ^{13}C label from glucose into these metabolites, MRS has been used to determine the separate rates of glucose oxidation in these cell types. The metabolism of glutamatergic neurons, GABAergic neurons, and glia is coupled by neurotransmitter cycles. In the glutamate/glutamine cycle, glutamate released from nerve terminals (by either vesicular release or transport reversal) is transported into surrounding glial cells, and converted to glutamine. Glutamine in then transported out of the glia and into the neurons, where it is converted back to glutamate, thereby completing the cycle (Fig. 25.1). By following the flow of ^{13}C label from glutamate into glutamine, the rate of the glutamate/glutamine cycle may be determined using MRS. Through a similar strategy the GABA/glutamine cycle may be measured.

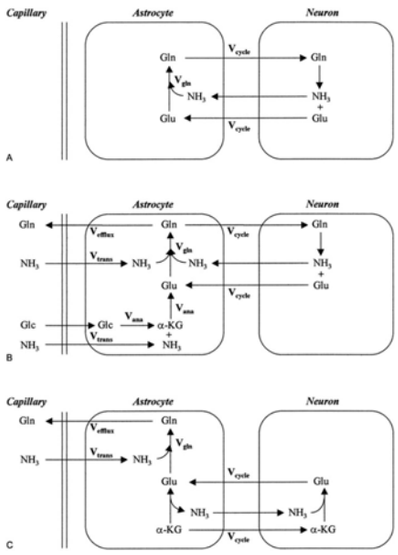

FIGURE 25.1. Schematic representations of the glutamate/glutamine cycle between neurons and astrocytes and the detoxification pathway of glutamine synthesis. **A:** The glutamatine/glutamate cycle between neurons and astrocytes. Released neurotransmitter glutamate is transported from the synaptic cleft by surrounding astrocytic end processes. Once in the astrocyte, glutamate is converted to glutamine by glutamine synthetase. Glutamine is released by the astrocyte, transported into the neuron, and converted to glutamate by phosphate-activated glutaminase (PAG), which completes the cycle. **B:** Including the ammonia detoxification (or anaplerotic) pathway of glutamine synthesis. The net rate of glutamine synthesis reflects both neurotransmitter cycling (V_{cycle}) and anaplerosis (V_{ana}). The stoichiometric relationships required by mass balance between the net balance of ammonia and glutamine and V_{ana} are given in Eq. 2. **C:** An alternative model for neuronal glutamate repletion in which the astrocyte repletes the lost neuronal glutamate by providing the neuron with α-ketoglutarate [or equivalently other tricarboxylic acid cycle (TCA) intermediates] (32,33 and 34). α-Ketoglutarate is converted back to glutamate by neuronal glutamate dehydrogenase. Glc, glucose; a-KG, α-ketoglutarate: V_{trans}, net rate of net ammonia transport into the brain (VNH4 in the text); V_{efflux}, rate of glutamine efflux from the brain; V_{ana}, anaplerotic flux; V_{cycle}, rate of the glutamate/glutamine cycle; V_{gln}, rate of glutamine synthesis. Using [2-^{13}C] glucose (27) and [2-^{13}C] acetate precursors these pathways may now be distinguished.

The application of MRS to study brain glutamate and GABA metabolism and the coupling of neurotransmitter cycling to neuroenergetics have provided several new and controversial insights into the relationship of brain metabolism and function. Contrary to the previous view of a separate metabolic and neurotransmitter pool of glutamate, glutamate release and recycling have been shown to be a major metabolic pathway. MRS studies of GABA metabolism in the rodent and human brain have suggested that there is also an important role of the metabolic pool of GABA in inhibitory function. Another key finding is that the glutamate/glutamine cycle in the cerebral cortex is coupled in a close to 1:1 ratio to neuronal (primarily glutamatergic) glucose oxidation above isoelectricity. This finding, in combination with cellular studies, has led to a model for the coupling between functional neuroenergetics and glutamate neurotransmission. The coupling between neurotransmission and neuroenergetics provides a linkage between the functional imaging signal and specific neuronal processes. This chapter reviews these findings and discusses some of their implications for functional imaging.

MRS is a low spatial resolution method, with a resolution for studying neurotransmitter systems of approximately 1 to 4 mm^3 in animal models and 7 to 40 mm^3 in human brain. Even in the best case the MRS signal is the sum of the signal from a large number of neurons and glia including many different subtypes. Fortunately, nature has localized key enzymes and metabolites involved in neurotransmitter cycling in specific cell types, which greatly simplifies the interpretation of the MRS measurements. The evidence of the cellular compartmentalization of metabolism largely derives from invasive methods with cellular and subcellular resolution, which are reviewed here. As with any new technique there are still uncertainties due to methodologic issues. Studies performed to validate the MRS measurements will be reviewed, and present limits in measurement accuracy and interpretation delineated.

IN VIVO ^{13}C MRS MEASUREMENTS OF THE PATHWAYS OF GLUCOSE OXIDATION: FINDINGS AND VALIDATION

Part of "25 - Magnetic Resonance Spectroscopy Studies of the Glutamate and Gaba Neurotransmitter Cycles and Functional Neuroenergetics "

This section reviews studies in which MRS was used to measure the pathways of glucose oxidation in the cerebral cortex. Glucose oxidation under nonfasting conditions is almost the exclusive source of energy for the brain. The localization of key enzymes involved in GABA and glutamate metabolism in specific cell types provides the capability for MRS to study their separate neuroenergetic requirements. As shown in Fig. 25.2 , which is a ^{13}C MRS spectrum obtained by Gruetter and co-workers (35) at 4 T, the chemical specificity of MRS allows the flow of ^{13}C label from glucose to be followed into several metabolites in the brain coupled to energy metabolism including aspartate, GABA, glutamate, and glutamine. The major finding of these studies is that in normal conditions in nonactivated human cerebral cortex and in rodent models, glucose oxidation in glutamatergic neurons accounts for between 60% and 80% of cerebral cortex energy consumption. The remaining 20% to 40% is primarily distributed between GABAergic neurons and glia.

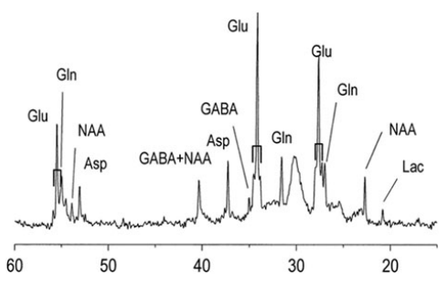

FIGURE 25.2. ^{13}C magnetic resonance spectroscopy (MRS) spectrum in the occipital/parietal lobe at 4 T. The figure shows a 50-minute accumulation ^{13}C MRS spectrum obtained at 4 T approximately 60 minutes after the start of a 1-^{13}C glucose infusion. The spectrum was obtained from a 72-mL volume centered on the midline in the occipital/parietal lobe. The top trace is an expansion of regions of the bottom trace. Labeled resonances include the C2, C3, and C4 positions of glutamate, glutamine, aspartate, and γ-aminobutyric acid (GABA) and the C3 position of lactate. As described in the text (see In Vivo 13C MRS Measurements of the Pathways of Glucose Oxidation: Findings and Validation), the localization of the synthetic enzymes and pools of GABA and glutamine to GABAergic neurons and glia, respectively, and the localization of the majority of the glutamate pool to glutamatergic neurons, allows the relative rates of glucose oxidation in these cell types to be determined from the flow of ^{13}C label into these pools. (From Gruetter R, Seaquist ER, Kim S, et al. Localized in vivo ^{13}C-NMR of glutamate metabolism in the human brain: initial results at 4 tesla. *Dev Neurosci* 1999;20:380–388, with permission.)

MRS Measurement of the Rate of Glucose Oxidation in Glutamatergic Neurons

The initial use of MRS to study brain metabolism was to measure glucose oxidation by following the flow of ^{13}C isotope from [1-^{13}C] glucose into the C4 position of glutamate (2 ,6). Figure 25.3 diagrams the flow of ^{13}C label from a [1-^{13}C] glucose precursor to C4-glutamate and subsequently C4-glutamine. Glucose is metabolized to pyruvate by the glycolytic pathway, which labels C3-pyruvate. The

label is then transferred to the tricarboxylic acid cycle (TCA) by the actions of pyruvate dehydrogenase (PDH) and citrate synthase. When the label reaches C4-α-ketoglutarate it is transferred to the large neuronal glutamate pool by the high activity exchange reactions of the amino acid transaminases and mitochondrial/cytosolic transporters. The large glutamate pool was first identified in ^{14}C tracer studies (40). Based on kinetic and immunohistochemical staining studies, it is believed to correspond to the glutamate pool of glutamatergic neurons (18 ,41 ,42). Due to the rate of these exchange reactions being many times faster than the TCA cycle the glutamate pool acts as a label trap for isotope that enters the neuronal TCA cycle via pyruvate dehydrogenase (17 ,18). ^{13}C MRS may be used to measure the accumulation of ^{13}C label into the trapping glutamate pool, and the kinetic curves analyzed by metabolic modeling to calculate the rate of the neuronal TCA cycle (18). The trapping pool assumption is not essential to determine the rate of the TCA cycle because subsequent labeling in the C3 position of glutamate can be measured to allow calculation of the label exchange rate (17 ,18). Because glucose is the primary fuel for neuronal oxidation, the measurements of the TCA cycle may be converted to measurements of glucose oxidation using known stoichiometries (17 ,18).

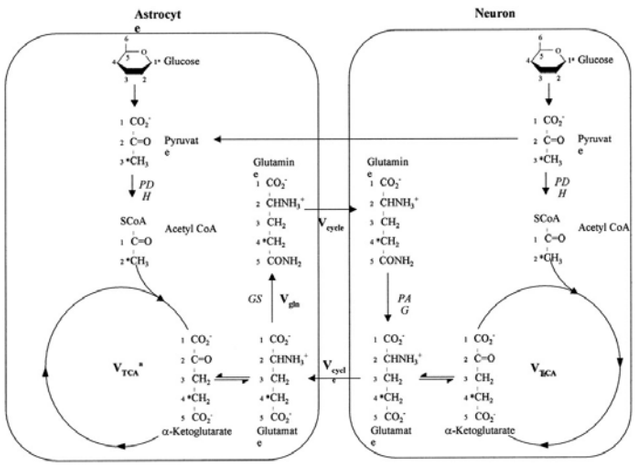

FIGURE 25.3. Isotopic labeling of C4-glutamine by the glutamate/glutamine cycle from a [1-^{13}C] glucose precursor. Infused [1-^{13}C] glucose labels neuronal C3-pyruvate. This label is then incorporated via the combined action of pyruvate dehydrogenase and the TCA cycle into α-ketoglutarate, which is in rapid exchange with glutamate due to the action of several transaminases. The large glutamate pool in the neuron acts as a label trap with [4-^{13}C]-glutamate accumulating at the rate of the neuronal TCA cycle. Released [4-^{13}C] glutamate from the nerve terminal is taken up by glial transport and the ^{13}C label is transferred to [4-^{13}C] glutamine through the action of glutamine synthetase at the rate of the glutamate/glutamine cycle. Interpretation of glutamine labeling is complicated by ^{13}C label entering by the astrocyte pyruvate dehydrogenase reaction. MRS studies using ^{15}N ammonia, [2-^{13}C] glucose, and [2-^{13}C] acetate, as well as comparison with traditional measurements of the uptake of net glutamine precursors, have shown that the majority of labeling in glutamine from [1-^{13}C] glucose is from the glutamate/glutamine cycle (27,36,37,38 and 39).

The rate of neuronal glucose oxidation has been determined in several studies from ^{13}C MRS and ^{1}H-^{13}C MRS measurements of cerebral cortex glutamate turnover from a [1-^{13}C] glucose precursor in animal models (2 ,14 ,15 ,16 and 17 ,21 ,22 ,25 ,26 and 27) and humans (12 ,13 ,18 ,19 ,29 ,31 ,35 ,43 ,44). Comparison of the rates of neuronal glucose oxidation measured in these studies with conventional arteriovenous (AV) difference and PET measurements of total glucose consumption found that the majority (between 70% and 90%) of total glucose oxidation in the rat and human brain is associated with the large glutamate pool, believed to reflect glutamatergic neurons, measured by MRS. In two recent ^{13}C MRS studies of resting awake human occipital parietal cortex, in which other pathways of glucose metabolism were directly measured, a similar range of between 60% (35) and 80% (29) of total glucose oxidation was calculated for the large glutamate pool. The large percentage of cortical synapses that are glutamatergic and the high electrical activity of glutamatergic pyramidal cells (4 ,45) may explain why such a large fraction of total glucose oxidation is associated with glutamatergic neurons.

A caveat to the interpretation of the glutamate turnover measurement is that glutamate is present in all brain cells. Based on the sensitivity limitations of staining methods and kinetic studies in measuring glutamate levels in glia and other neuron types, particularly GABAergic, the assignment of the fraction of glucose oxidation occurring in glutamatergic neurons may be overestimated by up to 20%. In the future, the fraction of glutamate in glia may be measured more accurately through dynamic ^{13}C MRS measurements of glutamate and glutamine labeling during the infusion of labeled acetate that is incorporated into the brain selectively in the glia (28 ,38 ,39).

MRS Measurements of the Rate Glucose Oxidation in GABAergic Neurons

GABA is the major inhibitory neurotransmitter and may represent over 30% of the synapses in the cerebral cortex (4 ,46 ,47). GABA is synthesized from glutamate in GABAergic neurons by the enzyme glutamic acid decarboxylase (GAD). GABA may then be returned to the TCA cycle through successive action of the GABA shunt enzymes, GABA-transaminase, and succinic semialdehyde dehydrogenase, or released from the neuron. Almost all of the brain GABA pool is localized to GABAergic neurons under normal conditions. The labeling of the GABA pool from [1-^{13}C] glucose provides a minimum estimate of the rate of glucose oxidation in the GABAergic neuron. The estimate is a minimum because label may bypass GABA and continue from α-ketoglutarate/glutamate into the TCA cycle directly. *In vitro* MRS analysis of cerebral cortex from extracts of rats infused with [1-^{13}C] glucose has been used to measure the time course of labeling in the GABA and glutamate pools (24 ,48). The isotopic labeling results of the Manor et al. (24)

study were analyzed with a metabolic model to determine the relative rates of glucose oxidation in the glutamate and GABA pool. Under conditions of α-chloralose anesthesia the rate of glucose oxidation in GABAergic neurons was estimated to be between 10% and 20% of total neuronal glucose oxidation. This value is similar to previous estimates obtained using isotopic methods and by inhibiting the degradative enzyme GABA transaminase (24). It should be noted that determination of the rate of GABA synthesis from isotopic methods depends on the assumption that the glutamate precursor pool for GABA is severalfold lower in concentration than GABA, an assumption that is consistent with findings using cellular staining (41 ,42). In the recent studies of human cerebral cortex (13 ,29 ,35), the rate of GABA synthesis, and by inference glucose oxidation in the GABAergic pool, was estimated to be on the order of 10% of total glucose oxidation, although no rates were given. In the future, with the higher sensitivity available using inverse MRS methods in combination with the development of ultrahigh field magnets for human studies, measurements of the rate of glucose oxidation in GABAergic neurons should be possible in humans.

In Vivo MRS Measurements of the Rate of Glucose Oxidation in Glia

A long-term controversy in brain metabolism studies has been the rate of glucose oxidation in glial cells. Early estimates range from 10% to over 50% of glucose oxidation (49). MRS may be used to measure the rate of glial glucose oxidation based on the localization of the enzyme glutamine synthetase in the glia (50). This localization allows the rate of the glial TCA cycle to be calculated from the labeling of glutamine from glial glutamate. The most quantitative early findings were by Van den Berg and co-workers (40), who, using ^{14}C isotopic labeling strategies, assigned a rate to glial pyruvate dehydrogenase, which they referred to as the small glutamate pool, of 15% to 25% of total pyruvate dehydrogenase (neuronal + glial) activity. The pyruvate dehydrogenase rate is equal to the rate of complete glucose oxidation by the TCA cycle plus the rate of net glial anaplerosis. These measurements were performed using extract analysis of whole brains. Two recent ^{13}C MRS measurements of humans have measured glial pyruvate dehydrogenase as accounting for between 8% (29) and 15% (35) of total pyruvate dehydrogenase activity in the occipital parietal lobe. A limitation of these studies is that they did not measure the rate of the glial TCA cycle, only the pyruvate dehydrogenase step, and therefore the total oxidative energy produced in the glia was not calculated. In a preliminary study in human cerebral cortex using [2-^{13}C] acetate, which is exclusively incorporated into the astrocyte (28), as a tracer Lebon et al. (38) found that the glial TCA cycle accounts for approximately 15% of total glucose oxidation.

Summary and Remaining Questions

In vivo MRS measurements of nonactivated cerebral cortex in rats and humans have found that from 60% to over 80% of glucose oxidation is associated with the large glutamate pool, reflecting primarily glutamatergic neurons. The remainder is primarily distributed between GABAergic neurons and glia. The development of new labeling strategies such as [2-^{13}C] acetate and higher sensitivity MRS measurements should allow the contributions of these cell types to be more accurately determined. Within the error of the MRS measurements, and the contribution of glutamate pools in other neuronal classes to the glucose oxidation measurement, there may be up to 10% of total glucose oxidation available for other cell types such as dopaminergic and serotoninergic nerve terminals. An objection that has been raised to these findings is the possibility that small highly metabolically active pools may be missed by the MRS method. Under nonstimulated conditions the good agreement of the MRS measurement with AV difference and PET measurements of total glucose consumption indicate that the contribution of these small pools is not large. MRS measurements of glucose metabolism during cortical activation will be reviewed below (see *In Vivo* MRS Measurements of Neuroenergetics During Functional Activation).

IN VIVO MRS MEASUREMENTS OF THE RATE OF THE GLUTAMATE/GLUTAMINE CYCLE: FINDINGS AND VALIDATION

Part of "25 - Magnetic Resonance Spectroscopy Studies of the Glutamate and Gaba Neurotransmitter Cycles and Functional Neuroenergetics "

The function of the glutamate/glutamine cycle is to prevent depletion of the nerve terminal glutamate pool by synaptic release. Glial cells have a high capacity for transporting glutamate from the synaptic cleft in order to maintain a low ECF (extracellular fluid) concentration of glutamate (50 ,51). *In vivo* and *in vitro* studies indicate that glutamate released by the neuron is taken up by the glia and converted to glutamine by glutamine synthetase (53 ,54), an enzyme found exclusively in glia (52). Glutamine is transported from the glia into the ECF where it is taken up by neurons and converted back to glutamate through the action of phosphate-activated glutaminase (PAG) (55). Based on extensive data from isotopic labeling studies, immunohistochemical staining of cortical cells for specific enzymes, isolated cell, and tissue fractionation studies, it has been proposed that glutamate (as well as GABA) taken up by the glia from the synaptic cleft may be returned to the neuron in the form of glutamine (40 ,56 ,57 and 58). The generally accepted model of the glutamate/glutamine neurotransmitter cycle is shown in Fig. 25.1A .

Despite a wealth of evidence from enzyme localization and isolated cell studies, the rate of the glutamate/glutamine cycle and its importance for brain function have been controversial due to difficulties in performing measurements in the living brain. Because the neurotransmitter glutamate is packaged in vesicles (59 ,60), controversy has arisen about the fraction of glutamate actually involved in the cycle, leading to the concept of a small “transmitter” versus a large “metabolic” glutamate pool. Supporting the concept that glutamate neurotransmitter flux is a small fraction of total glucose metabolism are findings in isolated cells and nonactivated brain slices of a low rate of label incorporation from [1-^{13}C] glucose (61). The concept of a metabolically inactive neurotransmitter pool was brought into question in 1995, when, using ^{13}C nuclear magnetic resonance (NMR), we measured a high rate of glutamine labeling from [1-^{13}C] glucose in the occipital/parietal lobe of human subjects (12). A high rate of glutamine synthesis was calculated from these data (18). At the time of the initial ^{13}C NMR study, the rate of the glutamate/glutamine cycle could not be calculated due to the lack of a model for distinguishing isotopic labeling from this cycle from other sources of glutamine labeling, most significantly removal of cytosolic ammonia produced by metabolism and uptake of plasma ammonia (62). Net ammonia removal requires the de novo glutamine synthesis via the anaplerotic pathway in the glia. In addition, several other pathways, including the glial TCA cycle, have been proposed as providing significant precursors for glutamine

synthesis (61 ,62). To calculate the rate of the glutamate/glutamine cycle, Sibson et al. (25) developed a metabolic model for separating the pathways of glutamine synthesis.

This section reviews ^{13}C MRS measurements of the glutamate/glutamine cycle, emphasizing studies performed to validate the MRS technique. The important and surprising result of these studies is that the glutamate/glutamine cycle is a major metabolic flux, far exceeding de novo glutamine synthesis. The rate of the glutamate/glutamine cycle in the awake resting human cerebral cortex is between 60% and 80% of total glucose oxidation.

Development of a Two-Compartment Metabolic Model of Glutamine Metabolism to Separately Determine the Rate of the Glutamate/Glutamine Cycle and Anaplerotic Glutamine Synthesis

The rate of the glutamate/glutamine cycle is calculated from the time course ^{13}C labeling of glutamine relative to the labeling of its precursor neuronal glutamate. If neuronal glutamate were the only precursor of glutamine, the calculation would be straightforward. Unfortunately, the calculation is complicated by label from [1-^{13}C] glucose entering both the neuronal and glial TCA cycles via pyruvate dehydrogenase. Glutamate in both cell types will be labeled in the C4 position by exchange with α-ketoglutarate in the TCA cycle (Fig. 25.3). The flow of label from C4-glutamate into C4-glutamine is proportional to the total rate of glutamine synthesis. However, unless the relative flow of ^{13}C label into the glial glutamate pool from the glial pyruvate dehydrogenase and neuronal glutamate are distinguished, the fraction of glutamine synthesis due to the glutamate/glutamine cycle cannot be calculated. To determine the rate of the glutamate/glutamine cycle from a [1-^{13}C] glucose precursor, we developed a metabolic model to constrain the rate of glutamine labeling from glial pyruvate dehydrogenase.

Glutamine production via glutamine synthetase requires two substrates, glutamate and ammonia. As shown in the flow diagram of Fig. 25.1A , glutamine synthesis receives precursor glutamate from both glial uptake of released neurotransmitter glutamate and glial anaplerosis. A mathematical model was developed to interpret isotopic data in order to separate these pathways (25 ,27 ,29 ,36). The model extends previous formulations by imposing mass balance constraints on the brain glutamate and glutamine pools that relate the rate of de novo glutamine synthesis to the net uptake of anaplerotic precursors from the blood. Glutamine efflux is the primary source of nitrogen removal from the brain (49 ,62). Nitrogen must be removed from the brain in order to maintain low concentrations of ammonia, which when elevated will interfere with brain function (62). Because at steady state the concentration of glutamine remains constant, loss of glutamine by efflux (V_{efflux}) must be compensated for by de novo synthesis of glutamine by anaplerosis (V_{ana}). For de novo synthesis by anaplerosis, pyruvate derived from glucose is converted by CO_2 fixation (V_{CO2}) to oxaloacetate by the enzyme pyruvate carboxylase, which is active only in the glia (54). Through the action of the TCA cycle oxaloacetate is converted to α-ketoglutarate, which may be converted to glutamate either by ammonia fixation via glia glutamate dehydrogenase or alternatively through transamination with other amino acids (37). Glial glutamate is then converted to glutamine by glutamine synthetase. One or two ammonia molecules are fixed per glutamine molecule synthesized through anaplerosis, depending on the relative fluxes of NH_4^+ fixation versus transamination. Applying nitrogen mass balance constraints leads to the relationship V_{NH4} = (1 to 2)V_{efflux} at steady state. The additional requirement of carbon mass balance leads to the following relationship:

$$V_{ana} = V_{efflux} = V_{CO2} = (\tfrac{1}{2} \text{ to } 1)V_{NH4+} \qquad [1]$$

Total glutamine synthesis is then related to synthesis for ammonia detoxification (V_{ana}) and the glutamate/glutamine cycle (V_{cycle}) by the following expression:

$$V_{gln} = V_{cycle} + V_{ana} \qquad [2]$$

Note that V_{CO2} may be higher than V_{ana} if anaplerosis is needed to replace TCA cycle intermediates lost by oxidative processes or pyruvate recycling (63 ,64).

Examination of Eq. 2 indicates that V_{cycle} may be derived from a measurement of V_{gln} from a ^{13}C MRS experiment in combination with a measurement of any of the rates linked by mass balance considerations to anaplerotic glutamine synthesis. A limitation of isotopic measurements of flux is that isotopic exchange cannot be distinguished from net flux. The linkage between the labeling of glutamine through glial pyruvate dehydrogenase and the brain anaplerosis flux allows the validation of isotopic measurements of glutamine ^{13}C and ^{15}N labeling against traditional AV difference measurements.

The glutamate/glutamine cycle measurement using a [1-^{13}C] glucose precursor also includes contributions from the GABA/glutamine cycle (34 ,57 ,65). GABA is the main inhibitory neurotransmitter, and has been measured by *in vivo* ^{1}H and ^{13}C MRS in animals and humans (12 ,13 ,24 ,29 ,35 ,66) (see In Vivo MRS Studies of GABA Metabolism and the Effects of Disease and Pharmacologic Treatment on Human GABA Metabolism , below). The glutamate/glutamine and GABA/glutamine pathway may be distinguished using [2-^{13}C] glucose and [2-^{13}C] acetate as precursors as described below and in the section In Vivo MRS Studies of GABA Metabolism .

^{13}C NMR Studies of the Glutamate/Glutamine Cycle in Rat Cerebral Cortex

To determine the rate of glutamine synthesis, rats were studied under α-chloralose anesthesia in a 7-T modified Bruker

Biospec spectrometer. A small ^{13}C surface coil was used for transmission and reception. The spectroscopic volume was localized primarily to the motor and somatosensory cortices. The rats were infused with [1-^{13}C] glucose, and the time course of label incorporation into the C4 positions of glutamate and glutamine was measured. The time courses were fitted using differential equations describing the proposed model of glutamate/glutamine cycle. The rate of the neuronal TCA cycle as measured from label incorporation into the C4-glutamate was 0.46 ± 0.12 μmol/g-min [mean ± standard deviation (SD), *n* = 5]. The rate of glutamine synthesis (V_{gln}) was 0.21 ± 0.04 μmol/g-min (*n* = 5), which was nearly half the rate of the TCA cycle (25). These results indicate that glutamine synthesis is a major metabolic pathway in the rat cerebral cortex.

Validation of the Metabolic Model by Comparison of the Increase in the Rate of Glutamine Synthesis During Hyperammonemia with Independent Measures of Net Ammonia Uptake, CO_2 Uptake, and Glutamine Efflux

Elevated plasma ammonia increases the rate of the anaplerotic pathway of glutamine synthesis (62) in order to remove ammonia from the brain. The metabolic model predicts that under conditions of elevated plasma ammonia the increase in the rate glutamine synthesis is stoichiometrically coupled to the increase in the uptake of the anaplerotic substrates CO_2 and ammonia and the efflux of glutamine from the brain ($\Delta V_{gln} = \Delta V_{ana} = \Delta V_{efflux} = \Delta V_{CO2} = ½\Delta V_{NH4s}$). To test the ^{13}C MRS measurement, glutamine synthesis in rat cerebral cortex was measured under normal and elevated plasma ammonia concentrations. Rats were made hyperammonemic (0.35 ± 0.08 mM plasma ammonia vs. basal levels of 0.05 ± 0.01 mM) by a primed continuous infusion of ammonia and studied after 4 hours of hyperammonemia to ensure metabolic steady state. The neuronal TCA cycle rate was not significantly increased under these conditions relative to the control condition, which suggests that brain electrical activity and by inference the glutamate/glutamine cycle were not substantially altered. The rate of glutamine synthesis under hyperammonemic conditions increased by 0.11 ± 0.03 μmol/g-min relative to the rate under normal plasma ammonia levels. The increase in the rate of glutamine efflux (V_{efflux}) measured by AV difference under similar conditions was 0.10 μmol/g-min (67), in good agreement with ΔV_{gln}. Studies that have used ^{14}C isotope to measure the increase in V_{CO2} with hyperammonemia found a rate of ˜0.15 μmol/min-g (68), which is slightly higher than measured by ^{13}C MRS, possibly due to the need for additional incorporation of CO_2 to replace TCA cycle intermediates lost by oxidation. As described below, both AV difference and direct isotope incorporation measurements of ammonia fixation into glutamine under hyperammonemic conditions are also consistent with the predictions of the model. The agreement between the increase in V_{gln} determined by ^{13}C MRS and the increase measured by conventional methods in anaplerotic substrate utilization and glutamine efflux predicted by Eq. 2 provides strong experimental support for the ability to determine V_{cycle} under normal physiologic conditions.

^{15}N MRS Studies to Test the Relationship Between Anaplerotic Glutamine Synthesis and Ammonia Detoxification

^{15}N MRS is a useful method for both *in vitro* and *in vivo* study of cerebral glutamate/glutamine metabolism under hyperammonemic conditions based on the measurement of [5-^{15}N] glutamine and [2-^{15}N] glutamate/glutamine (69 ,70). Incorporation of ^{15}N labeled ammonia into the N5 position of glutamine may be analyzed to calculate the flux through glutamine synthetase. In the absence of label exchange, the rate of incorporation of labeled ammonia into the N2 position of glutamate + glutamine may be analyzed to calculate the rate of glutamate dehydrogenase.

The relationships in Eq. 2, which were used in the modeling of the ^{13}C MRS data to deconvolute ^{13}C labeling in C4-glutamine from neuronal glutamate and glial PDH, are based on mass balance and previous AV difference and ammonia trapping studies. To further test the relationship of Eq. 2 between the rate of ammonia uptake in the cerebral cortex (V_{NH4+}) and anaplerotic glutamine synthesis (V_{ana}), total ammonia uptake was calculated from the time course of the sum of ^{15}N labeled N5 glutamine and N2 glutamate + glutamine in rat cerebral cortex during infusion of ^{15}N ammonia. These were the only compounds into which appreciable ^{15}N label incorporation was observed, which agrees with previous findings that the major flows of ammonia in the brain involve these metabolites (62). The calculated V_{NH4+} from these data was 0.13 ± 0.02 μmol/g-min (*n* = 6). Based on the stoichiometric relationship of the model of $½\Delta V_{NH4} = \Delta V_{ana}$, a rate of anaplerotic glutamine formation of 0.065 ± 0.01 μmol/g-min was predicted. From this measurement an increase in the cerebral glutamine pool during the infusion of 0.065 μmol/min/g × 180 min = 11.7 μmol/g of glutamine was predicted. This calculation is in excellent agreement with the measured increase in glutamine concentration at the end of the study of 11.1 ± 0.4 μmol/g (36).

^{13}C MRS Determination of the Rate of the Glutamate/Glutamine Neurotransmitter Cycle Under Normal Physiologic Conditions

To determine the rate of the glutamate/glutamine cycle from a [1-^{13}C] glucose precursor under physiologic conditions,

Sibson et al. (25) measured V_{gln} and calculated V_{ana} using Eq. 2 and previously published measurements (62 ,71). The value of V_{ana} calculated in this manner ranged from 0.00 to 0.04 μmol/g-min. Comparison with the ^{13}C MRS measurement of V_{gln} of 0.21 ± 0.04 μmol/g-min, yields a V_{cycle} that is 80% to 90% of the rate of glutamine synthesis. A similar high percentage of V_{cycle} was calculated using measurements of the net incorporation of $^{14}CO_2$ into the cerebral cortex (72). The CO_2 measurement is coupled to total brain anaplerosis, which may be higher than anaplerosis used for net glutamine synthesis, and therefore represents the maximum estimate of this flux.

Validation of the Measurement of Glutamine Synthesis by Comparison of Rates Calculated from ^{15}N MRS and ^{13}C MRS Results

To obtain an independent measurement of V_{gln} and V_{ana}, ^{15}N MRS was used to measure the rate of ^{15}N-labeled ammonia incorporation into the N5 position of glutamine and the unresolved resonance of N2 glutamate plus glutamine (36). A mathematical analysis based on the model was used to derive V_{gln} from the MRS measurement of the time course of [5-^{15}N]glutamine and [2-^{15}N] glutamate + glutamine. The labeling in the first hour was almost exclusively within the N5 position of glutamine, which is consistent with the delayed onset of anaplerosis previously reported under these conditions (73) and previous measurements using ^{13}N and ^{15}N labeled ammonia (62 ,69). The low initial rate of anaplerosis allows the rates determined from the ^{15}N NMR study to be compared with the rates measured by ^{13}C NMR under normal physiologic conditions. The measured V_{gln} of 0.20 ± 0.06 μmol/g-min (mean ± SD, *n* = 6) from these studies (36) is in excellent agreement with the results from the ^{13}C NMR measurement of 0.21 ± 0.04 μmol/g-min (25).

Validation of the ^{13}C MRS Measurement of the Glutamate/Glutamine Cycle, and Assessment of Alternate Models of Neuronal/Glial Trafficking, Through Comparison of Results Using [1-^{13}C] Glucose, [2-^{13}C] Glucose, $^{15}NH4$, and [2-^{13}C] Acetate as Precursors

Several alternative models to the glutamate/glutamine cycle (Fig 25.1A ,Fig 25.1B) have been proposed. In one alternative model the ^{13}C labeling of glutamine represents an internal glial glutamate/glutamine cycle as opposed to trafficking between the neuron and glia. Label enters C4-glutamine from [1-^{13}C] glucose in this model through exchange in the glial cell between glutamate and glutamine catalyzed either through the reverse reaction of glutamine synthetase, or alternatively via glial phosphate activated glutaminase. Released neuronal glutamate in this model is taken up directly by the nerve terminal. In another alternate model, diagrammed in Fig. 25.1C , the glia releases α-ketoglutarate, or equivalently citrate or malate, to the neuron to replace the carbon skeleton of released glutamate (32 ,34 ,64). In support of this pathway, which is referred to here as the glutamate/α-ketoglutarate cycle, several TCA cycle intermediates including malate, α-ketoglutarate, and citrate are released from glia in cell culture and may be taken up by synaptosomes and cultured neurons (32 ,33 and 34).

The two pathways of glutamate trafficking shown in Fig. 25.1 cannot be distinguished on the basis of a ^{13}C MRS study using [1-^{13}C] glucose as the label source. As described above, [1-^{13}C] glucose will label both the glial and neuronal glutamate pools directly via pyruvate dehydrogenase. An alternative strategy is to use isotopic precursors that exclusively introduce label into the glia. Analysis of the flow of isotope from the glia into the neuronal glutamate pool yields the rate of total neuronal/glial glutamate trafficking. Comparison with the rate calculated using [1-^{13}C] glucose gives the fraction of neuronal/glutamate trafficking due to the glutamate/glutamine cycle (27 ,36).

The initial use with MRS of the strategy of glial selective precursors to calculate the fraction of glutamate trafficking due to the glutamate/glutamine cycle measurement was by Shen et al. (36), who calculated the relative fraction of the glutamate/glutamine cycle and glutamate/α-ketoglutarate cycle, using ^{15}N MRS measurement of the labeling in glutamine and glutamate from $^{15}NH4^+$. Under hyperammonemic conditions the rate of ^{15}N ammonia incorporation into the N5 and N2 position of glutamine is the same in the glutamate/α-ketoglutarate cycle because only the anaplerotic pathway of glutamine synthesis is present. In contrast, in the glutamate/glutamine cycle, there is additional incorporation of ^{15}N label into the N5 position of glutamine selectively in the glia (due to the localization of glutamine synthetase) due to the cycle. To distinguish these models, the endpoint ^{15}N enrichment of the N2 positions of glutamate and glutamine were calculated relative to the glutamine N5 position for each model using the N5 glutamine labeling curve as an input and compared with experimental values. As shown in Fig. 25.4 , the low ^{15}N fractional enrichment of the N2 position of glutamine and glutamate relative to glutamine N5 at the end of the study strongly supports the glutamate/glutamine cycle as the primary pathway of neuronal glutamate repletion.

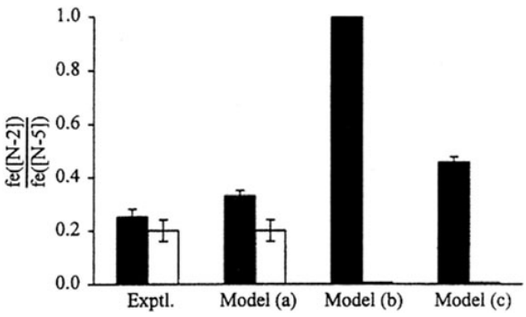

FIGURE 25.4. Calculated $^{15}N2/^{15}N5$ fractional enrichment ratios of glutamine and glutamate for three models of glial glutamine synthesis. Three models of neuronal glutamate completion were compared with experimental results in which the time course of [5-^{15}N] glutamine and [2-^{15}N] glutamine and glutamate were measured by ^{15}N nuclear magnetic resonance (NMR) in the cortex of a rat infused with ^{15}N-labeled ammonia at 7 T (36). The measured ratio at the end of the infusion is in excellent agreement with the ratio predicted if the glutamate/glutamine cycle is the major pathway of astrocytic repletion of released neuronal glutamate (model *a*, which is diagrammed in Fig 25.1A,Fig 25.1B). If instead the cycle was internal to the astrocyte the N2/N5 glutamine relative ^{15}N enrichment would be two times higher than measured and no labeling would have been observed in N2 glutamate (model *b*). If glutamate neurotransmitter repletion took place through the astrocytes providing the neurons with α-ketoglutarate (model *c*, which is diagrammed in Fig 25.1C), the rate of anaplerotic and total glutamine synthesis would be similar and the N5/N2 ratio of glutamine would be close to 1.0 as opposed to the measured ratio of 0.25. A similar labeling strategy has recently been used with [2-^{13}C] glucose and [2-^{13}C] acetate, both substrates that selectively label glutamine through glial specific pathways, and has put an upper limit of the rate of the α-ketoglutarate/glutamate cycle at 20% of the total rate of glutamate trafficking, the remainder being due to the glutamate/glutamine cycle (27,38).

An additional test of the glutamate/glutamine cycle model was recently performed using 2-^{13}C] glucose as an isotopic precursor (27). Label from [2-^{13}C] glucose enters the inner positions of glutamate and glutamine only through pyruvate incorporation into the TCA cycle by pyruvate carboxylase, which is localized to the glia (27 ,74). The initial flow of label from this precursor is into the glial TCA cycle intermediates, and then glial glutamate and glutamine (27).

Subsequently, neuronal/glial cycling moves the label to the neuron where it labels the large glutamate pool. The labeling measured in the glutamate pool is the sum of all trafficking pathways from the glia. In contrast the rate of labeling of glutamine from a [1-^{13}C] glucose precursor is a measure of the glutamate/glutamine cycle. *In vivo* and *in vitro* ^{13}C MRS at 7 T was recently used to measure the labeling time course of glutamate and glutamine in the cerebral cortex of rats under hyperammonemic and normoammonemic conditions during infusion of either [1-^{13}C] or [2-^{13}C] glucose (27). The rate calculated for the neuronal/glial glutamate cycle was similar, with both labels indicating that the glutamate/glutamine cycle is the major pathway of neuronal/glial glutamate trafficking accounting for between 80% and 100% of total glutamate trafficking. A similar conclusion was recently reported for human cerebral cortex using [2-^{13}C] acetate as a precursor (38), which selectively introduces label into glutamate and glutamine through glial pyruvate dehydrogenase.

The Effect of Glutamate Oxidation on the Glutamate/Glutamine Cycle Measurement and Estimates of Its Rate In Vivo

An alternate pathway of neuronal/glial glutamate trafficking is glial glutamate oxidation (10 ,63 ,64). In this pathway glutamate taken up by the glial cell is transaminated into α-ketoglutarate and enters the TCA cycle. Reactions in the TCA cycle convert α-ketoglutarate to oxaloacetate, which is then converted to pyruvate by the action of malic enzyme. The pyruvate formed from glutamate is oxidized in the TCA cycle through the action of pyruvate dehydrogenase. Glutamate lost to the brain by this pathway is then replaced by anaplerosis through pyruvate carboxylase. Evidence of this pathway is derived primarily from isolated cell cultures. It has been proposed that the fraction of glutamate going through this pathway increases with brain electrical activity (64).

The major effect of the glutamate oxidation pathway on the MRS measurement of the glutamate/glutamine cycle is to cause the fraction of glutamine synthesis of net anaplerosis to be overestimated and V_{cycle} to be consequently underestimated, because the labeling of the internal positions of glutamine from the two pathways from [1-^{13}C] and [2-^{13}C] glucose is similar. The unambiguous *in vivo* determination of glutamate oxidation requires the ^{13}C label flow from glutamate to pyruvate to be measured (10 ,63). This measurement is complicated by other metabolic pathways that produce similar labeling patterns, including scrambling of isotopic labeling into other positions of glucose in the liver (23 ,27 ,63 ,75), and as a consequence glutamate oxidation has not been definitively demonstrated *in vivo* under normal physiologic conditions. Suggestive evidence of this pathway is the finding in several studies that the rate of anaplerosis under normal ammonia conditions calculated from labeling of glutamine by ^{13}C labeled glucose is approximately two to three times higher than that predicted from measurements of brain glutamine efflux (27). An alternate possibility is that rather than glutamate oxidation this extra labeling reflects cycling between oxaloacetate and pyruvate to generate reduced nicotinamide adenine dinucleotide phosphate (NADPH) reducing equivalents in the glia, a pathway that has been shown to be highly active in the liver (75).

Validation of the ^{13}C MRS Glutamate/Glutamine Cycle Measurement by Correlation with Brain Electrical Activity

If the ^{13}C labeling measured in glutamine by ^{13}C MRS is due to the glutamate/glutamine cycle, then the calculated rate of this pathway should correlate with brain electrical activity. Neuronal glutamate release is known to increase with neuronal depolarization associated with action potentials.

To test this prediction, ^{13}C MRS was used to measure the rates of neuronal glucose oxidation and the glutamate/glutamine cycle in the rat cerebral cortex at three levels of cortical electrical activity: isoelectric EEG induced by high-dose pentobarbital anesthesia, and at two milder levels of anesthesia (26). During isoelectric conditions, under which minimal glutamate release takes place, almost no glutamine synthesis was measured, consistent with the conclusion that the ^{13}C MRS measurement of glutamine synthesis primarily reflects the glutamate/glutamine cycle. Above isoelectricity, the rates of the glutamate/glutamine cycle and neuronal glucose oxidation both increased with higher electrical activity. The relationship measured in this study between the rate of the glutamate/glutamine cycle and neuronal glucose oxidation is described below (see Determination of the *In Vivo* Coupling Between the Rate of the Glutamate/Glutamine Neurotransmitter Cycle and Neuronal Glucose Oxidation).

^{13}C MRS Measurements of the Rate of the Glutamate/Glutamine Cycle in Human Cerebral Cortex

In 1994 we first demonstrated that *in vivo* ^{13}C NMR may be used to measure the rate of glutamine labeling (12 ,18) from [1-^{13}C] glucose in human occipital/parietal cortex. These studies showed clearly that glutamine is labeled rapidly from [1-^{13}C] glucose in the human cerebral cortex. However, the rate of the glutamate/glutamine cycle was not uniquely determined in the initial experiments due to the inability to distinguish the glutamate/glutamine cycle from other sources of glutamine labeling. To determine whether there is a similar high rate of the glutamate/glutamine cycle in human cerebral cortex as in the rat, we (29) and Gruetter and co-workers (13 ,35) have determined this rate from ^{13}C MRS measurements in the human occipital/parietal lobe.

A time course from the study of Shen and co-workers (29) showing the rapid labeling of C4-glutamine and C4-glutamate from [1-^{13}C] glucose in a single subject is shown in Fig. 25.5 . A best fit of the metabolic model is plotted through the data. A lag is clearly shown in the labeling of C4-glutamine relative to C4-glutamate, which is consistent with the large neuronal glutamate pool being the main precursor for glutamine synthesis. The combination of the metabolic model validated in the rodent and improved MRS sensitivity allowed the rate of the glutamate/glutamine cycle, the neuronal TCA cycle, the glial TCA cycle, and anaplerotic glutamine synthesis to be calculated from the ^{13}C MRS data. The analysis gave a total TCA cycle rate of 0.77 ± 0.05 μmol/min/g (mean ± SD, n = 6), a neuronal TCA cycle rate of 0.71 ± 0.02 μmol/min/g, a glial TCA cycle rate of 0.06 ± 0.02 μmol/min/g, a glutamate-glutamine cycle rate of 0.32 ± 0.04 μmol/min/g (mean ± SD, n = 6), an anaplerotic glutamine synthesis rate of 0.04 ± 0.02, and a glucose oxidation rate of 0.39 ± 0.03 μmol/min/g (mean ± SD, n = 6). In agreement with studies in rat cortex, the glutamate/glutamine cycle is a major metabolic flux in the resting human brain with a rate approximately 80% of the rate of total glucose oxidation.

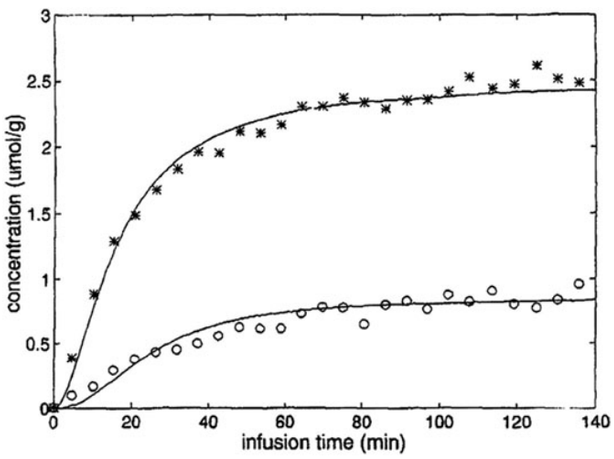

FIGURE 25.5. *In vivo* ^{13}C NMR time course of the human occipital/parietal lobe: the time course from one subject of the concentrations of [4-^{13}C] glutamate and [4-^{13}C]glutamine during a [1-^{13}C] glucose infusion, and the best fit of the two-compartment model to these data. At time 0 on the plot an intravenous infusion of [1-^{13}C] glucose was started. The model is shown to provide an excellent fit to the data. The rise of [4-^{13}C] glutamine is clearly seen to lag the labeling of [4-^{13}C] glutamate, consistent with neuronal glutamate being the main precursor for glutamine synthesis via the glutamate/GABA/glutamine cycle. *, glutamate; ○, glutamine. (From Shen J, Petersen KF, Behar KL, et al. Determination of the rate of the glutamate-glutamine cycle in the human brain by *in vivo* ^{13}C NMR. *Proc Natl Acad Sci USA* 1999;96:8235–8240, with permission.)

In a study performed at 4 T, Gruetter and co-workers (13) measured rapid labeling of glutamate and glutamine from infused [1-^{13}C] glucose using ^{13}C MRS. A high rate of the glutamate/glutamine cycle was measured using a two-compartment model, similar to the model used by Shen and co-workers (29). The improved spectroscopic resolution provided by the higher field strength at 4 T allowed the additional positions of the C2 and C3 resonances of aspartate, glutamate, and glutamine to be incorporated into the modeling. More recently Gruetter and co-workers (35) studied six subjects using localized ^{13}C MRS measurements of a 45-mL volume in the occipital lobe. The main differences from the rates derived from the Shen et al. (29) study are a higher rate of anaplerosis, approximately 25% of total glutamine synthesis as opposed to 11% in the Shen et al. study and a somewhat lower rate of the neuronal TCA cycle of 0.62 ± 0.05 μmol/min/g. The lower calculated neuronal TCA cycle rate was due to a lower rate of neuronal mitochondrial α-ketoglurate/glutamate exchange calculated from the data than in a previous study by Mason and co-workers (18). The lower exchange rate was due to the assignment of a higher concentration of aspartate in the glutamatergic

neuron and glutamate in the astrocyte in the metabolic model of Gruetter and co-workers. The higher anaplerosis rate also reflects differences in which the isotopic data was modeled. In the Shen et al. study anaplerosis was calculated primarily from the labeling kinetics of C4-glutamine and C4-glutamate, whereas in the Gruetter et al. (35) study it was calculated primarily from the measurement of the time course of the differential ^{13}C labeling of the C2, C3, and C4 glutamate and glutamine resonances. Both approaches suffer from needing to deconvolute ^{13}C label entering these carbon positions from pyruvate dehydrogenase from the label entering via pyruvate carboxylase. In the future these differences should be reconcilable by using labeling strategies such as [2-^{13}C] glucose, which labels glutamate and glutamine internal positions only by pyruvate carboxylase. If the anaplerotic pathway is due to glutamate oxidation (see Validation of the 13C MRS Glutamate/Glutamine Cycle Measurement by Correlation with Brain Electrical Activity , above) as opposed to ammonia detoxification, the rate of the glutamate/glutamine cycle reported in both studies is an underestimate by the calculated rate of anaplerosis. The differences in the anaplerotic flux calculated in these studies should not obscure the major point of agreement—that the glutamate/glutamine cycle is major metabolic pathway with a rate accounting for between 60% and 80% of total glucose oxidation in the cerebral cortex.

Cellular and Molecular Evidence that Astroglia have a Major Role in the Uptake of Glutamate Released from Neurons

The high rate of the glutamate/glutamine cycle indicates that astroglial uptake of glutamate and GABA plays a key role in maintaining the low extracellular levels of these neurotransmitters needed for proper receptor-mediated functions. There is considerable evidence from several lines of research that support this conclusion. Overstimulation of glutamate receptors can lead to excitotoxicity (76 ,77). Studies of glutamatergic synapses have shown them to be closely surrounded by glial end processes possessing high densities of glutamate transporters (78). Glutamate and GABA transporters are sodium dependent and electrogenic and are present on both neurons and glia (58 ,78 ,79 and 80). Glutamate transporters have an affinity, K_m, of 1 to 3 μM (80), which is in the range of normal estimated ECF glutamate concentrations. Immunohistochemical studies have showed that the glutamate transporters GLT-1 and GLAST (glutamate astrocytic transporter) are localized primarily in astrocytes (48 ,81 ,82 and 83), whereas EAAC1 is found on neurons (51). Antisense oligonucleotides directed against the astrocytic glutamate transporters GLT-1 or GLAST *in vivo* results in elevated ECF glutamate *in vivo* and excitotoxicity (84 ,85). The majority of glutamate uptake after its release appears to be either postsynaptic or astroglial (86 ,87), although an electrophysiologic study of the hippocampal slice suggests that astroglial uptake dominates (88).

Summary and Remaining Questions

MRS allows the glutamate/glutamine cycle to be measured from the labeling of glutamate and glutamine by ^{13}C and ^{15}N labeled precursors. The major complications in determining the rate of the glutamate/glutamine cycle from isotopic measurements are separating the labeling of glutamine from the glutamate/glutamine cycle from alternate pathways of glutamine synthesis and isotopic exchange, and distinguishing different pathways of neuronal/glial glutamate trafficking. To overcome these obstacles the metabolic modeling of the glutamate/glutamine cycle has been extended to include ammonia detoxification, alternate pathways of glutamate trafficking, and glutamate oxidation (27). The MRS rate measurement has been validated by several strategies including (a) comparison of the rate of glutamine synthesis measured under different ammonia levels with measurements of anaplerotic substrates by AV difference and isotopic trapping methods (25); (b) comparison of the rates of glutamine synthesis and the glutamate/glutamine cycle calculated from the isotopic labeling from [1-^{13}C] glucose, [2-^{13}C] glucose, ^{15}N ammonia, and [2-^{13}C] acetate (27 ,35 ,36 ,39); and (c) measurement of the rate of the glutamate/glutamine cycle as a function of brain electrical activity (26 ,37). The results of these studies indicate that the glutamate/glutamine cycle is the major pathway of glutamine synthesis and neuronal/glial glutamate trafficking under normal conditions, with a rate similar to the rate of neuronal glucose oxidation under conditions of high electrical activity. Measurements in awake nonstimulated human cerebral cortex have found that the rate of the glutamate/glutamine cycle is between 60% and 80% of total glucose oxidative metabolism (29 ,35).

Objections have been raised to the MRS measurement of the glutamate/glutamine cycle for having neglected alternate pathways of glutamate trafficking and the need for comparison with direct measurements of neuronal glutamate release. As described above, isotopic strategies have been developed to assess these pathways and under physiologic conditions they were found to account for less than 20% of glutamate trafficking. However, under pathologic conditions such as seizure the rate of these pathways may be much higher. Glutamate oxidation may have a significant contribution to total neuronal/glial glutamate trafficking. However, the unambiguous *in vivo* measurement of glutamate oxidation will require strategies for eliminating isotopic labeling from other pathways. Although direct measurement of bulk neuronal release of glutamate for comparison with ^{13}C MRS is presently not possible, advances in molecular and cellular methods for studying glutamate transport indicate that neurotransmission is the major, if not exclusive, pathway of glutamate release from glutamatergic neurons and the vast

majority of this flux is taken up by astroglia in the cerebral cortex. Correlation of the MRS glutamate/glutamine cycle with indirect measures of neuronal glutamate release such as microdialysis and nerve terminal labeling would be highly desirable, as would further studies better defining the relevant pool sizes and enzyme distribution in glia and glutamatergic neurons, particularly in regions other than the cerebral cortex.

DETERMINATION OF THE *IN VIVO* COUPLING BETWEEN THE RATE OF THE GLUTAMATE/GLUTAMINE NEUROTRANSMITTER CYCLE AND NEURONAL GLUCOSE OXIDATION

Part of "25 - Magnetic Resonance Spectroscopy Studies of the Glutamate and Gaba Neurotransmitter Cycles and Functional Neuroenergetics "

This section presents evidence from MRS and other studies for a model of the coupling between the glutamate/glutamine cycle and glial glucose uptake and subsequent neuronal oxidation. The model is based on work in cellular systems primarily by Magistretti and co-workers (90) and recent findings, using ^{13}C MRS in rat cortex, that the glutamate/glutamine cycle (a) increases in rate with increasing brain electrical activity in a near 1:1 stoichiometry with neuronal glucose oxidation (26), and (b) is 60% to 80% of the rate of total glucose oxidation in the awake nonstimulated cerebral cortex (13 ,26 ,29 ,35 ,37). Several comprehensive reviews of the evidence from molecular and cellular studies supporting glial localization of glucose uptake related to functional neuroenergetics have been published by Magistretti and co-workers (52 ,89) and are not duplicated here. The focus of this section is on the evidence from *in vivo* studies that support the model and key tests that remain to be performed.

Determination by ^{13}C MRS of the Relationship Between the Glutamate/Glutamine Cycle and Neuronal Oxidative Glucose Consumption

To determine the relationship between the glutamate/glutamine cycle and cerebral cortex neuroenergetics, ^{13}C MRS was used to measure the rate of neuronal glucose oxidation and the glutamate/glutamine cycle in rat cortex under conditions of isoelectric EEG induced by high-dose pentobarbital anesthesia, and at two milder levels of anesthesia (26). The rate of neuronal glucose oxidation and the glutamate/glutamine cycle was calculated using a two-compartment metabolic model from the isotopic turnover of C4-glutamate and C4-glutamine. Under isoelectric conditions, at which minimal glutamate release takes place, almost no glutamine synthesis was measured, consistent with the conclusion that the ^{13}C MRS measurement of glutamine synthesis primarily reflects the glutamate/glutamine cycle. Above isoelectricity, the rates of the glutamate/glutamine cycle and neuronal glucose oxidation both increased with increasing electrical activity. The results, shown in Fig 25.6 , indicate an approximately 1:1 relationship between the increase in the rates of the glutamate/glutamine cycle and neuronal glucose oxidation with brain activity. Under the highest cortical activity studied, the glutamate/glutamine cycle rate was approximately 80% of the rate of neuronal glucose oxidation. A similar ratio of the rate of the glutamate/glutamine cycle to the rate of neuronal glucose oxidation has been reported for measurements of awake nonstimulated human cerebral cortex (13 ,29 ,35).

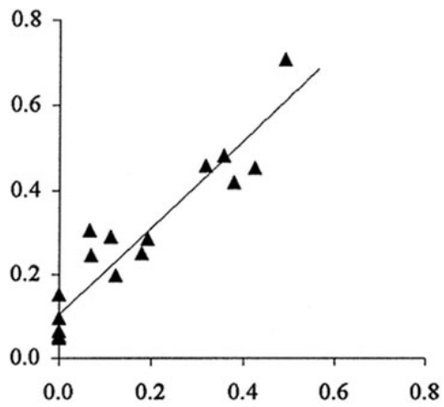

FIGURE 25.6. An approximately 1:1 correlation between the rate of oxidative glucose consumption and the rate of the glutamate glutamine cycle. The rate of neuronal glucose oxidation ($CMR_{glc(ox)}$) and the glutamate/glutamine cycle (V_{cycle}) was measured by ^{13}C MRS at 7 T in the rat somatosensory cortex at different levels of cortical activity induced by anesthesia. A significant positive correlation (p <.001) was found between $CMR_{glc(ox)}$ and V_{cycle}. The regression line shown is $y = 1.04x + 0.10$ with a Pearson product-moment correlation coefficient, r, of 0.94. (From Sibson NR, Dhankhar A, Mason GF, et al. Stoichiometric coupling of brain glucose metabolism and glutamatergic neuronal activity. *Proc Natl Acad Sci USA* 1998;95:316–321, with permission.)

A Model for the Stoichiometric Coupling of the Glutamate/Glutamine Cycle to Neuronal Glucose Oxidation

Figure 25.7 shows a model that provides a mechanistic explanation for the observed ratio of the rates of the glutamate/glutamine cycle to neuronal glucose oxidation (26 ,37 ,90). The model is an extension of the model proposed by Magistretti and co-workers that nonoxidative glial glycolysis is coupled to glutamate uptake due to the preference of the glia to use glycolytic adenosine triphosphate (ATP) to pump out the cotransported three Na^+ ions (52 ,90 ,91). The pyruvate and lactate formed by glial glycolysis would then be transported to the neuron where it is oxidized. Prior to the

in vivo ^{13}C MRS studies, the evidence for the model was primarily from enzyme localization studies and isolated cell studies (see refs. 89 and 90 for reviews of these studies). Both lines of evidence of localization have been criticized based on the presence of the enzymes required for glucose transport and glycolysis in the neurons, and the strong dependence of glutamate-stimulated glial glucose metabolism on cell culture conditions (92).

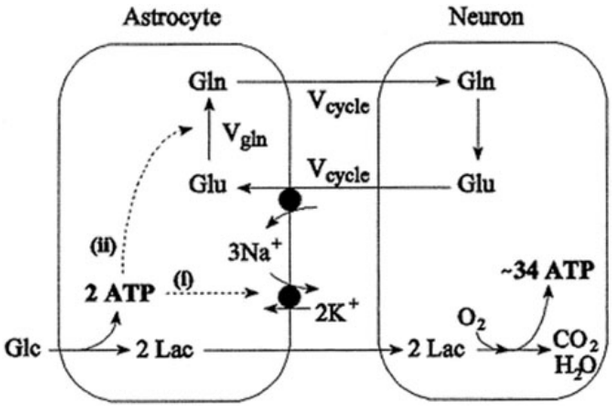

FIGURE 25.7. A metabolic model coupling the glutamate/glutamine cycle to oxidative glucose consumption. In this model the two molecules of adenosine triphosphate (ATP) required by the astrocyte to take up one molecule of glutamate (Glu) and convert it through glutamine synthetase to glutamine (Gln) are provided by nonoxidative glycolysis of one molecule of glucose (Glc). The lactate produced by nonoxidative glycolysis is then released from the astrocyte and taken up by the neuron for oxidative glycolysis. Glc, glucose; Lac, lactate; V_{gln}, rate of glutamine synthesis; V_{cycle}, rate of the glutamate/glutamine cycle. (From Sibson NR, Dhankhar A, Mason GF, et al. Stoichiometric coupling of brain glucose metabolism and glutamatergic neuronal activity. *Proc Natl Acad Sci USA* 1998;95:316–321, with permission.)

Comparison of the In Vivo ^{13}C MRS Results with the Stoichiometry Predicted by the Model

The ambiguities in the determination of the relative rates of metabolic pathways from enzymatic localization and measurements of isolated cells are not unexpected. Metabolic control analysis has shown that the total activity of an enzyme within a metabolic pathway does not determine the flux through the pathway (93). Extrapolation to *in vivo* rates from studies of cell cultures is complicated by the difficulty of reproducing the complex cellular interactions that occur *in vivo* (64). To compare the results of the *in vivo* measurement with the predictions of the model, Sibson et al. (26) calculated the stoichiometric relationship between the glutamate/glutamine cycle and neuronal oxidative glucose consumption. Glutamate is cotransported into the glia with two to three Na^+ ions, with one K^+ ion countertransported (60 ,78 ,94). Transport of three Na^+ ions out of the glia by the Na^+/K^+ adenosine triphosphatase (ATPase) on the glial end process membrane requires approximately one ATP molecule (91). Synthesis of glutamine from glutamate through glutamine synthetase requires one ATP molecule per glutamine molecule synthesized (53). If the ATP for this process were derived entirely from glycolysis, then a 1:1 stoichiometry is predicted between glial nonoxidative glucose consumption and the glutamate/glutamine neurotransmitter cycle. Provided that the lactate formed is released to the neurons for oxidation, then this predicted stoichiometry is in excellent agreement with the *in vivo* ^{13}C MRS findings.

If the model is correct, it may account for a substantial fraction of total glucose consumption in the awake nonstimulated cerebral cortex. Based on the measurements of the rate of the glutamate/glutamine cycle and total glucose oxidation in human cerebral cortex (13 ,29), between 60% and 80% of total brain glucose oxidation may be accounted for by this mechanism.

Additional In Vivo Evidence of the Model

The model (90) has been criticized for not leaving room for other energy consuming processes in the cerebral cortex. Within the error of the measurements, approximately 10% of total glucose oxidation is available for other neuronal systems such as dopaminergic or serotoninergic. The finding of the large majority of glucose oxidation in the cerebral cortex being associated with glutamatergic and GABAergic neurons and their surrounding astrocytes is not surprising, because cell staining studies have shown that the vast majority of synapses and neurons in the cerebral cortex are either glutamatergic or GABAergic (4).

A prediction of the model is that a large fraction of glucose uptake and phosphorylation is localized in the cerebral cortex to the glial end sheaths surrounding the synapses of glutamatergic neurons. In agreement with this prediction studies using ^{14}C-deoxyglucose autoradiography indicate that the majority of brain glucose uptake is used to support synaptic activity. Increased glucose uptake in response to functional stimulation in peripheral neurons and in cortex is primarily localized in dendritic and nerve terminal cortical layers (where there are associated glial end processes) and not in layers associated with cell bodies (1 ,95 ,96 and 97).

The rapid incorporation of ^{13}C label into glutamine by the glutamate/glutamine cycle indicates that the vesicular glutamate pool is rapidly turning over and is in dynamic equilibrium with cytosolic glutamate. This conclusion is in contradiction to the traditional view that the small vesicular pool is metabolically isolated from cellular glutamate metabolism (60 ,61). However, these studies were performed in cellular and tissue preparations, which have a low rate of synaptic metabolism relative to intact cerebral cortex. In support of this conclusion Conti and Minelli (42) showed that inhibition of PAG, which is enriched in nerve terminals (55)

and has been proposed to primarily replete the vesicular pool of glutamate (34), results in a similar rapid depletion of both synaptic and whole cell glutamate in the rat cerebral cortex.

Further support for the coupling between glial glycolysis and the glutamate/glutamine cycle is provided from studies performed looking at glutamine synthesis in mice in which the astrocytic TCA cycle was inhibited by injection with fluoroacetate (28). In these studies mice were given fluoroacetate and injected with a combination of [1,2-^{13}C] acetate and [1-^{13}C] glucose. From measurements of the isotopomer distribution in glutamate and glutamine, the labeling from glucose and acetate was distinguished. The labeling from acetate in glutamate and glutamine was greatly reduced by fluoroacetate administration, which the authors interpreted as resulting from the near-complete inhibition of the glial TCA cycle. Despite this inhibition, there was still a substantial amount of glutamine labeling from [1-^{13}C] glucose, approximately one-third to one-half the labeling found in the control mice. The only mechanism by which this labeling of glutamine from glucose could occur is the glutamate/glutamine cycle, because glutamate labeling in the astrocyte from glucose was completely blocked. The ability to maintain a high glutamate/glutamine cycle flux, despite the near-complete inhibition of glial mitochondrial ATP generation, has been interpreted by Bachelard (98) as supporting the importance of the glutamate/glutamine cycle as well as the potential coupling to glycolytic ATP production: “This singlet labeling of the C4 of glutamine, which can only be derived from [1-^{13}C] glucose metabolism in the neurones, also quite clearly demonstrates that even though the glial TCA cycle is blocked by the toxin, the glia are still capable of participating in the glutamate-glutamine cycle, taking up glutamate from the neurones and converting it to glutamine.”

Another testable prediction of the model is that if another substrate is supplied for neuronal oxidation, the decrease in glucose oxidation will be greater than the decrease in glucose consumption, due to the remaining need for glycolytic ATP to fuel the clearance of glutamate. Consistent with this prediction, an AV difference study of the anesthetized rat brain found that infusion of ß-hydroxybutyrate, which is an alternate fuel for brain oxidative ATP production, led to a two- to threefold greater decrease in glucose oxidation than in glucose consumption, with the difference accounted for by a large increase in the efflux of lactate from the brain (99). Consistent with this finding, Pan et al. (100) measured an increase in brain lactate in 3-day-fasted human subjects with elevated plasma ketone concentrations,

Summary and Remaining Questions

The linear relationship and stoichiometry found using ^{13}C MRS of the rates of the glutamate/glutamine cycle and neuronal glucose oxidation support a direct mechanistic coupling between the glutamate/glutamine cycle and glial glucose uptake. This mechanism may account for between 60% and 80% of the rate of total glucose oxidation in awake nonstimulated human cerebral cortex, and possibly an even larger fraction of the increment in glucose oxidation with stimulation (5 ,90). However, there are alternate potential explanations for the *in vivo* results that need to be tested. Most importantly, it will be necessary to devise strategies for directly distinguishing glial glucose uptake from neuronal glucose uptake and phosphorylation in the intact cerebral cortex. In addition, the stoichiometry between neuronal glucose oxidation and the glutamate/glutamine cycle remains to be measured under conditions of sensory stimulation, and in different brain regions.

IN VIVO MRS STUDIES OF GABA METABOLISM AND THE EFFECTS OF DISEASE AND PHARMACOLOGIC TREATMENT ON HUMAN GABA METABOLISM

Part of "25 - Magnetic Resonance Spectroscopy Studies of the Glutamate and Gaba Neurotransmitter Cycles and Functional Neuroenergetics "

GABA is the major inhibitory neurotransmitter in the cerebral cortex (46 ,47). It is synthesized from glutamate in specialized cells called GABAergic neurons. The release of GABA by a GABAergic neuron inhibits the electrical activity of adjacent neurons. Extensive studies in animals and isolated brain cells and slices have shown that GABAergic function is altered in a variety of models of neurologic and psychiatric disease (46 ,101 ,102). Several antiepileptic and psychiatric drugs are targeted at the GABAergic system. GABA is overlapped in the *in vivo* ^{1}H MRS spectrum by the more intense resonances of macromolecules (103), glutathione, and creatine. The development of ^{1}H MRS spectral editing of GABA in animals and humans (6 ,66 ,104 ,105) has provided a new window on studying GABA metabolism and GABAergic function in animals and humans. Several of the main findings using MRS to study alterations in GABA metabolism in disease and the effect of pharmacologic treatment on GABA metabolism are reviewed below.

MRS Studies of the Effect of the Antiepileptic Drug Vigabatrin on GABA Metabolism

Vigabatrin irreversibly inhibits the enzyme GABA transaminase (GABA-T). GABA-T catalyzes the breakdown of GABA in GABAergic neurons and in astrocytes. By inhibiting GABA-T, the drug leads to an elevation in GABA concentration. The ability of ^{1}H MRS editing to measure GABA elevated by GABA-T inhibitors was first demonstrated in the rat brain (106 ,107). Subsequent MRS editing studies of vigabatrin action on patients have made several new observations relevant to optimum administration of the drug including (a) chronic dosing above 3 g per day

fails to additionally increase GABA concentration (108), (b) GABA concentration reaches a maximum level within 2 hours of initial drug administration (109), (c) the effectiveness of vigabatrin in controlling seizures depends on elevating GABA concentration above the mean level found in nonepileptic subjects (108), (d) GABA concentration is increased by over two times the predrug concentration within 2 hours of an acute dose of 3 g of vigabatrin and remains elevated over 48 hours after a single dose of vigabatrin (109), and (5) there is no down-regulation of GABA-A receptors during chronic dosing with vigabatrin (see refs. 110 and 111 for a review of these studies). Figure 25.8 shows two edited spectra of total GABA obtained from the visual cortex before and after chronic vigabatrin treatment of a patient of epilepsy (108 ,112).

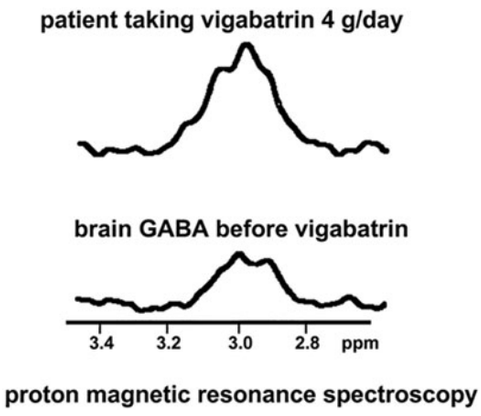

FIGURE 25.8. *In vivo* ^{1}H MRS spectra of total edited GABA from the occipital lobe of a patient with epilepsy before and after treatment with vigabatrin. The ^{1}H MRS spectra were obtained using spectral editing (112) from a 14-cm^{3} volume centered on the midline in the visual cortex. Chronic treatment with vigabatrin led to an over twofold increase in the concentration of total edited GABA, which is the sum of GABA and homocarnosine.

Cortical GABA Synthesis Is Reduced Following Prolonged GABA-Transaminase Inhibition

An initial finding in ^{1}H MRS studies of vigabatrin action in epilepsy patients was that the drug failed to raise GABA above a dose of 3 g/day (108). The enzymatic mechanisms controlling GABA levels *in vivo* are complex, involving short-term regulation of GAD by modulators (e.g., ATP, P_i) that affects the binding of cofactor pyridoxal phosphate, longer-term regulation involving enzyme protein levels, availability of glutamate precursors and their pathways (e.g., GABA-glutamine cycling), and postsynaptic and astroglial catabolic pathways. GAD exists as two major isoforms (GAD_{67} and GAD_{65}) in the brain; each is the product of separate genes (113 ,114) and each has distinct kinetic properties (114 ,115). GAD_{67} is distributed throughout the cytoplasm of GABAergic neurons, whereas GAD_{65} is associated with synaptic terminals. Recently, it was shown that the 67-kd isoform of GAD protein is reduced in response to elevated levels of GABA *in vitro* and *in vivo* (116 ,117). Differential control of the GAD isoforms suggests that they may mediate different fluxes. To investigate the effects of elevated GABA on GABA synthesis and quantitatively assess the role of the GAD isoforms in GABA synthesis, rates of turnover of cortical glutamate and GABA were determined in anesthetized rats during an infusion of [1-^{13}C] glucose after administration of the GABA-transaminase inhibitor vigabatrin (500 mg/kg, i.p.), to increase GABA levels (24). GABA concentration was increased twofold at 24 hours. Tricarboxylic acid cycle flux was not affected by vigabatrin treatment compared to nontreated rats despite the increased GABA level. An analysis of the turnover data revealed a ~70% decrease in the rate of GABA synthesis following vigabatrin-treatment (control, 0.14 μmol/g/min; vigabatrin-treated, 0.04 μmol/g/min). The reduction in GABA synthesis concomitant with the selective inhibition of GAD_{67} suggests that GAD_{67} accounts for the major fraction of GABA synthesis in the rat cerebral cortex under anesthetized nonstimulated conditions. This conclusion is supported by studies of GAD_{67} and GAD_{65} in knockout mice (118 ,119), which have found an order of magnitude greater reduction in GABA concentration in the mice with a GAD_{67} knockout. The isoform composition of human brain is presently unknown.

Elevation of GABA by Other Antiepileptic Drugs

^{1}H MRS studies have found that several antiepileptic drugs, with no known metabolic mechanisms of action on the GABAergic system, also lead to a rapid elevation of GABA concentration. These drugs include GABApentin, topirimate, and lamotragine (120 ,121 ,122 ,123 and 124). The elevation of GABA may be an important mechanism in the effectiveness of these medications as antiepileptic compounds. In addition, these findings provide evidence that the regulation of GABA metabolism is tightly integrated with the regulation of GABAergic function. Figure 25.9 shows a time course of the elevation of GABA after administration of an acute dosage of topirimate. As with vigabatrin, the concentration of GABA reaches a maximum of two times the predrug concentration within 2 hours of drug administration. A similar rapid elevation of GABA was measured after an acute dosage of GABApentin (122 ,124). The ability of ^{1}H MRS to track the response of the GABAergic system to pharmacologic therapy may potentially be useful for developing optimum dosing strategies.

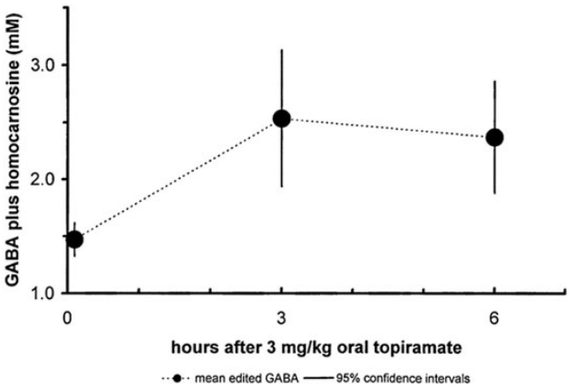

FIGURE 25.9. A time course of GABA plus homocarnosine concentration after administration of topiramate. Topiramate at 3 mg/kg was administered to six volunteers without epilepsy. ^{1}H MRS spectral editing measurements were performed at 4 T (123). GABA levels were measured to peak within 3 hours after administration of topiramate at approximately two times the predrug levels. A study looking at the acute effect of topiramate on GABA levels of epileptic patients found that the increase was almost entirely due to GABA (121). The GABA plus homocarnosine concentrations are normalized to a creatine concentration of 9 μmol/g for comparison with measurements by Petroff and co-workers (111), and the predrug concentrations are in excellent agreement. (Redrawn from Kuzniecky RI, Hetherington HP, Ho S, et al. Topiramate increases cerebral GABA in healthy humans. *Neurology* 1998;51:627–629.)

Effects of Neurologic and Psychiatric Disease on GABA Concentration

Impaired GABAergic function has been implicated in the etiology of epilepsy (101). Consistent with this proposal, ^{1}H MRS editing studies have found decreased GABA in adult epilepsy (111 ,125) and pediatric epilepsy (126). In epilepsy the release of cytosolic GABA has been proposed as an important mechanisms for seizure suppression (127 ,128). The finding that a low GABA concentration was strongly associated with poor seizure control in epilepsy supports this proposal. Further support for a role of cytosolic GABA concentration in inhibiting cortical excitability comes from the finding that the improvement in seizure control of subjects administered vigabatrin chronically depended on the elevation of cerebral cortex GABA concentration (108).

In addition to epilepsy, reduced GABA concentration has been found in unipolar depression (129), alcohol withdrawal, and hepatic encephalopathy (130). These disorders are associated with an alteration in inhibitory GABAergic function. The finding of low GABA associated with these disorders is additional evidence that the brain metabolic GABA pool has an important role in GABAergic function. The finding in unipolar depression appears paradoxical because the condition is not associated with enhanced cortical excitability. A potential explanation of this finding is that the low GABA concentration in this disease is a compensation for the reduction in excitatory glutamatergic activity (129).

Parsing the Edited GABA Resonance

The edited GABA resonance consists of GABA and the GABA derivative homocarnosine, which is a condensation product of GABA and histidine. Homocarnosine is a neuromodulator present in a specific subclass of GABAergic neurons in the primate brain. Short TE ^{1}H MRS with macromolecule suppression may be used to measure the homocarnosine histidine proton resonances in the downfield region of the short TE spectrum (103 ,112). Combining the homocarnosine measurement and the total GABA editing measurements has allowed the separate measurement of homocarnosine and GABA. Through modification of the editing selectivity, the GABA derivative pyrolidinone may also be measured in the edited spectrum (131). It was recently shown that GABA, homocarnosine, and pyrolidinone have different time courses in response to a first-time challenge with vigabatrin (109).

Estimate of the GABA/Glutamine Cycle in Nonstimulated Human Cerebral Cortex

The *in vivo* ^{13}C MRS measurement may potentially be extended to study the rate of GABA synthesis and the GABA/glutamine cycle (34 ,65). However, the ability to directly measure GABA synthesis at 2.1 T is limited by the [2-^{13}C] GABA resonance being overlapped at 2.1 T by the isotopomer sideband of the [4,3-^{13}C] glutamate resonance. Due to the entry of GABA into the glial TCA cycle at the level of succinate, the labeling kinetics of C4-glutamine derived from GABA are indistinguishable from label entering through anaplerosis. From the results of Shen et al. (29), the maximum estimate of the rate of the GABA/glutamine cycle, obtained by assuming that V_{ana}, is entirely due to GABA, would be approximately 10% of the rate of glutamine synthesis (29). In the 4-T studies of Gruetter et al. (13 ,35), the C2 resonance of GABA was resolved (Fig. 25.2), which indicates that direct quantitation of the rate of GABA synthesis and the GABA/glutamine cycle will be possible in human cerebral cortex at higher field strengths.

Summary and Remaining Questions

The ability of ^{1}H MRS to measure regional levels of GABA and GABA derivatives has provided a new window on the GABAergic system in neurologic and psychiatric disease. Reduced levels of cerebral cortex GABA have been found in patients with adult and pediatric epilepsy, depression, and alcohol withdrawal. Studies have found that several of the new generation of antiepileptic drugs raise GABA levels,

and GABA elevation may be related to their effectiveness in seizure depression. The recently demonstrated ability to perform GABA spectroscopic imaging (105) opens up the potential for using regional variations in GABA level diagnostically and to track the effectiveness of drugs targeted at the GABAergic system.

Two important questions are raised by these findings: What is the relationship between GABA levels and the rate of the GABA/glutamine cycle? What is the relationship between the GABA/glutamine cycle and cortical excitability? A preliminary study has recently demonstrated the ability to use isotopic labeling strategies, similar to those developed to measure the glutamate/glutamine cycle, to measure the rate of the GABA/glutamate cycle (39). This strategy, in combination with the manipulation of GABA levels either pharmacologically or through transgenic methods, may provide significant insight into how the regulation of GABA concentration affects GABAergic function.

IN VIVO MRS MEASUREMENTS OF NEUROENERGETICS DURING FUNCTIONAL ACTIVATION

Part of "25 - Magnetic Resonance Spectroscopy Studies of the Glutamate and Gaba Neurotransmitter Cycles and Functional Neuroenergetics "

Under physiologic conditions brain oxygen and glucose consumption are tightly coupled (49), with between 90% and 95% of glucose uptake being completely oxidized. The tightness of this coupling during brain activation was questioned when Fox and co-workers (132) measured by PET a mean increase of 51% in CMR_{glc} in the primary visual cortex of humans during stimulation by a flashing checkerboard pattern accompanied by only a 5% increase in oxygen consumption ($CMRO_2$). This finding was surprising because of the 16- to 18-fold lower ATP production from nonoxidative glycolysis compared with the complete oxidative consumption of glucose. It was concluded from these results that the energy for supporting electrical activity derives primarily from nonoxidative glycolysis as opposed to glucose oxidation (132 ,133). More recently, the greater increase in cerebral blood flow than oxygen consumption that leads to the BOLD (blood oxygenation level dependent) effect has been taken as evidence of the hypothesis of stimulated neuronal activity requiring little energy (134).

The apparently minimal need for energy from glucose oxidation to support stimulated neuronal activity is paradoxical because of the considerable evidence that the majority of energy consumption in the nonstimulated brain, which primarily uses glucose oxidation, is to support neuronal electrical activity. This evidence includes the critical dependence of brain function on oxygen delivery, the 50% to 70% reduction of brain energy requirements under isoelectric conditions (133), and the ^{13}C MRS findings of a high activity of the glutamate/glutamine cycle in the resting awake brain and the linear coupling of this rate to neuronal glucose oxidation (see the above sections In Vivo MRS Measurements of the Rate of the Glutamate/Glutamine Cycle: Findings and Validation , and Determination of the *In Vivo* Coupling Between the Rate of the Glutamate/Glutamine Neurotransmitter Cycle and Neuronal Glucose Oxidation). Furthermore, there is no cellular evidence that stimulated and nonstimulated neuronal activity have different energetic requirements. As discussed below (see Implications of MRS Studies for Understanding Brain Function), the ambiguity created by the variable degree of uncoupling between glucose consumption and oxidation hinders the interpretation of the functional imaging signal quantitatively in terms of changes in neuronal activity.

MRS provides a powerful tool for studying the question of metabolic coupling between glucose and oxygen by allowing measurements of the rates of nonoxidative glycolysis and glucose oxidation. MRS experiments have shown that under stimulated conditions the majority of energy for functional activity is from glucose oxidation (14 ,15 ,135). They have also confirmed the presence of metabolic uncoupling at high levels of brain activity (136 ,137 and 138). A model has been proposed to explain the uncoupling of glucose consumption and oxidation during certain types of stimulation as an extension of the normal energetic processes used to support the glutamate/glutamine cycle (139).

MRS Studies of Lactate Generation and Glucose Oxidation During Sensory Stimulation

A prediction of the presence of uncoupling of the increase of glucose consumption and oxidation during visual activation is that there will be an elevation of lactate in the visual cortex. Several laboratories have found an increase in lactate concentration (136 ,137 and 138) during visual stimulation of the human visual cortex by ^{1}H MRS of approximately 0.2 to 4 μmol/g-min within 2 to 6 minutes of activation. The small increase in lactate is consistent with earlier findings in animal models (40).

The degree of mismatch between the increase in glucose consumption and oxidation during sensory stimulation was studied by Hyder and co-workers (14 ,15) using forepaw stimulation of an anesthetized rat measured the rate of increase in neuronal glucose oxidation from the ^{13}C isotopic turnover of glutamate using POCE (proton observe carbon edit) heteronuclear editing. These studies found a large increase in the rate of glucose oxidation during sensory stimulation (Fig. 25.10). This increase was in good agreement with previous measurements of the increase in total glucose consumption (140). While within the accuracy of the measurements there was room for a significant rate of nonoxidative glycolysis, the contribution of nonoxidative glycolysis to total cerebral ATP production during activation would be minor due to the much greater number of ATP molecules produced by the complete oxidation of glucose (32 ,33 ,34 ,35 and 36) than by nonoxidative glycolysis to lactate (2).

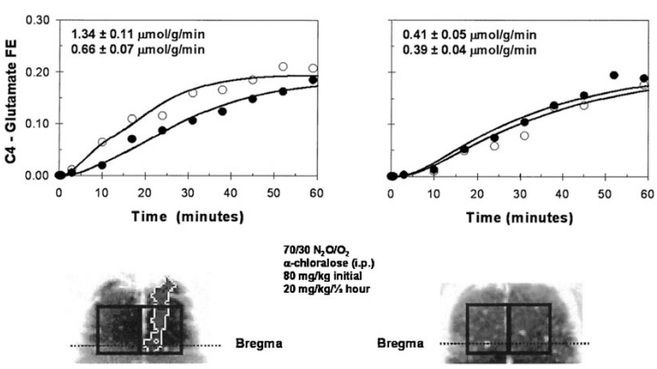

FIGURE 25.10. Time course of C4 glutamate labeling in the ipsi- and contralateral somatosensory cortex of a rat during single forepaw electrical stimulation. *In vivo* ^{1}H-^{13}C MRS spectra were obtained from two 24-μL volumes, positioned in the ipsi- and contralateral somatosensory cortex of rats at 7 T. The spectroscopic volumes are superimposed on a coronal image. The time courses on the right shows the labeling of C4-glutamate during the infusion of a control rat. The time courses on the left were obtained during single forepaw electrical stimulation. The *lighter region* on the image obtained during stimulation is the superposition of the blood oxygenation level dependent (BOLD) functional MRI (fMRI) obtained during the study. The rate of labeling on the contralateral side to the stimulation is observed to increase to approximately two times the rate of the ipsilateral side. The rates on the figure are the calculated rates of the TCA cycle from the group of rats studied in the contra- and ipsilateral volumes. (Redrawn with data from Hyder F, Rothman DL, Mason GF, et al. Oxidative glucose metabolism in rat brain during single forepaw stimulation: a spatially localized $^{1}H[^{13}C]$ NMR study. *J Cereb Blood Flow Metab* 1999;17:1040–1047.)

Calculation of the Relative Contributions of Glucose Oxidation and Nonoxidative Glycolysis to the Incremental Energy Production During Brain Activation

Two recent papers reviewed the increase in glucose oxidation during cognitive and sensory reported in a large number of studies, and concluded that in almost all reports the majority of incremental energy production is from glucose oxidation (131 ,141). Table 25.1 presents the measured fractional change in the rate of total glucose consumption (cerebral metabolic rate of glucose metabolism, CMR_{glc}) and oxidation (cerebral metabolic rate of oxygen, $CMRO_2$) in the human visual cortex during visual stimulation. The studies tabulated used either PET or quantitative functional MRI (fMRI) (142 ,143 ,144 ,145 ,146 ,147 ,148 and 149). In most cases the increase in $CMRO_2$ is greater than reported by Fox et al. (132), and the increase in CMR_{glc} is less. These differences have been attributed to differences in stimulation paradigms, with greater uncoupling from simple stimuli and almost complete coupling from complex stimuli (142 ,149). As shown in the table, even in the most extreme reports of uncoupling the fraction of the increment in total ATP production supplied by glucose oxidation is larger than that supplied by nonoxidative glycolysis.

			Energy Yield (%)		
Stimulation	ΔCMR_{glc} (%)	ΔCMR_{O_2} (%)	(non-ox)CMR_{glc}	(ox)CMR_{glc}	Reference
Visual	51	5	38	62	Fox et al. (132)
	28	28	6	94	Marrett and Gjedde (142)
	29	29	7	93	Marrett and Gjedde (142)
	(31)	16	(10)	90	Davis et al. (143)
	23	(20)	6	(94)	Chen et al.
	24	(20)	6	(94)	Reivich et al. (144)
	(31)	25	(7)	93	Hoge et al. (145)
	(31)	30	(6)	94	Kim et al. (146)
	(31)	5	(27)	73	Kim and Ugurbil (147)
Average	31	20	8	92	
Seizure	400	267	8	92	Borgstrom et al.

Tabulated are the reported increments in CMR_{glc} and CMR_{O_2} from studies using positron emission tomography (PET) or quantitative functional magnetic resonance imaging (MRI) to measure these parameters. The increase in adenosine triphosphate (ATP) production was calculated for each study using a value of 2 ATP molecules produced per glucose molecule consumed in the glycolytic pathway, and 32 additional ATP molecules produced when glucose is completely oxidized. The energy yield is expressed as the percent of the total increase in ATP production from nonoxidative glycolysis [(non-ox)CMR_{glc}] and the oxidative breakdown of glucose in the TCA cycle [(ox)CMR_{glc}]. As shown in the table, even in the most extreme reported cases of uncoupling between CMR_{glc} and CMR_{O_2} the majority of ATP production is from glucose oxidation due to the greater ATP yield. CMR, cerebral metabolic rate.

TABLE 25.1. NEUROENERGETIC YIELD WITH STIMULATION

A limitation of both the PET and quantitative fMRI measurements of oxygen consumption is that they depend on assumptions about blood flow/oxygen delivery coupling in order to derive rates (131). The measurement of glucose oxidation by MRS gets around the requirement of detailed knowledge, or calibration, of this parameter by directly measuring the flow of labeled glucose into the TCA cycle. The recent demonstration of high spatial resolution POCE measurements of glucose oxidation in human visual cortex at 4 T indicate that this method is ready to address this question in the human visual and other sensory systems (31 ,44).

The Glycogen Shunt, a Model of the Mismatch Between Glucose Consumption and Oxidation During Stimulated Neuronal Activity

The results tabulated in Table 25.1 show that the degree of mismatch between the increment in glucose consumption and glucose oxidation is the greatest for stroboscopic stimuli, which require alternate periods of intense activation followed by a quiescent period. For example, in visual stimulation the greatest mismatch was reported for a flashing red dot matrix (132), while no mismatch was found for

the increase from a colored alternating radial checkerboard, which produces a continuous level of stimulation (142 ,149). The largest sustained mismatch between glucose consumption and oxidation occurs in bicuculline-induced status epilepticus where total glucose consumption increases to fourfold the prestatus value, whereas oxidation is increased twofold (49 ,148). In bicuculline-induced status epilepticus, brain cerebral cortex electrical activity is characterized by a burst of intense firing followed by a suppressed period of little electrical activity.

We have proposed a model to explain these observations based on the requirement for ATP from glial glycolysis to supply the ATP needed for glial glutamate clearance and glutamine synthesis (see Determination of the *In Vivo* Coupling Between the Rate of the Glutamate/Glutamine Neurotransmitter Cycle and Neuronal Glucose Oxidation , above). In this model the majority of glucose required to fuel the pumping of glutamate from the synaptic cleft during the intense bursts of neuronal firing induced by sensory stimulation is provided by brain glycogen (150 ,151). Glycogen phosphorylase is kinetically well suited for rapid increases in activity through its regulation by signaling pathways and phosphorylation. There is *in vivo* evidence that brain glycogen may be rapidly mobilized to support function including in status epilepticus (49) and in physiologic brain activation (152 ,153 and 154). In the glycogen shunt model, after an initial period of glycogen depletion during intense stimulation, a steady state is reached in which the glycogen used to rapidly generate ATP for the transport of glutamate into the glial cell and conversion to glutamate during bursts of intense activity is resynthesized during the interim quiescent periods. Only one ATP molecule is produced per glucose moiety used by this pathway, instead of the two produced by glycolysis, and therefore the stoichiometry between the glutamate/glutamine cycle and glial glucose uptake changes to 1:1 from 1:2. The 1:2 ratio is approximately the ratio measured during status epilepticus, in which almost all cortical electrical activity is involved in a burst and suppress pattern. The presence of simultaneous synthesis and breakdown of glycogen has been demonstrated in the exercising muscle (155), and more recently in the cerebral cortex of the stimulated and anesthetized rat (152). Figure 25.11 describes the model schematically.

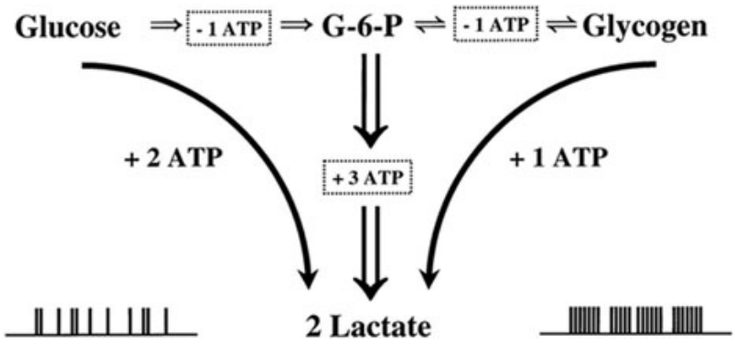

FIGURE 25.11. A schematic diagram of the glycogen shunt model. Glucose taken up by the glia can flow through two pathways after phosphorylation to glucose 6-phosphate. In the standard pathway (*left arrow*), which occurs during normal electrical activity, glucose 6-phosphate is directly converted to lactate by glycolysis producing two ATP molecules per glucose molecule. The stoichiometry between glucose uptake and glutamate transport and conversion to glutamine is 1:1 in this pathway. The majority of lactate is subsequently oxidized in the neuron. In the glycogen shunt pathway (*right arrow*), which occurs during intense repeated bursts of electrical activity, such as in seizures or intense sensory stimulation, glucose is synthesized into glycogen first before being converted to lactate. An ATP molecule is used in the synthesis of glycogen, resulting in a reduction in the energetic yield from the pathway to one ATP molecule per glucose molecule. The stoichiometry between glucose uptake and glutamate transport is increased to 2:1 in this pathway. The extra lactate produced in the shunt pathway is not required for neuronal energy metabolism and eventually leaves the brain.

Summary and Remaining Questions

In vivo MRS studies have made significant contributions to the understanding of functional neuroenergetics. The measurement of the glutamate/glutamine cycle under different levels of electrical activity (see the above sections In Vivo MRS Measurements of the Rate of the Glutamate/Glutamine Cycle: Findings and Validation , and Determination of the *In Vivo* Coupling Between the Rate of the Glutamate/Glutamine Neurotransmitter Cycle and Neuronal Glucose Oxidation) has shown that the majority of brain energy production in even the nonstimulated state supports neuronal activity. Several MRS studies have provided insight into the mismatch between glucose consumption and oxidation during sensory stimulation. Lactate elevation during visual stimulation provided direct validation of the findings using PET (132) of the mismatch between oxygen consumption and glucose consumption (136 ,137 and 138). Although there is a significantly greater increase in glucose consumption than oxidation in certain stimulated states, studies of

the rate of neuronal glucose oxidation during sensory stimulation in the rat cerebral cortex have shown that neuronal glucose oxidation provides the majority of energy production in the stimulated state (14 ,15). The conclusion derived from the MRS studies is consistent with PET measurements of the mismatch when the much greater efficiency of ATP production from glucose oxidation is taken into account (135), as shown in Table 25.1 . A potential explanation of the mismatch has been proposed based on the requirement for rapid glycolytic energy generation to clear glutamate from the synaptic cleft during the bursts of intense neuronal firing associated with stimulated neuronal activity (151). In this glycogen shunt model, the power required is provided by rapid glycogen breakdown. The glycogen is resynthesized during the inter-burst periods resulting in a reduction in the normal stoichiometry between glutamate transport into the glia and glial glucose uptake from 1:1 to 1:2.

Several major questions remain to be addressed on the neuroenergetic support of functional activity. Paramount among these is the need for a measurement of the glutamate/glutamine cycle during sensory stimulation. In addition, although the majority of the increase in energy consumption during stimulation is associated with glutamatergic neurons (15 ,156), the relative contributions of glia and GABAergic neurons are not known. At present there are only minimal data from brain studies supporting the glycogen shunt model of the mismatch between glucose consumption and oxidation. Studies measuring glycogen turnover directly under these conditions (30) may be able to directly test this hypothesis, and better establish the role of glycogen in functional neuroenergetics.

IMPLICATIONS OF MRS STUDIES FOR UNDERSTANDING BRAIN FUNCTION

Part of "25 - Magnetic Resonance Spectroscopy Studies of the Glutamate and Gaba Neurotransmitter Cycles and Functional Neuroenergetics "

The stoichiometry of the rate of the glutamate/glutamine cycle and oxidative glucose metabolism has implications for connecting models of brain function at the macroscopic level, as studied by functional imaging, with neurobiological studies at the level of synapses and networks of neurons. This section reviews work in which this relationship was used to calibrate the PET and fMRI signals and neuroenergetic signals, which are either indirectly or directly measures of functional glucose metabolism, with neurotransmitter cycling (5 ,139 ,157). Some implications of this calibration for the interpretation of brain functional imaging are explored.

Calibration of the Relationship Between the Glutamate/Glutamine Cycle and the PET and BOLD MRI Functional Imaging Signal

At present, functional PET and fMRI are not quantitated in terms of specific neuronal processes involved in information transfer. The functional imaging signal in PET and fMRI is either directly or indirectly coupled to the change in glucose oxidation with activation (1 ,2 ,134). The tight coupling between the glutamate/glutamine cycle and neuronal glucose oxidation in the rat cerebral cortex (26 ,90) provides a relationship for calibrating the functional imaging signal to the specific neuronal process of glutamate release and recycling (5).

The similarity of the ratio of the rates of the glutamate/glutamine cycle to neuronal glucose oxidation in human cerebral cortex and the rat cerebral cortex supports a similar relationship holding for the awake nonstimulated human cerebral cortex. Although studies are needed to establish the exact stoichiometry during sensory or other external stimulation, it is reasonable to extrapolate a positive (and possibly stoichiometric) relationship between changes in the rate of neuronal glucose oxidation and the glutamate/glutamine cycle during activation. Using this relationship, the functional imaging signal may be converted to a first order to changes in the rate of glutamate/glutamine neurotransmitter cycle (5). The advantage of performing this calibration over the direct MRS measurement of the glutamate/glutamine cycle is that several orders of magnitude of higher spatial and temporal resolution is possible with the MRI measurement.

Estimate of the Total Neuroenergetics Used to Support Functional Neuronal Activity During Sensory Stimulation

An assumption in the conventional interpretation of functional imaging is that the increment in neuronal activity during brain activation is sufficient to support the incremental mental processes in a region during sensory stimulation or a cognitive task (5). This interpretation is trivially valid if there is insignificant neuronal activity in the nonstimulated state. The high rate of the glutamate/glutamine neurotransmitter cycle found by ^{13}C MRS in the nonstimulated brain raises the question of whether the incremental neuronal activity is sufficient for mental processing or if the total regional neuronal activity is needed. This question was addressed by analyzing previous studies that measured the change in glucose consumption during stimulation in the sensory cortices of animals stimulated under anesthetized and awake conditions. The studies chosen used anesthetics that interfere minimally with the electrical response to sensory stimulation (157). During anesthesia, the baseline glucose consumption was reduced by as much as two- to threefold. Based on the standard paradigm, a constant increment of neuronal activity, and by inference glucose consumption, during stimulation would be expected regardless of whether the animal was anesthetized or awake. In contrast, if the majority of regional neuronal activity was required for sensory processing, then the glucose consumption required during stimulation would be similar whether the animal was awake or anesthetized. The prediction of these two models is diagrammed in Fig. 25.12 . Results from a number of studies indicated that a similar level of cortical activity was reached during stimulation, independent of the degree of suppression of resting glucose consumption by the anesthesia (139 ,157). These results were supported by the MRS studies that found a large increment in glucose oxidation with somatosensory stimulation under α-chloralose anesthesia (15 ,156). This finding supports the view that during stimulation the total neuronal activity in sensory regions is required to support brain function. Results of this literature survey have recently been reinforced by similar results using quantitative MRI to measure changes in oxygen consumption in the same animal at two different levels of anesthesia (158).

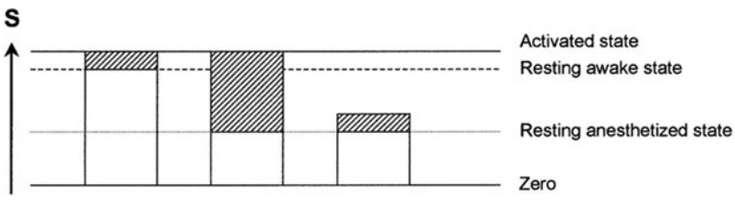

FIGURE 25.12. Schematic representation of possible increase in the functional imaging signal, as measured by neuroenergetics, upon sensory stimulation for an animal that is nonanesthetized (**A**) and anesthetized (**B,C**). The difference in the magnitude of the functional imaging signal, as quantified by glucose oxidation, between stimulated and nonstimulated states is represented by the *shaded rectangles*. In functional imaging these increments are commonly used to identify focally activated regions. The remaining signal, which is represented by *white rectangles*, is removed by fMRI analysis methods. ^{13}C MRS studies have shown that a large fraction of the total signal is from neuroenergetic processes coupled to neuronal activity. If the neuronal activity needed to perform the task was the same as the increment from the awake state, then the increase in the signal upon stimulation would be the same for the anesthetized or awake states (compare **A** and **C**). If instead a large fraction of the total neuronal activity in the region supports the sensory processing, then the incremental signal from anesthesia would be much larger (compare **A** and **B**). A survey of results in the literature showed that in most cases, when anesthetics such as α-chloralose that do not block stimulated electrical activity are used, the total glucose consumption and oxidation rises to the same absolute level during stimulation independent of the initial awake state. These results support the magnitude of the neuronal activity required to support a task (**B**) being substantially larger than the increment in neuronal activity over the resting awake state (**C**). (From Shulman RG, Rothman DL, Hyder F. Stimulated changes in localized cerebral energy consumption under anesthesia. *Proc Natl Acad Sci USA* 1999;96:3245–3250, with permission.)

Implications of the Calibration of the Functional Imaging Signal on the Standard Interpretations of Functional Imaging Studies

The goal of many functional imaging studies is to determine the anatomic location of brain regions involved in performing mental processes. To achieve this goal, subjects are given cognitive or motor tasks to perform, or exposed to sensory stimulation, while being scanned. The degree of involvement of a region in the performance of a task is determined by the increment in the magnitude of the imaging signal relative to the signal when the subject is in a resting state, or performing some other task. An implicit assumption in this analysis often used is that the size of the increment of the signal is proportional to the total neuronal activity recruited by these mental processes (3 ,5 ,159).

As described above, MRS studies have shown that the total neuronal activity in a region, as quantified by the glutamate/glutamine cycle, is much larger than the incremental increase with functional activation. The impact on interpretation of knowing the total magnitude of, as opposed to the incremental, neuronal activity associated with the processing of a stimulus or task may be illustrated through a simple example. Consider a hypothetical experiment in which two subjects perform a cognitive task. In one subject the regional increment in the functional imaging signal in the frontal lobe, quantified as the change in the rate of glucose oxidation, is 1% of the resting rate of total glucose oxidation. In the second subject the same task induces a signal/rate increment of 2%. In the standard interpretation, the second subject recruited twice the neuronal activity to perform the task as the first subject. If instead these increments are calibrated as increments in the glutamate/glutamine cycle the relative difference in neuronal activity is only

a few percent. This example shows that knowing the total size of the signal associated with neuronal activity is important in cases where inferences are being made about differences in the level of neuronal activity, such as when functional imaging is used to study the effects of drugs or disease on brain function (139 ,160). It is also important in the interpretation of functional imaging data to locate a mental process or function (5).

Implications for Studies of Brain Function

The prevailing theory used to interpret functional imaging studies, particularly of cognitive processes, is based on cognitive psychology (3 ,139 ,159 ,161). In the cognitive psychology model of the brain, complex mental processes are broken down using information theory into component processes, sometimes called modules. Functional imaging is used to locate these postulated modules. The search for specialized functional areas has been facilitated by analysis methods such as statistical parametric mapping. These methods identify regional changes in the imaging signal based on the statistical significance of the temporal correlation of the signal changes with the mental processes postulated by the investigator (which are expressed in the design matrix) involved in performing a task (162). In the statistical representation of brain activity, the magnitude of the regional neuronal activity is often ignored in favor of a binary representation as “active” and “inactive.” Statistical methods have been widely adopted to analyze fMRI data. A key assumption often used in the statistical representation of brain function is that the regional neuronal activity used for performing a mental process is independent and separable from the activity of other regions (162 ,163), as well as the neuronal activity recruited by other processes being supported within the same region.

The use of MRS to calibrate neuroimaging provides the potential for examining complex regional brain interactions that do not fulfill the strict modular criteria of independence. Several lines of experiments have shown that parallel regional brain functions interact, and alter the magnitude of the neuronal activity used in processing a stimulus or task (163 ,164 and 165). An example are the studies by Desimone's group (164) on the effect of attention upon the neuronal activity, as measured by the distribution of single neuron firing rates in a region, associated with visual perception. An illustrative set of experiments used two closely spaced visual signals within the same receptor field of a particular region of the striate cortex. The change in neuronal firing rate obtained from one stimulus was found to depend critically on the degree of attention paid to the nearby stimulus. Consistent with this result, an effect of attention on the magnitude fMRI BOLD signal in the human extrastriate cortex has been reported (165 ,166). The calibration of the functional imaging signal in terms of the glutamate/glutamine cycle will extend these studies by allowing these interactions between regions to be described quantitatively in terms of neuronal activity changes, as is presently is done only in electrophysiology studies of animal cerebral cortex. This quantitation should allow the exploration of these complex interactions in much finer detail in humans than is presently possible.

In addition to providing enhanced capability to understand horizontal interactions between brain regions, the calibration of neuroimaging by MRS also allows a vertical dimension of neuronal activity to be explored. The MRS finding of a high rate of the glutamate/glutamine cycle even under nonstimulated conditions is consistent with recent experimentally based proposals that maintaining a constant high level of neuronal activity is critical for brain function. Two recent experiments support this hypothesis. The need for substantial unfocused neuronal activity for the service of even sensory responses was suggested by a recent experiment of Grinvald's group (167). Starting with the recognition that “cortical neurons are spontaneously active in the absence of external input even in primary sensory areas,” the authors studied the correlation between single-unit recordings and real-time optical imaging, which provided a measure of total neuronal activity in the region. They concluded by suggesting that “in the absence of stimulation the cortical network wanders through various states represented by coherent firing of different neuronal assemblies,” and that a stimulus pushes the network into a state representing the stimulus. Analogously, Singer (168) measured the temporal synchronization of neuronal responses and concluded, “Of the many responses of V1 those that become synchronized best will be particularly effective in influencing neurons in higher areas.” These studies both support the presence of a large amount of neuronal activity in the unstimulated state and suggest a role for this activity in brain function. The results from MRS studies provide quantitative measures of the total amount of stimulated and unstimulated activity in a region, and thereby can provide a quantitative basis for analysis.

SUMMARY AND CONCLUSIONS

Part of "25 - Magnetic Resonance Spectroscopy Studies of the Glutamate and Gaba Neurotransmitter Cycles and Functional Neuroenergetics "

Below is a summary of the major findings of MRS studies of the glutamate/glutamine cycle, GABA/glutamine cycle, and functional neuroenergetics, and some of the implications of these findings for understanding brain function.

Approximately 60% to 80% of total glucose oxidation (and energy consumption) in the nonstimulated cerebral cortex is by glutamatergic neurons, with most of the remainder in GABAergic neurons and glia (13 ,18 ,24 ,26 ,27 ,29 ,35 ,38).

The energetic needs of glutamatergic and GABAergic neurons and glia dominate cerebral cortex energy requirements.

In the awake nonstimulated cerebral cortex of humans

and rats, the rate of the glutamate/glutamine cycle is 60% to 80% of total glucose oxidation (13 ,26 ,29 ,35):

1. Glutamate release and recycling is a major metabolic pathway.
2. Glutamate metabolism and neurotransmission can no longer be conceptually separated.
3. The nonstimulated awake brain has a high level of neuronal activity, most likely greater than the increment in activity with external stimulation.

The rate of the glutamate/glutamine cycle increases linearly with neuronal glucose oxidation in a close to 1:1 stoichiometry (26):

1. Energy metabolism in cortical glutamatergic neurons is tightly coupled to glutamate release and recycling.
2. The stoichiometry supports a model in which astrocyte glucose uptake is coupled mechanistically to the glutamate/glutamine cycle (90) through the need for glycolytic ATP to transport glutamate into the astrocyte and synthesize glutamine.
3. The increase in glucose consumption measured during functional activation may be directly coupled to the glutamate/glutamine cycle, providing a calibration for the functional imaging signal.

The GABA level in human cerebral cortex is reduced in epilepsy, alcohol withdrawal, and depression and is raised by several pharmacologic treatments (111 ,129):

1. The concentration of the metabolic pool of brain GABA may play a critical role in inhibitory GABAergic function.
2. Measuring cerebral cortex GABA level provides a useful index of brain GABAergic function and the effectiveness of certain antiepileptic drugs.

Reduction in the activity of GAD_{67} by elevation of GABA leads to a major reduction in the rate of GABA synthesis under nonstimulated conditions (24):

1. GAD_{67} is the major enzyme controlling nonstimulated GABA synthesis in the rate cerebral cortex.
2. Through regulation of GABA concentration GAD_{67} may play a key role in the etiology and pharmacology of epilepsy and other neurologic and psychiatric disorders.
3. The ability of ^{13}C MRS to measure the rate of GABA synthesis in combination with GABA/glutamine neurotransmitter cycling (39) may allow the functional roles of GAD_{65} and GAD_{67} isoforms to be distinguished quantitatively.

The glycogen shunt model provides a mechanistic explanation for the apparent uncoupling of glucose consumption and oxidation during sensory stimulation (151).

The majority of energy to support incremental and total neuronal activity during sensory stimulation is provided by neuronal oxidative glucose metabolism (14 ,131 ,156):

1. The total as opposed to incremental neuronal activity is required to support brain function during sensory stimulation (143).
2. A large amount of unfocused neuronal activity in the nonstimulated state is required for brain function.

The Spatial, Temporal, and Interpretive Limits of Functional MRI

Peter A. Bandettini

Peter A. Bandettini: Unit on Functional Imaging Methods, Laboratory of Brain and Cognition, National Institute of Mental Health, Bethesda, Maryland.

Since the inception of functional magnetic resonance imaging (fMRI) in 1991, an explosive growth in the number of users has been accompanied by steady widening of its range of applications. A recent search of the National Library of Medicine database for articles with *fMRI* or *BOLD* (blood oxygenation-dependent) in the title revealed more than 1,000 citations. Improvements continue in pulse sequence design, data processing, data interpretation, and the tailoring of cognitive paradigms to the unique advantages and limits of the technique. This chapter describes the receding limits of fMRI. Specifically, the limits of spatial resolution, temporal resolution, interpretability, and implementation are discussed. The goal is to give the reader a perspective of the evolution of fMRI in the past 9 years and a sense of excitement regarding its ultimate potential.

A user of fMRI primarily is interested in extracting at least one of three types of neuronal information: where neuronal activity is happening, when it is happening, and the degree to which it is happening. To extract this information optimally, an understanding of the basics of some of the more esoteric details is necessary, which are presented in this chapter. First, the basics of fMRI contrast are discussed. Second, the key of fMRI interpretation, the *neuronal–hemodynamic transfer function*, is described. Third, an overview of methods by which neuronal activation is played out in fMRI subjects and subsequently measured is provided. In this section, the popular technique of *event-related fMRI* (ER-fMRI) is described in detail, along with emerging methods of neuronal information extraction. Fourth, the issues of temporal and spatial resolution are discussed. Fifth, the limits of interpretation and the potential for further neuronal–hemodynamic information extraction are discussed. Lastly, some implementation limits are finally given as a practical guideline.

CONTRAST IN fMRI

Part of "26 - The Spatial, Temporal, and Interpretive Limits of Functional MRI "

Several types of physiologic information can be mapped with fMRI. This information includes baseline cerebral blood volume (1 ,2 and 3), changes in blood volume (4), baseline and changes in cerebral perfusion (5 ,6 ,7 ,8 ,9 and 10), and changes in blood oxygenation (11 ,12 ,13 ,14 ,15 ,16 and 17). Recent advances in fMRI pulse sequence and experimental manipulation have allowed quantitative measures of cerebral metabolic rate of oxygen ($CMRO_2$) changes and dynamic, noninvasive measures of blood volume with activation to be extracted from fMRI data (18 ,19 and 20).

Blood Volume

In the late 1980s, the use of rapid MRI allowed tracking of transient signal intensity changes over time. One application of this utility was to follow the T2*- or T2-weighted signal intensity as a bolus of an intravascular paramagnetic contrast agent passed through the tissue of interest (2). As it passed through, susceptibility-related dephasing increased then decreased as the bolus washed out. The area under these signal attenuation curves is proportional to the relative blood volume. In 1990, Belliveau and colleagues (4) took this technique one step further and mapped blood volume during rest and during activation. The first maps of brain activation obtained with fMRI were demonstrated with this technique. As soon as the technique was demonstrated, it was rendered obsolete (for brain activation imaging) by the use of an endogenous and oxygen-sensitive contrast agent—hemoglobin.

Blood Oxygenation

As early as the 1930s, it was known that hemoglobin is paramagnetic and deoxyhemoglobin is diamagnetic (21). In 1982, it was discovered that changes in blood oxygenation change the T2 of blood, but it was not until 1989 that

this knowledge was used to image *in vivo* changes in blood oxygenation (22). Blood oxygenation-dependent contrast, coined *BOLD contrast* by Ogawa et al. (23), was used to image the activated brain for the first time in 1991. Interestingly, Ogawa et al. predicted its utility for functional brain imaging; however, they predicted a signal *decrease* rather than a signal *increase*, as implied by some earlier positron emission tomography (PET) results by Fox and Raichle (24) suggesting that the oxygen extraction fraction decreased during activation. The first results of the use of BOLD contrast were published in 1992 (13 ,15 ,23). Because of its sensitivity and ease of implementation, the contrast used to observe susceptibility changes with changes in blood oxygenation is the most commonly used functional brain imaging contrast, and this is the technique primarily discussed in this chapter. The cascade of events that follow brain activation and lead to BOLD signal changes is shown in Fig. 26.1 .

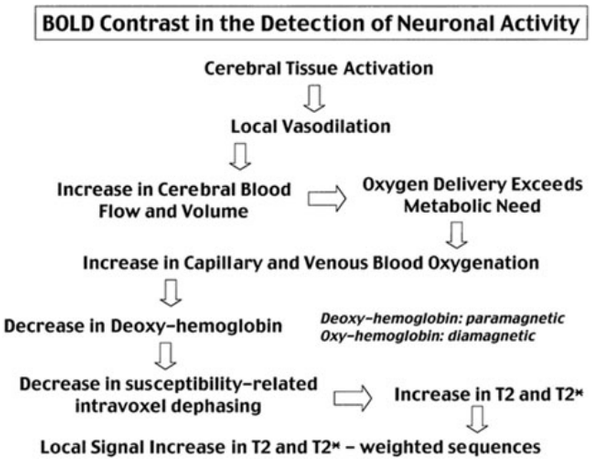

FIGURE 26.1. The cascade of hemodynamic and magnetic resonance imaging events that occur following brain activation.

Blood Perfusion

An array of new techniques exist for mapping cerebral blood *perfusion* in humans. Arterial spin labeling-based perfusion mapping MRI techniques are similar to those applied in other modalities, such as PET and single-photon emission computed tomography (SPECT); in-flowing blood is tagged and then allowed to flow into the imaging plane. The radiofrequency (RF) tagging pulse is usually a 180-degree pulse that "inverts" the magnetization.

Generally, these techniques can be subdivided into those that use continuous arterial spin labeling, which involves continuously inverting blood flowing into the slice, and those that use pulsed arterial spin labeling, which periodically inverts a block of arterial blood and measures the arrival of that blood into the imaging slice. Examples of these techniques are *echo-planar imaging with signal targeting and alternating RF* (EPISTAR) (25) and *flow-sensitive alternating inversion recovery* (FAIR) (10 ,26). Recently, a pulsed arterial spin-labeling technique known as *quantitative imaging of perfusion using a single subtraction* (QUIPSS) has been introduced (27).

Hemodynamic Specificity

With each of the above-mentioned techniques for imaging volume, oxygenation, and perfusion changes, the precise type of observable cerebrovascular information can be more finely delineated. Although this information is typically more than the cognitive neuroscientist requires, it is useful to give an abbreviated summary of how specific MRI can actually be. Regarding susceptibility contrast imaging, spin-echo sequences are more sensitive to small susceptibility compartments (capillaries and red blood cells), and gradient-echo sequences are sensitive to susceptibility compartments of all sizes (28 ,29 ,30 and 31). Outer-volume RF saturation removes in-flowing spins (32), thereby reducing non–susceptibility-related inflow changes when short-repetition time (with high flip angle) sequences are used. Diffusion weighting or "velocity nulling," involving the use of $b > 50$ s/mm^2, reduces the intravascular signal (33), thereby reducing, but not eliminating, large-vessel effects (intravascular effects are removed but extravascular effects remain) in gradient-echo fMRI and all large-vessel effects in spin-echo fMRI. Performing BOLD contrast fMRI at high field strengths has the same effect as diffusion weighting in the context of susceptibility-based contrast because the T2* and T2 of venous blood becomes increasingly shorter than the T2* and T2 of gray matter as field strength increases; therefore less signal arises from venous blood at higher field strengths. (34). Figure 26.2 is a schematic diagram summarizing the pulse sequence selectivity of the specific aspects of the vasculature.

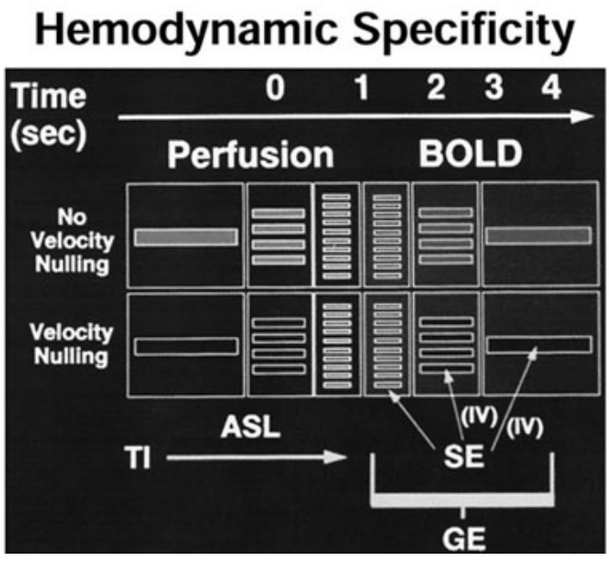

FIGURE 26.2. The vascular tree, including arteries *(left)* and arterioles, capillaries, and veins *(right)*. If the inside of the vessel drawing is filling in, the signal has an intravascular contribution. Arterial spin labeling (ASL) is differentially sensitive to the arterial–capillary region of the vasculature, depending on the inversion time (TI) used and whether or not velocity nulling (otherwise called *diffusion weighting*) gradients are used. A small amount of velocity nulling and a TI of about 1 s make ASL techniques selectively sensitive to capillaries. Susceptibility-based techniques, including gradient-echo and spin-echo, are also differentially sensitive to specific aspects of the vasculature. Gradient-echo techniques are sensitive to susceptibility perturbers of all sizes; therefore, they are sensitive to all intravascular and extravascular effects. Spin-echo techniques are sensitive to susceptibility perturbers about the size of a red blood cell or capillary, so that they are sensitive to intravascular effects in vessels of all sizes and to extravascular capillary effects. Velocity nulling makes gradient-echo sequences sensitive to extravascular capillary-to-vein effects, and makes spin-echo sequences selectively sensitive only to capillary effects. See color version of figure.

Cerebral Metabolic Rate of Oxygen

Recently, advances in mapping activation-induced changes in the $CMRO_2$ with fMRI have been developed (18 ,20 ,35 ,36 and 37). The basis for such measurement is that BOLD and perfusion contrast can be explained by the combination of a handful of parameters. The key, then, is either to constrain the contrast or manipulate the physiologic state such that the number of parameters reduces to one or two. Normalization by means of a hypercapnia has evolved as a method for mapping changes in $CMRO_2$ (18). The basic idea is that when the brain is activated, increases in flow, volume, and oxygenation are accompanied by an increase in $CMRO_2$. When a subject at rest is undergoing a hypercapnic stress (5% CO_2), the cerebral flow, volume, and oxygenation increase without an accompanying increase in $CMRO_2$; therefore,

less oxygen is extracted from the blood stream, so that the blood oxygenation change, relative to the perfusion change, is greater than with brain activation. By comparing the ratio of the (simultaneously measured) perfusion and BOLD signal changes during hypercapnia and during brain activation, $CMRO_2$ information can be derived.

HEMODYNAMIC TRANSFER FUNCTION

Part of "26 - The Spatial, Temporal, and Interpretive Limits of Functional MRI "

The hemodynamic transfer function is referred to here as the combined effect on the fMRI signal change by the spatial and temporal variation in neuronal–vascular coupling, blood volume, blood flow, blood oxygenation, hematocrit, and vascular geometry, among other things. A goal of fMRI method development is to characterize this transfer function completely (i.e., its spatial, temporal, pulse sequence, subject, physiologic, and pharmacologic dependencies), so that more precise inferences can be made about underlying neuronal activation location, magnitude, and timing. The ultimate limits of fMRI depend on this characterization. This goal is particularly relevant in the context of understanding pharmacologic effects on brain function.

After the onset of activation, or rather after the neuronal firing rate has passed an integrated temporal–spatial threshold, either direct neuronal, metabolic, or neurotransmitter-mediated signals reach arteriole sphincters and cause dilation. The time for this initial process to occur is likely to be less than 100 ms. After vessel dilation, the blood flow rate increases by 10% to 200%. The time for blood to travel from arterial sphincters through the capillary bed to pial veins is about 2 to 3 s. This transit time determines how rapidly the blood oxygenation saturation increases in each part of the vascular tree. As shown in Fig. 26.2 , depending on the pulse sequence used, different aspects of the hemodynamics are manifested.

Location

In resting state, hemoglobin oxygen saturation is about 95% in arteries and 60% in veins. The increase in hemoglobin saturation with activation is largest in veins, changing from about 60% to 90%. Likewise, capillary blood saturation changes from about 80% to 90%. Arterial blood, already saturated, shows no change. This large change in saturation is one reason why the strongest BOLD effect is usually seen in draining veins.

The second reason why the strongest BOLD effect is seen in draining veins is that activation-induced BOLD contrast is highly weighted by blood volume in each voxel. Because capillaries are much smaller than a typical imaging voxel, most voxels, regardless of size, likely contain about 2% to 4% capillary blood volume. In contrast, because the size and spacing of draining veins are on the same scale as most imaging voxels, it is likely that veins dominate the relative blood volume in any voxel that they pass through. Voxels that pial veins pass through can have 100% blood volume, whereas voxels that contain no pial veins may have only 2% blood volume. This stratification in blood volume distribution strongly determines the magnitude of the BOLD signal.

As suggested in Fig. 26.2 , different pulse sequence weightings can give different locations of activation. For example, Fig. 26.3 shows the activation in the motor cortex with two different functional MRI contrast weightings collected in the same plane—perfusion and BOLD. Although much overlap is seen, the hot spots vary by as much as 10 mm. The perfusion change map is sensitive primarily to *capillary* perfusion changes, whereas the BOLD contrast activation map is weighted mostly by veins. A potential worry regarding fMRI location is that venous blood, flowing away from the activated area, may maintain its elevated oxygen

saturation as far as a centimeter away. When brain activation is observed on a scale of centimeters, this has not been a major concern. Nevertheless, this issue is discussed in detail later in the chapter.

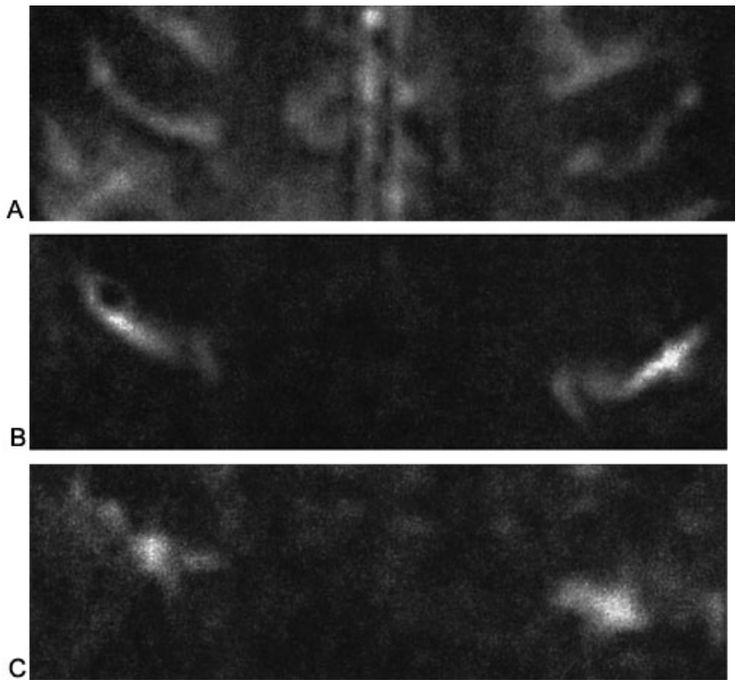

FIGURE 26.3. Comparison of activation-induced signal changes in perfusion and BOLD (blood oxygenation-dependent) measurements. Both measurements were obtained at 3 T. Perfusion measurements were obtained by using FAIR-EPI (flow-sensitive alternating inversion recovery echo-planar imaging) with an inversion time of 1,400 ms. BOLD (blood oxygenation-dependent) measurements were obtained by using gradient-echo EPI with an echo time of 30 ms.

Latency

One of the first observations made regarding fMRI signal changes is that after activation, the BOLD signal takes about 2 to 3 s to begin to deviate from baseline (16 ,38). Because the BOLD signal is highly weighted toward venous oxygenation changes, with a flow increase, the time for venous oxygenation to begin to increase is about the time that it takes blood to travel from arteries to capillaries and draining veins, which is 2 to 3 s. The hemodynamic “impulse response” function has been effectively used to characterize much of the BOLD signal change dynamics (39 ,40 and 41). This function has been derived empirically by performing very brief and well-controlled stimuli. In addition, it can be derived by deconvolving the neuronal input from the measured hemodynamic response (42 ,43). This type of analysis assumes that the BOLD response behaves in a manner that can be completely described by linear systems analysis, which is still an open issue. Regardless, observed hemodynamic response to any neuronal activation can be predicted with a reasonable degree of accuracy by convolving expected neuronal activity timing with the BOLD “impulse response” function. This function has typically been mathematically described by a γ variate function (39).

If a task onset or duration is modulated, the accuracy to which one can correlate the modulated input parameters to the measured output signal depends on the variability of the signal within a voxel or region of interest. In a study by Savoy et al. (44) addressing this issue, variability of several temporal sections of an activation-induced response was determined. Six subjects were studied, and for each subject, 10 activation-induced response curves were analyzed. The relative onsets were determined by finding the latency with which the correlation coefficient was maximized with each of three reference functions representing three parts of the response curve: the entire curve, the rising section, and the falling section. The standard deviations of the whole curve, rising phase, and falling phase were found to be 650, 1,250, and 450 ms, respectively.

Across-region differences in the onset and return to baseline of the BOLD signal during cognitive tasks have been observed. For example, during a visually presented event-related word stem completion task, Buckner et al. (45) reported that the signal in visual cortex increased about 1 second before the signal in the left anterior prefrontal cortex. One might argue that this observation makes sense from a cognitive perspective because the subject first observes the word stem and then, after about a second, generates a word to complete this task. Others would argue that the neuronal onset latencies should not be more than about 200 ms. Can inferences of the cascade of brain activation be made on this time scale from fMRI data? Without a method to constrain or work around the intrinsic variability of the onset of BOLD signal over space, such inferences should not be made in temporal latency differences below about 4 s.

Lee et al. (46) were the first to observe that the fMRI signal change onset within the visual cortex during simple visual stimulation varies from 6 to 12 s. These latencies were also shown to correlate with the underlying vascular structure. The earliest onset of the signal change appeared to be in gray matter, and the latest onset appeared to occur in the largest draining veins. Similar latency dispersions in motor cortex have been observed. In one study, latency differences, detected in visual cortex with the Hilbert transform, did not show a clear correlation of latency with evidence for draining veins (47).

Figure 26.4 is a summary of the sources of temporal variability. Figure 26.4A shows a plot of the average time course from the motor cortex as a result of 2-second finger tapping. As mentioned, the first source of variability is the intrinsic noise in the time series signal. The standard deviation of the signal is on the order of 1%. The second source of variability is that of the hemodynamic response. As mentioned, this ranges from 450 to 1,250 ms, depending on whether one is observing the rising phase of the signal or

the falling phase. The third source of variability is the latency spread over space.

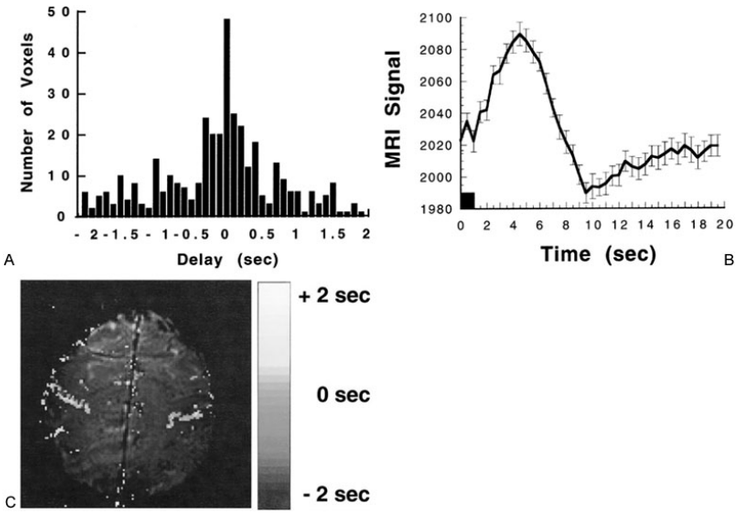

FIGURE 26.4. Demonstration of several of the limits of functional magnetic resonance imaging temporal resolution. Echo-planar imaging was performed at 3 T by using a Bruker Biospec 3T/60 equipped with a local head gradient coil. A time course series of axial images (matrix size = 96 × 96, field of view = 20 cm, echo time = 40 ms, repetition time = 500 ms, flip angle = 80 degrees) through the motor cortex was obtained. Bilateral finger tapping was performed for 2 s, followed by 18 s of rest. These figures demonstrate that the upper temporal resolution is determined by the variability of the signal change in time and space. **A:** Time course of the signal elicited by tapping fingers for 2 s. The standard deviation at each point is in the range of 1% to 2%. The standard deviation of the hemodynamic change, in time, is in the range of 450 to 650 ms. **B:** Map of the dot product (a measure of the activation-induced signal change magnitude) and the relative latencies or delays of the reference function (the plot in **A** was used as the reference function) at which the correlation coefficient was maximized. The spatial distribution of hemodynamic delays has a standard deviation of about 900 ms. The longest delays approximately match the regions that show the highest dot product and the area where veins are shown as *dark lines* in the T2*-weighted anatomic image. **C:** Histogram of relative hemodynamic latencies. This was created from the latency map in **(B)**.

The plot in Fig. 26.4A was used a reference function for correlation analysis and allowed to shift ± 2 s. Figure 26.4B is a histogram of a number of voxels in an activated region that demonstrated a maximum correlation with the reference function at each latency (relative to the average latency) to which the reference function was shifted. The spread in latencies is more than 4 s. Figure 26.4C includes a map of dot product (measure of signal change magnitude) and latency; the regions showing the longest latency roughly correspond to the regions that show the largest signal changes. Although these largest signal changes are likely downstream draining veins, it is important to note that this approximate correlation between latency and magnitude is extremely weak. Many very small signal changes show very long latencies. It is also interesting to note that the inverse, that many large signal changes show short latencies, is typically not true. This implies that many downstream vessels may be almost fully diluted back to resting state oxygenation, therefore showing only a small signal change but still a large latency. Again, work is ongoing to characterize this effect better.

Magnitude

As previously discussed, the magnitude of the fMRI signal change is influenced by many variables across subjects, neuronal systems, neuronal systems, and voxels. Making a complete and direct correlation between neuronal activity and fMRI signal change magnitude in a single experiment will remain impossible until all the variables can be characterized on a voxel-related basis. Because of these primarily physiologic variables, the magnitude of BOLD signal changes on brain activation maps typically ranges from 1% to 5% [at, say, 1.5 tesla (T), gradient-echo sequence, echo time of 40 ms]. The picture is not that bleak, though. In the past several years, considerable progress has been made in characterizing

the magnitude of the fMRI signal changes with underlying neuronal activity.

The progressive series of studies was as follows: First, as mentioned previously, it was clear that areas that showed significant BOLD signal change were in the appropriate neuronal area corresponding to specific, well-characterized tasks. Second, inferred neuronal modulation was carried out by systematically varying some aspect of the task. Clear correlations between BOLD signal change magnitude and visual flicker rate, contrast, word presentation rate, and finger tapping rate were observed (13 ,48 ,49 and 50). This parametric experimental design represented a significant advance in the manner in which fMRI experiments were performed, enabling more precise inferences, not about the BOLD signal change with task modulation. Nevertheless, of course, the degree of neuronal activation (i.e., integrated neuronal firing over a specified area) was still inferred.

Recently, several more intriguing studies have emerged correlating measured neuronal firing rate with well-known stimuli in animals (51) and humans (52 ,53) and demonstrating a remarkably high correlation between BOLD signal change and electrophysiologic measures.

Linearity

Related to the topic of signal change magnitude is that of BOLD signal change linearity. It has been found that, with very brief stimulus durations, the BOLD response shows a larger signal change magnitude than expected if one assumes that it behaves as a linear system (54 ,55). This greater than expected BOLD signal change is generally specific to stimulus durations below 3 s. Reasons for nonlinearities in the event-related response can be neuronal, hemodynamic, or metabolic in nature. The neuronal input may not be a simple boxcar function. Instead, an increased neuronal firing rate at the onset of stimulation (neuronal “bursting”) may cause a slightly larger amount of vasodilation that later plateaus at a lower steady-state level. The amount of neuronal bursting necessary to change the hemodynamic response significantly, if a linear neuronal-hemodynamic coupling is assumed, is quite large. For example, to account for the almost double functional contrast for the experimental relative to the linear convolution-derived single-event responses, the integrated neuronal response greater than 2 s must double. If it is assumed that neuronal firing is at a higher rate only for about the first 50 ms of brain activation, the neuronal firing rate must be 40 times greater than steady state for this duration.

BOLD contrast is highly sensitive to the interplay of blood flow, blood volume, and oxidative metabolic rate. If, with activation, any one of these variables changes with a different time constant, the fMRI signal may show fluctuations until a steady state is reached (56 ,57). For instance, an activation-induced increase in blood volume would slightly reduce the fMRI signal because more deoxyhemoglobin would be present in the voxel. If the time constant for blood volume changes were slightly longer than that of flow changes, then the activation-induced fMRI signal would first increase, then be reduced as blood volume later increased. The same could apply if the time constant of the oxidative metabolic rate were slightly slower than that of flow and volume changes. Evidence for an increased oxidative metabolic rate after 2 min of activation is given by Frahm et al. (57), but no evidence suggests that the time constant of the increase in oxidative metabolic rate is only seconds longer than the flow increase time constant—as would be required to be applicable only to relatively high-amplitude single-event responses. These hemodynamics, which may also differ on a voxel-related basis, remain to be characterized fully.

SCANNER-RELATED ISSUES

Part of "26 - The Spatial, Temporal, and Interpretive Limits of Functional MRI "

A complete discussion of all scanner-related issues and potential solutions is beyond the scope of this chapter. A rudimentary yet necessary description of the most basic problems and solutions is presented in the following sections. Most practitioners of functional MRI typically undergo a painful, frustrating, and prolonged period of learning about all scanner-related limitations and issues. Some give up hope completely. Those who are determined usually emerge hopeful again, and with a much better “feel” for what can and cannot be done in regard to brain imaging. This learning process also applies to understanding the physiology of the signal, but typically the greatest anguish arises in the context of MRI pulse sequences and hardware.

In the first place, all the categories listed below are more or less linked. In this section, an attempt is made to walk the reader informally through the trade-offs and issues involved in performing an fMRI experiment.

Acquisition Rate

Image acquisition rate is ultimately limited by how fast the signal can be digitized and by how rapidly the imaging gradients can be switched. MRI can be logically divided into single-shot and multishot techniques. In single-shot imaging, spins are excited with a single excitation pulse and all the data necessary to create an image are collected at once. Echo-planar imaging (EPI) is the most common single-shot technique; with one “echo,” a single “plane” is acquired. Multi-shot techniques are most commonly used for high-resolution anatomic imaging. In clinical scanning (with multi-shot imaging), a single “line” of raw data is acquired with each RF excitation pulse. Because of the relatively long time it takes for the longitudinal magnetization to return to equilibrium (characterized by the T1 of the tissue), a certain amount of time, between 50 and 500 ms, is spent waiting between shots; otherwise, soon no signal would be

left. It would be “saturated.” Because of this necessary waiting time, multishot techniques are typically slower than single-shot techniques. For a 150-ms “waiting time,” or repetition time (TR), an image with 128 lines of raw data would take 150 ms multiplied by 128, or 19.2 s.

In the case of EPI, the entire data set for a plane is typically acquired in about 20 to 40 ms. In the context of performing a BOLD experiment, the echo time (TE) is about 20 to 40 ms. Along with some additional time for applying other necessary gradients, the total time for an image to be acquired is about 60 to 100 ms, so that 10 to 16 images can be acquired in a second. Improvements in digital sampling rates and gradient slew rates will allow small improvements, but essentially, this is about the upper limit for imaging humans.

In the context of an fMRI experiment with EPI, the typical image acquisition rate is determined by how many slices can temporally fit into a TR. For whole-brain imaging, approximately 20 slices (5-mm thickness) are required to cover the entire brain. This allows a TR of about 1.25 to 2 s at minimum. This image collection rate is more than adequate to capture most of the details of the slow and dispersed hemodynamic response.

Spatial Resolution

The spatial resolution is also primarily determined by gradient strength, digitizing rate, and time available. For multishot imaging, as high a resolution as desired can be achieved if one is willing to wait. One can keep on collecting lines of data with more RF pulses. For EPI, the signal decay rate (described by T2* with gradient-echo EPI and by T2 with spin-echo EPI) plays a significant role in determining the resolution. One can sample for only so long before the signal has completely decayed away. For this reason, the resolution of EPIs is generally much lower than that of multishot images. To get around this problem, two further strategies are commonly used. The first is multishot EPI, in which the full EPI acquisition is used multiple times (but many fewer times than in typical clinical multishot imaging) and interleaved to increase the resolution. The second is to perform an operation called *conjugate synthesis*, which basically makes use of the fact that, in raw data space, half of the data is redundant. This allows at most twice the resolution, with some cost in signal to noise and image quality. An example of multishot EPI is shown in Fig. 26.5 .

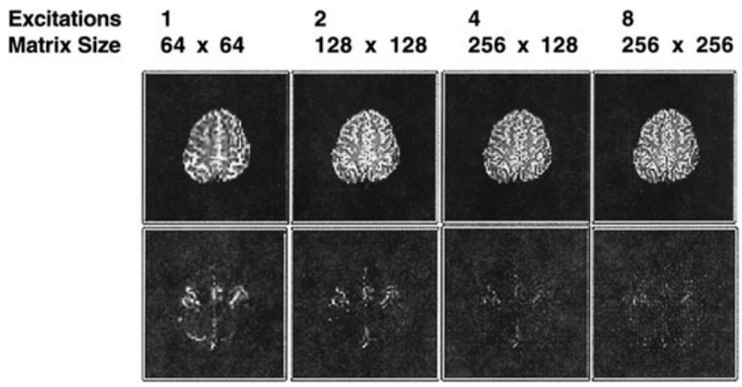

FIGURE 26.5. An example of multishot echo-planar imaging. Number of excitations ranged from 1 to 8. The image resolution increases but the signal to noise and functional contrast to noise decrease. In addition, instabilities are introduced into the time course by the use of multishot imaging.

Signal to Noise

The signal to noise and the functional contrast to noise are influenced by many variables. These include, among others, voxel volume, TE, TR, flip angle, receiver bandwidth, field strength, and RF coil used. Not considering fMRI for a moment, the image signal to noise is increased with larger voxel volume, shorter ET, longer RT, larger flip angle (to 90 degrees), narrow receiver bandwidth, higher field strength, and smaller RF coil. That said, in the context of fMRI, the functional contrast to noise is optimized with a voxel volume equaling the size of the activated area, TE ≈ gray matter T2*, short TR (optimizing samples per unit time), flip angle = Ernst angle = Cos (-TR/T1), narrow receiver bandwidth, high field strength, and smaller RF coil. Of course, all of these variables come at some expense to others.

Stability

Theoretically, the noise, if purely thermal in nature, should propagate similarly over space and across time. In fMRI, this is not at all the case because each image is essentially captured in 40 ms and the time series is collected in minutes. Stability is much more of an issue on the longer time scale.

Flow and motion are correlated in many areas with cardiac and respiratory cycles. Subject movement and scanner instabilities also contribute. Single-shot techniques have generally better temporal stability than multishot techniques because, with multishot techniques, the image is collected over a larger time scale; instabilities on a longer time scale enter into the image creation itself. This leads to nonrepeatable ghosting patterns that generally decrease temporal signal to noise ratio. Work is ongoing to characterize and reduce temporal instabilities for both single-shot and multishot imaging techniques (58 ,59). Correction techniques include cardiac gating (60), navigator pulses (61 ,62), and raw data reordering (63 ,64).

Image Quality

Image quality issues that are the most prevalent are image warping and signal dropout. Although books can be written on this subject, the description here is limited to the bare essentials.

Image warping is fundamentally caused by either or both of two factors, B_o-field inhomogeneities and gradient nonlinearities. A nonlinear gradient causes nonlinearities in spatial encoding, so that the image is distorted. This is primarily a problem when local, small-gradient coils are used that have a small region of linearity that drops off rapidly at the base and top of the brain. With the growing prevalence of whole-body gradient coils for performing EPI, this problem is no longer a major issue. If the B_o field is inhomogeneous, as is typically the case with imperfect shimming procedures, particularly at higher field strengths, the protons are processing at frequencies different from those expected in their particular location. This causes image deformation in the areas of poor shim, particularly with the long readout window or acquisition time of EPI. A solution is either to shim better (65 ,66) or map the B_o field and perform a correction based on this map (67).

Signal dropout is related to the problem described above in that it is also caused by localized B_o-field inhomogeneities, typically at interfaces of tissues having different susceptibilities. If within a voxel, because of the B_o inhomogeneities, spins are of different frequencies, their signals cancel each other out. Several strategies exist for reducing this problem. One is, again, to shim as well as possible at the desired area. Because of still imperfect shimming procedures, this is usually not satisfactory. The other is to reduce the voxel size (increase the resolution), so that stratification of different frequencies is reduced within a voxel. The third is to choose the slice orientation such that the smallest voxel dimension (in many studies, the slice thickness is greater than the in-plane voxel dimension) is perpendicular to the largest B_o gradient. For this reason, many studies are performed with the use of sagittal or coronal slice orientations.

As with many of the topics discussed, much more can be said, but the goal here is simply to provide an introduction and references to additional reading material.

BEST RESULTS SO FAR

Part of "26 - The Spatial, Temporal, and Interpretive Limits of Functional MRI "

The primary discussion up to this point has focused on the limits imposed by the scanner and the hemodynamics. In this section, some of the most successful, thought-provoking, and innovative fMRI studies, from a methodologic perspective, performed as of September 2000 are discussed. The best results in temporal and spatial resolution are presented.

Temporal Resolution

As explained in previous sections, MR images can be acquired at an extremely rapid rate; therefore, scanner-related limits are not the prime determinant of the upper limits of temporal resolution in fMRI. The key to increasing the temporal resolution in fMRI is either to characterize the hemodynamic response better or to work around its limits. The results described here are examples of this work during the past few years.

To obtain information about relative onsets of cascaded neuronal activity from hemodynamic latency maps, it is possible to determine *relative* latency changes on modulation of the task timing. In a study of Savoy et al. (68), activation onset latencies of 500 ms were discernible when they used a visual stimulation paradigm in which the left and right hemifields were stimulated at relative delays of 500 ms. First, the subject viewed a fixation point for 10 s. Then, the subject's left visual hemifield was activated 500 ms before the right. Both hemifields were activated for 10 s, then the left hemifield stimulus was turned off 500 ms before the right.

Although with careful choice of region of interest, from which the time course plot is made, these onset differences can be shown, maps of latency cannot reveal the onset differences because, as mentioned, the variability over space, which is about 4 s, dominates the inserted 500-ms variability from left to right hemifield.

To *map* the relative latency differences between hemifields, it is necessary to modulate the relative stimulation timing. As an extension of their results, the left—right onset order was switched so that, in the second run, the right hemifield was activated and turned off 500 ms before the left. Latency maps were made for each onset order and subtracted from each other to reveal a clear delineation between the right and left hemifields that was not apparent in each of the individual maps. This operation and the resulting *relative* latency map is shown in Fig. 26.6 . These maps are of the change in onset of one area relative to another, not of absolute latency. It is also useful to note that the standard deviation of these maps is reduced simply to the standard

deviation of the latencies in each voxel, not the standard deviation of the latencies over space. Maps such as these can be extremely useful in determining which regions of activation are modulated relative to other areas with a specific task timing modulation.

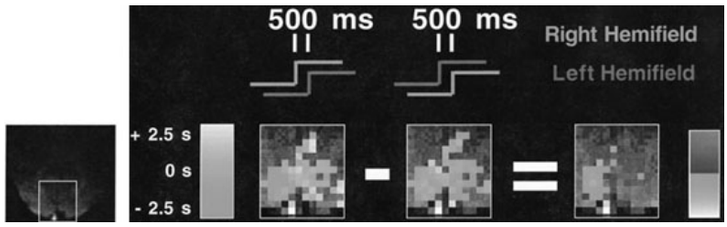

FIGURE 26.6. The use of latency maps and task modulation to extract relative latencies. Activation within a region of visual cortex is shown. In one condition *(left)*, the right visual hemifield stimulation precedes the left by 500 ms. In the other condition *(middle)*, the left visual hemifield precedes the right hemifield stimulation by 500 ms. Latency maps from both these conditions show an across-voxel spread of ± 2.5 s, which is too large to identify clearly the relative latencies across hemifields. However, once the data are normalized for this intrinsic variance by directly comparing the hemodynamic response from the two different lags within individual voxels, the offset between the left and right hemifields can be observed *(right)*. This demonstration suggests that normalization of the hemodynamic lag can allow small relative temporal offsets to be identified. These normalized offsets can then be compared across regions to make inferences about neuronal delay. For this experiment, the repetition time was 400 ms. See color version of figure.

Published work by Menon et al. (69), Kim et al. (70), Richter et al. (71), and Bandettini (72) has explored the temporal resolution limits of fMRI. The results of Menon et al. (69), similar to those mentioned above, indicate that relative brain activation timings on the order of 50 ms can be discerned.

In the study of Richter et al. (71), a parametrically varied event-related mental rotation task was used. Each mental rotation task was presented individually. A high correlation between task duration and event-related width was demonstrated. The longer the task took to accomplish (larger rotation angle), the wider the event-related response was shown to be in specific parietal locations.

Spatial Resolution

The hemodynamic point spread function was first considered and characterized by Engel et al. (73 ,74 and 75). Localization to 1.1 mm was determined.

The first successful mapping of ocular dominance columns in humans was published by Menon et al. (76). Their intriguing results show that the optimal way to pull out differences in activation across closely spaced units is to perform very brief stimuli so as not to reduce the dynamic range of the oxygenated blood that is flowing away beyond the unit of activation.

In regard to MRI pulse sequence, it is important to note that mapping cortical columns multishot imaging is required (76). Performance of multishot imaging requires either navigator echoes or shot-to-shot phase-correction schemes. If these are not performed, temporal stability is seriously compromised.

Many have argued that some aspects of the BOLD signal change dynamics are more spatially localized to neuronal activity. Specifically, the evasive “pre-undershoot” has been indicated as such (77 ,78). The rationale is that this transient “dip” in the signal that occurs 0.5 to 2 s after the onset of activation and quickly gives way to the much larger signal increase is secondary to direct extraction of oxygen from the blood by adjacent activated tissue. Recently published work has demonstrated the utility of such an approach for mapping cortical columns in animals (79 ,80 and 81).

The highest-resolution fMRI performed with single-shot EPI was obtained by Jesmanowicz et al. (82). Here, a partial k-space strategy was used to obtain a presumed 256 × 256 resolution. The actual resolution achieved is debatable because T2* effects reduced the resolution below that implied by the matrix size.

NEURONAL ACTIVATION INPUT STRATEGIES

Part of "26 - The Spatial, Temporal, and Interpretive Limits of Functional MRI "

Much of this chapter has been devoted to the basics and some esoteric issues regarding fMRI. This section provides an overview of the types of neuronal input strategies with which fMRI has been used to extract information about what the brain is doing. Given a question of brain function, what are the available strategies that one can use to design their paradigm? A schematic summary of these strategies appears in Fig. 26.7 .

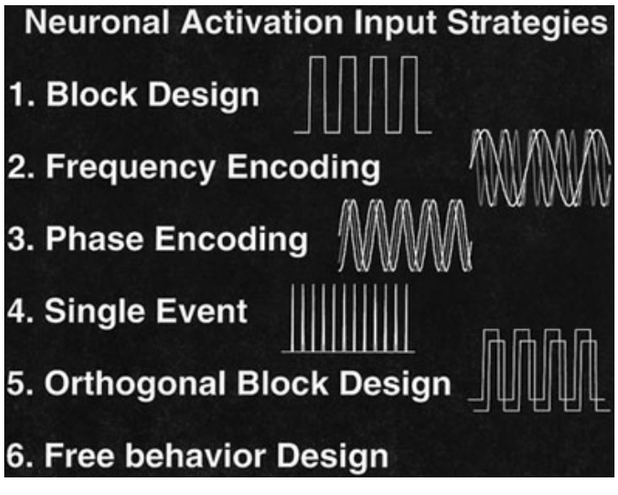

FIGURE 26.7. Overview and schematic depiction of types of neuronal input strategies available in functional magnetic resonance imaging. In addition, parametric designs, which involve systematically varying some aspect of the intensity of the neuronal input, can be applied to any of the design strategies.

Block Design

A block design paradigm was the first used in fMRI and is still the most prevalent neuronal input strategy. Borrowed

from previous PET studies, it involves having a subject alternately perform a task for at least 10 s, then a control task for a similar time, so that the hemodynamic response reaches a steady state in each condition. This is a useful technique in that it is easy to implement, and standard statistical tests can be used to compare each condition.

Phase and Frequency Encoding

Phase encoding of a stimulus involves varying some aspect of the stimulus in a continuous and cyclic manner. This strategy has been most successfully used in retinotopic mapping (75 ,83 ,84). In this type of study, the eccentricity of a visual stimulus ring is continuously varied; then, after the most extreme eccentricity is reached, the cycle is repeated. The data are typically subjected to Fourier analysis, and the areas that show a signal change temporal phase that correlates with the stimulus phase are mapped. This is a powerful technique because it makes use of the entire time series, in that there are no “off” states, and lends itself to Fourier analysis. This method has also been used for somatotopic mapping (85) and tonotopic mapping (86).

Frequency encoding is much less common but can be achieved for certain types of stimuli. The method is to designate a specific on–off frequency for each type of stimulus used. Again, Fourier analysis reveals the most power under a spectral peak corresponding to the brain area specific to the particular on/off frequency. The utility of this method has been demonstrated in mapping left and right motor cortex by cueing the subject to perform a finger-tapping task at different on–off rates for each hand (87).

Orthogonal Designs

Orthogonal task design is a powerful extension of block design. The basic concept is that if one designs two different task timings to create BOLD responses that are orthogonal to each other, then these tasks can be performed simultaneously during a single time series collection with no cross-task interference, so that comparison is much more precise. This technique was pioneered by Courtney et al. (88). In their study, six orthogonal tasks were designed into a single time series. This type of design also lends itself to event-related studies.

Parametric Designs

As mentioned in the section on magnitude, parametric designs are powerful in that more precise statements can be made about relative neuronal activity. A parametric task design simply involves systematically varying some aspect of the task during the time series. This may be a finger-tapping rate, stimulus contrast or flicker rate, cognitive load, or attention demand, and instead of mapping the magnitude of the change with a single task, the slope of the change corresponding to a task is mapped. In this manner, relative brain activation magnitude may be teased out of the time series.

Event-Related Designs

Before 1995, a critical question in event-related fMRI was whether a transient cognitive activation could elicit a significant and usable fMRI signal change. In 1996, Buckner et al. (45) demonstrated that event-related fMRI in fact lends itself quite well to cognitive neuroscience questions. In their study, a word stem completion task was performed; a block design and an event-related strategy were used. Robust activation in the regions involved with word generation were observed in both cases.

Given the substantial number of recent reports of event-related fMRI (40 ,41 and 42 ,65 ,89 ,90 ,91 ,92 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 ,108 ,109 ,110 ,111 and 112), it can probably be said that this is one of the more exciting developments in fMRI since its discovery.

The advantages of event-related activation strategies are many (113). These include the ability to randomize task types in a time series more completely (114 ,115 and 116), the ability to analyze fMRI response data selectively based on measured behavioral responses to individual trials (111), and the option to incorporate overt responses into a time series. Separation of motion artifact from BOLD changes is possible by use of the temporal response differences between motion effects and the BOLD contrast-based changes (91).

When a constant ISI is used, the optimal interstimulus interval (ISI) is about 10 to 12 s. Dale and Buckner (43) have shown that responses to visual stimuli, presented as rapidly as once every 1 s, can be adequately separated by

using overlap correction methods. Overlap correction methods are only possible if the ISI is varied during the time series. These results appear to demonstrate that the hemodynamic response is sufficiently linear that deconvolution methods can be applied to extract overlapping responses. Burock et al. (95) have demonstrated that remarkably clean activation maps can be created with an average ISI of 500 ms. If one assumes that the hemodynamic response is essentially a linear system, there appears to be no obvious minimum ISI in attempts to estimate the hemodynamic response. Dale has suggested that an exponential distribution of ISIs with a mean as short as psychophysically possible is optimal for estimation (100). Of course, the speed at which one can present stimuli depends on the study being performed. Many cognitive tasks may require a slightly longer average presentation rate.

Future work in event-related experimental optimization rests on what further information can be derived from these responses. Between-region, between-voxel, between-subject, and stimulus-dependent variations in amplitude, latency, shape, and responsivity of the event-related fMRI responses are still relatively uncharacterized. Reasons for these differences are also still unclear.

Free Behavior Designs

With many types of cognitive neuroscience questions, it is not possible to constrain the timing or performance of a task precisely. It is necessary to allow the subject to perform the task “freely” and obtain a continuous measurement of the performance, then use the measurement as a reference function for subsequent time series analysis. Examples of this type of design are emerging. As an example, skin conductance changes are difficult to predict or control. In a study by Patterson et al. (117), skin conductance was simultaneously recorded during an array of tasks and during “rest.” The skin conductance signal change was then used as a reference function in the fMRI time series analysis. In several cortical and subcortical regions, signal changes were observed that were highly correlated with the skin conductance changes. Without the use of this measurement, such signal changes would have appeared as noise. It is thought that this type of design will become more prevalent as methods to monitor subject performance or state precisely become more sophisticated.

CONCLUSION

Part of "26 - The Spatial, Temporal, and Interpretive Limits of Functional MRI "

This chapter has attempted to combine a review of the fundamentals of fMRI with a glimpse of the state of the art. Starting with the basics of fMRI contrast, the discussion moved on to hemodynamic transfer function—the basis of understanding fMRI signal change. Characteristics related to the hemodynamic transfer function include location, latency, magnitude, and linearity. Then, perhaps less provocative but still important issues of working with an MRI scanner and understanding some practical limitations were discussed. A sampling of best results, those successfully bringing into play many of the features of experimental design and analysis already mentioned, was presented. The chapter ended with a brief overview of neuronal input strategies, or rather, ways in which one can activate the brain in the context of an fMRI experiment.

Functional MRI is about 9 years old and apparently still at the beginning of its growth curve in terms of users and applications. Clinical applications are just beginning, whereas cognitive neuroscience applications are in full swing. The field of fMRI continues to develop along intertwining paths of understanding signals, creating tools, and refining the questions being asked.

The central nervous system (CNS) spans across different levels of organization, covering the gamut from genes to behavior. It is the aim of neuroscience to elucidate all these levels at a gross and an ultrastructural resolution and to define the relationships among them. One of the highest levels of organization is the systems level, which includes the motor, sensory, and central neural systems. Among the central systems are included those related to cognitive function, such as attention, memory, language, and executive function. Each system can be considered as a set of interconnected processors or centers constituted by nerve cells. Their physical connections are composed of axons of different lengths that can form fascicles as they run from origin to destination. Within the neocortex, these connections are selective and architectonic (1). How cytoarchitecture, connections, and function relate within the neocortex is a fundamental problem in neuroscience. This question addresses basic organizational principles of the nervous system and aims to elucidate the mechanisms through which the cerebrum mediates behavior (2 ,3). Behavior, to a large extent the product of cerebral function and at the same time a modulator of this function, is certainly the key to solving the problem of meaning related to any neural system. To explore thoroughly the behavioral dimension of an organism, it appears necessary to perform studies *in vivo*. If experiments were designed in such manner that information related to structure was gathered along with behavioral information, we would have an ideal setting for structural–functional or, in the case of disease, anatomic–clinical correlation. This can be done in the domain of neuroimaging by using currently available technology in an unprecedented way. In the past two centuries, functional–structural correlations were derived mostly from experimental nonhuman material, whereas anatomic–clinical correlations were derived principally from human behavioral and, eventually, postmortem lesion analyses. With the tremendous development of magnetic resonance imaging (MRI) technology—both structural and functional MRI (fMRI) and magnetic resonance spectroscopy (MRS)—the study of the structure, function, and metabolism of the living human is an ongoing reality.

One of the latest advancements of MRI technology has been *diffusion tensor imaging* (DTI), a technique capable of measuring the diffusivity of water molecules and rendering visible the preferential orientation of their movement. As water molecules diffuse within the brain, their movement is constrained by the structural “fingerprint” of the tissue. If the tissue is equally distributed in all directions, like light in a room, then a “random walk” of water molecules occurs and their diffusion is *isotropic* (i.e., “equally behaving” in all directions). On the other hand, within a strongly oriented tissue such as a white matter tract, water diffusion is not equal in all directions but is instead *anisotropic*, specifically predominant along the direction of the tissue. The strongly parallel axonal arrangement within a fiber bundle creates a highly oriented and anisotropic environment for

water molecules. Because DTI can measure the anisotropy and orientation of a tissue, and because brain white matter can be characterized to a large extent by its orientation and anisotropy, the detection of white matter fiber pathways has become feasible in the living brain.

Tractography (i.e., the "writing" or tracing of tracts) has been considered to be the most difficult task in neuroanatomy (4). To delineate neuroanatomic connections exactly, white matter fiber tracts have been traced systematically in postmortem experimental material during the last decades. It has emerged from studies in nonhuman primates that fiber pathways establish connections between distinctive architectonic cortical areas, and that they constitute fundamental components of neural systems that subserve specific functions (1 ,5 ,6). Extensive research during the past two centuries in higher brain function (and aphasiology in particular) has demonstrated the tight relationship between damage of commissural or associational fiber tracts and breakdown in cognitive human behavior (7 ,8 and 9). In the light of brain organization at a systems level in terms of architecture and its connections, it becomes evident how relevant the precise knowledge of neocortical pathways is to the understanding of human behavior in normal and disease states. Although the delineation of fiber tracts has been accomplished precisely and comprehensively in postmortem nonhuman primates, this goal has not been met in humans satisfactorily. Moreover, the study of fiber tracts *in vivo* is only beginning and is largely based on MRI techniques. DTI is one avenue that may provide solutions to the connectional structure of the CNS. Even though the identification and reconstruction of major fiber bundles has been accomplished with the use of DTI and computational techniques, the basic problems related to the biological sources of the DTI signal remain to be clarified. Thus, to achieve a comprehensive understanding of the sensitivity and specificity of the DTI technique, studies addressing both the gross and ultrastructural level of the white matter are necessary.

In this chapter, we overview the connectional composition of the cerebrum, emphasizing the morphology and architectonic structure of its pathways. Subsequently, we overview the DTI technique and illustrate its use at an ultrastructural and a gross neuroanatomic level. In this perspective, we elaborate on three representative white matter fiber pathways of the brain and emphasize how they can be mapped in terms of computational MRI neuroanatomy. Additionally, we discuss the utility, potential, and limitations of the DTI technique in the context of its applications and its integration within a larger neurofunctional MRI examination. For this purpose, we present a case of amyotrophic lateral sclerosis that we studied with MRI, DTI, MRS, and fMRI.

OVERVIEW OF WHITE MATTER PATHWAYS

Part of "27 - Diffusion Tensor Imaging "

Anatomic Connections

The white matter of the CNS contains axons serving corticocortical, commissural, cortico-subcortical, and cerebellar connections. These connections can be categorized in three principal classes—namely, associational, commissural, and projectional. Intrahemispheric associational corticocortical connectivity in particular is accomplished in general by (a) short U fibers that constitute the local circuitry within a gyrus, (b) intermediate-range fibers within the extent of a lobe, and (c) long association pathways that connect different lobes (10). A tract can be described at a morphologic level in terms of a set of descriptors (i.e., its stem, splay, and origins and terminations), whereas the set or map of its architectonic connections is its principle structural descriptor.

Morphologic Descriptors of a Fiber Pathway

Conceptually, a white matter fiber pathway is a group of axons that originate from a set of neuronal bodies and end on one or more sets of target neurons. Morphologically, we can distinguish three different components in a fiber bundle—namely (a) a compact portion or "stem" or "stalk" (11), where the axons run together to form a fascicle; (b) a zone of divergence/convergence called *spray* (12) or *splay*, where the axons fan out; and (c) the distal, peripheral *origins* and *terminations*, where the axons either originate or end. However, in current MRI research, the term *extreme periphery* seems more practical than the terms *origin* and *termination* for a couple of reasons. First, DTI does not allow the identification of this portion of a fiber pathway clearly enough to justify the application of such specific terminology. Second, both the corticocortical associational and the commissural connections are generally bidirectional, meaning that within the stem of a tract fibers are running in both directions; thus, origins and terminations pertaining to the same fiber tract occur in adjacent locations. The differentiation of these features is well beyond the current spatial resolution capabilities of DTI. Therefore, at a morphologic level, a comprehensive delineation of a fiber pathway should include its stem, splay, and extreme periphery. A description of the extreme periphery of an association fiber tract is related to a cortical field of origin or termination (Fig. 27.1).

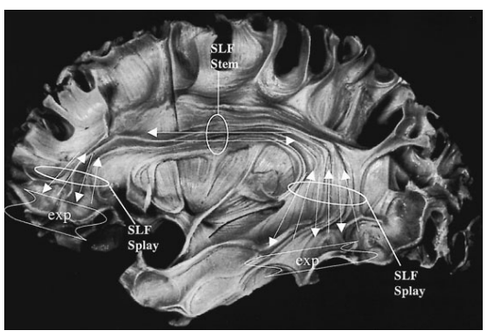

FIGURE 27.1. Morphologic description of a fiber pathway. In this lateral preparation of Ludwig and Klingler (53), the sample tract is the human superior longitudinal fasciculus, which is a long, associational, corticocortical connection. Its three components are (a) the stem, where axons run compactly and in a bidirectional fashion; (b) the splays or sprays, where the axons diverge or converge; and (c) the extreme peripheries, the cortical regions within which the axons originate or terminate. *Arrows* denote the bidirectionality of axons within the stem and the splays of the fiber tract as they run from origin to termination.

Architectonic Connections

The detailed characterization of a fiber pathway in terms of its cytoarchitectonic correlates is a fundamental step for the understanding of cerebral structural and functional organization. These issues have been addressed at the architectonic level in experimental animals and in human postmortem material. In particular, cerebral cytoarchitecture has been described precisely in both the human and the experimental animal, such as the macaque. In the experimental nonhuman primate, the white matter fiber pathways have been delineated precisely and comprehensively (i.e., in terms

of their stems, splays, and origins and terminations). Although this is currently the case for the nonhuman primate, the status of research in human brain anatomic connectivity is very different.

Studies in Human Postmortem Material

In human postmortem material, traditional techniques such as myelin stain, bichromate fixation, and gross anatomic dissection allow visualization of the stems of these fiber bundles (10). With very few exceptions, in which dyes such as the carbocyanine dye (DiI) were used for very short connections (13), histologic description of human fiber pathways is incomplete because it does not provide a detailed understanding of their origins and terminations, and no technique is available that can identify with certainty the origin and distal terminations of a fiber pathway satisfactorily in the human. The closest inferences at this level of description are obtained from white matter degeneration studies of brains with specific neurologic damage. Most of these studies deal with cortico-subcortical connections and are not specific because the cortical lesions that cause the remote degeneration are very large (10 ,14).

Studies in the Experimental Nonhuman Primate

Experimental approaches with available techniques have addressed the problem of origin and termination of fiber pathways in the monkey. The injection of radioactively labeled amino acids (15) into nonhuman primate brain with appropriate histologic processing techniques permits the accurate and reliable interpretation of the origins, trajectories, and terminations of the subcomponents of the various fiber pathways of the CNS. With this technique, a number of studies of the fiber connections between the different lobes of the cerebral cortex, between the two hemispheres, and between the cerebral cortex and subcortical regions have been carried out in the monkey. These studies have demonstrated that the various fiber bundles are distinct and occupy unique trajectories from origin to termination.

Extrapolation from Animal Experimental Material to Human Material

In the monkey, it is known how different pathways correlate with radioactively labeled material, so that their origin and termination can be delineated. Because the stems of the major pathways are similar in the monkey and the human, one can extrapolate the origins and terminations of the observed pathways in the human to correlate specific fiber pathways with cortical architectonic fields. Drawing these inferences, we can formulate for each individual fiber bundle a specific map that characterizes the tract in terms of its connections.

Maps of Anatomic Connectivity

A map of anatomic connectivity (MAC) is a *set of neuroanatomic regions interconnected by a particular white matter fiber pathway*, and we can symbolize it as $PATHWAY_{MAC}$. For instance, the MAC for cingulum bundle (CB) would be CB_{MAC} (Fig. 27.2). Whereas in the human we have precise knowledge only of the stem of this bundle, the architectonic connections in the nonhuman primate are well documented. A comprehensive description of maps for anatomic cerebral connectivity has been formulated, derived from anatomic studies in the human and by extrapolation from experimental material, and has been integrated in the context of a methodology for topographic characterization and quantification of human forebrain white matter (16 ,17). Because of their versatility, MACs could be relevant in the formulation of more sophisticated tractographic experiments and in interpreting neurofunctional data. Integrating the neuroanatomic knowledge of fiber tracts within an fMRI experiment is an additional challenge, but at the same time it seems to be key if we are to study behavior in normal and clinical conditions, which implies the study of fiber pathways *in vivo*.

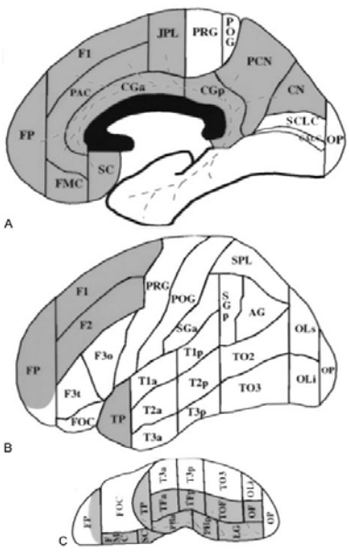

FIGURE 27.2. Map of cortical anatomic connectivity (MAC) for the cingulum bundle (CB), or CB_{MAC}. The connections of the CB are represented in the mesial **(A)**, lateral **(B)**, and ventral **(C)** views of the human brain on a cortical parcellation system (46). The *shaded area* in blue within the frontal pole in the ventral view corresponds approximately to the rostral part of the frontoorbital cortex that is anterior to the transverse orbital sulcus. AG, angular gyrus; CALC, intracalcarine cortex; CGa, cingulate gyrus, anterior; CGp, cingulate gyrus, posterior; CN, cuneiform cortex; CO, central operculum; F1, superior frontal gyrus; F2, middle frontal gyrus; F3o, inferior frontal gyrus, pars opercularis; F3t, inferior frontal gyrus, pars triangularis; FMC, frontal medial cortex; FO, frontal operculum; FOC, frontal orbital cortex; FP, frontal pole; H1, Heschl gyrus; INS, insula; JPL, juxtaparacentral cortex; LG, lingual gyrus; OP, occipital pole; OF, occipital fusiform gyrus; OLi, lateral occipital cortex, inferior; OLs, lateral occipital cortex, superior; PAC, paracingulate cortex; PCN, precuneus; PHa, parahippocampal gyrus, anterior; PHp, parahippocampal gyrus, posterior; PO, parietal operculum; POG, postcentral gyrus; PP, planum polare; PRG, precentral gyrus; PT, planum temporale; SC, subcallosal cortex; SCLC, supracalcarine cortex; SGa, supramarginal gyrus, anterior; SGp, supramarginal gyrus, posterior; SPL, superior parietal lobule; T1a, superior temporal gyrus, anterior; T1p, superior temporal gyrus, posterior; T2a, middle temporal gyrus, anterior; T2p, middle temporal gyrus, posterior; T3a, inferior temporal gyrus, anterior; T3p, inferior temporal gyrus, posterior; TFa, temporal fusiform, anterior; TFp, temporal fusiform, posterior; TO2, middle temporal gyrus, temporooccipital; TO3, inferior temporal gyrus, temporooccipital; TOF, temporooccipital fusiform gyrus; TP, temporal pole. See color version of figure.

In Vivo Analysis of Fiber Pathways

The capability of studying tracts in the living human brain opens up a new window in structural–functional and anatomic–clinical relationships. Currently, the detection of

fiber tracts *in vivo* has been addressed by MRI techniques such as DTI. DTI analysis enables us to characterize a white matter fiber pathway in terms of its orientation, location, and size. To date, tractography has been performed in two different ways. Using *manual* or *model-independent methods*, we can derive the trajectory of the fiber bundle and approximate its extreme peripheries (12). Using mathematically driven *model-based methods*, we can also trace a fiber pathway (18 ,19 and 20). In the section on applications, we give examples in which both methods are used and different tracts are visualized in two and three dimensions. Although the field of DTI-based brain tractography is expanding rapidly with impressive results, it has to be pointed out that certain basic conceptual obstacles still need to be overcome. For instance, in this stage, it has not been demonstrated that we are able to delineate completely and precisely a fiber tract in the brain by means of any DTI analysis technique. At the most, we can identify and characterize the stems of the major fiber tracts (12 ,21); however, the problem of elucidating the splays and extreme peripheries of the bundles remains to be solved reliably. Therefore, when we use the term *pathway*, *tract*, or *bundle*, we currently refer to its stem.

OVERVIEW OF DIFFUSION TENSOR IMAGING

Part of "27 - Diffusion Tensor Imaging "

Self-diffusion of molecules has been studied with magnetic resonance methodologies for several decades (22 ,23). For comprehensive reviews of the use of diffusion in nuclear magnetic resonance, we refer the reader to other sources (24 ,25 and 26). With respect to the physical principles underlying diffusion (also known as *brownian motion*), water in tissues with an oriented structure tends to diffuse more *along* the orientation of the tissue structure (Fig. 27.3). The incoherent motion of the diffusing water, when it occurs in the presence of a magnetic field gradient, leads to dephasing of the MR signal. This dephasing produces signal attenuation (SA), which is related to the magnitude of diffusivity of the water along the direction and magnitude of the applied gradient in an exponential fashion. For anisotropic gaussian diffusion, the SA is proportionate to

$$q_1 = \text{atan}(z/x) \;/\; n/2$$

$$q_2 = \text{atan}(y/h) \;/\; p/2$$

$$\text{where } h = \text{sqrt}(z^2 + x^2).$$

For isotropic diffusion, this reduces to the Stejskal–Tanner relation: $SA = SA_0\, e^{-bD}$, where D is the diffusion coefficient and b is the diffusion sensitivity factor. Note that $b = \gamma^2 g^2 \delta^2 (\Delta - \delta/3)$, where the values of g, δ, and Δ correspond to the values of the gradient amplitude, duration, and spacing, respectively, and γ is the hydrogen gyromagnetic ratio (27). The diffusion process can be parameterized by a 3 × 3 symmetric tensor, which can be represented by an ellipsoid, as shown in Fig. 27.3 .

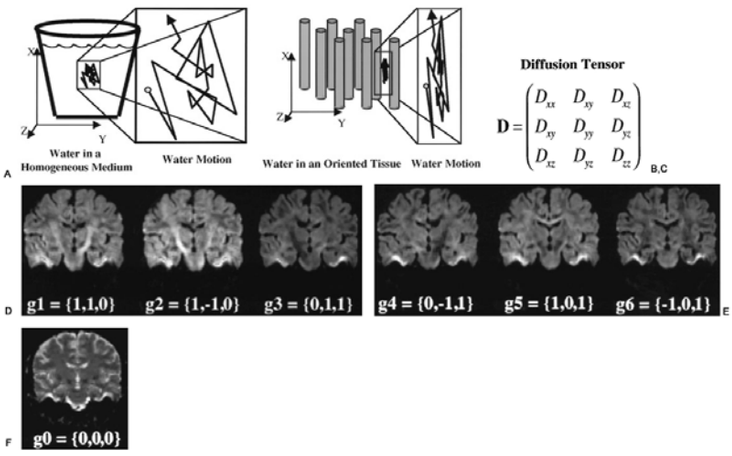

FIGURE 27.3. Schematic representation of water diffusion in the presence of **(A)** a nonoriented tissue structure and **(B)** an oriented tissue structure. Water mobility is highest along the direction with least interference—that is, along the direction of the fibers. **D,E:** Overview of the procedural steps involved in diffusion tensor acquisition. Six images with gradient sampling directions of g_1 = {1, 1, 0}, g_2 = {1, -1, 0}, g_3 = {0, 1, 1}, g_4 = {0, -1, 1}, g_5 = {1, 0, 1}, and g_6 = {-1, 0, 1}, and an additional baseline acquisition with no diffusion gradients, g_0 = {0, 0, 0}, are acquired. The six first data sets (gradients g_1 through g_6) are analyzed relative to the baseline acquisition with no diffusion encoding (g_0). This set of observations is sufficient to define the symmetric diffusion tensor representation of water self-diffusion, shown in **(C)**. See color version of figure.

HOW DO WE “BUILD” A DIFFUSION IMAGE?

Part of "27 - Diffusion Tensor Imaging "

The acquisition of the DTI requires the acquisition of six directionally weighted samples of the effect of the diffusion process relative to the axes of the imaging system. Specifically, the magnitude of the diffusion attenuation in MR signal along the *x*, *y*, and *z* axes themselves, as well as in the *xy*, *xz*, and *yz* directions, must be measured. The attenuation of MR signal in the presence of gradients in each of these directions is calculated relative to an image acquired with no diffusion encoding (baseline). Hence, seven (six directions, one baseline) acquisitions for each slice level are required. Once the tensor is sampled, the magnitude calculated from the trace expresses the *total* (no directionality) diffusivity at each voxel location (Fig. 27.4).

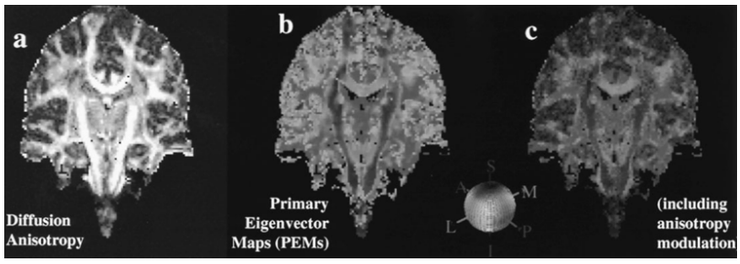

FIGURE 27.4. The tensor representation can be visualized in many ways. **A:** *Diffusion anisotropy*, defined as the relative magnitude of the major axis of the diffusion ellipsoid in comparison with the minor axes, can be visualized; in this figure, regions of high anisotropy are bright, yielding an observable substructure within the cerebral white matter. **B:** A primary eigenvector map (PEM) can be generated to observe the orientation of the major axis of the diffusion ellipse in three-dimensional space; red indicates medial–lateral, blue indicates superior–inferior, and green indicates anterior–posterior orientation, respectively. **C:** The PEM can include anisotropy modulation if the intensity of the color is made proportional to the degree of anisotropy present in each voxel. Regions of high anisotropy can be colored with intense color, whereas regions of low anisotropy have a pale coloring, so that the underlying anatomic image can be viewed. See color version of figure.

The directionality of diffusion is assessed by an eigen decomposition of the diffusion tensor. The largest eigenvalue corresponds to the major axis of the diffusion ellipsoid and so represents the major directionality of diffusion at that location.

Color Coding

A color is assigned for each voxel location by using the primary eigenvector (corresponding to the largest eigenvalue) of the diffusion tensor. At each voxel, the absolute values of the *x*, *y*, and *z* components are used as the red, green, and blue color values, respectively, such that a red voxel in the image means the vector points left–right (or right–left), green means anteroposteriorly (or posteroanteriorly), and blue represents superoinferiorly (or inferosuperiorly). For instance, if a vector points mostly in the red direction, then the *x* value of the vector will be large and the color will be pure red; otherwise, the color will be a mixture of red, green, and blue, depending on the magnitudes of the vector components (i.e., on the direction of the vector). In Fig. 27.4 , this color coding scheme is shown with the appropriate color painted onto a sphere, and the principal eigenvector map (PEM) is the result of color-coding a tensor image (Fig. 27.4).

Modulation by Anisotropy

To further distinguish white matter fiber pathways from other regions, the color is modulated by a measure of anisotropy of the voxel. This emphasizes the stems (i.e., the compact portions of the fiber tracts) by diminishing the brightness of everything else. Here, *anisotropy* can be either lattice (21 ,28 ,29) or fractional (30) anisotropy. Figure 27.4C shows the effect of anisotropy modulation.

“ZORRO”

Part of "27 - Diffusion Tensor Imaging "

In the section on applications, we illustrate tractographic representations of different pathways that have been created with use of a novel tool for DTI data analysis. This tool, which we call *zorro* (for its capability to create masks), is described here.

Zorro is a program for visualization and quantitative measurement of diffusion-weighted MR tensor scans. It was written with the “visualization toolkit” (31). Its main purpose is to create “masks” interactively that designate regions of voxels in the three-dimensional (3D) data. The masks are then used to make 3D visualizations and quantitative measurements, such as volume, anisotropy, and direction. The program loads both tensor files and their registered nonattenuated baseline echo-planar imaging (T2-EPI) files. Anisotropy values are calculated from the tensor data (e.g., fractional, lattice), or they are loaded if they were previously calculated. A rough segmentation into brain, background (air), and cerebrospinal fluid is performed with use of the T2-EP image, and this facilitates visualization of the data by providing an anatomic context. Zorro can display all three colorized diffusion eigenvectors, anisotropy images, the T2-EP image, the segmented image, and all mask images. A mouse click prints all numeric data for a given voxel (the full tensor, anisotropy values, and mask values). The brightness and contrast can be adjusted for both color (vector) and grayscale (scaler) images, and there are options to show and hide the background and cerebrospinal fluid in the color images and to enable and disable the anisotropy modulation of colors. Any number of different voxel “masks” can be created by clicking on particular voxels. One click adds the voxel to the mask being edited, and another turns it off. Once chosen, various statistics may be calculated from any value associated with every voxel in the mask. Different masks may be combined in binary operations (and, or, xor).

Masks may be semiautomatically created by using “region growing.” For this, a mouse click starts the region at a “seed” voxel, and then each of the seed';s neighbors in 3D is added to the region if the neighbor is similar enough to the seed voxel. A voxel is “similar enough” if, for instance, its anisotropy and primary diffusion direction differ from the seed's by less than some given threshold. Once a neighbor is included, it becomes a seed, and its neighbors are checked to see if they should be included in the result. In zorro, the three kinds of region growing are *direction of interest*, *change in angle*, and *flow*. For all types, one can also specify an anisotropy threshold, so that if the anisotropy of the neighbor is below this threshold, it will not be included in the result. Region growing can also be 2D instead of 3D and can be prevented in cerebrospinal fluid regions or the background region.

Flow Region Growing

Flow region growing involves three vectors: the seed voxel's primary diffusion vector, the neighbor's primary diffusion

vector, and the displacement vector (a vector from the seed voxel location to the neighbor voxel location). A neighbor voxel is included if the displacement vector matches both the seed and neighbor voxels' primary diffusion vectors. This match is determined by comparing a threshold to the product of the dot products of the displacement vector with the seed and the neighbor's primary diffusion vectors. This means that both primary diffusion vectors are pointing in a direction similar to that of the displacement vector.

Change-in-Angle Region Growing

Here, a neighbor is included in the mask if its direction is close enough to the seed direction. This match is determined by comparing a threshold to the acrcosine of the dot product of the seed's and neighbor's primary diffusion vectors. As the region grows, the angle is defined by the new seeds.

Direction of Interest

Here, an absolute direction is specified and each neighbor is included if its direction is close enough to a user-specified direction of interest. This match is determined by comparing a threshold to the acrcosine of the dot product of the user-specified direction of interest and the neighbor's primary diffusion vector. Again, growing can be limited in each of these region-growing methods by providing a threshold for anisotropy and by choosing not to grow out of the 2D slice or into the background or cerebrospinal fluid.

The problem with region growing is that noisy data may cause the region to “escape” and grow out of a region where it might be expected to remain. Besides allowing the interactive examination of tensor and anisotropy data, zorro also produces three kinds of output: mask statistics, angular histograms, and 3D visualization with the use of “boxels.”

Mask Statistics

After all voxels in a mask have been chosen by manual editing, region growing, or a combination thereof, zorro prints the average and variance of fractional and lattice anisotropies taken over all voxels in the given mask.

Angular Histogram

The primary diffusion direction (an angle in 3D) can be represented by two angles (q_1, q_2). An angular histogram then can be presented as a 2D image in which each pixel is a bin of the histogram and the brightness of a pixel represents the height of that bin. The size of the image represents the number of bins chosen to characterize each angle, n. Angles are calculated and then scaled to a range of $\pm n/2$. For a given primary diffusion vector (x,y,z):

$q_1 = \text{atan}(z/x) / n/2$

$q_2 = \text{atan}(y/h) / p/2$

where $h = \text{sqrt}(z^2 + x^2)$.

To create the histogram, for each voxel of the mask, the bin (pixel location) indicated by these two scaled angles for the primary diffusion vector is incremented.

3D Visualization by “Boxels”

“Boxels” are a method for visualizing DTI data in which all tensor information can be seen at the same time. Along with color coding and modulation by anisotropy, boxes are drawn to indicate the directions and relative lengths of all three vectors. The orientation and lengths of the three parallel faces are proportional to the eigenvectors and eigenvalues, respectively.

APPLICATIONS AND DISCUSSION

Part of "27 - Diffusion Tensor Imaging "

Diffusion tensor imaging tractography has opened up the capability to study white matter fiber pathways in the living brain in clinical conditions and in normality, and can be integrated within more general structural–functional, clinical, and behavioral paradigms. However, basic problems remain to be elucidated. At an anatomic level, fiber tracts can be delineated precisely only at the level of their stems, not at their splays and extreme peripheries. This is a challenging problem that should be solved if DTI is to enable us to delineate tracts in their entirety. At a signal analysis level, a fundamental question relates to the source of the DTI signal. For instance, the relative contributions of the intracellular and extracellular compartments to the diffusion signal are not known with certainty (32 ,33 ,34 and 35). One powerful approach to the solution of this problem is study at the ultrastructural level.

Ultrastructural Studies

To acquire a better understanding of *in vivo* diffusion MR measurements in the nervous system, we investigated the diffusion of water in excised sciatic nerve of mice. Fixed and freshly excised nerves were placed straight in a tube and immersed in Fluorinert (Sigma, St. Louis, Missouri). The sample was positioned in a solenoid with its axis coinciding with the nerve axis and perpendicular to B_0. Also, it was possible to exploit the particular geometry of the sample to align the nerve axis with one of the field gradients (in these experiments, the g_y gradient, or 0, 1, 0). The diffusion MRI experiments were performed at 2.0 tesla (T) (proton frequency

of 84.74 MHz) on a SISCO (Varian Associates, Palo Alto, California) system equipped with an 18-cm horizontal-bore superconducting magnet (Nalorac, Martinez, California) and a set of coils capable of producing 120-mT/m field gradients. Proton MR diffusion-weighted images were obtained by using a spin-echo sequence with an echo time of 50 ms and a repetition time of 1 s. The measurements were performed at room temperature (21°C). Typically, 12 scans were averaged. The *b* values used for diffusion weighting were 0, 200, 400, 800 and 1,600 s • mm^2. The slice thickness was 2 mm, and the field of view was 7.5 × 7.5 mm^2 with an in-plane resolution of 256 × 128 pixels. Figure 27.5A shows a transaxial proton image of a nerve obtained with a *b* value of 0.

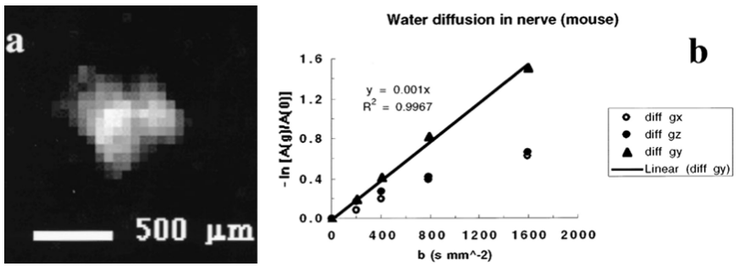

FIGURE 27.5. A: Transaxial proton image of the sciatic nerve of a mouse. **B:** Graph illustrating the variation of the magnetic resonance signal as a function of the orientation of the diffusion gradient. The *circles* (open and closed) correspond to measurements with the diffusion gradients applied in the plane perpendicular to the nerve axis. The *triangles* correspond to diffusion measurements obtained by using the gradient parallel to the nerve axis. The anisotropy of the restriction to the diffusion of water molecules in the cellular compartments is clearly shown.

The effect of restriction to molecular diffusion within the nerve is shown in Fig. 27.5B . Diffusion gradients applied along directions g_x = (1,0,0) and g_z = (0,0,1), which were perpendicular to the nerve axis g_y = (0,1,0) in these experiments, show that the presence of more barriers (i.e., cell membranes and cytoplasmic fibers) hinder molecular diffusion across rather than along the nerve.

Macroscopic Studies

In a sense, the cerebral white matter can be considered as a finite set of discrete and topographically organized fiber pathways or connections that convey connectivity within the brain, and the physical connections in their entirety would make up *anatomic connectivity*. On the other hand, the physiologic outcome of activities of neuronal assemblies, which is coherent in nature and is expressed in the correlated time structure of the firing pattern of its member neurons, would be the basis of *functional connectivity* (i.e., the temporal correlation between remote neurophysiologic events) (36). In the context of a functional experiment, functional connectivity would allow us an array of possible interpretations. The simplest of these solutions that can replicate the observed functional connectivity describes the interactions and connections that are sufficiently active to be detectable at the time of observation. This simplest solution is the *effective connectivity*, which accounts for the interaction that one neural system exerts on another (37).

In vivo DTI-based fiber tract analysis is relevant for the study of *structural-functional* and *anatomic-clinical* relationships. The details of systems neuroanatomy are critical for studies of lesion analysis and for the analysis and interpretation of metabolic and functional neuroimaging data. Damage to specific fiber pathways correlates with the decreased cerebral metabolism pattern observed in stroke patients. Functional activation studies in which PET and fMRI are used contribute to the knowledge of the spatial distribution of cortical and subcortical processing elements. In the creation of effective connectivity models, actual knowledge of brain anatomy is an integrative part because it is utilized for the design of the *a priori* model used in structural equation modeling (38 ,39 ,40 and 41). Use of actual individual information regarding *in vivo* white matter fiber pathway topography and volumetry may optimize and increase the predictive power of these models. These anatomic and neuroimaging studies of the constituents of the fiber tracts and the connections of the human cerebral cortex will be important in acquiring an understanding of the distributed neural circuits that subserve normal brain function. They will also pave the way for future morphometric studies of the white matter fiber systems in normal populations, and for lesion–deficit correlations in patients with focal brain lesions.

The significance of this method is underscored in the study of normal white matter neuroanatomy and also of several *diseases that affect the cerebral white matter*, such as stroke, head trauma, spinal cord injury, and neurodegenerative diseases. Applications of the DTI technique in white matter pathway analysis in normal persons and in cases of *amyotrophic lateral sclerosis* are illustrated. Three normal tracts—the corticospinal projection, the corpus callosum, and the cingulum fiber system—have been selected for the illustration because of their different orientations and also because they represent distinctive classes of connection (i.e., projectional, commissural, and associational, respectively). We have used "zorro" in these examples to show the various ways in which tractography can be performed. Specifically, the corpus callosum and the corticospinal tracts were handpicked, whereas the cingulum fiber system was reconstructed automatically in three dimensions. The results are shown in Fig. 27.6 and Fig. 27.7 .

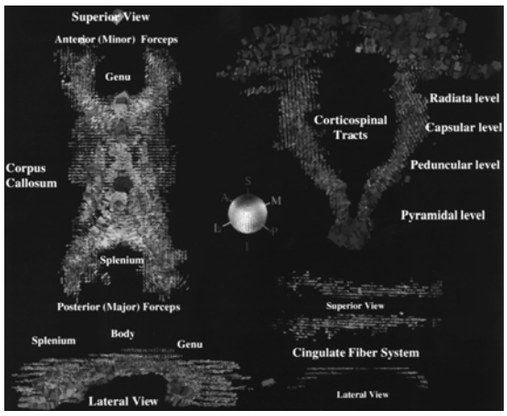

FIGURE 27.6. Three-dimensional reconstruction of stems of individual pathways of a living normal young adult human subject. Note that scaling of tracts is unequal. Red indicates medial–lateral, blue indicates superior–inferior, and green indicates anterior–posterior orientation, respectively, as shown in the color-coded sphere in the center of the figure. For this caption, three representative fiber tracts were selected based on class of pathway provenience and orientation. The corpus callosum, a commissural tract with general mediolateral orientation, is shown in superior and lateral views. Specifically, its genu, body, and splenium are colored in red because they run mediolaterally, whereas its anterior (forceps minor) and posterior (forceps major) forcipes are colored in green because they are oriented anteroposteriorly. The corticospinal tract, a projectional pathway with superior–inferior orientation, is depicted in blue in a frontal view. Finally, the cingulum bundle, a long, associational corticocortical fiber tract with anterior–posterior orientation, is colored green above the body of the corpus callosum for its major trajectory, whereas it is colored blue along its vertically oriented portions in front of the genu and behind the splenium of the corpus callosum. See color version of figure.

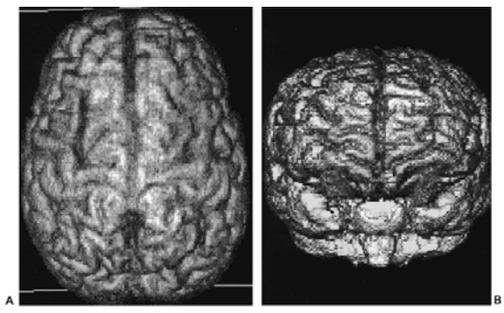

FIGURE 27.7. Three-dimensional (3D) reconstruction of fiber tracts within the three-dimensionally rendered brain of a normal young adult. **A:** A combined 3D representation of the cingulum bundle (green) and the corpus callosum (red). **B:** A composite 3D rendition of the corticospinal projection (blue) and the corpus callosum (red). Red indicates medial-lateral, blue superior-inferior, and green anterior-posterior orientation, respectively. See color version of figure.

Amyotrophic Lateral Sclerosis

In amyotrophic lateral sclerosis (ALS), as degeneration of the upper motor neuron occurs, a progressive damage to the corticospinal tract has been documented in the caudorostral direction (42 ,43 ,44 and 45). We used DTI in two patients (cases 1 and 2) to document pronounced bilateral reduction in the size of the corticospinal tract at the level of the medulla oblongata. Case 1 illustrates an integrated MRI examination of structure, function, and metabolism. A change in morphology of the corticospinal tract can be appreciated in conventional MR images or in the T2-EP images at its ventral surface shown in Fig. 27.8 A,D. However, these MRI techniques do not allow an accurate definition of the borders of the tract. With the aid of tractographic DTI, the corticospinal tract is readily visualized as it courses rostrocaudally. In addition, bordering structures can be visualized, such as the inferior olivary nucleus; thus, a more precise definition of the caudal borders of the corticospinal tract allows quantification of the fiber pathway at this anatomic level. Fractional and lattice anisotropy indices were measured in a 13-voxel region (voxel size = $2 \times 2 \times 2$ mm^3) for the corticospinal tract in the medulla, as shown in Fig. 27.8C . The average fractional anisotropy index was .49 ± .02, and the lattice anisotropy index was .30 ± .01. In this case, in addition to DTI, we collected single-voxel MRS measurements in medulla, and the data indicated metabolic changes—loss of NAA (*N* = acetylaspartate) and possibly elevated glutamate/glutamine (glx), shown in Fig. 27.8H . Similarly, we acquired MRS measurements in the right and left primary motor cortex, shown in Fig. 27.8H . Of note is that the observed metabolic pattern showed a slightly decreased NAA/Cr (creatine) ratio in the left motor cortex in comparison with the contralateral counterpart. Finally, fMRI was acquired while flexion was performed (frequency of 1.5 Hz) with either the left or right hand. An expanded area of activation was observed in the left hemisphere that corresponded with this patient's motor symptomatology (i.e., right-hand weakness much greater than left-hand weakness) (Fig. 27.8I).

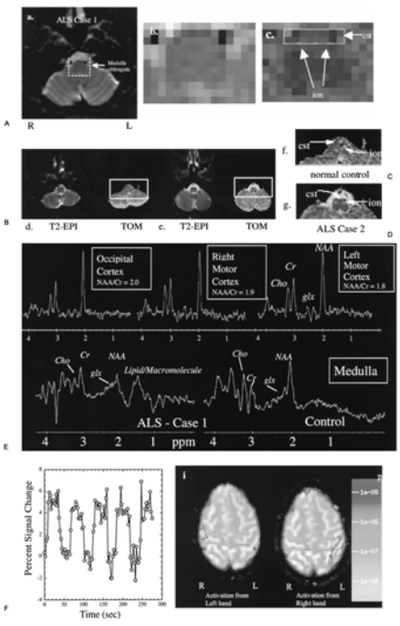

FIGURE 27.8. Comparison of diffusion tensor imaging in the brainstem (medulla oblongata) of a normal control **(D,F)** and two patients with amyotrophic lateral sclerosis, ALS case 1 **(A-C)** and ALS case 2 **(E,G)**. A T2 echo-planar image (T2-EPI) and tensor orientation map (TOM) are included at each level. In this image, green voxels indicate anteroposteriorly, red indicate mediolaterally, and blue indicate superoinferiorly oriented diffusion directions. **H:** Four magnetic resonance spectra from an ALS patient (case 1). The spectra in the top row come from a point resolved spectroscopy sequence (PRESS) with TR (repetition time)/TE (echo time) 2,000/144 ms in either left motor cortex (hand area), right motor cortex (hand area), or occipital cortex. The occipital cortex serves as a control region that is essentially unaffected by ALS. A slight asymmetry in the NAA/Cr and glx/Cr values between left and right motor cortex perhaps reflects the large motor asymmetry in this patient. Also shown on the bottom are PRESS spectra from medulla in the same patient and from a normal control (TR/TE 2,000/30 ms). Note the lower NAA/Cr values in the patient and the higher intensity in the glx region. **I:** This figure shows activation in the hand motor cortex after performance of hand flexion (frequency of 1.5 Hz) with either the left or right hand. Note the expanded area of activation in the left brain, which correlates with the asymmetry of symptoms. The left hand is essentially normal, whereas the right hand is much more severely affected. No difference was noted in frequency of performance of the task with the left or right hand. Also shown is a time course from a region of interest in left motor cortex showing the response of the BOLD (blood oxygenation-dependent) signal to the off and on periods. AG, angular gyrus; CALC, intracalcarine cortex; CGa, cingulate gyrus, anterior; CGp, cingulate gyrus, posterior; CN, cuneiform cortex; CO, central operculum; F1, superior frontal gyrus; F2, middle frontal gyrus; F3o, inferior frontal gyrus, pars opercularis; F3t, inferior frontal gyrus, pars triangularis; FMC, frontal medial cortex; FO, frontal operculum; FOC, frontal orbital cortex; FP, frontal pole; H1, Heschl gyrus; INS, insula; JPL, juxtaparacentral cortex; LG, lingual gyrus; OP, occipital pole; OF, occipital fusiform gyrus; OLi, lateral occipital cortex, inferior; OLs, lateral occipital cortex, superior; PAC, paracingulate cortex; PCN, precuneus; PHa, parahippocampal gyrus, anterior; PHp, parahippocampal gyrus, posterior; PO, parietal operculum; POG, postcentral gyrus; PP, planum polare; PRG, precentral gyrus; PT, planum temporale; SC, subcallosal cortex; SCLC, supracalcarine cortex; SGa, supramarginal gyrus, anterior; SGp, supramarginal gyrus, posterior; SPL, superior parietal lobule; T1a, superior temporal gyrus, anterior; T1p, superior temporal gyrus, posterior; T2a, middle temporal gyrus, anterior; T2p, middle temporal gyrus, posterior; T3a, inferior temporal gyrus, anterior; T3p, inferior temporal gyrus, posterior; TFa, temporal fusiform, anterior; TFp, temporal fusiform, posterior; TO2, middle temporal gyrus, temporooccipital; TO3, inferior temporal gyrus, temporooccipital; TOF, temporooccipital fusiform gyrus; TP, temporal pole (46). See color version of figure.

Integrated Magnetic Resonance Neurologic Examination

Diffusion tensor imaging can be an important part of a comprehensive neurofunctional MRI examination. Quantitative assessment of anatomic volume as measured by morphometric MRI (46), of fiber pathway anisotropy and size by DTI, of metabolic state by MRS, and of functional state by fMRI provides a highly multidimensional data space for the elucidation of structural, functional, behavioral, and clinical correlates. For instance, the relative contributions of each of these imaging modalities can be assessed for any developmental, aging, or degenerative process with the use of principal component analysis. This leads to an optimized, temporally efficient MRI neurologic examination that captures the salient features of the structural, metabolic, and functional states as they change over time. Monitoring these manifestations enables us to elucidate the neurobiological underpinnings of normal brain development and aging in addition to the endpoints of etiology, natural history, and therapeutic intervention in disease states (47). The ALS case 1 is an example of this application. We have proposed using this technique to assess the changes in both motor cortical “remapping” and recruitment of additional cortical areas that may occur progressively in ALS. We successfully performed fMRI in this same patient (Fig. 27.8A), in addition to MRS and DTI. The data indicated larger areas of activation in the left than in the right hemisphere and reflected the motor asymmetry of this patient. The pattern of activation in the right hemisphere was essentially normal, whereas that in the left hemisphere showed recruitment of posterior parietal and association areas. This pattern of “expansion” of cortical activation has also been observed in other neurodegenerative conditions, such as Parkinson disease (48 ,49) and stroke (50 ,51 and 52).

CONCLUSION

Part of "27 - Diffusion Tensor Imaging "

An understanding of the human cerebral white matter, specifically its fiber pathways, is needed. Historically, this objective was achieved to a certain extent in postmortem material, and the findings were therefore of limited practical value. The advancement of neuroimaging technology with such techniques as DTI has made it possible to study human white matter fiber pathways *in vivo*, and therefore in clinical conditions. The DTI method opens up a new approach, *tractography*, for studying the various white matter fiber pathways that are particularly involved in normal cognitive

processing and in certain disease states, such as language, developmental, psychiatric, and demyelinating disorders. In addition, this imaging technique may allow a better understanding of the state of white matter pathways during development, aging, and recovery following brain damage. Finally, the integration of DTI in a more comprehensive MR neurologic examination would allow us to monitor the evolution of a pathologic condition and thus elucidate the endpoints of etiology, natural history, and therapeutic intervention in disease states.

Activation Paradigms in Affective and Cognitive Neuroscience: Probing the Neuronal Circuitry Underlying Mood and Anxiety Disorders

Richard J. Davidson

Richard J. Davidson: Laboratory for Affective Neuroscience, University of Wisconsin, Madison, Wisconsin.

Virtually all forms of psychopathology are associated with disturbances in various aspects of affect and cognition. Although most clinical research has relied on relatively coarse phenomenologic descriptions of symptoms, recent work in neuroimaging with behavioral activation paradigms offers a new and more penetrating look at specific cognitive and affective processes in psychopathology. This new trend is predicated on the view that we must go beyond phenomenology to understand the brain circuitry that is associated with complex mood and anxiety disorders. Advances in our understanding of these conditions will emerge from research that is designed to examine more specific cognitive and affective processing abnormalities. This work holds promise in revealing additional targets for therapeutic intervention, both behavioral and pharmacologic. It also will be important in helping to expose the heterogeneity of these disorders and in offering more meaningful ways in which to parse various subtypes. Finally, by examining the impact of particular therapeutic interventions on functional brain activity elicited in the context of activation paradigms, a better understanding of the impact of these interventions on specific subcomponents of the brain circuitry underlying affect and cognition is likely to emerge.

In this chapter, some key elements of the circuitry that is most relevant to understanding mood and anxiety disorders are first reviewed. The role of individual differences in the functional activity of this circuitry is then considered. The next section reviews key approaches and findings of activation paradigms that have been used in this area. The chapter concludes with a summary and a discussion of future trends in this rapidly developing area.

CIRCUITRY OF AFFECT AND COGNITION IN MOOD AND ANXIETY DISORDERS

Part of "28 - Activation Paradigms in Affective and Cognitive Neuroscience: Probing the Neuronal Circuitry Underlying Mood and Anxiety Disorders "

The review presented in this section of the key components of the circuitry underlying aspects of emotion and cognition that are most relevant to mood and anxiety disorders is gleaned mostly from studies of lesions experimentally produced in animals, the human lesion literature, and neuroimaging studies in normal humans. The review focuses on various territories of the prefrontal cortex, amygdala, hippocampus, and anterior cingulate cortex. Collectively, these studies provide important clues regarding the types of activation paradigms that are most promising for use in patients with mood and anxiety disorders to probe the underlying circuitry of affect and cognition. Research in which activation paradigms with neuroimaging are applied in patients with mood and anxiety disorders is reviewed in a subsequent section.

Prefrontal Cortex

A large corpus of data at both the animal and human levels implicates various sectors of the prefrontal cortex (PFC) in both cognition and emotion. The PFC is not a homogeneous zone of tissue; rather, it has been differentiated on the basis of both cytoarchitectonic and functional considerations. The three subdivisions of the primate PFC that have been consistently distinguished are the dorsolateral, ventromedial, and orbitofrontal sectors of the PFC. In addition, it appears that important functional differences exist between the left and right sides within some of these sectors.

The role of the PFC in cognitive control has recently been reviewed (1), so it is not extensively considered here other than to underscore that a major function of the PFC in general is “to extract information about the regularities

across experiences and so impart rules that can be used to guide thought and action" (1). One of the principal roles of the PFC is to represent goal-relevant information, a key component of both complex thought and emotion. As many studies at the nonhuman primate level have now documented, reward-related information plays a key role in modulating the activity of PFC neurons. Activity in both lateral and ventromedial zones of the PFC is associated with the identity and size of expected rewards (2). This component of PFC activity is likely governed by a dopaminergic input from the ventral tegmental area of the midbrain (see ref. 1 for review). Our notion of the role of the PFC in pre-goal attainment positive affect is based on this corpus of research, which is discussed below (3 ,4).

The case for the differential importance of left and right PFC sectors in emotional processing was first made systematically in a series of studies of patients with unilateral cortical damage (5 ,6 and 7). Each of these studies compared the mood of patients with unilateral left or right-sided brain damage and found a greater incidence of depressive symptoms following left-sided damage. In most cases, the damage was fairly gross and likely included more than one sector of the PFC and often other brain regions as well. The general interpretation that has been placed on these studies is that depressive symptoms are increased following left-sided anterior PFC damage because this brain territory participates in certain forms of positive affect, particularly pre-goal attainment positive affect; damage leads to deficits in the capacity to generate this form of positive affect, a hallmark feature of depression (8). It should be noted that not all studies support this conclusion. In a recent metaanalysis of lesion studies, Carson et al. (9) failed to find support for this hypothesis. Davidson (10) has previously reviewed many of these studies and has addressed a number of critical methodologic and conceptual concerns in this literature. The most important of these issues is that according to the diathesis stress model of anterior activation asymmetry proposed by Davidson and colleagues (11 ,12 and 13), individual differences in anterior activation asymmetry, whether lesion-induced or functional, represent a diathesis. As such, they alter the probability that specific forms of emotional reactions will occur in response to the requisite environmental challenge. In the absence of such a challenge, the pattern of asymmetric activation will simply reflect a propensity but will not necessarily culminate in differences in mood or symptoms. In a recent study of mood sequelae in patients with unilateral lesions with the largest sample size to date (*n* = 193), Morris et al. (14) found that among stroke patients, it was only in those with small lesions that the relation between left PFC damage and depressive symptoms was observed. It is likely that larger lesions intrude on other brain territories and mask the relation between left PFC damage and depression.

A growing corpus of evidence in normal intact humans is consistent with the findings derived from the lesion studies. Davidson and colleagues have reported that induced positive and negative affective states shift the asymmetry in prefrontal brain electrical activity in lawful ways. For example, film-induced negative affect increases relative right-sided prefrontal and anterior temporal activation (15), whereas induced positive affect elicits an opposite pattern of asymmetric activation. This general pattern has been replicated by others using similar measures (16 ,17). In positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies, with considerably better spatial resolution, similar PFC activations have been reported, although many important methodologic details must be considered in interpreting the findings (see ref. 4 for review). The most important of these is considered in a later section. In addition, a body of evidence supports the conclusion that individual differences in baseline levels of asymmetric activation in these brain regions are lawfully related to variations in dispositional affective style (18).

The ventromedial PFC has been implicated in the anticipation of future positive and negative affective consequences. Bechara and colleagues (19) have reported that patients with bilateral lesions of the ventromedial PFC have difficulty anticipating future positive or negative consequences, although immediately available rewards and punishments do influence their behavior. Such patients show decreased levels of electrodermal activity in anticipation of a risky choice in comparison with controls, whereas controls exhibit such autonomic change before they explicitly know that a choice is risky (20 ,21 and 22).

The findings from the lesion method when effects of small unilateral lesions are examined and from neuroimaging studies in normal subjects and patients with anxiety disorders converge on the conclusion that increases in right-sided activation in various sectors of the PFC are associated with increased negative affect. Less evidence is available for the domain of positive affect, in part because positive affect is much harder to elicit in the laboratory and because of the negativity bias (23 ,24). This latter phenomenon refers to the general tendency of organisms to react more strongly to negative than to positive stimuli, perhaps as a consequence of evolutionary pressures to avoid harm. The findings of Bechara et al. (19) on the effects of ventromedial PFC lesions on the anticipation of future positive *and* negative affective consequences are based on studies of patients with bilateral lesions. It will be of interest in the future to examine patients with unilateral ventromedial lesions to ascertain whether valence-dependent asymmetric effects are also present, although most lesions in this PFC territory are bilateral.

Systematic studies designed to disentangle the specific role played by various sectors of the PFC in emotion are lacking, although a growing corpus of work illustrates the functional differentiation among different sectors of the PFC in different aspects of cognitive control (25). Many theoretical accounts of emotion assign it an important role

in guiding action and organizing behavior toward the acquisition of motivationally significant goals (26 ,27). This process requires that the organism have some means of representing affect in the absence of immediately present rewards and punishments and other affective incentives. Such a process may be conceptualized as a form of affective working memory. It is likely that the PFC plays a key role in this process (28). Damage to certain sectors of the PFC impairs an individual's capacity to anticipate future affective outcomes and consequently results in an inability to behave in an adaptive fashion. Such damage is not likely to disrupt an individual's response to immediate cues for reward and punishment, only the anticipation before and maintenance after an affective cue has been presented. This proposal can be tested with current neuroimaging methods (e.g., fMRI) but has not yet been rigorously evaluated. With regard to the different functional roles of the dorsolateral, orbitofrontal, and ventromedial sectors of the PFC, Davidson and Irwin (4) suggested on the basis of both human and animal studies that the ventromedial sector is most likely involved in the representation of elementary positive and negative affective states in the absence of immediately present incentives. The orbitofrontal sector has most firmly been linked to rapid learning and unlearning of stimulus-incentive associations and has been particularly implicated in reversal learning (29). As such, the orbitofrontal sector is likely key to understanding aspects of emotion regulation (30). One critical component of emotion regulation is the relearning of stimulus-incentive associations that may have been previously maladaptive, a process likely requiring the orbitofrontal cortex. The dorsolateral sector is most directly involved in the representation of goal states toward which more elementary positive and negative states are directed.

Amygdala

A large corpus of research at the animal (mostly rodent) level has established the importance of the amygdala in emotional processes (31 ,32 and 33). Because many reviews of the animal literature have appeared recently, a detailed description of these studies is not presented here. LeDoux and colleagues have marshaled a large corpus of compelling evidence to suggest that the amygdala is necessary to establish conditioned fear. Whether the amygdala is necessary to express that fear following learning and whether the amygdala is the actual locus where learned information is stored is still a matter of some controversy (34 ,35). The classic view of amygdala damage in nonhuman primates (resulting in major affective disturbances as expressed in the Kluver–Bucy syndrome, in which the animal exhibits an abnormal approach, hyperorality and hypersexuality, and little fear) is now thought to be a function of damage elsewhere in the medial temporal lobe. When very selective excitotoxic lesions of the amygdala are made that preserve fibers of passage, nothing resembling the Kluver–Bucy syndrome is observed (36). This diverse array of findings suggests a more limited role for the amygdala in certain forms of emotional learning, although the human data imply a more heterogeneous contribution.

Although the number of patients with discrete lesions of the amygdala is small, they have provided unique information about the role of this structure in emotional processing. A number of studies have now reported specific impairments in the recognition of facial expressions of fear in patients with restricted amygdala damage (37 ,38 ,39 and 40). Recognition of facial signs of other emotions have been found to be intact. In a study that required subjects to make judgments about the trustworthiness and approachability of unfamiliar adults based on facial photographs, patients with bilateral amygdala damage judged the unfamiliar persons to be more approachable and trustworthy than did control subjects (41). Recognition of vocalic signs of fear and anger was found to be impaired in a patient with bilateral amygdala damage (42), which suggests that this deficit is not restricted to facial expressions. Other researchers demonstrated an impairment of aversive autonomic conditioning in a patient with amygdala damage despite the fact that the patient demonstrated normal declarative knowledge of the conditioning contingencies (43). Collectively, these findings from patients with selective bilateral destruction of the amygdala suggest specific impairments on tasks that tap aspects of negative emotion processing. Most of the studies have focused on perception; the data clearly show the amygdala to be important in recognizing cues of threat or danger. The conditioning data also indicate that the amygdala may be necessary for acquiring new implicit autonomic learning of stimulus–punishment contingencies. In one of the few studies to examine the role of the amygdala in the expression of already learned emotional responses, Angrilli and colleagues (44) described a patient with a benign tumor of the right amygdala who underwent an emotion-modulated startle study. Among control subjects, they observed the well-known effect of startle potentiation during the presentation of aversive stimuli. In the patient with right amygdala damage, no startle potentiation was observed in response to aversive versus neutral stimuli. These findings suggest that the amygdala may be necessary for the expression of an already learned negative affect.

Hippocampus and Anterior Cingulate Cortex

In this section, the contributions of the hippocampus and anterior cingulate cortex (ACC) to emotion and cognition are briefly mentioned. A more extensive discussion of the contributions of this circuit to emotional and cognitive processing can be found in several recent reviews (4 ,45 ,46 and 47).

The hippocampus has been implicated in various aspects of memory (47), particularly declarative memory of the sort we experience when we consciously recall an earlier episode. The contribution of the hippocampus to emotion and affective

style has only recently begun to be gleaned from the available corpus of animal studies on its role in context-dependent memory (48). This literature has generally supported a role for the hippocampus in the learning of context. For example, when an animal is exposed to a procedure in which a discrete cue is paired with an aversive outcome, in addition to learning the specific cue–punishment contingency, the animal learns to associate the context in which the learning occurs with the aversive outcome. Lesions to the hippocampus abolish this context-dependent form of memory but have no effect on learning of the cue–punishment contingency. The fact that the hippocampus has a very high density of glucocorticoid receptors and participates in the regulation of the hypothalamic–pituitary–adrenal axis is particularly germane to the importance of this structure in regulating emotion. Basic research at the animal level has demonstrated the powerful impact of glucocorticoids on hippocampal neurons (32 ,49). Data indicate that the exogenous administration of hydrocortisone to humans impairs explicit memory that is presumably hippocampus-dependent (50), although other data that suggest that in more moderate amounts, cortisol may facilitate memory (Abercrombie, *unpublished doctoral dissertation*, Department of Psychology, University of Wisconsin at Madison, 2000). A number of investigators using MRI-based measures have reported that hippocampal volume is significantly decreased in patients with several stress-related disorders, including posttraumatic stress disorder (PTSD) (51) and depression (52 ,53), although several failures to replicate these findings have also been reported (54). In the studies in which hippocampal atrophy has been found, the implication is that excessively high levels of cortisol associated with the stress-related disorder cause hippocampal cell death and result in the hippocampal atrophy seen on MRI. Although virtually all these studies have focused on the effects of hippocampal changes on cognitive function, particularly declarative memory, we have proposed that the hippocampus also plays a key role in the context modulation of emotional behavior (55). Moreover, we have suggested that it is in the affective realm that the impact of hippocampal involvement in psychopathology may be most apparent, and that in persons with compromised hippocampal function, the normal context-regulatory role of this brain region is impaired, so that they consequently display emotional behavior in inappropriate contexts. This argument holds that what may be particularly abnormal in disorders such as PTSD and depression is not the display of “abnormal emotion” but rather the display of perfectly normal emotion in inappropriate contexts. For example, in the case of PTSD, extreme fear and anxiety were likely very adaptive in the original traumatic context. This extreme emotional response probably plays an important role in facilitating an organism's withdrawal from a threatening situation. However, in PTSD, this response is elicited in inappropriate situations. The patient with PTSD behaves like the animal with a hippocampal lesion in failing to modulate emotional responses in a context-appropriate manner. These suggestions are only inferential at the present time. Neuroimaging studies are needed to document the role of the hippocampus in this process in normal and disordered populations. In addition, further study is needed to understand how and why the hippocampus may preferentially extract and process information about context. Finally, some research (56) indicates that other structures with direct connections to the hippocampus (e.g., the bed nucleus of the stria terminalis) play a role similar to that of the hippocampus. More work is needed to understand the differential contributions of the various components of this circuitry.

Many studies that have used neuroimaging methods to probe patterns of brain activation during the arousal of emotion have reported that the ACC activates in response to emotion. Several investigators (45 ,57) have recently distinguished between cognitive and affective subdivisions of the ACC based on where activations lie in response to tasks that are purely cognitive versus those that include aspects of emotion. The various tasks used to make these inferences are described in a subsequent section. Based on the model of Carter et al. (58) of the role of the ACC in conflict monitoring in the cognitive domain, we have proposed that the affective subdivision of the ACC may play a similar role in emotion (4). When emotion is elicited in the laboratory, something of a conflict arises because social norms dictate certain rules for participant behavior that do not usually include the display of strong emotion. Thus, the very process of activating emotion in the unfamiliar context of a laboratory environment might activate the ACC. Carter et al. (58) have suggested that ACC activation results in a call for further processing by other brain circuits to address the conflict that has been detected. In most individuals, automatic mechanisms of emotion regulation are likely invoked to dampen strong emotion that may be activated in the laboratory. The initial call for the processes of emotional regulation may result from ACC activation.

PROBING THE NEURAL CIRCUITRY OF AFFECT AND COGNITION IN PATIENTS WITH MOOD AND ANXIETY DISORDERS: CONCEPTUAL AND METHODOLOGIC CONUNDRA

Part of "28 - Activation Paradigms in Affective and Cognitive Neuroscience: Probing the Neuronal Circuitry Underlying Mood and Anxiety Disorders "

In this section, some of the key conceptual and methodologic issues in the use of activation paradigms to probe dysfunctions in the underlying neural circuitry of cognition and affect in patients with mood and anxiety disorders are considered. Issues specific to the study of dysfunctions in the circuitry of emotion in children are considered in a recent review by Davidson and Slagter (59). A key issue that is often neglected in the design of activation studies is the specification of how deficits in the process that is being

studied may account for the symptoms of the disorder. For example, many of the early PET studies in patients with various types of psychopathology used easy continuous performance tasks in which behavioral differences between groups were not expected to occur, or they used unilateral somatosensory stimulation (see ref. 60 for review of early studies). Just what the hypothesized relation was between abnormalities in activation patterns in response to such tasks and symptoms of the disorder being studied was most often not specified in these earlier studies. The better the conceptual link between task performance and symptomatology, the more useful an activation paradigm will be for revealing the underlying deficits in the disorder in question. Several examples of strong conceptual connections between specific task-related deficits and symptomatology in both the cognitive and affective domains are available and can be consulted by the interested reader (see ref. 61 for an example in the cognitive domain and ref. 30 for an example in the affective domain).

The use of tasks that require active performance on the part of subjects poses a host of methodologic issues that are crucial for studies of psychopathology. One of the most important of these is matching the difficulty of an experimental task with that of a control task. This is an issue with a long history in experimental research in psychopathology (62), although the neuroimaging field has yet to appreciate its significance fully. When performance on two tasks is compared between groups, it is imperative that the difficulty of the two tasks be matched. If one task is more difficult than the other task in normal subjects, than a differential deficit on one versus the other task may be a consequence of differences in task difficulty and not specific to the processes that are putatively required for performance of the task. Chapman and Chapman (62) have provided many examples of such artifactual group differences that are products of variation in task performance rather than reflections of differential deficit. It is therefore essential in neuroimaging studies for activation tasks to be matched in this way. If the tasks that are being compared in imaging studies are not matched, then any difference found in activation between tasks may arise as a consequence of differences in the difficulty level of the tasks. Unfortunately, the neuroimaging literature is replete with task comparisons for tasks that do indeed differ in the level of difficulty and thus are particularly problematic for comparisons between groups. The challenge is to design control conditions that are matched to the experimental conditions in regard to basic stimulus and response components, in addition to task difficulty. In one of the few studies to have addressed this potential source of confound, Barch et al. (63), using fMRI, found that the sustained PFC increases in working memory tasks were a function of specific task requirements when they compared such tasks to control tasks that were matched in level of difficulty but did not require working memory.

In studies with patients, investigators frequently wish to examine changes over time with treatment. In this way, effects that may be specifically associated with the symptoms of the disorder can be disentangled from those associated with vulnerability to the disorder. The latter class of effects may also arise as a consequence of scarring—effects produced by having once had the disorder. In experimental designs that require subjects to be scanned and administered tasks on two or more occasions, it is imperative to have data on the test–retest stability of the effects in question. If the effects do not show stability over time, it becomes difficult to interpret group differences in change over time in task activations. We have strongly advocated the psychometric assessment of both psychophysiologic (64) and neuroimaging (65) measures. Such assessments can turn up important surprises. Resting regional glucose metabolism measured with PET is frequently used to assess baseline differences in regional brain activation in various forms of psychopathology. Using MRI coregistration and regions of interest, we recently examined the test–retest stability across a 6-month period of such baseline measures of glucose metabolism in subcortical regions implicated in affective processing. We found that all the regions we examined showed good test–retest stability, including the left and right hippocampus, left and right anterior caudate region, left and right thalamus, and the left amygdala, but not the right amygdala (65). The right amygdala apparently varied over time, in part because metabolic rate in this region was more affected by the stress of the first scan in comparison with activation elsewhere.

Emotional pictures are frequently used to provoke changes in affect in imaging studies (66). When these pictures are used to compare patients and controls over time, it is again important to establish that the effects produced are stable over time in normal subjects. We used startle to probe the test–retest stability of the potentiation produced by negative pictures and the attenuation produced by positive pictures, and we found poor stability when the same pictures were used on both occasions. It was only when different pictures were used, matched on valence and arousal characteristics to the original set, that we found better stability (64). These data underscore the importance of not assuming that effects will be stable over time and the utility of actually measuring the test–retest stability of both task performance and activation changes in normal subjects before conducting a longitudinal study of changes in patients.

The final issue I wish to raise here pertains to studies in which emotion is provoked by specific task manipulations, such as pleasant and unpleasant pictures, guided imagery, monetary rewards and punishments, and symptom provocation with the use of actual feared objects, pictures of objects, or imagined objects. When such paradigms are used, it is imperative for the investigator to verify independently the presence of the intended affective state. Ideally, such verification should include more than self-report measures. For example, peripheral biological indices (e.g., emotion-modulated

startle, electrodermal activity) can often be effective when utilized in imaging studies to provide an independent index of the effects of the intended emotion. Moreover, when such measures are used, correlations between activations produced by the task in question and changes in the peripheral biological index can be computed and are often revealing. For example, Furmark et al. (67) found that subjects showing larger conditioned electrodermal changes in a classic conditioning task showed greater increases in blood flow in the right amygdala during conditioning.

ACTIVATION STUDIES IN PATIENTS WITH MOOD AND ANXIETY DISORDERS

Part of "28 - Activation Paradigms in Affective and Cognitive Neuroscience: Probing the Neuronal Circuitry Underlying Mood and Anxiety Disorders "

Most of the extant imaging studies of patients with mood disorders have been performed with PET while the subjects are in a baseline state. These findings have been recently reviewed elsewhere (68). Recent studies using these methods have reported associations between the severity of particular symptom clusters and patterns of regional blood flow or metabolism (69 ,70 and 71). These studies have underscored the importance of differentiating among various symptoms of depression and illustrate the lawful relations that can be gleaned by examining associations between specific symptoms and patterns of regional brain activity. The few studies using activation paradigms that have been conducted in patients with mood disorders have utilized complex cognitive tasks designed to activate the PFC and ACC. Several studies from Dolan's group (72 ,73 and 74) assessed the relationship of regional blood flow to performance on complex planning tasks during depressed mood in normal subjects and unipolar depressives. Depressed subjects failed to show normal task-related increases in blood flow in regions of the PFC, ACC, basal ganglia, and thalamus.

Several reports have been published of deficits in task performance in depressed patients in which tasks were used that have been extensively studied in previous neuroimaging or neuropsychological research. For example, Merriam et al. (75) studied Wisconsin Card Sorting performance in a large group of patients with major depression who had been without medication for at least 28 days. They found significant deficits on various indices of the Wisconsin Card Sorting task in these patients in comparison with controls. Moreover, patients with more severe depression, reflected in the Hamilton Depression Scale, performed more poorly. Merriam et al. (75) interpreted their data as consistent with suggestions of a dysfunction in prefrontal function in depression.

Other investigators have suggested that in addition to prefrontal deficits, right-sided parietal dysfunction can also contribute to specific symptoms of depression (76). Henriques and Davidson (77), using extremely carefully psychometrically matched verbal and spatial tasks chosen to reflect left- and right-sided posterior cortical function, found a selective deficit on the spatial cognitive task (dot localization) in depressed subjects in comparison with controls. Moreover, in this study, measures of brain electric activity paralleled the performance data and revealed deficits in activation in the right posterior scalp.

We have begun using positive and negative emotional pictures to probe affective processing in depressed patients and controls and to examine changes over time with treatment (see ref. 78 for early preliminary findings). In more recent work with this same paradigm, we have found that patients show a reduction in MR signal intensity in the amygdala in response to negative versus neutral pictures with treatment, whereas controls tested at the same points in time do not. Moreover, the magnitude of MR signal change in the amygdala predicts treatment response (55).

A unique strategy used in research on mood disorders is the short-term depletion of tryptophan among remitted depressed patients maintained on selective serotonin reuptake inhibitors. The depletion of tryptophan, which reduces the presynaptic availability of serotonin, often results in depressive relapse. Thus, this method can be powerfully harnessed to examine activation patterns during the production of depressive relapse in mood-disordered patients. Bremner at al. (79) examined regional metabolic rate with PET during tryptophan depletion and placebo. When they compared subjects who showed a depletion-induced relapse in symptoms with those without relapse, they found that tryptophan depletion resulted in decreases in regional metabolism in the dorsolateral PFC, thalamus, and orbitofrontal cortex in patients who relapsed, but not in patients without relapse. Furthermore, patients who relapsed had a higher baseline (i.e., placebo) metabolism in several areas, including the dorsolateral PFC, orbitofrontal cortex, hippocampus, and amygdala, than those who did not relapse, which possibly suggests that increased basal activity in these structures increases vulnerability to depressive relapse.

We are currently using a task designed to elicit anticipatory positive affect, a form of positive affect that, as noted earlier in this article, is probably implemented at least in part in the dorsolateral PFC. We have hypothesized that this form of positive affect is abnormally decreased in patients with depression (80 ,81). The task we designed is a computerized “lottery” task in which subjects are required to choose digits that may or may not match the digits displayed by a computer after a 10-second delay during which the digits spin like a slot machine. We have found reliable attenuation of startle magnitude at selected points in time during this task (82), and we are now studying a variant of this task in the scanner with fMRI in both normal persons and patients with depression.

Many more studies have been performed in patients with various anxiety disorders (see ref. 83 for recent review). In general, most studies that have used either symptom provocation or other procedures designed to activate the amygdala have found greater activation in this region in response to

such stimuli in anxious patients than in controls. For example, in two studies using script-driven imagery and PET to assess regional blood flow, increased activation was found in the amygdala of patients with PTSD (84 ,85). In a more recent study comparing patients with PTSD and controls, Rauch et al. (86) reported an increased activation of the amygdala in the PTSD patients in response to masked facial expressions of fear versus masked expressions of happiness.

Right-sided activation in various territories of the PFC has been found as a general characteristic of anxiety when symptoms are provoked in patients with several different anxiety disorders (e.g., obsessive-compulsive disorder, simple phobia, and PTSD) (87). In a series of studies that used PET to measure regional cerebral blood flow, Fredrikson and colleagues (88; see ref. 89 for review) reported increases in secondary visual associative regions in patients with snake phobia in response to the presentation of phobia-relevant visual stimuli (e.g., pictures of snakes) versus control visual stimuli. Interestingly, in a separate group of patients with arachnophobia, this pattern did not change after the administrative of diazepam when the subjects were rescanned (90). Using fMRI, Birbaumer et al. (91) explored activation of the amygdala of patients with social phobia relative to that in healthy controls as they were exposed to slides of neutral faces and aversive odor stimuli. The subjects in this study were all male; seven had been given a DSM-IV diagnosis of social phobia and five were healthy controls matched for age, sex, and education. Neutral faces, which do not lead to amygdala activation in nonpsychopathologic humans (92), and aversive odors, which are significantly associated with amygdala activation in comparison with a no-odorant control condition (93), were presented to all the subjects. Birbaumer et al. (91) compared activation in the thalamus and amygdala in the two groups. In both groups, odors elicited greater bilateral activation in the amygdala than in the thalamus. In contrast, the social phobics responded to the faces with significantly greater bilateral amygdala activation than did the controls. However, no difference in regional activation of the thalamus was found between the two groups in response to the neutral faces. Interestingly, although significant amygdala activation was noted in the social phobics, their subjective ratings of the faces did not differ from those of the controls.

SUMMARY AND CONCLUSIONS

Part of "28 - Activation Paradigms in Affective and Cognitive Neuroscience: Probing the Neuronal Circuitry Underlying Mood and Anxiety Disorders "

This chapter began with discussion of some key components of the circuitry underlying affect and cognition that are most relevant to an understanding of affective and cognitive dysfunction in patients with mood and anxiety disorders. Emphasis was placed on the PFC, amygdala, hippocampus, and ACC. Next, some important conceptual and methodologic problems that plague research in this area were considered. The relevance of the task chosen in activation studies to the underlying symptoms of the disorder should be made explicit in this type of research. Several psychometric problems were then considered, including the issues of matching experimental and control tasks according to level of difficulty and of establishing the reliability of tasks before using them in longitudinal studies of patients in whom changes produced by treatment are being examined. Finally, in studies of emotion, the importance of independent verification of elicitation of the intended emotion was emphasized.

Recent activation studies in patients with mood and anxiety disorders were reviewed. It should be apparent from this review that studies using this strategy are currently lacking despite its obvious importance in revealing the abnormalities in circuitry that underlie basic cognitive and affective processes. It is imperative that the next generation of clinical investigators be trained in the methods and techniques of affective and cognitive neuroscience, the area where such activation paradigms are typically first developed.

It is also imperative that the results of burgeoning research on cognitive and affective information-processing deficits in mood and anxiety disorders (see ref. 94 for review) be used to develop new tasks that can be applied with neuroimaging to probe the circuitry associated with specific types of processing anomalies. For example, an extensive corpus of literature has now documented biases in forms of explicit memory in depression and biases in attention in various types of anxiety disorders. This information can be used to design activation paradigms that are more closely linked to the various hypothesized underlying information-processing deficits. Such research should help to uncover abnormalities in the circuitry underlying the processing of emotion and cognition in patients with mood and anxiety disorders, and should also provide new targets for novel therapeutic approaches.

Interactions Among Neuronal Systems Assessed with Functional Neuroimaging

Christian Büchel

Karl Friston

Christian Büchel: Cognitive Neuroscience Laboratory, Department of Neurology, Hamburg University, Hamburg, Germany.

Karl Friston: Wellcome Department of Cognitive Neurology, London, United Kingdom.

In the late nineteenth century, the early investigations of brain function were dominated by the concept of functional segregation. This approach was driven largely by the data available to scientists of that era. Patients with circumscribed lesions were found who were impaired in one particular ability while their other abilities remained largely intact. Indeed, descriptions of patients with different kinds of aphasia (an impairment of the ability to use or comprehend words), made at this time, have left a permanent legacy in the contrast between Broca's and Wernicke's aphasia. These syndromes were thought to result from damage to anterior or posterior regions of the left hemisphere, respectively. In the first part of the twentieth century, the idea of functional segregation fell into disrepute and the doctrine of “mass action” held sway, according to which higher abilities depended on the function of the brain “as a whole” (1). This doctrine was always going to be unsatisfactory. However, with the resources available at the time, it was simply not possible to make any progress studying the function of the “brain as a whole.” By the end of the twentieth century, the concept of functional segregation had returned to domination.

The doctrine is now particularly associated with cognitive neuropsychology and is enshrined in the concept of double dissociation (2). A double dissociation is demonstrated when neurologic patients can be found with “mirror” abnormalities. For example, many patients have been described who have severe impairments of long-term memory but whose short-term memory is intact. In 1969, Warrington and Shallice (3) described the first of a series of patients who had severe impairments of phonologic short-term memory but no impairments of long-term memory. This is a particularly striking example of double dissociation. It demonstrates that different brain regions are involved in short- and long-term memory. Furthermore, it shows that these regions can function in a largely independent fashion. This observation caused major problems for theories of memory, extant at the time, according to which inputs to long-term memory emanated from short-term memory systems (4).

Functional brain imaging avoids many of the problems of lesion studies, but, here too, the field has been dominated by the doctrine of functional segregation. Nevertheless, it is implicit in the subtraction method that brain regions communicate with each other. If we want to distinguish between brain regions associated with certain central processes, for example, then we design an experiment in which the sensory input and motor output are the same across all conditions. In this way, activity associated with sensory input and motor output will cancel out. The early studies of reading by Petersen et al. (5) and Posner et al. (6) are still among the best examples of this approach. The design of these studies was based on the assumption that reading goes through a single series of discrete and independent stages; visual shapes are analyzed to form letters, letters are put together to form words, the visual word form is translated into sound, the sound form is translated into articulation, and so on. By a comparison of suitable tasks (e.g., letters vs. false font, words vs. letters), each stage can be isolated and the associated brain region identified. Although subsequent studies have shown that this characterisation of the brain activity associated with reading is a considerable oversimplification, the original report still captures the essence of most functional imaging studies; a number of discrete cognitive stages are mapped onto discrete brain areas. Nothing is revealed about how the cognitive processes interact or how the brain regions communicate with each other. If word recognition really did depend on the passage of information through a single series of discrete stages, we

would at least like to know the temporal order in which the associated brain regions are engaged. Some evidence comes from encephaloelectrographic and myoelectrographic studies. In fact, we know that word recognition depends on at least two parallel routes—one of meaning and one of phonology (7). Given this model, we would like to be able to specify the brain regions associated with each route and have some measure of the strengths of the connections between these different regions.

In this chapter, we show how new methods for measuring effective connectivity allow us to characterize the interactions between brain regions that underlie the complex interactions among different processing stages of functional architectures.

DEFINITIONS

Part of "29 - Interactions Among Neuronal Systems Assessed with Functional Neuroimaging "

In the analysis of neuroimaging time series (i.e., signal changes in a set of voxels, expressed as a function of time), functional connectivity is defined as the *temporal correlations between spatially remote neurophysiological events* (8). This definition provides a simple characterization of functional interactions. The alternative is effective connectivity, *the influence one neuronal system exerts over another* (9). These concepts originated in the analysis of separable spike trains obtained from multiunit electrode recordings (10 ,11). Functional connectivity is simply a statement about the observed correlations; it does not comment on how these correlations are mediated. For example, at the level of multiunit microelectrode recordings, correlations can result from *stimulus-locked transients*, evoked by a common afferent input* , or reflect *stimulus-induced oscillations*, phasic coupling of neural assemblies mediated by synaptic connections (12). Effective connectivity is closer to the notion of a connection, either at a synaptic (cf synaptic efficacy) or cortical level. Although functional and effective connectivity can be invoked at a conceptual level in both neuroimaging and electrophysiology, they differ fundamentally at a practical level. This is because the time scales and nature of neurophysiologic measurements are very different (seconds vs. milliseconds and hemodynamic vs. spike trains). In electrophysiology, it is often necessary to remove the confounding effects of stimulus-locked transients (that introduce correlations *not* causally mediated by direct neural interactions) to reveal an underlying connectivity. The confounding effect of stimulus-evoked transients is less problematic in neuroimaging because propagation of signals from primary sensory areas onward is mediated by neuronal connections (usually reciprocal and interconnecting). However, it should be remembered that functional connectivity is not necessarily a consequence of effective connectivity (e.g., common neuromodulatory input from ascending aminergic neurotransmitter systems or thalamocortical afferents), and when it is, effective influences may be indirect (e.g., polysynaptic relays through multiple areas). In this chapter, we focus only on effective connectivity. More details about functional connectivity can be found in Friston et al. (8).

EFFECTIVE CONNECTIVITY

Part of "29 - Interactions Among Neuronal Systems Assessed with Functional Neuroimaging "

A Simple Model

Effective connectivity depends on two models: a mathematical model, describing “how” areas are connected, and a neuroanatomic model, describing “which” areas are connected. We shall consider linear and nonlinear models. Perhaps the simplest model of effective connectivity expresses the hemodynamic change at one voxel as a weighted sum of changes elsewhere. This can be regarded as a multiple linear regression, in which the effective connectivity reflects the amount of rCBF (regional cerebral blood flow) variability, at the target region, attributable to rCBF changes at a source region. As an example, consider the influence of other areas *M* on area *V1*. This can be framed in a simple equation:

$$V1 = M c + e \qquad [1]$$

where *V1* is an $n \times 1$ column vector with n scans, M is an $n \times m$ matrix with m regions and n observations (scans), c is an $m \times 1$ column vector with a parameter estimate for each region, and e is a vector of error terms.

Implicit in this interpretation is a mediation of the influence among brain regions by neuronal connections with an effective strength equal to the (regression) coefficient c. This highlights the fact that the linear model assumes that the connectivity is constant over the whole range of activation and does not depend on input from other sources.

Experience suggests that the linear model can give fairly robust results. One explanation is that the dimensionality (the number of things that are going on) of the physiologic changes can be small by experimental design. In other words, the brain responds to simple and well-organized experiments in a simple and well-organized way. Generally, however, neurophysiologic interactions are nonlinear, and the adequacy of linear models must be questioned (or at least qualified). Consequently, we focus on a nonlinear model of effective connectivity (13).

Structural Equation Modeling

The simple model above is sufficient to analyze effective connectivity to one region at a time (e.g., *V1* or *V2*). We will now introduce structural equation modeling as a tool allowing for more complicated models comprising many

regions of interest and demonstrate how nonlinear interactions are dealt with in this context. The basic idea behind structural equation modeling differs from the usual statistical approach of modeling individual observations. In multiple regression or ANCOVA (analysis of covariance) models, the regression coefficients derive from the minimization of the sum of squared differences of the predicted and observed dependent variables (i.e., activity in the target region). Structural equation modeling approaches the data from a different perspective; instead of variables being considered individually, the emphasis lies on the variance–covariance structure.* Thus, models are solved in structural equation modeling by minimizing the difference between the observed variance–covariance structure and the one implied by a structural or path model. In the past few years, structural equation modeling has been applied to functional brain imaging. For example, McIntosh et al. (14) demonstrated the dissociation between ventral and dorsal visual pathways for object and spatial vision by using structural equation modeling of positron emission tomographic (PET) data in the human. In this section, we focus on the theoretic background of structural equation modeling and demonstrate this technique with the use of functional magnetic resonance imaging (fMRI).

In terms of neuronal systems, a measure of covariance represents the degree to which the activities of two or more regions are related (i.e., functional connectivity). The study of variance–covariance structures here is much simpler than in many other fields; the interconnection of the dependent variables (regional activity of brain areas) is anatomically determined, and the activation of each region can be directly measured with functional brain imaging. This represents a major difference from “classic” structural equation modeling in the behavioral sciences, in which models are often hypothetical and include latent variables denoting rather abstract concepts, such as intelligence.

As mentioned above, structural equation modeling minimizes the difference between the observed or measured covariance matrix and the one that is implied by the structure of the model. The free parameters (path coefficients or connection strengths; *c* above) are adjusted to minimize the difference between the measured and modeled covariance matrix.† (See ref. 15 for details.)

An important issue in structural equation modeling is the determination of the participating regions and the underlying anatomic model. Several approaches to this issue can be adopted. These include categoric comparisons between different conditions, statistical images highlighting structures of functional connectivity, and nonhuman electrophysiologic and anatomic studies (16).

With respect to anatomic connectivity in humans, the advent of new MR techniques promises a better characterization of neuronal connectivity in humans. Diffusion tensor imaging measures the anisotropy of diffusion in the brain. The main anisotropy exists in the white matter because the orientation of neuronal fibres (axons) allows molecules to diffuse more easily along the fiber than in other directions. Therefore, the main direction of the diffusion tensor reflects the underlying orientation of white matter tracts. Through tracing algorithms, it is now possible to infer the connectivity of individual regions (e.g., activations derived from an fMRI study) in an individual brain (17) (Fig. 29.1).

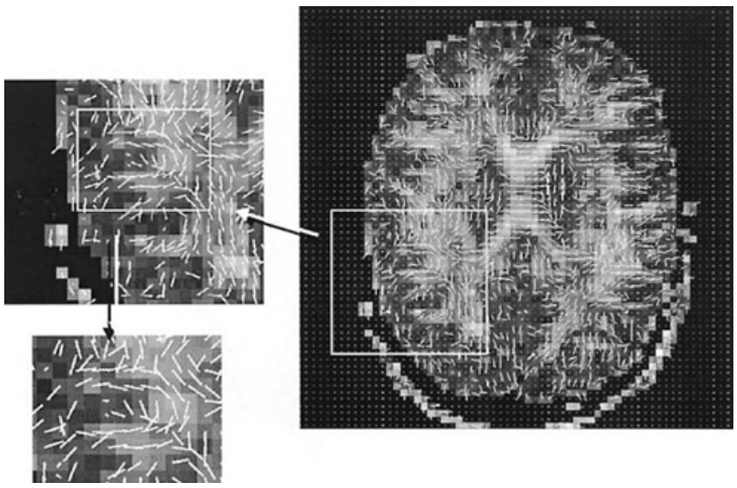

FIGURE 29.1. Axial diffusion tensor image, obtained by using a TurboSTEAM diffusion sensitized pulse sequence on a Siemens Vision 1.5T MR scanner. Voxel size 3 × 3 × 3 mm. Average of 20 replications. *Needles* in each voxel show the largest eigenvector of the tensor (i.e., the main orientation of diffusion within this voxel). In white matter, the major axis of diffusion is constrained by the orientation of white matter tracts and therefore provides a good estimate of the direction of fiber bundles (17). As expected, the corpus callosum in the center of the image shows predominantly horizontal fibers connecting both hemispheres. In the occipital cortex, parts of the optic radiation with a predominantly anterior–posterior fiber orientation can be seen. The precision of the method is highlighted by the demonstration of corticocortical U fibers, magnified in the small image. (From Nolte U, Finsterbusch J, Frahm J. Rapid whole brain diffusion mapping without susceptibility artifacts using diffusion-weighted single-shot STEAM MRI. *Proceedings of the eighth annual meeting of the International Society of Magnetic Resonance in Medicine*, Denver, 2000:807.)

A model is always a simplification of reality; exhaustively correct models either do not exist or are too complicated to understand. In the context of effective connectivity, one has to find a compromise between complexity, anatomic accuracy, and interpretability. Mathematical constraints on the model also exist; if the number of free parameters exceeds the number of observed covariances, the system is underdetermined and no single solution exists.

Each estimated model can be analyzed to give an overall

goodness-of-fit measure for use when different models are compared with each other. A "nested model" approach can be used to compare different models (e.g., data from different groups or conditions) in the context of structural equation modeling. A so-called null model is constructed in which the estimates of the free parameters are constrained to be the same for both groups. The alternative model allows free parameters to differ between groups. The significance of the differences between the models is expressed by the difference of the goodness-of-fit statistic. Consider the following hypothetical example. Subjects are scanned under two different conditions (e.g., *attention* and *no attention*). The hypothesis might be that within a system of regions *A, B, C*, and *D*, the connectivity between *A* and *B* is different under the two attentional conditions. To determine whether the difference in connectivity is statistically significant, we estimate the goodness-of-fit measure for two models. Model 1 allows the connectivity between *A* and *B* to take different values for both conditions. Model 2 constrains the path coefficient between *A* and *B* to be equal for *attention* and *no attention*. If the change of connectivity between *attention* and *no attention* for the connection of *A* and *B* is negligible, the constrained model (model 2) should fit the data as well as the free model (model 1). We can now infer whether the difference of the two goodness-of-fit measures is significant. Nonlinear models can also be accommodated in the framework of structural equation modeling by introducing additional variables containing a nonlinear function (e.g., $f(x) = x^2$) of the original variables (18). Interactions of variables can be incorporated in a similar fashion, wherein a new variable, containing the product of the two interacting variables, is introduced as an additional influence. We will now demonstrate these ideas with an example. More details of structural equation modeling, including the operational equations, can be found in ref. 15 .

Example: Learning

In the first example, we were interested in changes in effective connectivity over time as expected during paired-associates learning (19). In the case of object-location memory, several functional studies have demonstrated activation of ventral occipital and temporal regions during the retrieval of object identity and, conversely, increased responses in dorsal parietal areas during the retrieval of spatial location (20). These results suggest domain-specific representations in posterior neocortical structures that are closely related to those involved in perception, a finding that accords with the segregation of ventral and dorsal pathways in processing categoric or spatial stimulus features, respectively. Another phenomenon observed in some learning studies is a decrease of neural responses (i.e., adaptation) to repeated stimulus presentations. This repetition suppression has been replicated consistently in primate electrophysiologic and human functional imaging studies (21). For object-location learning, it is intuitively likely that two specialized systems need to interact to establish an association. Domain-specific representations or repetition suppression is not sufficient to account for this associative component. In other words, functional segregation and localized response properties cannot account for associative learning alone.

In our fMRI experiment, decreases in activation during learning, indicative of repetition suppression, were observed in several cortical regions in the ventral and dorsal visual pathway. Within the framework of repetition suppression, it has been hypothesized that decreases in neural responses are a secondary result of enhanced response selectivity (22). By analogy to the development and plasticity of cortical architectures, this refined selectivity is likely to be a consequence of changes in effective connectivity within the system at a synaptic level. We explicitly addressed this notion by characterising time-dependent changes in effective connectivity during learning.

The experiment was performed on a 2-tesla (T) MRI system equipped with a head volume coil. fMRI images were obtained every 4.1 seconds with echo-planar imaging (48 slices in each volume). Six subjects had to learn and recall the association between 10 simple line drawings of real-world objects and 10 locations on a screen during fMRI. Each learning trial consisted of four conditions: *encoding, control, retrieval*, and *control* (Fig. 29.2A). The behavioral data acquired during *retrieval* demonstrated that all six subjects were able to learn the association between object identity and spatial location, for all 10 objects, within eight learning blocks, as indicated by the ensuing asymptotic learning curves (Fig. 29.2B).

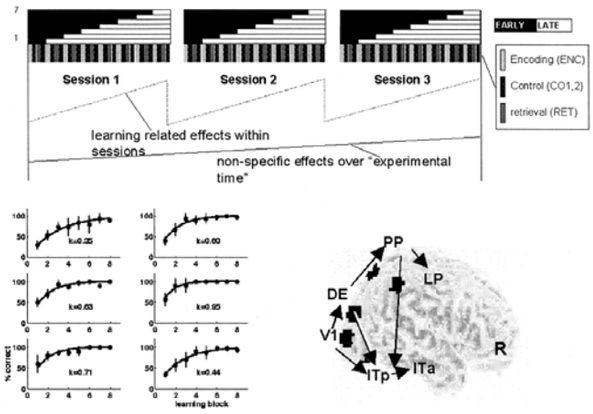

FIGURE 29.2. Changes in effective connectivity over time in paired-associates learning. **A:** Design of the study. Blocks of *encoding* and *retrieval* were alternated with control conditions. Subjects had to complete three individual learning sessions to avoid the confounding effect of time. **B:** Behavioral performance data for each of the six subjects averaged across all three learning sessions. **C:** Anatomic model. Processing of object identity is mainly a property of the ventral visual pathway, whereas object location is a property of the dorsal stream. We focused on the interstream connections (mainly posterior parietal cortex to posterior inferotemporal cortex) based on the hypothesis that learning the association of object identity and spatial location leads to an increase in effective connectivity between the ventral and dorsal streams. (From Büchel C, Coull JT, Friston KJ. The predictive value of changes in effective connectivity for human learning. *Science* 1999;283:1538–1541, with permission.)

The structural model used in the analysis embodies connections within and across ventral and dorsal visual pathways and was based on anatomic studies in primates (Fig. 29.2C). Primary visual cortex was modeled as the origin of both pathways. In addition to "interstream" connections between dorsal extrastriate cortex and the fusiform region and between the posterior parietal cortex and the posterior inferotemporal cortex, we included direct connections based on a hierarchic cortical organization. Given our hypothesis relating to changes in effective connectivity between dorsal and ventral pathways, the path analysis focused on the connection between posterior parietal cortex (PP, dorsal stream) and posterior inferotemporal cortex (ITp, ventral stream). We divided each learning session into EARLY (first part) and LATE (second part) observations and estimated separate path coefficients for each partition.

The path coefficient between PP and ITp increased significantly during learning in the group ($p < .05$) and was confirmed by an analysis of individual subjects showing an increase in effective connectivity between PP and ITp of 0.27. In contrast to the connections between streams, connections within the dorsal pathway decreased over time.

The estimated change in connectivity from PP to ITp

clearly depended on the cutoff point between EARLY and LATE. To establish unequivocally a relationship between neurophysiologically mediated changes in connectivity and behavioral learning, we examined the relationship between the temporal pattern of effective connectivity changes and learning speed for all sessions and subjects. We estimated the differences in effective connectivity for seven EARLY and LATE partitions by successively shifting the cutoff. The cutoff time at which the connectivity change peaked was used as a temporal index of changes in effective connectivity (i.e., plasticity). The significant regression of *k*, a measure of learning speed* , on this plasticity index indicated that for sessions showing fast learning (i.e., high value of *k*), the maximum difference in path coefficients between PP and ITp was achieved earlier in the session (i.e., EARLY comprises fewer scans relative to LATE) (Fig. 29.3). In other words, the temporal pattern of changes in effective connectivity strongly predicted learning or acquisition.
