One of the major concerns with the potential use of marijuana, and, for that matter with any of the cannabinoids, is the observation that these agents produce a multiplicity of effects, and they all seem to occur at similar doses. One possible way to overcome this problem is to develop a delivery mechanism that limits the distribution of the drug to the desired site of action. This is particularly difficult when the site of action is in the brain, as it is with the cannabinoids and their potential usefulness in treating symptoms of mental illness. One potential therapeutic use of the cannabinoids is in the treatment of glaucoma. Local administration directly into the eye is the preferred mechanism of drug delivery. One of the problems of using cannabinoids in this fashion is that they are insoluble and must be administered in a vehicle, which may have deleterious effects when it is placed in the eye. An optimal delivery for this indication would be to have a water-soluble cannabinoid (93) with good efficacy in lowering intraocular pressure that can be applied directly to the eye and not be irritating. The direct application of such a drug would provide the intended therapeutic effect and would not produce the undesirable side effects that would be observed if the drug were absorbed into the general circulation.

The reemergence on the debate of the use of marijuana for medicinal purposes has also been the impetus for developing an acceptable delivery form of aerosolized cannabinoids. A nebulizer was used to generate an aerosol with sufficiently small particle size such that exposure to rodents produced pharmacologic effects, These results demonstrate that the development of an aerosolized form of cannabinoids for human medicinal use is feasible (94).

Future Developments

Selective Receptor Agonists and Selective Pharmacologic Profiles

Because the cannabinoids have multiple effects on so many different body functions at approximately the same dose, considerable effort continues to be directed toward identifying the portion of the cannabinoid molecule that is most responsible for each unique pharmacologic effect. The identification of multiple cannabinoid receptors and the observation that certain cannabinoids have selectivity for one type of receptor over the other are encouraging (95 ,96). Further research into different receptor types and the identification of specific endogenous ligands for each of these receptor types will provide guidance for the medicinal chemist synthesizing new and, one hopes, more selective cannabinoids. The hypothesis that each receptor subtype has its own specific ligand, as in the case of AEA preference for the CB_1 receptor, is a reasonable approach. These investigations will be guided by the continued progress in the efforts of researchers to identify and understand the cellular and molecular effects of the cannabinoids. Mechanisms may be found that will help to provide selectivity resulting from the effects of the cannabinoids on an intracellular site of action. The more detail we know about the genetic influences and the structural makeup of the receptors and other cellular elements, the better we will be able to design cannabinoids with selective activity.

Another approach to identifying cannabinoids with more selectivity of action is to investigate the interactions of exogenously administered substances with AEA and other endogenous cannabinoids. If one were to hypothesize that an altered tonic activity of the endogenous cannabinoid system is at the basis of some neurologic disorders, there are again two approaches that could be taken in the search for more selective agents. One would be to alter either the synthesis or degradation of the endocannabinoids, and the other is to modulate their actions. An example of the latter approach would be to compete with or block the receptor or to interfere with the signaling events through which the endogenous compound produces its effect. The advantage of these approaches would be that drugs interfering with endocannabinoid metabolism or action would exhibit higher effects in those tissues where the levels and activity of endocannabinoids are pathologically altered.

Selective Transport Blockers and Enzyme Inhibitors

Several blockers of AEA-facilitated transport have been developed so far, but only two were shown to enhance the actions of AEA *in vivo* or *in vitro*. The most widely used one, AM404, potentiates AEA analgesic effects in the hot plate test and inhibition of adenylate cyclase (97), although it also activates vanilloid receptors. Inhibitors of FAAH have also been developed (98), a potent and selective one of which, palmitylsulfonylfluoride (AM347), acts as a covalent inhibitor (99). The most potent irreversible FAAH inhibitor developed so far is methylarachidonoylfluorophosphonate (100), which unfortunately also binds to CB_1 receptors. Future studies will have to establish whether defective biosynthesis or exaggerated metabolism of endocannabinoids contributes to pathologic conditions, and, therefore, whether therapeutically useful drugs can be developed using these or more selective inhibitors of AEA degradation. These compounds are likely to act most efficaciously only at the site where AEA and 2-AG levels are pathologically altered, and, also for this reason, they will be devoid of undesired psychotropic side effects.

Receptor Antagonists

Ideally, the development of an antagonist to any new drug would be an asset to provide protection against an accidental overdose or to reverse the effects in a hypersensitive individual. Clearly, an antagonist is a very useful tool for studies directed toward elucidation of the pharmacologic profile of the agonist. The development of an antagonist as a new therapeutic agent requires the same demonstration of efficacy and safety needed for a cannabinoid agonist. As discussed earlier, a cannabinoid agonist may have potential therapeutic uses for disorders that have characteristics opposite to the pharmacologic effects of THC. Conversely, cannabinoid antagonists may have potential in treating memory impairment, obesity, and perhaps certain psychiatric disorders associated with marijuana use. The basis of the therapeutic usefulness of a cannabinoid antagonists rests on the premise that the endogenous cannabinoid system is under tonic control, and the antagonist can either block the actions of the endogenous ligand or exert inverse agonist effects by interactions with the cannabinoid receptor.

Therapeutics for Nicotine Addiction

Reese T. Jones

Neal L. Benowitz

Reese T. Jones: Department of Psychiatry, University of California, San Francisco, California.

Neal L. Benowitz: Departments of Medicine, Psychiatry, and Biopharmaceutical Sciences, University of California, San Francisco; Division of Clinical Pharmacology and Experimental Therapeutics, Medical Service, San Francisco General Hospital Medical Center, San Francisco, California.

About 25% of adults in the United States smoke tobacco cigarettes. Most continue smoking because they are addicted to nicotine. That nicotine is central to maintaining tobacco use is well established (49). When asked, 70% of cigarette smokers report that they would like to quit. Each year, less than 1% will actually succeed without any therapeutic interventions. Few other conditions in medicine present nicotine addiction's mix of lethality, prevalence, cost, and relative therapeutic neglect, despite effective and readily available treatment interventions. Health care providers too often fail to assess or treat tobacco addiction despite substantial evidence that even brief therapeutic interventions are effective (2).

Worldwide potential benefits of prevention and adequate treatment are staggering (96). More than 1.2 billion people regularly smoke tobacco. During the twentieth century, only approximately 0.1 billion people died of tobacco use–related illnesses. If current smoking patterns continue, 1 billion additional people will die of smoking-related illness during this century. Half will die during middle age. About 4 million people died of tobacco-related disease in 1998. Projections indicate 10 million tobacco-related deaths yearly by the year 2030, with 70% of those deaths in developing countries. Reducing the number of current smokers by 50% would avoid 25 million premature deaths in the first quarter of this century and about 150 million more by midcentury (96).

Understanding the role of nicotine in sustaining tobacco addiction offers a basis for optimal and rational treatments for preventing or stopping smoking (49). Nicotine addiction has much in common with other addictions, so consideration of therapeutics should help in development of therapies for less common addictions to stimulants such as cocaine and amphetamines or to other drugs. Nicotine addiction resulting from tobacco cigarette smoking is emphasized. Other routes for nicotine delivery, chewing tobacco, buccal and nasal snuff, and smoked pipes and cigars, deliver substantial amounts of nicotine but with different pharmacokinetics, although the pharmacology is otherwise similar. Nicotine is addicting when it is delivered by any route, but special attributes and the ubiquity of cigarette delivery systems warrant special attention.

WHY DO PEOPLE SMOKE?

Part of "107 - Therapeutics for Nicotine Addiction "

Although the pharmacologic effects of nicotine are essential to sustaining tobacco smoking, the beginnings of tobacco addiction result from nonpharmacologic learned or conditioned factors, social settings, personality, and genetics (4). Taking nicotine enhances an addicted smoker's mood and performance. Nicotine is rewarding. Smoking is an extremely effective way of rapidly and conveniently delivering concentrated doses of nicotine to the brain (4 ,5). Nicotine smokers appear able to discriminate small, rewarding effects from each individual puff and to titrate nicotine dose from each cigarette. From the typical 10 puffs per cigarette, a one pack-per-day smoker receives 73,000 distinct drug reinforcements per year. Although nicotine can enhance mood directly, what is even more important for understanding nicotine addiction therapeutics is that when nicotine is taken by an addicted smoker, the negative consequences of prior nicotine use are diminished. A nicotine withdrawal syndrome is relieved (4).

Most smokers say they want to stop smoking (2 ,13). Most adults have made several attempts to quit and require four or more attempts before quitting permanently. Relapse typically occurs because of disrupted emotional state, work performance, enjoyment of leisure activities, and interpersonal relationships. Life-threatening smoking-related illness should motivate one to quit, yet 50% of smokers after a

myocardial infarction continue to smoke (13 ,49). Smokers with lung or throat cancer or those suffering from chronic obstructive lung disease behave similarly.

Tobacco-taking behavior is made more likely to recur, reinforced by the pharmacologic actions of nicotine (49). With each successive cigarette, a beginning smoker, usually an adolescent, learns to associate certain moods, situations, and environmental factors with the rewarding effects of nicotine. Associations between cues associated with smoking, anticipated nicotine effects and the resulting urge to use tobacco (craving) become all important in maintaining smoking.

Smoking is more likely in certain situations: after a meal, with coffee or alcohol, and with friends who smoke (49). Associations between events and smoking repeated thousands of times make for powerful cues facilitating an urge to smoke. Manipulation of smoking paraphernalia, taste, smell, and sensations from smoke in upper airways become associated with pleasurable effects. Unpleasant or dysphoric moods come to serve as conditioned cues for smoking. For example, an adolescent smoker, usually within the first year of smoking, learns that not having a cigarette available is associated with feelings of irritability and learns that just a few puffs from a cigarette diminish irritability and other dysphoric nicotine withdrawal symptoms. After hundreds of repeated experiences, irritability from any source serves as a cue for smoking.

Left to nature, it is unlikely that many people would make or find a cigarette, light it, and smoke it (49). Conditioning and learning linking nicotine pharmacology and environmental contingencies are facilitated by advertising encouraging, often in subtle ways, the use of tobacco. In the beginning, teenage smokers teach each other. Quickly, links between the pharmacologic actions of nicotine and associated behaviors become powerful (7). Conditioning loses its power only gradually without nicotine delivered in the right dose and context. Conditioning is a major factor in relapse to nicotine use after quitting. Dealing with it is important in any therapeutics for nicotine addiction.

Many smokers report that smoking improves concentration and elevates mood. Cigarette smoking or nicotine administration improves attention, reaction time, and problem-solving, particularly in recently abstinent smokers (55 ,74). Smokers typically report enhanced pleasure and reduced anger, tension, depression, and stress after a cigarette. Whether enhanced performance and improved mood after smoking are mostly or entirely the result of the relief of abstinence symptoms or rather are intrinsic effects of nicotine on the brain remains unclear (49). Improvement in the performance of nonsmokers after nicotine suggests at least some direct enhancement (8).

NICOTINE PHARMACOKINETICS AND METABOLISM

Part of "107 - Therapeutics for Nicotine Addiction "

Some special attributes of smoked nicotine delivery are important for understanding mechanisms and therapeutics of tobacco addiction (5 ,49). Nicotine, a tertiary amine structurally similar to acetylcholine, binds to nicotinic cholinergic receptors in the brain and elsewhere. During smoking nicotine, steam distilled from the burning tobacco is inhaled into the small airways and alveoli on small droplets of tar, buffered to a physiologic pH, absorbed rapidly into the pulmonary capillaries, and thence into systemic arterial blood. Initial arterial blood levels of nicotine are two to six times greater than venous levels (11). Within 10 to 20 seconds after each puff, relatively high levels of nicotine reach the brain. Nicotine levels in plasma and in brain tissue then decline rapidly because of rapid distribution into peripheral tissues.

During a typical smoker’s day, peak and trough plasma and brain nicotine levels vary considerably before and after each cigarette, but nicotine gradually accumulates over 6 to 8 hours of repeated smoking because of nicotine’s 2-hour half-life (5). By midafternoon, relatively constant, steady-state, venous plasma levels, 20 to 40 ng/mL, are reached, but with transient 50-ng/mL increments in arterial and brain levels after each cigarette. During sleep, plasma concentration of nicotine falls progressively but is still measurable on awakening when the first cigarette of the next day is smoked, typically within 30 minutes of awakening. Thus, smoking results in exposure of brain to nicotine 24 hours of each day but with regular brain level perturbations after each puff and each cigarette (5 ,12).

Smokers regulate smoked nicotine intake to maintain their preferred range of concentrations by varying puff and inhalation timing, volume, and number (49). Nicotine intake and resulting plasma levels vary. Smokers can compensate for differing machine-determined nicotine yields to obtain a preferred dose of nicotine whether smoking a high- or low-yield brand (39). Nicotine delivered by cigarettes offers smokers individualized control of nicotine dose unattainable by other nicotine delivery systems (49). The special attributes of smoked nicotine dosimetry are relevant when designing animal experiments to model human tobacco dependence properly (53) and when considering nicotine replacement therapies (NRTs). In contrast to smoking, chewing tobacco and snuff deliver nicotine through oral or nasal mucosa. Plasma and brain nicotine concentrations rise more gradually, reach plateau levels after about 30 minutes, and then decline slowly over the next few hours (5).

NICOTINE RECEPTOR-BASED NEURAL MECHANISMS RELEVANT TO THERAPEUTICS

Part of "107 - Therapeutics for Nicotine Addiction "

Nicotine binds stereoselectively to a diverse family of nicotinic cholinergic receptors widely distributed in brain, autonomic ganglia, adrenal medulla, and neuromuscular junctions (15 ,16). Nicotine’s effects on nicotinic cholinergic receptors in the brain enhance release of an array of neurotransmitters; dopamine, norepinephrine, acetylcholine, serotonin,

vasopressin, ß-endorphin, glutamate, γ-aminobutyric acid, and others (12 ,49). Nicotinic cholinergic receptors have varied functional characteristics, different chemical conductances for sodium and calcium, and variable sensitivity to different nicotinic agonists (17 ,92). Receptor diversity probably accounts for the diverse effects of nicotine experienced by smokers (19). The undoubtedly complex relationships between specific nicotinic cholinergic receptor subtypes and release of specific neurotransmitters are still to be fully characterized (92). Neurotransmitter release is assumed to mediate nicotine effects such as arousal, relaxation, cognitive enhancement, relief of stress, and depression.

A brain nicotinic cholinergic receptor is a ligand-gated ion channel, with five subunits. Most brain nicotinic cholinergic receptors are composed of α and ß subunits. The α subunits are responsible for ligand binding. The ß subunits mediate other aspects of receptor function (29). The nicotinic cholinergic receptor, consisting of α-4 and ß-2 subunits, accounts for 90% of high-affinity nicotine binding in rat brain and may play a critical role in stimulant and rewarding effects (21). The ß-2 subunit is critical for dopamine release, judging from studies of knockout mice lacking that subunit who have less nicotine-induced dopamine release and do not self-administer nicotine as do wild-type mice (76).

When nicotine binds to nicotine receptors, allosteric changes lead to different functional states including a resting state, an activated state (channel open), and two desensitized states (channel closed) (10). Receptor change to the desensitized state probably accounts for tolerance and for the observation that tolerance to nicotine is associated with increased numbers of nicotinic cholinergic receptors in animals during chronic nicotine treatment and in brains of human smokers (24 ,25 ,26 and 27).

Nicotine's effects on brain dopaminergic and noradrenergic systems are important in reinforcing self-administration (49). The mesolimbic dopamine system is assumed to mediate pleasurable and other rewards from nicotine as with other drugs of abuse. Nicotinic receptors are on the nerve terminal membranes in the nucleus accumbens and on membranes of the dopamine-secreting neurons innervating nucleus accumbens located in the midbrain. Unlike cocaine and amphetamine, which exert effects by binding to presynaptic dopamine transporters on nerve terminal membranes, nicotine's effects depend more on modulating the flow of impulses to the terminal field (17). As happens after repeated exposure to other stimulants, repeated exposure to nicotine results in sensitization of its effects on dopamine release in the accumbens. There appears to be co-stimulation of *N*-methyl-D-aspartate (NMDA) receptors for glutamate because the development and the expression of the sensitized dopamine response is attenuated or blocked by the administration of NMDA-receptor antagonists. In this respect, some consequences of repeated nicotine exposure on these pathways are similar to those of other stimulant drugs. The consequences of nicotine's modulating effects on multiple neuronal systems remains to be determined (49).

Sustained exposure to nicotine desensitizes some but not all nicotinic cholinergic receptors and results in a state in which nicotine is needed to maintain normal neurotransmission. As nicotine levels decrease, diminished neurotransmitter release or altered modulation of neurotransmitter systems (17) contributes to a relative deficiency state and in humans, symptoms of lethargy, irritability, restlessness, inability to concentrate, depressed mood, and other symptoms making up the nicotine withdrawal syndrome. Plasma concentrations of nicotine in smokers are sufficient to desensitize mesolimbic dopamine neuron nicotinic receptors reinforcing nicotine self-administration. Thus, self-administration of eight to ten nicotine bolus doses (puffs) during the smoking of each cigarette would cause gradually decreasing dopamine release in the nucleus accumbens. With each successive cigarette and gradually rising levels of brain nicotine, desensitization would increase. If so, tobacco smokers continue to smoke during the latter half of each smoking day under conditions in which nicotine is less likely to stimulate neurotransmitter release than while smoking the first cigarettes of the day. Thus, other mechanisms likely contribute to the rewarding properties of nicotine in the latter portion of the daily cycle of smoking (49).

Nicotine increases or decreases brain serotonin levels, depending on concentration and pattern of exposure (16). A possible role for serotonin release in reward mechanisms is suggested by selective serotonin ($5\text{-}HT_3$) antagonists that reduce nicotine reinforcing effects. Chronic exposure to nicotine results in reduced capacity to synthesize 5-HT in serotonergic terminals. Postmortem human studies indicate that tobacco smoking is associated with reductions in hippocampal 5-HT and 5-hydroxyindole acetic acid (16). Functional consequences of the nicotine-induced changes in 5-HT remain to be established but could partially explain anxiety reduction commonly reported by smokers. Increased 5-HT release could result in anxiety and related symptoms common during the early stages of nicotine withdrawal (49).

Nicotine-mediated release of norepinephrine plays a role in the release of adrenocorticotropic hormone (ACTH) and cortisol. Nicotine, acting on α-7 cholinergic receptors, releases glutamate, enhances fast excitatory synaptic transmission possibly contributing to improved learning and memory (28 ,36), and regulates dopaminergic function. Activation of the locus ceruleus produces behavioral arousal with nicotine-increased burst firing an adaptive reaction to stressful situations (49). Activation of nicotinic cholinergic receptors in the adrenal medulla releases epinephrine and perhaps ß-endorphin, a factor contributing to nicotine's systemic actions (12).

In addition to brain receptor-mediated effects, nicotine activates afferent nerves, an effect possibly accounting for the importance of sensory phenomena in cigarette smoking satisfaction and important in shaping conditioned aspects of smoking behaviors. For example, intravenous nicotine

produces burst firing of locus ceruleus neurons before injected nicotine reaches the brain (47). After an initial rapid onset, brief activation that can be blocked by a peripheral nicotine antagonist, a second longer-lasting activation, mediated by central nicotinic receptors, occurs (31).

NATURAL HISTORY OF NICOTINE DEPENDENCE

Part of "107 - Therapeutics for Nicotine Addiction "

Most nicotine addicts begin smoking during adolescence. Adolescent smoking has been increasing since the 1990s. In the United States, about 3 million adolescents smoke. Each day, 6,000 more begin. Most perceive themselves to be dependent on nicotine within their first year of smoking. Adolescent daily smokers appear to inhale doses of nicotine similar to doses inhaled by adults. When asked, about 50% report wanting to quit, and 71% report having tried and failed (49). Adolescents report withdrawal symptoms similar to those reported by adults (32).

Without treatment interventions, smoking quitting rates in adolescent smokers in the United States are comparable to those of addicted adult smokers. Young, still experimenting smokers are likely to become regular smokers; however, the proportion of adolescents who go on to regular smoking and what influences the progression remain obscure. The first symptoms of nicotine dependence occur within weeks of the onset of occasional use, often before daily smoking begins (7). As many as one-third to one-half of adolescents experimenting with cigarettes become regular smokers.

Interventions to prevent progression to tobacco addiction in adolescents are less effective than in adult smokers (33). Adolescents have less interest in treatment, high treatment dropout rates, and low quitting rates (20). Reviews of adolescent tobacco smoking conclude that better characterization of nicotine dependence (35) and assessment of pharmacotherapies are needed, given the almost epidemic proportions of smoking in adolescents.

RISK FACTORS

Part of "107 - Therapeutics for Nicotine Addiction "

Comorbidity

Some smokers report that smoking helps relieve their depression and other mood disorders. Others become severely depressed when they stop smoking (16 ,52). Smokers are more likely to have experienced major depression, and those who have are less likely to quit smoking (37). Several mechanisms may link smoking and depression (16). Depression sensitizes patients to the dysphoric effects of stressful stimuli. Smokers exposed to stressful stimuli become conditioned to nicotine's diminishing of the adverse effects. Nicotine-related decreases in 5-HT formation and release in the hippocampus could be a factor. Stopping addicting drugs, including tobacco, has been hypothesized to result in a negative affect state with dysphoria, malaise, and inability to experience pleasure that has been termed *hedonic dysregulation* (84). Smokers may be protected from such consequences by the antidepressant properties of nicotine.

Consistent with a notion that nicotine may be self-administered by some smokers to manage affective disorders is an uncontrolled study reporting that transdermal nicotine lessened depression in nonsmokers with major depression (56). Another intriguing connection is that cigarette smoking inhibits activity of brain monoamine oxidase (MAO) A and B as measured in the brains of smokers and nonsmokers by positron emission tomography using MAO ligands (40 ,41). Smokers have a 30% to 40% suppression of brain MAO A and B activity. Medications that inhibit MAO sometimes have antidepressant activity. Conceivably, cigarette smoking could have similar effects. Finally, some researchers suggest that links between depression and cigarette smoking result from a common genetic predisposition (42).

Schizophrenia is a risk factor for nicotine addiction; approximately 80% of patients with schizophrenia smoke (43). An abnormality in neuronal nicotinic acetylcholine receptor expression or function may be involved in the neuropathophysiology of schizophrenia. Nonschizophrenic smokers have increased nicotinic receptor binding in postmortem brain hippocampus, cortex, and caudate with increasing tobacco use. In contrast, schizophrenic smokers have reduced nicotinic receptor levels, a finding suggesting abnormal regulation of high-affinity neuronal nicotinic receptors after nicotine use (43). One theory linking schizophrenia and susceptibility to nicotine addiction comes from observations that schizophrenic patients often have abnormalities in auditory sensory gating. Sensory gating is mediated by functions of the α-7 nicotinic cholinergic receptor (44). Cigarette smoking and nicotine improve abnormal sensory gating in humans and animals. The abnormality of sensory gating in schizophrenia has been linked to the gene also encoding the α-7 subunit (45).

Dependence on alcohol, heroin, cocaine, and other drugs frequently coexists with nicotine addiction (4). Alcohol and nicotine addiction have common heritability (46 ,60). Stimulant drug exposure may cross-sensitize to neurochemical effects of other stimulants, so nicotine and other stimulants enhance the effects of one another (14 ,48). Because all addicting drugs release dopamine in the mesolimbic system, drugs may be interacting or substituting for one another to produce common changes in dopamine-related reinforcement.

Genetics

Nicotine addiction involves multiple genetic and environmental factors (50 ,51). Genetic factors account for a significant proportion in the variation in the use of tobacco in twin studies, with heritabilities estimated to be as high as

84% and 82% for liability to lifetime and current tobacco use, respectively (9), influencing both initiation and maintenance of tobacco smoking (60). Another twin pair study (51) reported a similar pattern, with genetic factors appearing more important than environment (78% versus 22%) in smoking initiation and in development of dependence (72% versus 28%). Genetic factors also appeared important for the appearance of alcohol dependence (55% versus 45%), consistent with a common genetic vulnerability and showing that nicotine and alcohol dependence occur together (60). Environmental factors more strongly determined age of first use of tobacco and alcohol, whereas latency between first use and patterns of regular use were more genetically determined (54). A major genetic influence accounting for about 70% of the variance in risk in a group of Vietnam era twin pairs is consistent with other studies suggesting that heritable traits such as sensitivity to nicotine are relevant to smoking prevention and treatment (18).

Genetically determined dopamine receptor functional differences and genetic variation in hepatic enzyme activity important in metabolizing nicotine suggest possible mechanisms. Individuals with TaqIA alleles (A1 and A2) and TaqIB (B1 and B2) of the D2 dopamine receptor gene had earlier onset of smoking, smoked more, and made fewer attempts to quit (58). Specific gene mutations, including those associated with dopamine D2 receptors (23) and dopamine transporter proteins (95), have been implicated as possible determinants for nicotine addiction. People lacking a fully functional genetically variable enzyme CYP2A6 important in the metabolism of nicotine to cotinine are slow nicotine metabolizers (30). This genotype may be important in protecting against tobacco dependence because of impaired nicotine metabolism and may be important as well in determining dose and response to NRTs.

Tobacco and Nicotine Exposure During Pregnancy

In the United States, about 25% of pregnant women smoke cigarettes, and so each year about 1 million babies are exposed *in utero* to tobacco smoke (89). That so many pregnant women smoke has important implications both for the determinants of tobacco addiction and its therapeutics. Tobacco smoking has long been known to present considerable fetal risks (59). Less well appreciated is that nicotine itself is a neuroteratogen (89). Nicotine given to rats during gestation or adolescence at levels assumed to be consistent with those in human smokers alters gene expression and produces long-lasting central nervous system cellular damage, by reducing cell number and impairing synaptic activity and cell signaling (62). Developing brain cells appear particularly vulnerable. In adult rats, similar exposure stimulates nicotinic cholinergic receptors without lasting cellular changes. Some of nicotine’s effects on cell numbers continue post partum, well after termination of nicotine exposure. The alterations in synaptic function plausibly would account for associated behavioral disruptions evident in humans (98) and in animal models (1 ,62 ,89).

Nicotine doses that do not produce growth retardation still produce central nervous system cell damage, loss, and synaptic dysfunction. The fetal effects of nicotine may be greater during the later stages of pregnancy, a finding suggesting the first trimester is the most desirable period for NRT during pregnancy. Based on the rat data, it may be preferable to introduce NRTs early in pregnancy to try to reduce the fetal exposure to nicotine before the second or third trimester. In the rat models, episodic nicotine delivery, as happens with smoking, is associated with less nicotine exposure to the fetus than continuous exposure from a nicotine patch. Of course, fetal exposure to tobacco smoke presents a host of other toxins besides nicotine.

Maternal smoking during pregnancy has long-term behavioral consequences in humans (89 ,98). Cognitive deficits, behavioral problems in childhood, particularly attention-deficit/hyperactivity disorders, conduct disorders, and substance abuse in the exposed children are associated with maternal smoking. Children whose mothers smoked ten or more cigarettes daily during pregnancy had a fourfold increased risk of prepubertal-onset conduct disorder in boys and a fivefold risk in adolescent-onset drug dependence in girls (98). The outcomes are not explained by other risk factors. Maternal prenatal smoking appeared to be related to future criminal behavior in male children, with a dose–response relationship between intensity of third trimester smoking and arrest history of 34-year-old men whose mothers smoked during pregnancy (63). Although such studies are limited by retrospective maternal reports of smoking behaviors during pregnancy, there is a consistency with outcomes in studies directly assessing maternal smoking.

MANAGEMENT AND THERAPEUTICS OF NICOTINE ADDICTION

Part of "107 - Therapeutics for Nicotine Addiction "

Ideally, therapeutics for nicotine addiction should be available for the 80% of the world’s smokers who live in low- and middle-income countries. Within those countries, smokers have the lowest income, are the least educated, and have the poorest access to health care. Thus, from a world view, cost of therapeutics and access become important considerations. Prevention is obviously an important strategy, but strategies to prevent tobacco addiction must deal with a politically powerful and wealthy multinational industry promoting use of tobacco (64). The tobacco industry in the United States alone spent 6 billion dollars in 1998 to market cigarettes, about 18 million dollars each day. More is spent promoting tobacco use elsewhere in the world. Although successful prevention strategies exist (65), well-funded competition encouraging tobacco use will remain (64).

More intensive therapeutics typically include behavioral interventions combined with NRT delivered over a series of sessions. Individual or group behavioral treatments appear almost equally effective. Intensive treatment programs are effective in assisting even very dependent smokers to stop for a few months. However, as with other addictions, relapse is a major problem. Initial quitting rates of 50% to 60% at 1 month typically decrease to 20% to 30% at 1 year. Various relapse-prevention procedures have been tried. None has proven clearly effective. Most tobacco addicts repeat the quitting process on average every 3.5 years and try three or four times before finally stopping forever (66). In that respect, stopping smoking is similar to overcoming addictions to other psychoactive drugs. Tobacco addiction treatment programs are cost-effective. Average treatment costs per year of life saved are $1,000 to $2,000 per year for brief counseling alone and $2,000 to $4,000 per year of life saved with more intensive counseling and pharmacotherapy to aid in smoking cessation (34 ,67). Smoking cessation treatments are less costly per year of life saved than are generally accepted therapies for hypertension, hypercholesterolemia, and other chronic disorders.

Therapeutics: Clinical Guidelines

Guidelines for treating tobacco dependence were published in 2000 by the United States Public Health Service (2 ,13). The detailed report resulted from critical review of approximately 6,000 peer-reviewed articles on tobacco addiction therapeutics and 50 metaanalyses based on that literature (69).

The major general conclusions were as follows:

1. Tobacco dependence is a chronic condition warranting repeated treatment until abstinence is achieved.
2. Effective treatments for tobacco dependence exist. All tobacco users should be offered treatment.
3. Clinicians and health care systems must institutionalize consistent identification, documentation, and treatment of every tobacco user at every visit.
4. Brief tobacco dependence treatment is effective. Every tobacco user should be offered at least brief treatment.
5. There is a strong relationship between the intensity of tobacco dependence counseling and effectiveness.
6. Three types of counseling are especially effective: practical counseling, social support as a part of treatment, and social support outside of treatment.
7. Five pharmacotherapies for tobacco dependence are effective: nicotine gum, nicotine inhaler, nicotine nasal spray, nicotine patch, and bupropion. At least one of these medications should be prescribed in the absence of contraindications.
8. Tobacco dependence treatments are cost-effective when compared with other medical and disease prevention interventions. Health insurance plans should include as a benefit the counseling and pharmacotherapies identified as effective in the guideline (2).

Contemporaneous reviews of tobacco addiction therapeutics (59 ,70 ,71 ,72 and 73) and an extensive report on tobacco addiction pharmacology and therapeutics from the Royal College of Physicians (49) offered similar conclusions. A summary review from the Cochrane Tobacco Addiction Review Group identified and summarized evidence of efficacy for tobacco addiction therapeutics (91). Details of the 20 systematic reviews are available on the Internet in the Cochrane Library (75). The reviews used a similar strategy and reviewed much the same literature on tobacco addiction therapeutics as did the Public Health Service review.

The Cochrane reviews considered the results from randomized controlled trials having at least 6 months of follow-up (91). Sustained abstinence or point prevalence quit rates were used in the metaanalysis as necessary. Simple advice from physicians presented during routine care was studied in 31 trials that included 26,000 smokers in a variety of clinical settings. Brief advice increased quit rate more than no advice (odds ratio, 1.69; 95% confidence interval, 1.5 to 1.98). Individual counseling was better than brief advice or usual care. Group therapy was more effective than self-help materials alone but not consistently better than interventions with more personal contact. Self-help informational material and printed descriptions of behavioral strategies had a small treatment effect (75 ,91).

Nicotine Replacement Therapeutics

NRT decreases the discomfort of nicotine withdrawal. The relatively stable brain nicotine levels resulting from NRT should facilitate a desensitized state for some nicotinic cholinergic receptors. Because some nicotinic receptor subtypes are more desensitized than others, both nicotine agonistic and desensitization mechanisms could operate together in NRT. In a nicotine-induced desensitized state, norepinephrine release normally stimulated by endogenous acetylcholine would be diminished. Other neurotransmitter release normally stimulated by endogenous acetylcholine could be diminished as well. The resulting NRT modulation of mood states in itself could be rewarding. In addition, some blunting of the reinforcing effects of cigarettes smoked during cessation lapses is likely during NRT. However, the mechanisms of NRT still remain uncertain because the intensity of withdrawal alone is not a good predictor of success for ultimately stopping smoking (3). Even though withdrawal symptoms can be diminished by NRT, other mechanisms, learning coping skills, and replacing some of the positive effects of nicotine are important as well. Whatever the mechanisms, NRT is clearly effective and safe for helping smokers to quit (70).

The Cochrane review of clinical trials with nicotine gum, transdermal nicotine patches, nasal spray, and inhalers concluded

that NRT enhanced early cessation and reduced early relapse when compared with placebo (75 ,91). All products enhanced quitting smoking about twofold. Quitting rates, depending on intensity of concurrent behavioral interventions, ranged from 10% to 30% of patients with a 1-year follow-up. Higher nicotine doses were more effective, although the dose–response function is shallow. NRT did not appear to have significant dependence potential or to cause significant harm (70). Characteristics of long-term NRT users resembled those of treatment failures. It appeared many would be smoking or smoking more if NRT were not available.

However, 70% to 90% of addicted smokers fail to stop smoking despite NRT. Why (77)? Most studies included only nicotine-addicted smokers, so the usefulness of NRT for less addicted smokers remains uncertain. Although recommendations have been made for use of combinations of NRT products, for example, patch plus spray, patch plus gum, or higher-dose NRT, too few trials preclude clear evidence of effectiveness. Long-term reduction in smoking by concomitant use of NRT while smoking continues is being investigated (78). Nicotine inhalers and skin patches have been used safely and with sustained reduction in smoking for up to 30 months (79 ,80).

Particularly for highly dependent smokers, nicotine replacement from patches and gum probably delivers nicotine to the brain too gradually and without the transient but rewarding brief surges in brain nicotine levels from puffing on a cigarette (5 ,19). Nicotine nasal sprays or inhalers more closely approximate smoking in this respect, but only partially so, and clinically they do not offer advantages to patch failures (77). An inhaled nicotine aerosol would, in principle, be an ideal substitute nicotine delivery system, but despite many attempts, a practical inhaled aerosol system providing the control over dose offered by a tobacco cigarette has not been brought to market.

Non–Nicotine Replacement Pharmacotherapies

The consequences of neuroadaptive changes in brain function associated with chronic nicotine exposure should, in principle, be modified by appropriate neurochemical interventions (71 ,81 ,82). Pharmacotherapies mimicking nicotine’s neurochemical effects by increasing or modulating brain levels of dopamine, epinephrine, serotonin, and other neurotransmitters should correct the neurochemical deficiency states associated with nicotine withdrawal. Pharmacotherapies may also mimic some of nicotine’s actions on brain reward systems. Nicotinic receptor antagonism offers an additional strategy. Although treatment with anxiolytics did not improve outcome, antidepressants, bupropion, and nortriptyline increased quit rates (2 ,83 ,91). The mechanisms by which antidepressant drugs benefit smoking cessation are yet to be determined. The neurochemical consequences of chronic nicotine exposure have similarities to the effects of some antidepressants (16 ,52 ,84).

Bupropion

As with many pharmacotherapies, recognition that bupropion could be useful for treating tobacco addiction resulted from serendipitous observations. Smokers being treated with bupropion for depression reported less desire to smoke or greater success in stopping smoking. Bupropion is structurally related to phenethylamines resembling an anorectic drug diethylproprion and is believed to assist smoking cessation by blocking neuronal uptake of dopamine and norepinephrine and possibly by decreasing firing of the locus ceruleus (71). Bupropion and some other antidepressants functionally antagonize some nicotinic cholinergic receptors in muscle and autonomic ganglia and reduce receptor response to nicotine (85). Whether antidepressant drugs similarly antagonize brain nicotine receptors is undetermined.

Bupropion was effective judging from two large trials and two smaller unpublished ones (86). Bupropion alone or combined with a nicotine patch was more effective than the patch alone (87). Although the drug caused dry mouth and insomnia, serious side effects were uncommon. Bupropion was as effective in patients with a history of depression as with those without such a history (88). When given to a group of smokers not trying to quit permanently, bupropion decreased some withdrawal symptoms but had no effect on craving (86). Bupropion was a more cost-effective therapeutic agent for tobacco addiction than NRT (68).

Other Therapies With and Without Utility

Clonidine shares some pharmacologic effects of bupropion and tricyclic antidepressants. The Cochrane review of six clinical trials of clonidine found increased smoking quit rates, but side effects of sedation and postural hypotension posed problems for many patients (75 ,91).

Sensory stimulants mimic mouth and airway sensory responses to smoking that become associated with the pharmacologic effects of nicotine and thus become reinforcers. Ascorbic acid aerosols and citric acid inhalers evaluated in cessation trials reduce craving and some withdrawal symptoms over the short term (71).

The effects of opiate antagonists on cigarette smoking have been studied to examine how opioid systems modulate smoking behavior and to determine whether opioid antagonists could be useful to aid in smoking cessation (22). Naloxone precipitates opiate withdrawal-like symptoms and increases desire to smoke (38). The effects of naloxone or naltrexone on *ad libitum* smoking over brief periods in a laboratory were inconsistent, but some smokers smoked less. A clinical trial compared naltrexone, 50 mg daily for 12 weeks, or placebo, with or without transdermal nicotine (61). Only transdermal nicotine increased abstinence rates.

Naltrexone had no effect on cessation rates. Transdermal nicotine reduced craving and cigarette smoking in smokers who did not quit. Naltrexone had no such effects. Another 4-week trial of naltrexone or placebo found no difference in smoking 6 months later (93). Thus, the clinical trial data indicate no useful role for opioid antagonists in smoking cessation therapy despite the suggestive laboratory results.

Nicotinic receptor antagonism offers another possible strategy. A nicotine antagonist mecamylamine has been investigated as a cessation aid both alone and in combination with NRT (59 ,71). Mecamylamine started before quitting smoking and continued afterwards appeared useful in two studies (94). Combined use of mecamylamine and nicotine patch increased quit rate more than nicotine alone, a finding leading to consideration of mecamylamine blockade of nicotine's rewarding effects (97).

Circulating antibodies binding nicotine in blood and preventing its reaching the brain would be functionally equivalent to a receptor antagonist's preventing nicotine receptor access. Antibodies have been induced by immunization of rats with nicotine linked to an immunogen (68). Immunized animals had reduced brain nicotine concentrations and reduced behavioral and cardiovascular effects after intravenous nicotine (68). Whether immunization alters the reinforcing effects of nicotine remains to be determined.

Lobeline, a nonpyridine alkaloid and partial nicotine receptor agonist from the Indian tobacco plant *(Lobelia inflata),* has long been used in proprietary smoking treatments (59 ,71). Although no longer marketed in the United States, lobeline is available elsewhere. No clinical trials had more than a 6-month follow-up. The drug was judged unproven by the Cochrane review (75 ,91).

ACTH has been suggested to aid smoking cessation, based on the notion that nicotine increases ACTH and cortisol release and that during nicotine withdrawal, there may be a state of hypoadrenocorticism. Uncontrolled trials with small numbers of smokers given a few ACTH injections during the first week after quitting reported high quit rates or decreased smoking, but without controlled clinical trials, ACTH must still be considered unproven (71).

Silver acetate has long been available as an over-the-counter smoking deterrent in the form of chewing gum, lozenges, and spray. A reaction with cigarette smoke produces an unpleasant metallic taste, the basis for this aversive therapy. Several clinical trials reported short-term efficacy, particularly in less addicted smokers (71). Whenever the urge to smoke is great, it is easy to stop silver acetate use, so it does not appear an effective therapeutic for severe nicotine addiction.

The effectiveness of other aversion therapies, acupuncture, hypnotherapy, and exercise was at best considered uncertain (75 ,91).

FUTURE RESEARCH

Part of "107 - Therapeutics for Nicotine Addiction "

As nicotinic cholinergic receptor subtype–specific agonists and antagonists are developed, more specific treatments for nicotine addiction in subtypes of smokers should result (49). Possibly, medications useful for treating affective disorders, schizophrenia, Alzheimer disease, and other brain disorders may result as well from such research. (15 ,16 ,43).

Adolescent smoking initiation rates remain high (49). Beginning smoking among young adults is common (90) and is perhaps increasing (57). Although we understand much about nicotine addiction (2), we still do not know enough to prevent people from becoming addicted or how best to treat highly dependent tobacco users (77).

Research on vulnerability to nicotine addiction should include linking of phenotypes of nicotine response and other aspects of tobacco dependence to genotypes related to specific receptors and other proteins involved in nicotine addiction (49). Study of the mechanisms of nicotine reinforcing effects in people with affective disorders (16), schizophrenia (43), and other drug dependence is important. Study of hormonal and psychosocial mechanisms will help us to understand gender differences in nicotine addiction (99). Longitudinal studies of children of mothers who smoke, with better measures of smoke exposure *in utero* and assessments of behavior through childhood, will better define the natural history of nicotine addiction and will lead to better strategies for prevention and cessation interventions (1 ,49 ,62 ,89 ,98).

CONCLUSION

Part of "107 - Therapeutics for Nicotine Addiction "

Research since the early 1980s has expanded our understanding of nicotine addiction. Now the challenge is to translate knowledge of the biology of nicotine addiction into pharmacotherapies and other therapeutics addressing individual differences in addicted smokers. To do so will require the development of new drugs, better understanding of existing ones, and wisdom needed to match optimal therapies to individual smokers. Much the same could be said about therapeutics for all drug addictions.

Psychedelic Drugs

Henry David Abraham

Una D. McCann

George A. Ricaurte

Henry David Abraham: Department of Psychiatry, Harvard Medical School, Cambridge, Massachusetts.

Una D. McCann: Department of Psychiatry and Behavioral Sciences, The Johns Hopkins School of Medicine, Baltimore, Maryland.

George A. Ricaurte: Department of Neurology, The Johns Hopkins School of Medicine, Baltimore, Maryland.

As defined in this chapter, the term *psychedelic drugs* includes both classic hallucinogens [i.e., indolalkylamines and phenylalkylamines, such as lysergic acid diethylamide (LSD) and mescaline, respectively], "dissociative" drugs [i.e., arylcyclohexamines, such as phencyclidine (PCP) and ketamine], and substituted amphetamine analogues [i.e., phenylpropanolamines, such as 3,4-methylenedioxymethamphetamine (MDMA, "ecstasy")]. The use of psychedelic drugs dates from the dawn of recorded history and continues today. Indeed, in Western culture, their use appears to be on the rise. Despite the longstanding popularity of psychedelic drugs, controlled research evaluating their effects in humans has been surprisingly scant, and data from preclinical studies have been largely limited to the last several decades. This chapter reviews preclinical and clinical research involving indolalkylamines, arylcyclohexamines, and substituted amphetamines, for which LSD, PCP, and MDMA are used as the prototypes, respectively. Significant recent advances are highlighted, and promising areas toward which future research should be directed are identified.

INDOLALKYLAMINES

Part of "108 - Psychedelic Drugs "

Epidemiology

Surveys in the United States and Western Europe reveal an increased use of indolalkylamine hallucinogens. For example, trend data in the United States, gathered from 15,000 high school seniors, showed a rise in prevalence of lifetime hallucinogen use from 6% to 13.7% between 1986 and 1999 (1 ,2). Similarly, in Great Britain, the use of LSD rose from 7% to 11% between 1989 and 1993. Among German drug abusers, the prevalence of LSD use was reported at 14.1%, and 7.2% of Danes reported the use of hallucinogenic mushrooms (3).

In the United States, a survey of 633 undergraduates found that 23.8% had experimented with hallucinogenic mushrooms, and 16.3% had had experience with LSD. Among LSD users, 6.6% reported problems associated with LSD (Abraham and Koob, *unpublished data*). Of this group, 46.9% reported symptoms of hallucinogen persisting perception disorder (HPPD), 37.5% described alcohol dependence, 25% major depression, 18.8% persisting delusions, 15.6% panic attacks, and 12.5% auditory hallucinations. LSD use is most likely to occur between the ages of 18 and 25. Use is more common in male Caucasians and Hispanics. Of note is that although the parents of LSD users tend to be of a higher socioeconomic status, the users themselves exhibit an inverse relationship between LSD use and educational achievement (4).

Early Neurophysiologic Studies

Work in the 1950s intimated that hallucinogens simultaneously activate and depress neural systems in mammals. In 1953, Gaddum (5) reported that LSD antagonizes the effects of serotonin (5-HT). In the visual system, LSD decreased by 80% the amplitude of the postsynaptic response in the lateral geniculate nucleus of the cat following stimulation of the optic nerve (6). Pentobarbital was found to sensitize the cells to LSD, and asphyxia transiently overcame the LSD effect. These observations were among the first to suggest that in the visual system, LSD is inhibitory, like γ-aminobutyric acid (GABA), and is antagonized by excitatory amino acids released during hypoxia.

Neurophysiologic studies in animals and humans indicate that hallucinogens produce arousal (7). Multiple EEG studies of LSD in rabbits, cats, and humans have documented an increasing shift of alpha frequencies to low voltage, fast rhythms, and alpha disappearance (8). In studies of evoked sensory potentials in cats, a low dose of LSD facilitated both auditory and visual primary responses, whereas high doses depressed auditory responses while continuing

to facilitate visual responses (9). Thus, LSD appears to affect the midbrain and cerebral cortex, particularly the visual cortex, and its effects both stimulate and inhibit, depending on the system studied.

Behavioral Studies

A variety of behavioral models in animals have been employed to study psychedelics. The strength of such models over human studies is that ethical concerns are mitigated, experimental controls are more comprehensive, tissue is available for *in vitro* assessment, and genetic studies are possible with the use of knockout, mutagenesis, and antisense nucleotide strategies. The weakness of animal models is that they cannot provide a direct, reliable method to determine if or when an animal is hallucinating. Despite this limitation, drug discrimination paradigms have been useful in establishing comparative benchmarks between LSD, mescaline, and other hallucinogens, associating potency data with binding at specific receptor types, correlating animal potencies with human data, and describing structure–activity relationships (10). Sophisticated behavioral studies by Geyer et al. (11) suggest that LSD disrupts two fundamental mechanisms of filtering of sensory information, habituation and prepulse inhibition.

Neuropharmacology

The mechanism of action of the hallucinogens is one of the compelling questions in pharmacology, the answer to which promises insights into the mechanisms of perception, mood, and psychosis. Early studies of LSD in peripheral tissue implicated serotoninergic receptors in the mechanism of hallucinogenic activity. Freedman (12) found that LSD decreases brain 5-HT turnover. This effect correlated with behavioral changes and the plasma half-life of LSD, was limited to hallucinogens, and was replicated in several species. Hirschhorn and Winter (13) showed that rats can discriminate LSD and mescaline from saline solution. Discrimination fell in the presence of serotonin antagonists, supporting a 5-HT-agonist mechanism for the action of hallucinogens.

In intracellular recordings from serotoninergic dorsal raphe neurons of the rat brain *in vivo*, LSD directly inhibited firing, but other hallucinogens did not (14). In 1979, it was shown that the effects of LSD on cat behavior are dissociated from raphe responses and involve postsynaptic serotonin activity (15). The same year, Peroutka and Snyder (16) reported the discovery of multiple serotonin receptor types. A high density of 5-HT_{1A} autoreceptors was found on raphe neurons, which explained the direct inhibition of this system by LSD (17). Based on the ability of receptor antagonists to block hallucinogen discrimination in animals, it was proposed that hallucinogens act as agonists at postsynaptic 5-HT_2 receptors (18). Hallucinogen potency in animals was found to correlate with affinity at the 5-HT_2 receptor (19).

Chemistry

Considerable work has been directed at structure–activity relationships of the ergoline hallucinogens (20 ,21). Substitution at the N(1) position of LSD abolishes activity, as does substitution at the C(2) position with a halogen. (*R*)-stereochemistries are essential at both C(5) and C(8) for activity. Reduction of the double bond at the 9,10 position abolishes hallucinogenic activity. Hydroxylation of C(13), which may occur *in vivo*, confers a high level of dopaminergic potency on ergolines (21). Most interesting is that ethylation of LSD at N(6) enhances potency, as determined in both animal and human studies. A monoalkyl amide, a diastereomer of chlorobutyl LSD, is at least 50% more potent than LSD. In ligand binding at 5-HT_2, 5-HT_{1A}, D1, and D2 receptors, the (*R*)-2-butylamide substituent is likewise more potent. Cloning of the 5-HT-$_2$ receptor permitted replacement of aspartate 120 in second transmembrane domain with asparagine. This resulted in a significant decrease in affinity for LSD and abolished phosphatidylinositol turnover. Additionally, aspartate 155 is required for agonist and antagonist binding (22). Second messenger systems in hallucinogen-responsive receptors represent another promising avenue to unraveling the mechanism of hallucinogens. 5-HT_2 receptors are coupled to at least three transduction systems: potassium channels, cationic I_h channels, and phosphoinositide hydrolysis. The close correlation between hallucinogen affinities for the 5-HT_2 and 5-HT_{1C} receptors raises the possibility that the latter may play an independent or complementary role in hallucinogenic activity. This is supported by the fact that LSD is an agonist at 5-HT_{1C} receptors, as determined by phosphoinositide hydrolysis (23).

Recent Neurophysiologic Studies

More recent electrophysiologic studies of hallucinogens in animal models support the involvement of postsynaptic 5-HT_2 and 5-HT_{1C} receptors in hallucinogen activity. The locus ceruleus, considered a sensory novelty detector in the pons, projects widely throughout the brain. Hallucinogens indirectly decrease spontaneous activity in the locus ceruleus by activating $GABA_A$ inputs, and they enhance sensory responses of the locus ceruleus by activating excitatory inputs via *N*-methyl-D-aspartate (NMDA) receptors (24). 5-HT_{2A}-receptor antagonists block these effects. In rat piriform cortex, both 5-HT and hallucinogens at 5-HT_{2A} receptors excite GABAergic interneurons, which then induce inhibitory postsynaptic potentials (25). In prefrontal cortex, the opposite occurs, where the drugs release glutamate and increase excitatory potentials (26). Both 5-HT_{2A} and glutamatergic antagonists block this effect. Direct studies of neocortical

cells suggest that 5-HT_{2A} receptors induce glutamate release by a focal mechanism, not by impulse flow. Recently, it has been suggested that hallucinogens act at 5-HT_{2A} cortical receptors by promoting late, asynchronous excitatory potentials. In such a model, 5-HT itself would antagonize hallucinogens by activating 5-HT_1 receptors (14). This model explains the clinical observation that selective serotonin reuptake inhibitors blunt the effects of LSD, whereas serotonin depletion enhances them.

Although the dominant hypothesis of hallucinogenic activity currently is that it results from partial agonism at the 5-HT_{2A} receptor, similar affinity and agonism data exist for the 5-HT_{2C} receptor (27). Finally, functional interaction is likely to occur between receptor types and subtypes.

Recent Human Studies of Indolalkylamine Hallucinogens

The extraordinary mental effects of LSD described in 1943 by Hofmann prompted hope in the following two decades that a powerful therapeutic tool was at hand. The drug was used experimentally to treat neuroses, childhood schizophrenia, sociopathy, and alcoholism, and as a comfort to the terminally ill (28). Methodologies were inadequate by contemporary standards, and no treatment stands unambiguously as effective. In recent years, renewed interest in hallucinogen research has been sparked by the emergence of positron emission tomography (PET), single-photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI) technologies. For example, PET studies by Vollenweider and colleagues (29) have shown that psilocybin, another hallucinogen, increases frontal glucose metabolism in healthy volunteers, which suggests that the behavioral effects of psilocybin involve the frontal cortex (Fig. 108.1). Similar imaging work has been done with the phenethylamine mescaline.

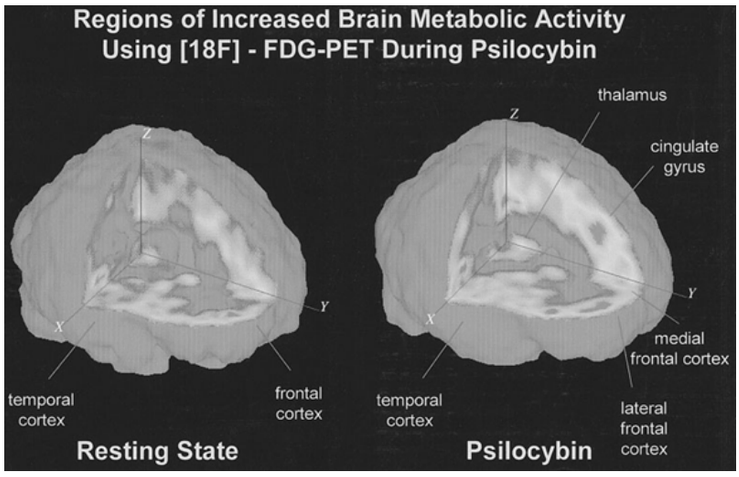

FIGURE 108.1. Positron emission tomography with [^{18}F]-fluorodeoxyglucose before and after a 15- or 20-mg dose of psilocybin in healthy volunteers. Psychotomimetic doses of psilocybin were found to produce a global increase in the cerebral metabolic rate of glucose, with significant and most marked increases in the frontomedial, frontolateral, anterior cingulate, and temporomedial cortex. The increase correlated positively with psychotic symptoms. (Modified from Vollenweider FX, et al. Positron emission tomography and fluorodeoxyglucose studies of metabolic hyperfrontality and psychopathology in the psilocybin model of psychosis. *Neuropsychopharmacology* 1997;16:257–272, with permission.) See color version of figure.

Human dose–response studies of hallucinogens since 1965 have been rare. Shulgin et al. (30) synthesized 179 phenethylamines and informally screened them in human volunteers for hallucinogenic potency. Strassman and Qualls (31), using DMT (N,N-dimethyltryptamine) in carefully screened and supervised subjects, were able to develop a hallucinogen rating scale and measure a number of dose-dependent neuroendocrine responses to the drug. Equally importantly, this work demonstrated that hallucinogen experimentation could be safe as well as informative.

Acute Adverse Psychiatric Effects of Hallucinogens

Clinically, the flow of thoughts, feelings, and perceptions that constitute a hallucinogenic experience can, on occasion, result in panic. Thus, a man who was using LSD while driving tried to crash the vehicle when he saw his companion turn into a giant lizard (32). The treatment for hallucinogen-induced panic is an oral benzodiazepine. The utter efficacy and rapidity of the response to this class of medications implicates GABA receptors as the neuromodulators of this hallucinogenic experience in humans.

Hallucinogen Persisting Perception Disorder

Hallucinogens sometimes appear to alter psychological functions years after drug use (32). Elkes et al. (33) originally noted recurrences of drug experiences, flashbacks, to occur episodically. Surveys among college students reveal that more than 40% of those using LSD report minor spontaneous visual experiences weeks to months after LSD use (32). Less common are patients who report persistent, continuous visual disturbances following LSD use. These people

are affected by a variety of disturbances, such as after-imagery, geometric pseudohallucinations, halos around objects, and the trailing of visual images as they move through the visual field (32).

Hallucinogen persisting perception disorder appears to be a permanent, or slowly reversible, disorder of disinhibition of visual processing, which suggests the defective sensory gating described by Braff and Geyer (34). Evidence for this comes from psychophysical experiments in which visual signals in subjects with HPPD persisted significantly longer than in LSD-naïve controls (35). Quantitative electrophysiology (qEEG) in this population shows abnormalities in visually evoked potentials as long as 26 years after last LSD use, consistent with visual disinhibition (36). Thus, these studies are consistent with others showing that the visual system is especially sensitive to the effects of LSD. Second, LSD hallucinations involve the cerebral cortex (37). Third, inhibitory systems appear, at least in certain circumstances, to be involved in LSD effects and probably LSD aftereffects. Fourth, flashbacks may in certain cases become long-lived, continuous, and probably permanent. And fifth, HPPD is associated with cortical disinhibition.

Recently, it has been found that the GABA agonist midazolam rapidly reduces experimentally induced afterimages in persons with HPPD to approximate the responses from controls without the disorder (Abraham, *unpublished data*). Clinically, GABA agonists are known to reduce, but not resolve, symptoms of HPPD symptoms. This modulation of after-imagery suggests that the visual dysregulation of HPPD may be related to a permanent loss of GABA-mediated inhibition. Risperidone, a 5-HT_2 antagonist, has been found to exacerbate HPPD in persons with the disorder (38). Nefazodone, also a 5-HT_2 antagonist, is associated with visual trailing phenomena. One suggestion regarding the etiology of HPPD is that LSD in vulnerable persons reduces the population of 5-HT_2 inhibitory interneurons modulating visual processing by excitotoxicity, thus reducing GABA efferents to glutamatergic neurons. Treatment for HPPD remains empiric and palliative. It may include benzodiazepines, sertraline, naltrexone, and clonidine. Nonaddictive agents are preferred in patients with histories of addiction.

Psychosis

Studies of LSD administration to research subjects report an incidence of subsequent psychosis in 0.08% to 4.6% of the samples. Psychiatric patient status appears to be a risk factor for the development of psychosis (39). Case histories tend to support phenomenology of a schizoaffective presentation with the added feature of visual disturbances. Positive symptoms of schizophrenia tend to be present. Effective treatments include neuroleptic, lithium, and electroconvulsive therapies.

ARYLCYCLOHEXAMINES

Part of "108 - Psychedelic Drugs "

The arylcyclohexamine PCP (“angel dust,” “peace pill”) can be considered the prototypal dissociative anesthetic. Other drugs in this class include ketamine and dizocilpine maleate (MK-801). PCP was first synthesized in the 1950s, when it was marketed as a surgical anesthetic under the trade name Sernyl. Initially widely used in surgical settings, it was withdrawn in 1965 because of its association with a variety of behavioral disturbances, including agitation, dysphoria, delirium, hallucinations, paranoia, rage, and violence (40). In approximately half of patients who received PCP, a psychotic syndrome developed that sometimes persisted for more than a week (41). Today, the psychotic syndrome produced by PCP or ketamine is considered a leading drug model of schizophrenia (42).

Chemistry

Phencyclidine and other dissociative anesthetics consist of a phenyl ring, a piperidine group, and a cyclohexyl ring. The two conformations of drugs in this class are categorized according to the cyclohexyl spine and subsequent location of the phenyl ring. In particular, if the phenyl ring is located in the axial plane, the drug is active, whereas location of the phenyl group in the equatorial plane renders the drug inactive. Ring number and substitutions can significantly alter the potency of drugs in this class (43).

Epidemiology

Until recently, typical PCP users were white, blue collar men with a high school (or partial high school) education working in unskilled or semiskilled jobs (40). However, dissociative anesthetics such as ketamine and PCP are increasingly used in the growing “club” or “dance” culture, and it appears that the popularity of these drugs has risen in young adults. Data from the Monitoring the Future Study indicate that lifetime prevalence rates of PCP use increased from 2.4% to 2.7% in young men ages 18 to 29 from 1997 to 1998, whereas use among twelfth graders remained at 3.9% in 1997 and 1998 and fell to 3.4% in 1999 (2).

Neuropharmacology

The mechanism of action of dissociative anesthetics is both unique and complex, involving a number of distinct neurotransmitter and neuromodulator systems. PCP behaves as a cholinergic antagonist at both central and peripheral sites, acting at both nicotinic and muscarinic receptors. (44). PCP is also a D2-receptor antagonist, and actions at this receptor are believed to underlie many of the behavioral symptoms that follow drug administration (40). In addition to D2 blockade, PCP increases the rate of dopamine release from synaptic vesicles and prevents dopamine reuptake inactivation.

Amphetamine-like activating effects of PCP are believed to involve not only dopamine uptake blockade but also actions of PCP in the frontal cortex and consequent neuromodulatory effects of the frontal cortex on the basal ganglia (45). Actions at σ and μ opiate receptors are thought to underlie the anesthetic effect of PCP, whereas actions at serotonin receptors may underlie its hallucinogenic effects (40). Notably, cross-tolerance occurs between PCP and the classic hallucinogens LSD, mescaline, and psilocybin (46), and PCP substitutes for LSD or mescaline in two-level drug discrimination studies in rats. PCP also binds to two specific PCP sites in the brain. One PCP receptor, located within the NMDA receptor-gated ion channel, is stimulated by NMDA-receptor agonists such as L-glutamate and can be modulated by a variety of modulatory agents, such as glycine-like amino acids and polyamines (47). A second, lower-affinity PCP receptor has been identified but is less well characterized (40).

Behavioral Effects in Humans

Phencyclidine produces a mixture of stimulant, depressant, anesthetic, and hallucinogenic effects, with the particular presentation dependent, in part, on dosage. In particular, low doses are associated with anticholinergic symptoms (red and dry skin, nystagmus, amnesia, conceptual disorganization); moderate doses are more likely to be associated with opiate receptor activity (anesthesia, dreamlike states); at high doses, dopaminergic symptoms predominate (hallucinations, paranoia). However, this rule of thumb should not be considered diagnostic. The mnemonic RED DANES was coined by Giannini and colleagues (48 ,49) to characterize eight acute symptoms of PCP intoxication that may be seen at any dose: rage, erythema, dilated pupils, delusions, amnesia, nystagmus in the horizontal plane, excitation, and skin dry. It is important to note that the toxic effects of PCP may persist for days because the half-life of PCP after overdose may be as long as 3 days (50).

In addition to acute toxicity, a number of researchers have reported persistent cognitive deficits in long-term PCP users, particularly in short-term memory function (51 ,52 ,53 and 54). Also, abrupt lapses into confusional states occurring weeks or months after PCP ingestion have been reported.

Phencyclidine Neurotoxicity

Olney and colleagues (55) were the first to report that single doses of PCP and related compounds (MK-801 and ketamine) lead to neurotoxic damage of neurons in layers III and IV of the posterior cingulate and retrosplenial cortex in rats. These cells display abnormal cytoplasmic vacuolization that is directly correlated with the potency of noncompetitive NMDA blockade. Initially, these were believed to be short-term changes, but higher doses of MK-801 were observed to cause necrotic changes persisting at least 48 hours after drug administration. Subsequently, other researchers reported a number of observations suggesting that PCP is neurotoxic. In particular, following PCP administration, vacuolization of neurons in hippocampal fields CA1 and CA3 and the subiculum has been demonstrated (56). PCP induces a microglial response and a 70-kilodalton heat shock protein in cerebellar Purkinje cells (57); most recently, it has been found that PCP induces apoptosis in striatopallidal cells in rats (58). The mechanisms for the actions of PCP at these various anatomic sites are likely to differ, with cortical injury involving activity of cholinergic, GABAergic, and adrenergic neuronal systems (59) and apoptotic changes observed in striatopallidal cells involving excess corticosteroids (58). Research is needed to determine whether PCP-induced neurotoxicity underlies the memory deficits seen in some PCP users.

SUBSTITUTED AMPHETAMINES (MDMA, “ECSTASY”)

Part of "108 - Psychedelic Drugs "

Chemistry

3,4-Methylenedioxymethamphetamine bears structural similarity to both the psychomotor stimulant amphetamine and the hallucinogen mescaline. Of the two optical isomers of MDMA, the dextrorotatory isomer exhibits more potent central nervous system activity (60). In contrast, most potent hallucinogenic amphetamines are more potent in their levorotatory forms (61). The aromatic methylenedioxy substituent of MDMA is similar to the substance found in oils of the natural products safrole and myristicin, once proposed to be the intoxicants of sassafras and nutmeg (62).

Epidemiology

Data from the most recent Monitoring the Future Study indicate that MDMA use has continued to rise since 1989 (1 ,2). For example, annual use of MDMA among college students rose from 2.4% in 1997 to 3.9% in 1998, with lifetime figures reflecting similar increases, from 4.7% in 1997 to 6.8% in 1998 (1). Notably, figures from 1996 to 1999 indicate that approximately 3% of eighth graders and approximately 8% of twelfth graders have experimented with MDMA in their lifetime (2), which suggests that in the United States MDMA use begins at an early age.

Patterns of Use

At present, MDMA is used primarily for recreational purposes, although some still advocate the use of MDMA for psychotherapeutic purposes (63). During the last decade, the most frequently reported use of MDMA has been in the context of large, organized social events known as “raves,” often held in warehouses or dance clubs. Festively

dressed “ravers” use MDMA as their drug of choice and typically dance through the night to music accompanied by computer-generated videos and laser light shows. The amount of MDMA typically used during raves varies widely, with doses ranging from 75 to 1,250 mg over several hours.

Acute Neurochemical Effects

The most pronounced acute biochemical effect of MDMA is increased 5-HT neurotransmission, brought about by a calcium-independent release of 5-HT from nerve endings (64). MDMA-induced 5-HT release involves both vesicular and plasma membrane monoamine transporter (65). Actions at the serotonin transporter are also thought to lead to reuptake inactivation (66). MDMA also appears to release dopamine, but this effect is less pronounced than those on serotonin neurons (66). Unlike the actions of classic hallucinogens, the acute neurochemical actions of MDMA are primarily indirect rather than mediated directly at postsynaptic 5-HT receptors, for which MDMA has s low affinity (67).

The binding potential of MDMA at a number of postsynaptic receptor sites and reuptake sites has been evaluated (68 ,69). The affinity of racemic MDMA for receptors was initially found to be greatest for the serotonin transporter (SERT), followed in turn by the α_2-adrenergic receptor, the 5-HT_2receptor, the histamine H1 receptor, and the muscarinic M1 receptor (70). In a subsequent study by Pierce and Peroutka (69), in which a more selective 5-HT_{2A}-receptor agonist, 2,5-dimethoxy-4-^{77}Br-amphetamine (DOB), was used, the binding potency of MDMA at 5-HT_{2A} receptors was greater than that at α_2-adrenergic receptors.

Behavioral Effects in Animals

The administration of MDMA in animals leads to typical signs of mild sympathomimetic stimulation; these include increased locomotor activity, heart rate, and body temperature in rats (71) and mydriasis, salivation, piloerection, and hyperthermia in dogs and monkeys (72 ,73). Locomotor studies suggest that MDMA can be distinguished from amphetamine, and in some behavioral paradigms, it appears to have a greater similarity to hallucinogens than to amphetamine (74).

In drug discrimination studies, MDMA substitutes for D-amphetamine in rats (75), pigeons (76), and monkeys (77). In contrast, despite structural similarities to mescaline, responses to MDMA differ from those to the hallucinogen DOB (61), but they are similar to those for the indolalkylamine α-methyltryptamine (78).

Animal studies investigating the abuse potential of MDMA are consistent with epidemiologic studies and abuse patterns previously described in humans. In particular, baboons self-administer MDMA (28). Rhesus monkeys trained to self-administer cocaine prefer MDMA to vehicle, and they sometimes administer MDMA at a higher rate than cocaine (79). In rats, MDMA lowers the electric threshold for self-stimulation in the medial forebrain bundle (80). Thus, in three different behavioral paradigms, MDMA appears to have significant potential for abuse.

Human Studies with MDMA

As would be predicted from studies in animals, MDMA exhibits both stimulant and hallucinogen-like activity. The stimulant effects of MDMA, typically noted shortly after drug ingestion, include increased heart rate, increased blood pressure, decreased appetite, increased alertness, and euphoria (81). Data regarding the effects of MDMA in humans come from both retrospective, uncontrolled studies and controlled, laboratory-based research. These studies are described below.

Greer and Tolbert (82) summarized experiences from 29 separate clinical therapy sessions during which MDMA was utilized as a psychotherapeutic adjunct. Patients received doses of MDMA ranging between 75 and 150 mg after a 6-hour fast (one subject, at his request, received a higher dose). A second dose of 50 or 75 mg was offered when the effects of the first dose began to subside. The 21 patients who were engaging in couples therapy reported increased closeness or enhanced communication with their partner, and all 29 patients reported positive attitudinal and emotional changes. Of the 29 patients, 22 reported “cognitive” benefits, such as “an expanded mental perspective, insight into problems, and issue resolution.” All patients reported adverse effects, including fatigue, jaw clenching, nausea, transient gait disturbance, and sympathomimetic symptoms.

In the first double-blinded, randomized study involving the prospective administration of MDMA to humans (83), subjects received MDMA orally at doses ranging from 0.25 to 1.0 mg/kg (17.5 to 70 mg in a 70-kg adult). These doses were associated with increased heart rate and blood pressure and positive psychological effects. In a second double-blinded, placebo-controlled study (84), the effects of MDMA (1.7 mg/kg; 119 mg in a 70-kg person) were evaluated in 13 MDMA-naïve healthy volunteers. MDMA was reported to enhance mood, a sense of well-being, and emotional sensitivity. Some subjects reported anxiety. Other symptoms reported included mild depersonalization and derealization, altered time perception, moderate thought disorder, poor coordination, heightened sensory awareness, and increased energy. A hypertensive reaction developed in one subject. Adverse subjective somatic effects of MDMA included jaw clenching, anorexia, impaired gait, and restless legs. After 24 hours, subjects’ complaints included poor energy and appetite, restlessness, insomnia, trismus, poor concentration, and brooding. In the most recent prospective, double-blinded study of MDMA administration in humans (85), the effects of 75 and 125 mg of MDMA were compared with those of 40 mg of amphetamine and placebo.

Both doses of MDMA led to significant increases in blood pressure (increases in systolic blood pressure averaging 40 mm Hg), heart rate (increases averaging 30 beats/min), and pupillary diameter in comparison with placebo. No hallucinations were reported following any drug. All active drugs led to increases in euphoria that were greatest following 125 mg of MDMA. MDMA was also reported to produce altered visual and auditory perception.

Neuroendocrine Effects

In rats, the systemic administration of MDMA leads to a pronounced elevation in levels of corticosterone and prolactin, accompanied by an elevation in temperature (86 ,87). These effects appear to be mediated by 5-HT receptors because they are attenuated or completely blocked by pretreatment with the 5-HT neurotoxin *p*-chlorophenylalanine (86). MDMA-induced increases in corticosterone levels and temperature are blocked by 5-HT_2-receptor antagonists but not by 5-HT_{1A}-receptor antagonists or nonspecific 5-HT-receptor antagonists. In contrast, MDMA-induced prolactin responses are not attenuated by either 5-HT_{1A}-receptor or 5-HT_2-receptor antagonists, which suggests that the two MDMA-induced neuroendocrine responses involve different 5-HT receptors.

Several studies have evaluated the neuroendocrine effects of MDMA in humans. MDMA doses of up to 75 mg are associated with increases in cortisol, and higher doses lead to increases in both cortisol and prolactin (83 ,85). Notably, evidence in both animals and humans is increasing that previous exposure to MDMA leads to alterations in neuroendocrine responses (87 ,88 ,89 ,90 ,91 and 92), possibly as a consequence of long-term effects on brain 5-HT neurons.

Biodisposition in Animals

The metabolic pathways of MDMA have been well characterized in several animal species. *In vivo* studies in rats have shown that MDMA is metabolized via *N*-demethylation, *O*-dealkylation, deamination, and conjugation (*O*-methylation, *O*-glucuronidation, and *O*-sulfation) (93). The (*S*)-(+)-MDMA isomer of MDMA appears to be metabolized more rapidly (94) and extensively (95) than the (*R*)-(-)-MDMA isomer, with half-life estimates being 73.8 and 100.7 minutes for (*S*)-(+)- and (*R*)-(-)-MDMA, respectively (94). Nonconjugated metabolites of MDMA are present in blood, brain, liver, feces, and urine for a 24-hour period following drug administration, with the exception of the *O*-dealkylated catechol metabolite, which is found only in brain tissue (93). This latter pathway, mediated via constitutive cytochrome P-450 isozymes, is a primary route of metabolism in rat brain microsomes.

Biodisposition in Humans

Three studies have evaluated the biodisposition of MDMA in humans (85 ,96 ,97). In the neuroendocrine study by Mas et al. (85), maximum concentrations of MDMA and elimination half-lives were evaluated for 75- and 125-mg doses of MDMA in healthy men. Maximum plasma concentrations were 130.9 and 236.4 ng/mL for the 75- and 125-mg doses respectively and reached peak at 1.8 and 2.4 hours following drug ingestion, respectively. Elimination half-life was 7.7 hours for the 75-mg dose of MDMA and 8.6 hours for the 125-mg dose. Plasma concentrations of (*R*)-(-)-MDMA exceed those of the (*S*)-(+) enantiomer (96). Most recently, de la Torre and colleagues (97) found that relatively small increases in MDMA doses are translated to disproportionate rises in MDMA plasma concentrations, even in persons with high levels of CYP2D6 activity (i.e., extensive metabolizers).

Clinically Reported Adverse Effects

Acute adverse medical effects of MDMA have been reviewed extensively elsewhere (98 ,99). These effects, which are undoubtedly related to the sympathomimetic and serotoninergic properties of MDMA, include nausea, vomiting, jaw clenching, bruxism, hypertension, palpitations, headaches, hyperreflexia, difficulty walking, urinary urgency, diaphoresis, anorexia, muscle aches or tension, hot and cold flashes, nystagmus, blurred vision, insomnia, and dry mouth.

Aside from one report of an acute hypertensive crisis in a prospective study (84), serious acute medical complications of MDMA use have appeared in the literature as case reports or reports from poison centers and coroners. Among the serious problems that have been associated with MDMA use are cerebrovascular incidents (100) and arrhythmias (101), likely related to the potent sympathomimetic and vasoconstrictive effects of MDMA. Electrolyte imbalance or the syndrome of inappropriate secretion of antidiuretic hormone, sometimes associated with cerebral edema or seizures, has been reported by numerous authors (102 ,103).

Numerous reports of chronic medical sequelae of MDMA have also been published, and readers are referred elsewhere for a more comprehensive review of this topic (98 ,99). One serious adverse medical event associated with MDMA, multiple organ system failure, appears to be directly related to the use of MDMA in raves, where users become hot and dehydrated in crowded conditions. In this setting, MDMA is associated with a life-threatening syndrome involving dehydration, hyperthermia, seizures, rhabdomyolysis, disseminated intravascular coagulation, renal failure, and death (104 ,105 and 106). This is reminiscent of the phenomenon of aggregation toxicity in animals (107), in which the lethality of amphetamines is greatly potentiated by crowded housing conditions. Reports of hepatotoxicity, aplastic anemia, and toxic leukoencephalopathy in MDMA users may be related to contaminants in MDMA synthesis or represent idiopathic drug reactions (108 and 109).

Adverse neuropsychiatric effects have also been associated with MDMA. Acute psychiatric complications of MDMA include panic attacks (110), psychosis (111), delirium (112),

and impulsive irrational behavior with subsequent severe medical consequences or death (101 ,113). Chronic neuropsychiatric syndromes reported in MDMA users include panic disorder (114), psychosis (115), aggressive outbursts (116), flashbacks (111), major depressive disorder (117), and cognitive disturbances (117).

Serotonin Neurotoxicity

Like its structural relative methylenedioxyamphetamine (118), MDMA is a well-documented serotonin neurotoxin in a variety of animal species (119 ,120 ,121 and 122). In nonhuman primates, MDMA-induced brain serotonin neurotoxicity is long-lasting and possibly permanent (123 ,124).

The administration of MDMA in animals leads to the persistent loss of a variety of markers specific to brain serotonin neurons. These include brain 5-HT itself (121); 5-hydroxyindolacetic acid (5-HIAA), the major metabolite of serotonin (125); tryptophan hydroxylase, the rate-limiting enzyme in serotonin synthesis (126); and the SERT, a structural protein on the 5-HT nerve terminal (119). Anatomic evidence also indicates a persistent loss of brain serotonin axons and axon terminals. For example, following MDMA administration, quantitative autoradiographic studies with radioligands that bind to the SERT, and immunocytochemical studies in which antibodies are directed at either serotonin or the SERT, show pronounced, long-lasting reductions of the SERT and reduced density of serotonin axons with sparing of serotonin cell bodies (127). These selective serotonin deficits have been observed up to 7 years after drug discontinuation in nonhuman primates (123).

Efforts to determine whether selective serotonin neurotoxicity develops in human MDMA users, as in animals exposed to MDMA, have been limited by the paucity of available methods for assessing the status of central nervous system serotonin structure and function in living humans. At present, two methods for detecting MDMA-induced brain 5-HT neurotoxicity in living humans have been validated. These include measurement of spinal fluid 5-HIAA and PET neuroimaging of the SERT. Both of these methods have demonstrated capability for detecting MDMAinduced neurotoxic injury in nonhuman primates (128 ,129). With these methods, two studies have shown decrements in human cerebrospinal fluid 5-HIAA that are similar to those seen in monkeys with known MDMA-induced 5-HT neurotoxic damage (92 ,130). Similarly, imaging studies with PET have revealed reductions in brain SERT binding in MDMA users that are similar to those seen in baboons with demonstrated MDMA-induced 5-HT damage (49). Further, reductions in the SERT could be correlated with the extent of previous MDMA use.

Studies attempting to identify the functional consequences of MDMA neurotoxicity in humans suggest that brain serotonin function is abnormal in human MDMA users. In particular, as previously described, abnormal neuroendocrine responses to the serotonin-releasing drugs fenfluramine and *m*-chlorophenylpiperazine (m-CPP) have been demonstrated in MDMA users. In the case of *m*-CPP, MDMA users also differ in their behavioral responses to drug. Several research groups have found cognitive impairments in MDMA users in comparison with controls, including decrements of visual and verbal memory, attention, and verbal reasoning (92 ,131 ,132 ,133 and 134). MDMA users have also been found to score higher on measures of impulsivity (88,135,136, but not 130), consistent with work showing an inverse relationship between 5-HT markers and impulsivity (137).

FUTURE RESEARCH DIRECTIONS

Part of "108 - Psychedelic Drugs "

Since Hofmann's discovery of LSD in 1943, significant progress has been made toward understanding the mechanism of action of LSD and other drugs in its class (Fig. 108.2). Despite advances in understanding the mechanism of hallucinogenic action, many questions remain unanswered. During the next decade, it should be possible to refine further the 5-$HT_{2A/1C}$ hypothesis of psychedelic activity, to characterize better the neuroanatomy of the pharmacologic action of LSD, and to use modern neuroimaging techniques to compare and contrast the effects of LSD with those of idiopathic psychiatric illnesses in which hallucinations are a feature. Similarly, future studies of PCP may elucidate certain aspects of idiopathic psychotic illnesses. Clinical studies in PCP users, like those previously conducted in MDMA users, should be directed toward determining whether humans, like rodents, are susceptible to PCP neurotoxic injury and defining the functional consequences of such injury if it occurs.

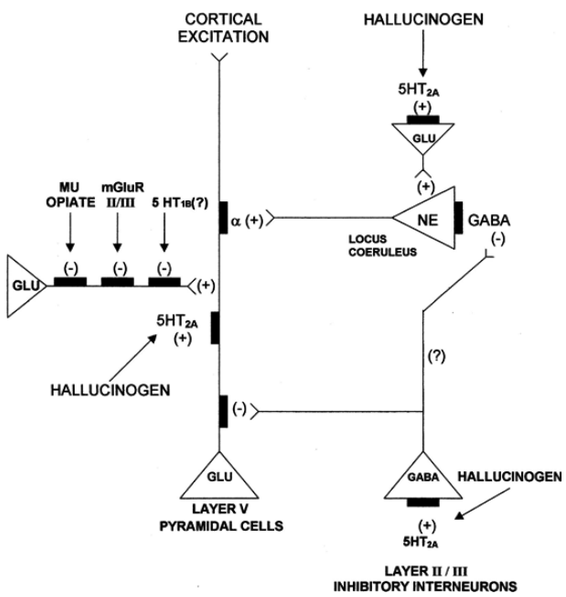

FIGURE 108.2. Schematic diagram of putative electrophysiologic mechanism of action of hallucinogenic drugs. Depicted are serotoninergic hallucinogenic inputs at the raphe nuclei and locus ceruleus projecting to the vicinity of apical dendrites of layer V pyramidal cells in the neocortex. Hallucinogens, acting as partial agonists at 5-hydroxytryptamine subtype 2A (5-HT_{2A}) receptors, induce the release of glutamate from excitatory nerve terminals. Also shown are inhibitory modulators of 5-HT_{2A}-induced glutamate release: γ-aminobutyric acid, μ opiate, group II and III metabotropic glutamate, and possibly 5-HT_{1B} receptors. NE, noradrenergic input; alpha$_1$, α_1-adrenergic receptor; mGluR II/III, group II and III metabotropic glutamate receptor; GABA, γ-aminobutyrate. (Modified from Aghajanian GK, Marek GJ. Serotonin and hallucinogens. *Neuropsychopharmacology* 1999;21:16S–23S, with permission.)

MDMA research during the next decade should also yield significant advances. Preclinical studies aimed at determining the mechanism of MDMA-induced 5-HT neurotoxicity may not only increase our understanding of serotonin neuronal function but also provide insight into idiopathic neurodegenerative illnesses and neuronal responses to injury. Long-term studies in nonhuman primates and humans will be essential to learn whether recovery from MDMA-induced 5-HT neurotoxicity can occur (and if so, under what conditions), and will be useful in defining the functional consequences of MDMA-induced neurotoxicity. It may be possible, by using information derived from preclinical studies, to design treatments for persons in whom chronic MDMA-related neuropsychiatric illnesses develop. Increased efforts should be directed toward identifying those at greatest risk for the development of MDMA-related neuropsychiatric illnesses. Finally, cost-effective methods should be devised to detect MDMA-induced neurotoxicity, so as to identify those who may benefit from alternative, science-based treatment strategies.

Epidemiology of Drug Dependence

James C. Anthony

James C. Anthony: Johns Hopkins University, School Of Hygeine And Public Health, Baltimore, Maryland.

If one judges solely by the cumulative table of contents of the official journal of the American College of Neuropsychopharmacology, *Neuropsychopharmacology*, the intersection where epidemiology meets neuropsychopharmacology is quite empty. When one looks elsewhere, the traffic becomes visible, with a scope that encompasses topics such as the characteristics of incarcerated drug users, adolescent drug use, epidemics of drug taking, the "overmedication" of American society, and postmarketing surveillance of new neuropsychopharmacologic drug products (e.g., see refs. 1 , 2 , 3 and 4).

One of the possible reasons that epidemiologic research articles have been seen rarely in *Neuropsychopharmacology* is the generally nonexperimental and observational character of the studies. In this respect, epidemiology shares features of astronomy, geology, ecology, and other sciences in which the evidence comes mainly from field studies, without the benefit of maximal control over experimental error and sometimes with heavy reliance on retrospection. This reliance on retrospection has been a source of considerable criticism, and a countervailing trend has developed toward prospective, longitudinal, and even randomized experimental studies in epidemiology. Nonetheless, the scale and environment of epidemiologic research introduce constraints not seen elsewhere in human biology and the biomedical sciences, even when epidemiology harnesses the power of a randomized trial.

Against a such a background, the primary goal of this chapter is to describe the focus of epidemiologic research in drug dependence and to elucidate the contributions that such research can make when connected with that in other areas of neuropsychopharmacology. A secondary goal is to aid neuropsychopharmacologists who may wish to know more about what can be learned by collaborating with epidemiologists.

For focus, this overview concentrates on the clinical syndromes of drug dependence, as defined in recent diagnostic and statistical manuals of the American Psychiatric Association (e.g., DSM-III, DSM-IIIR, and DSM-IV) and the tenth revision of the World Health Organization International Classification of Disease (ICD-10). The chapter is organized in relation to five main rubrics or subheadings for the subject matter of epidemiologic research. Under each rubric is included a selection of recent examples of epidemiologic evidence regarding drug dependence.

THE FIVE MAIN RUBRICS OF EPIDEMIOLOGY

Part of "109 - Epidemiology of Drug Dependence "

Morris (5) described seven "uses" of epidemiology, which can be simplified in relation to the five "rubrics" or main subheadings of epidemiology listed in Table 109.1 . These five rubrics offer an easily remembered way of organizing the central research questions and subject matter of this branch of biomedical science (6). Each rubric corresponds to a research question, and each research question demonstrates the substantive research focus of epidemiology and creates an opportunity to explain some of the concepts, principles, and methods that are used to make progress in epidemiology.

The Rubrics	General Issues	Research Questions Associated with Each Rubric
1. Quantity (Prevalence and incidence)	How many?	"In the population, how many are becoming new cases of drug dependence?" "How many already have become drug-dependent?"
2. Location (variation)	Where?	"In the population, does the frequency or occurrence of drug dependence cases vary from place to place, from time to time, or in relation to individual-level characteristics, conditions, or processes?"
3. Causes (Etiology)	Why?	"In the population, why do some people become drug-dependent while others are spared?"
4. Mechanisms	How?	"What sequences of circumstances, conditions, and processes lead to the development of drug dependence?"
5. Prevention and Control	What can be done?	"What can be done to prevent, reduce, or ameliorate the adverse impact of drug dependence?"

TABLE 109.1. THE MAIN RUBRICS AND RESEARCH QUESTIONS OF EPIDEMIOLOGY, AS APPLIED TO CLINICAL SYNDROMES OF DRUG DEPENDENCE

To some extent, the progress of an individual epidemiologic investigator can be plotted in relation to a mastery of the concepts, principles, and methods that fall under each rubric listed in Table 109.1 . In time, it may prove useful to plot the progress of epidemiology over generations of scientists in terms of the relative balance of attention to the more advanced rubrics. To some extent, progress may be represented by increased attention to issues addressed under the last three rubrics: causal inference, causal mechanisms, and means of prevention and control. As progress is made in future generations, the attention given to estimating how many people are affected and describing how cases are distributed within a population, from place to place or during successive seasons or years, may be correspondingly reduced.

RUBRIC 1, QUANTITY: "IN THE POPULATION, HOW MANY ARE BECOMING CASES?"

Part of "109 - Epidemiology of Drug Dependence "

Concepts and History

The first and most basic of the rubrics of epidemiology involves quantification of the disease burden. Generally, in epidemiologic research on disease states or health events, the main research questions under the rubric of quantity are these: “In the population of interest, how many people are affected?” and “How many people are becoming affected?” Expressed as a proportion of the total population size, the first question concerns the *prevalence* of the condition. Expressed as a rate, the second question concerns the *incidence* of the condition.

As a concept at the level of individuals within a population, the prevalence of a disease can be discriminated from its incidence. Prevalence relates to “an individual’s probability of *being* a case” at some point in time or during a specified interval, whereas incidence concerns “the individual’s probability or risk of *becoming* a case for the first time.” Accordingly, an *incident case* is one that has just become a case (6).

Examples of Epidemiologic Evidence under the Rubric of Quantity

Preclinical research describes a broad range of species that self-administer psychoactive drugs, sometimes to a point of maladaptation and self-harm. These studies have also demonstrated substantial within-species individual differences in predisposition to initiate or sustain drug-taking behavior. Clinical studies under controlled laboratory conditions have clarified that drug self-administration can be shaped by manipulating the profiles of available reinforcers, and by increasing the availability of nondrug reinforcers. Nevertheless, these laboratory studies have not been able to characterize the likelihood of becoming drug-dependent in free-living human populations. At the group level, with population-averaged estimates, this task has been accomplished by means of epidemiologic research in the community. Consider the group of internationally regulated, controlled drugs such as cannabis, cocaine, and heroin, and consider a clinical syndrome defined by the co-occurrence of sustained use of one or more of these drugs with features such as tolerance or withdrawal, with or without signs and symptoms of secondary harm (e.g., loss of a job, recurrent infection or abscess, drug overdose), as encompassed by the DSM-III concept of “psychoactive drug use disorders.” The first research to estimate the risk of becoming a DSMdefined case of “drug use disorder” was a coordinated set of prospective follow-up studies conducted as part of the National Institute of Mental Health Epidemiologic Catchment Area Program. Case ascertainment was via the diagnostic interview schedule method. Based on field survey evidence from these prospective studies of community-dwelling adults, most never treated for drug problems and studied between 1980 and 1985, the risk for becoming a case of “drug use disorder” was estimated at 1.1% per year for a community-dwelling adult in the United States (standard error, 0.4%). In other words, of the literally thousands of adults who did not have drug use disorder at the start of the follow-up interval, drug dependence or a related drug use disorder developed during the 1-year follow-up interval in just over 1% (7).

Ethanol was treated as a separate drug, with “alcohol use disorder” defined in terms of sustained use, tolerance or withdrawal, and secondary harms. Based on the Epidemiologic Catchment Area evidence, for a community-dwelling adult in the United States, the risk for becoming a case of alcohol use disorder was estimated at 1.8% per year (standard error, 0.4%), a risk some 70% greater than that for the development of dependence or a related disorder involving an internationally regulated psychoactive drug (7).

Roughly 10 years after the Epidemiology Catchment Area field studies, the National Comorbidity Survey provided new epidemiologic evidence to complement these estimates of the risk for becoming a case of drug use disorder. Although entirely retrospective and cross-sectional in character and lacking the prospective features of the Epidemiologic Catchment Area studies, the National Comorbidity Survey produced useful information necessary to estimate how many users of various classes of drugs had acquired a clinical syndrome of drug dependence, with the syndrome defined and made operational in relation to the DSM-IIIR criteria (8). Based on its nationally representative sample of community-dwelling Americans between 15 and 54 years of age in the early 1990s, the National Comorbidity Survey estimated how many persons had started taking each of several different drugs (e.g., alcohol, cannabis, cocaine), and also how many of them had become dependent on each drug (i.e., alcohol dependence, cannabis dependence, cocaine dependence). On this basis, it was possible to derive a population-average estimate for each drug; once someone had started taking a drug, how likely was it that he or she would have become drug-dependent?

From epidemiologic data derived retrospectively and cross-sectionally in the National Comorbidity Survey, it was determined that for persons who had consumed tobacco on at least once occasion, the probability of having become tobacco-dependent was an estimated 33%. Among persons who had consumed heroin, DSM-IIIR heroin dependence had developed in about 23% (standard error, 5.6%). Among those who had taken cocaine, cocaine dependence had developed in an estimated 16% to 17% (standard error, 1.5%), a value not too distant from that observed for alcohol dependence, 15% (standard error, 0.7%) (8).

The estimated probability that a clinical syndrome of dependence had developed was somewhat lower for users of cannabis, the psychostimulant drugs, anxiolytic–sedative–hypnotic drugs, hallucinogens such as lysergic acid diethylamide (LSD), and inhalant drugs (e.g., glue, gasoline). For example, among stimulant users, the estimate was about 1 in 9 (11%; standard error, 1.6%). For cannabis users, it was 1 in 11 (9%; standard error, 0.7%). Figure 109.1 shows these and other epidemiologic estimates based on the National Comorbidity Survey data (8).

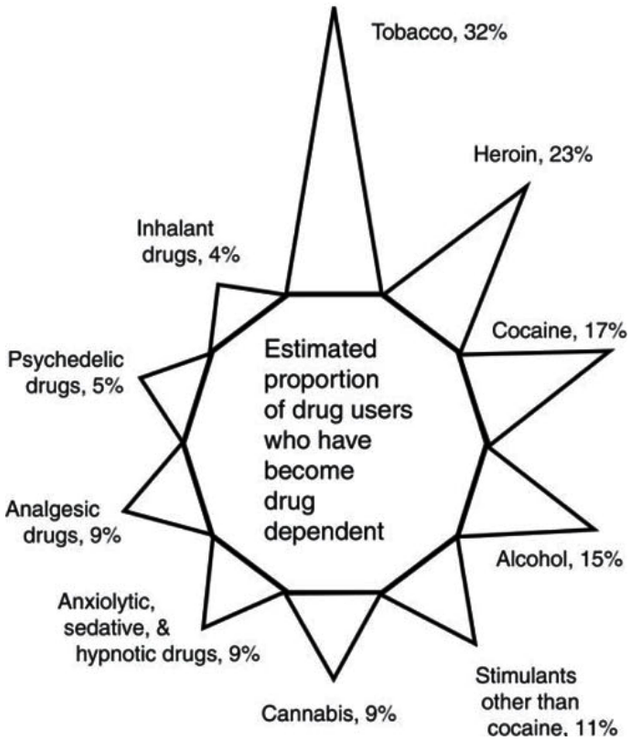

FIGURE 109.1. Estimated probability of drug dependence among drug users, by drug group. (From Anthony JC, Warner LA, Kessler RC. Comparative epidemiology of dependence on tobacco, alcohol, controlled substances, and inhalents: basic findings from the National Comorbidity Survey. *Exp Clin Psychopharmacol* 1994;2:244–268, with permission.)

The interpretation of epidemiologic estimates of this type can be tricky. These estimates certainly do not reflect which drugs are associated with a greater potential for dependence than others. In the community at large, exogenous factors, such as the relative availability of a drug (e.g., tobacco vs. cocaine), influence whether drug dependence has a chance to develop once drug use is initiated. In addition, some drug users do not survive from the time of first use to the time of field survey assessment, either dying or disappearing from the sampling frame of the epidemiologic survey before a diagnostic assessment can be completed (see ref. 8). Despite limitations such as these, estimates of this type draw attention to the variability in response to drugs such as nicotine and cocaine, even when laboratory studies demonstrate the robust reinforcing functions served by these drugs. In counterpoint, the laboratory studies demonstrate more limited reinforcing functions served by cannabis and LSD. Nonetheless, DSM-IIIR dependence syndromes appear to have developed in a substantial proportion of alcohol, cannabis, and hallucinogen users (Fig. 109.1).

A slightly different, and more complex, epidemiologic estimate has been derived by dividing the number of currently dependent drug users by the number of currently active drug users (see refs. 9 , 10 , 11 , 12 , 13 , 14 , 15 and 16). The complexity starts in estimating the numerator of the ratio; here, it is necessary to mix the probability of becoming dependent with the probability of continuing to be dependent. Complexity is sustained in estimating the denominator of the ratio. To focus on currently active drug users, it is necessary to mix the probability of starting to use the drug with the probability of continuing to use the drug. An additional complexity enters the picture because drug dependence, as a process, becomes one of the determinants of whether a person continues to use a drug once drug use has been initiated. Hence, the force of persisting drug dependence is exerted not only in the numerator of this ratio but also in its denominator. In

consequence, the resulting estimate cannot be interpreted as a risk for becoming dependent, much less as an indication of relative dependence liability. At best, this estimated ratio reflects the proportion of active drug users who may, in theory, require drug dependence treatment services—that is, it is an indicator of burden. This kind of statistic may be helpful in planning services. Its utility in etiologic studies is compromised by its complexity.

Table 109.2 presents the most recently published drug-specific estimates for the proportion of active drug users who have currently active drug dependence, based on the 1998 National Household Survey on Drug Abuse in the United States (14). Reading the table, one can see that 709 recently active cocaine users were included in the nationally representative survey sample of community-dwelling respondents ages 12 years and older. According to the population estimates, among active cocaine users in the study population, 38% reported at least one of seven active clinical signs or symptoms of cocaine dependence, and an estimated 18% reported at least three active clinical features. Applied in an estimate of burden in the general population, these values indicate that about 0.7% of the study population have a cocaine-related problem and about 0.3% have three or more cocaine-related problems, perhaps meriting treatment or intervention services. By comparison, the corresponding estimates for cannabis, based on 3,444 active cannabis users in the sample, indicate that 42% of active cannabis users reported at least one cannabis dependence problem and 17% reported three or more clinical features of cannabis dependence. In terms of population burden, an estimated 3.6% of the study population have an active cannabis problem and an estimated 1.5% have three or more active features of cannabis dependence. Values for alcohol and for tobacco cigarettes are included in Table 109.2 for comparison with the values for cocaine and cannabis.

Drug or Drug Group	Number of Active Drug Users in the Sample	Estimated Proportion with One or More Clinical Features of Active Drug Dependence (%)	Estimated Proportion with Three or More Clinical Features of Active Drug Dependence (%)
Cocaine	709	38	18
Cannabis	3,444	42	17
Alcohol	14,596	23	8
Tobacco	8,187	60	34

Data from *National household survey on drug abuse: main findings, 1998.* DHHS publication No. (SMA) 00-3381. Rockville, MD: Department of Health and Human Services, Substance abuse and Mental Health Services administration, 2000.

TABLE 109.2. ESTIMATED PROPORTION OF ACTIVE DRUG USERS WHO REPORT FEATURES OF ACTIVE DRUG DEPENDENCE

An increasing number of epidemiologic studies have started to produce estimates of this type, helping to quantify the number of affected cases in various parts of the world and for selected subgroups of the population, such as young adults. For example, Grant (15 ,16) estimated that alcohol dependence developed in about 20% of drinkers, that drug dependence developed in about 19% of persons initiating illicit drug use, and that 16% of active illicit drug users were dependent on illicit drugs. In addition to other recent U.S. survey estimates for the number of active dependence cases among active drug users (10 ,11 ,13 ,14 ,17), estimates have now been made for national populations or subpopulations in Australia, the United Kingdom, Germany, and other countries (18 ,19 and 20).

Against the background of rapidly accumulating prevalence estimates based on cross-sectional epidemiologic surveys, prospective studies and incidence estimates for the drug dependence syndromes have progressed much more slowly. Although prospective studies are much more difficult to complete, they cannot be omitted if we are to understand the force of drug-related morbidity, and distinguish the separate conditions and processes that promote the initiation of drug dependence, as distinct from the conditions and processes that sustain drug dependence once the syndrome has started. In this respect, it is unfortunate that the Epidemiologic Catchment Area estimates, now more than 15 years old, are currently our most authoritative values for the risk for the development of alcohol or other drug dependence in the U.S. adult population (7). Elsewhere in the world, prospectively gathered data on the incidence of clinically defined syndromes of alcohol or other drug dependence (21), sometimes obtained with rigorous methods in quite isolated populations (e.g., 22), are very limited.

Much of the postmarketing surveillance of a population’s actual experience with newly distributed medicines falls under the first rubric of epidemiology. Recent efforts to monitor the abuse potential of tramadol (Ultram) demonstrate the utility of epidemiologic concepts, principles, and methods at the intersection of epidemiology with neuropsychopharmacology (23).

Before we leave the rubric of quantity, it may be useful to note that several generations of epidemiologically oriented

scientists have attempted to estimate the number of “hard-core” drug users in the United States by extrapolating from the number of cases seen in treatment, law enforcement, or other facilities. In the earliest reports, the approach involved guessing the number of untreated or nonincarcerated drug users for every case registered in treatment or known by law enforcement authorities. Since the 1960s, sophisticated mathematical estimation procedures have been used, with advanced statistical treatments such as projections from truncated Poisson distributions and capture–recapture methods (see ref. 24).

This work is at the margin of the scientific enterprise. It may be understood best for its enduring political popularity. As a source of authoritative scientific evidence, it is of dubious value and based on assumptions that are not well tested and may never be testable. In a brief, pithy article, Newman and Cates (25) made this point 30 years ago, quoting from the classic study by Terry and Pellens (26): “As a matter of fact, it is not necessary to know the exact number of users or even the minimal extent, to realize that there are a large number [of addicts] and that the problem is serious.” Newman and Cates also summarized an observation made by the very talented epidemiologist Leon G. Hunt, whose work is mentioned in the next section. Hunt was quoted as saying, “The question is not whether there are three or four million [addicts], but that the number is several million rather than only several hundred thousand” (25).

The view espoused by Newman and Cates (25) actually was much more harsh. They wrote, “The great disparity of the findings of studies using different methods of enumeration generally ensures that data will be found to support any position, and contradictory information is simply ignored.” They concluded, “Objectives of studies that are intended to measure the incidence and prevalence of addiction must be reassessed in terms of experience. It is necessary to ask candidly what impact such research has had in the past and to question the premise that knowledge, for its own sake, is sufficient justification [to undertake these studies.]” This sentiment is especially appropriate in an era of dramatically increased investment by the U.S. government in surveys to estimate the number of active drug users in populations at the state level, with sample sizes for the U.S. National Household Survey on Drug Abuse growing from under 10,000 respondents per year in the early 1990s to more than 70,000 respondents per year in the early twenty-first century.

RUBRIC 2, LOCATION (VARIATION): “IN THE POPULATION, IS THERE ANY VARIATION IN THE OCCURRENCE OF CASES?”

Part of "109 - Epidemiology of Drug Dependence "

Concepts and History

The best epidemiologic studies to quantify the occurrence of drug dependence also have had a more general purpose of studying variations in prevalence or incidence in relation to characteristics of place (e.g., geographic variation), time (e.g., from year to year), or person (e.g., male vs. female drug users). Often, the analyses to disclose variation are not intended to produce links in a chain of causal inferences. Rather, the purpose of these analyses is description, as in Fig. 109.2 , or they may be a necessary step of clarifying variation before anyone undertakes a more probing causal analysis or new investigation (6).

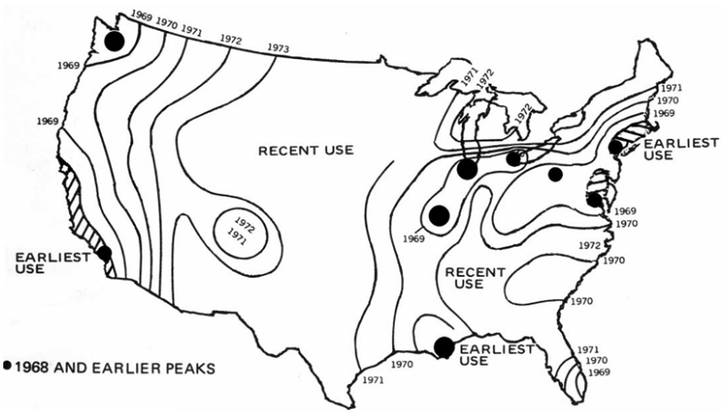

FIGURE 109.2. Retrospectively constructed geographic spread of the epidemic of heroin use in the United States during the Vietnam War era. Data from age at onset of cases admitted to treatment facilities. (From Greene MH, Kozel NJ, Hunt LG, et al. An assessment of the diffusion of heroin abuse to medium-sized American cities. Washington, DC: Special Action Office for Drug Abuse Prevention, 1974, with permission.)

Examples of Epidemiologic Evidence under the Rubric of Location

Two of the most robust findings from epidemiologic studies on the location of drug dependence cases within population subgroups are a male excess and an excess in the age group 15 to 44 years old, disclosed by both prevalence differences and relative risk estimates (see ref. 7). To be sure, the male excess in the occurrence of drug dependence can be contradicted with certain evidence involving some specific drugs, such as those in the group of anxiolytic, sedative, and hypnotic medicines. In addition, in some places, the use of opium derivatives is commonplace in persons in the later years of middle age and among the elderly, and several studies have noted a slight upturn in the risk for alcohol dependence during the last decades of life, at least among men (27). Nonetheless, these exceptions help prove the more general rule.

A recent intriguing discovery about male–female differences in drug use within the United States is that a male excess is found at the earliest stages of drug involvement; boys are more likely than girls to be exposed to opportunities to try illicit drugs. However, once presented with the opportunity, they are equally likely to try a drug (28). Furthermore, once drug use has started, women are almost as likely as men to become drug-dependent (12.6% vs. 16.4%), alcohol and cannabis being two noteworthy exceptions (8).

When cases are located in relation to time, the past 35 years have seen a marked increase in the prevalence of illicit drug use, mainly between 1965 and 1980, as illustrated for the United States in Table 109.3 . Analyses of retrospective data from the Epidemiologic Catchment Area studies and the National Comorbidity Survey have highlighted corresponding differences in the experiences of successive birth cohorts born during the first two-thirds of the twentieth century. According to this evidence, the risk for drug dependence has been markedly greater in persons born since World War II than in prior birth cohorts (17 ,29 ,30 and 31).

TABLE 109.3. ESTIMATED PREVALENCE OF ILLICIT DRUG USE IN THE UNITED STATES

Survey Year	Number of Survey Respondents	Estimated Proportion with a History of Illicit Drug Use (%)	Estimated Prevalence of Recent Illicit Drug Use (%)
1971–72	3,760[a]	15–22[a]	N/A[a]
1979	7,224	31.3	17.5
1985	8,021	34.4	16.3
1991	32,594	34.1	11.1
1992	28,832	33.3	9.7
1993	26,489	34.2	10.3
1994	17,809	34.4	10.8
1995	17,747	34.2	10.7
1996	18,269	34.8	10.8
1997	24,505	35.6	11.2
1998	25,500	35.8	10.6

[a]Data from the *National household servey on drug abuse: main findings, 1998.* DHHS publication No. (SMA) 00-3381. Rockville, MD: Department of Health and Human Services, substance abuse and Mental Health Services administration, 2000.

The location of cases in relation to geography also has been scrutinized in descriptive epidemiologic studies. Figure 109.2 provides a cartoon summary of an apparently epidemic spread of heroin use in the United States during the Vietnam War era, based on the analyses of Hunt (24) of heroin-dependent persons entering treatment and their age at onset of heroin use. Figure 109.3 pertains to the more recent outbreaks of cocaine involvement among young people

living in Chile and shows a substantially greater prevalence of coca paste (“pasta base”) smoking in areas in the north of the country, near the borders with coca-producing countries, than in the south of the country (32).

FIGURE 109.3. Estimated geographic distribution of coca paste smoking among Chilean youth, 1999. (From Dormitzer C, Caris L, Anthony JC. Parental attention and risk of coca paste smoking in Chile: preliminary data from the 1999 national school survey in Chile. Rockville, MD: Department of Health and Human Services, 2000, with permission.)

What is common to all these epidemiologic observations is that they describe, but do not explain or account for, the observed variation. We know that men have been more likely to become drug-dependent than women, but the studies that produced solid evidence on this variation have not helped us explain why this is so. The same is true for the epidemiologic observations of birth cohort differences, which prompt speculation about the greater availability of illicit drugs but then beg the question of what prompted the greater availability. The patterns of epidemic spread of heroin use in the United States remain unexplained, and it is possible that the exclusive attention to treated cases in the study of Hunt (24) may have produced a biased impression of the temporal sequencing of spread through different areas. Finally, at one level, the north–south pattern of coca paste smoking in Chile may be interpreted as a manifestation of proximity to the coca-producing countries, but no probing analysis has confirmed the impression that coca paste is substantially more available in the north. More probing epidemiologic analyses are required to confirm the impression left by initial descriptive observations of this type.

RUBRIC 3, CAUSES: “IN THE POPULATION, WHY DO SOME BECOME AFFECTED WHILE OTHERS ARE SPARED?”

Part of "109 - Epidemiology of Drug Dependence "

Concepts and History

What differentiates the rubric of “causes” from the rubric of “location” is the degree to which the analysis is oriented toward explaining and accounting for the observed phenomena, rather than merely describing the patterns of occurrence. To the extent that the search for causes can lead us toward more effective intervention maneuvers, work under this rubric merits a special status; many regard this search as one of the highest callings of epidemiology (33). Nonetheless, numerous examples show that epidemiologic research can have a considerable impact on the health of a population even before the search for causes is complete. John Snow’s effective demonstration that proper water sanitation can reduce or prevent outbreaks of cholera anticipated Robert Koch’s identification of *Vibrio cholerae* by several decades. Epidemiologic evidence plotting an offspring’s risk for Down syndrome by age of the mother at the time of delivery created one pathway toward effective prevention of trisomy 21 and associated conditions, although we still do not know the causes of the trisomies. HIV prevention efforts directed toward the unsafe sex practices of gay men in the United States helped to change the dynamics of the HIV/AIDS epidemic in the early 1980s, when many believed AIDS to be caused by inhalant drug use (“poppers”) and before isolation and identification of the AIDS-causing virus (6).

In some instances, weak links in the chains of disease causation have been spotted by epidemiologists working with basic quantitative methods, such as cross-tabulation or plotting of incidence estimates, as was done for maternal age and risk for Down syndrome. Complex diseases and conditions such as the drug dependence syndromes do not yield so readily; what might seem to be an apparently simple “chain” of causation actually turns out to be a complex “web” of causation of multifactorial origin.

As in the other sciences allied with neuropsychopharmacology, epidemiology sometimes can turn to the power of randomized, controlled trials and multiple replications for definitive evidence of the web of causation. However, a great many of the important questions in the intersection between epidemiology and neuropsychopharmacology cannot be answered with randomized, controlled trials; in some instances of “natural experiments,” the concept of replication leaves much to be desired.

With respect to a “natural experiment” that may never be repeated, we have the experience of members of the U.S. Armed Forces who served in Vietnam. Virtually all Vietnam veterans were exposed to the opportunity to try heroin within a span of a few months in-country; many (but not all) tried heroin when the opportunity arose (34). When diagnostic interview schedule field study methods were used to assess a large representative sample of Vietnam returnees, almost 20% of the study sample qualified as cases of active heroin dependence during the tour of duty. Nevertheless, no more than a fraction continued to use heroin or remained heroin-dependent once they returned stateside to home. O'Brien et al. (35) have suggested that heroin availability had much to do with this situation. Studying Vietnam veterans who came home to urban areas known for heroin availability, they found substantially higher fractions returning to heroin use. Nonetheless, even in this study sample, a great many heroin users did not come back from Vietnam to the United States and return to heroin dependence once they had settled in urban areas. These results challenge conventional notions of any inherent addictive quality, abuse potential, or dependence liability of heroin as a chemical substance. During an era of discovery that genetic predispositions are prominent among causes of drug dependence, these “subject as own control” results from once-in-a-lifetime natural experiments demonstrate that environmental contingencies also are important (36 ,37).

The Vietnam era research also highlights the necessarily observational character of much epidemiologic work; no responsible investigator would undertake a randomized, controlled trial of exposure to heroin in otherwise drug-naïve young adults. Recent evidence on the early onset of drug use raises similar issues. Since the 1960s, epidemiologic evidence from observational studies has accumulated about

age at first illicit drug use and the subsequent risk for drug problems, including drug dependence, as illustrated in Fig. 109.4 . Very simple cross-tabulations of study data were enough to bring this association to light (38 ,39 ,40 ,41 and 42).

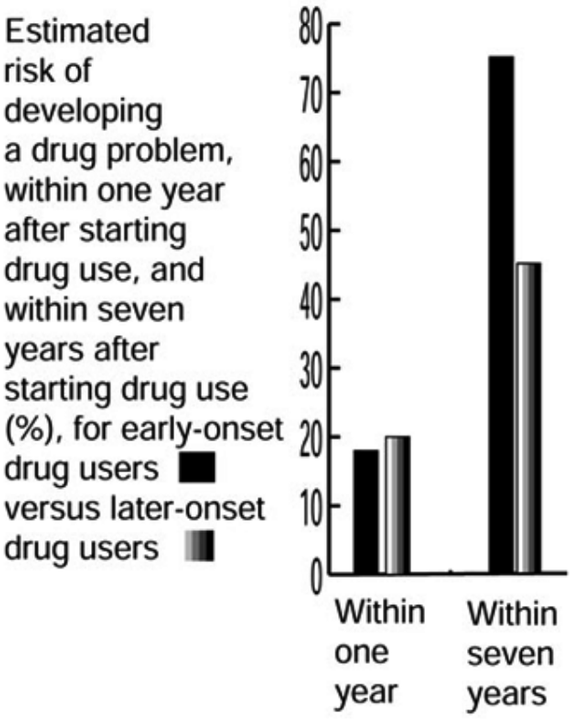

FIGURE 109.4. Estimated risk for the development of a drug problem 1 year after the start of illicit drug use and 7 years after the start of illicit drug use, by age at onset of illicit drug use. Data from National Institute of Mental Health Epidemiologic Catchment Area Program, 1980–1984. (From Anthony JC, Petronis KR. Early-onset drug use and risk of later drug problems. *Drug Alcohol Depend* 1995;40:9–15, with permission.)

Many observers have been convinced by this cross-tabular evidence and have inferred that drug dependence can be prevented by delaying the onset of illicit drug use. Nonetheless, some observers have noted that persons who start using drugs at an early age have more time to experience the hazards of drug use (38) or have other characteristics that make it seem that early age at onset is to blame for the excess when alternative explanations are more plausible (43 ,44). In addition, basic cross-tabulations typically cannot rule out the possibility of an underlying common predisposition, laid down at conception or later in development, that manifests itself not only in an earlier age at onset of drug use but also in a greater risk for becoming drug-dependent. If some predisposition regulates both age at onset and risk for drug dependence (e.g., something linked to a predisposition toward anxiety disorders or antisocial behavior), then efforts to delay age at onset of drug use may have a limited effect on risk for drug dependence.

In this type of context, a direct randomized, controlled trial is out of the question; no one would deliberately expose children to illicit drugs for the sake of experimental confirmation of the observational evidence. Instead, epidemiologists have turned to alternative approaches. First, the life table method developed by Edmund Halley (of comet fame) was used to clarify that the risk for drug problems is not simply a consequence of the fact that early-onset drug users have more time to experience drug problems (Fig. 109.4). Then, “survival analyses” were completed for different strata of the population (e.g., males vs. females) to rule out some of the worrisome predispositions that might lead to a distorted and imperfect view of causal relationships (38). Whereas a randomized, controlled trial may call on randomization to bring distorting predispositions into balance, epidemiologists seek an approximation of this balance via stratified analyses of observational study data or by “matching.” Just as a clinical researcher may match subjects by age or sex, epidemiologists create more homogeneity within “risk sets” by matching subjects on measured variables thought to represent confounding predispositions. Some of these confounding predispositions are genetic and can be matched within monozygotic twin pairs, or they are environmental and can be matched within neighborhoods of residence (6). Second, over and above stratification and matching, multiple regression methods and other forms of the generalized linear model have been used to make statistical adjustments for an array of suspected confounding variables, too many to control via matching or stratification. Finally, indirect randomized, controlled trials are being undertaken in a final push to challenge the belief that the early onset of drug use causes drug dependence. These indirect trials involve the random allocation of preventive interventions intended to delay the onset of drug use; subsequent post-intervention follow-up tests whether delayed onset of drug use is followed by a reduced risk for drug dependence.

In summary, whereas trialists may use a direct randomized, controlled trial to probe suspected causal relationships in the setting of a laboratory or experimental clinic, in the context of population research, epidemiology turns to tools such as stratification, matching, statistical modeling, and the indirect randomized, controlled trial, in which the causal factor is a proximal target for intervention and the condition to be prevented is a more distal outcome (6). Of course, many trialists also make use of stratification, matching, and statistical models—for example, when they anticipate that randomization will not yield completely balanced distributions or when randomization has failed to bring suspected confounding variables into balance. In this sense, a methodologic intersection exists between epidemiology and neuropsychopharmacology, the epidemiologist typically working with larger and less restricted samples at the population level rather than the smaller samples of patients seeking help seen in most clinical trials.

Examples of Epidemiologic Evidence under the Rubric of Causes

Challenging epidemiologic problems have surfaced in research on the suspected hazards of illicit drug use and neuropsychopharmacologic drug products. For example, during

the height of the cocaine epidemic in the late twentieth century in the United States, ethnographic studies of cocaine users and a limited number of case reports from psychiatrists drew attention to symptoms of panic anxiety, experienced not only during episodes of cocaine intoxication but also afterward. Because of some resonance with pharmacology and neurobiological theory, several clinicians inferred that cocaine use was precipitating panic attacks and panic disorder in persons who had not experienced them previously (45 ,46). Nonetheless, the ethnographic study samples were small (e.g., see ref. 47), and the research was based on relatively uncontrolled study designs (e.g., assessors were not blinded with respect to the suspected causal hypothesis).

In addition, it may not come as a surprise that cocaine users visiting psychiatrists had an apparent excess of a psychiatric condition. The well-known Berkson's bias (48) can account for a false appearance of comorbidity when samples are clinical rather than epidemiologic.

With Berkson's bias in mind, several epidemiologists investigated the suspected causal link of cocaine use to panic attack and panic disorder, each with the strengths of study methods that involved double-blinding with respect to the causal hypotheses (i.e., neither the clinical assessors nor the study participants knew that the hypotheses would be tested). One community sample study of young adults was oriented to anxiety in general rather than to discrete panic attacks specifically, and its general evidence about anxiety did not support the published clinical observations (49). However, drawing prospectively ascertained incident cases of first-time panic attack from within the Epidemiologic Catchment Area study sample, and using multiple regression methods to constrain a range of suspected confounding variables, another epidemiologic study produced statistically robust evidence that cocaine users in the community are about three times more likely to experience panic attacks than are age- and neighborhood-matched nonusers (46). A third study, which applied a new case-crossover research design for epidemiology to data from the National Household Survey on Drug Abuse, produced an estimated relative risk not too distant from the one observed in the prospective Epidemiologic Catchment Area studies (RR = 3) (50).

This example of a suspected psychiatric hazard of cocaine use illustrates how epidemiology makes use of study procedures such as standardized diagnostic assessment, double-blinding, matching, and multiple regression to strengthen the basis for causal inference from evidence based on nonrandomized observational studies. Nevertheless, more work has actually been done and the history of epidemiologic research is longer on the "other side" of co-occurring psychiatric disturbances and drug dependence, where the observed "comorbidity" is thought to arise because the psychiatric disturbance leads to drug dependence. Perhaps the oldest tradition of this type of comorbidity research started with clinical observations about sociopathy and criminal backgrounds in drug dependence cases sent to federal narcotics farms. For example, clinical investigators such as Kolb and Pescor (51) estimated that as many as 50% to 60% of incarcerated cases qualified as antisocial or socially maladapted, with evidence of social maladaption generally predating drug use.

The potential for a type of Berkson's bias is ripe in this context; one should not be too surprised to find an excess of socially maladapted persons among incarcerated prisoners of any stripe. Even so, it was more than 25 years after the initial observations before a proper epidemiologic investigation of this relationship was undertaken. This investigation was a "nonconcurrent prospective study" of children seen in child guidance clinics of the 1920s, some with record-based evidence of childhood rule breaking and deviance, and others without such evidence. The research team secured old child guidance records in the 1950s, and by the early 1960s they had successfully traced, reengaged, and used standardized diagnostic survey methods to assess the vast majority of the sample, who were then well into adulthood, mostly within or beyond the end of the effective period of risk for the development of drug dependence. To the extent that any single study can do so, this classic epidemiologic investigation set to rest most of the concerns about Berkson's bias and showed that prior childhood deviance is linked to a subsequent risk for dependence on heroin and other "narcotic" drugs, with the evidence tending to support a causal inference linking earlier deviance with later drug problems (52 ,53).

Numerous subsequent observational studies followed along this path, with the strength of community samples outside clinics and prisons, but generally with cross-sectional and retrospective research designs (53). One noteworthy exception was the Woodlawn Project "concurrent prospective study" of a large sample of first-graders recruited in the mid-1960s and followed later as teenagers and then as young adults. The teenage follow-up study produced evidence that resonated with the nonconcurrent prospective evidence from the child guidance study sample. Namely, an excess occurrence of "heavy" drug use was noted among teenage boys whose first-grade teachers had rated them as "aggressive" rule-breakers in the classroom (54; M. Ensminger, *personal communication*). Subsequent follow-up, when the teens had matured to adulthood and entered the fourth decade of their lives, showed an excess occurrence of cocaine use in association with teacher-rated aggression measured more than 20 years beforehand.

It is difficult to imagine a direct randomized, controlled trial to test the causal influence of antisocial, deviant, or aggressive behavior on later risk for drug dependence. Regrettably, the observational studies described to this point do not rule out the possibility of an underlying diathesis or predisposition that gives rise both to unruly behavior and to drug dependence, the first coming developmentally earlier in the expression of the diathesis, and the second developmentally

later (see ref. 55 for a recent discussion). This, of course, is one of the main problems of causal inference in contemporary "psychiatric comorbidity" research. Other problems include "shared methods covariation" resulting from heavy reliance on self-report and recall in the measurement of drug dependence and other psychiatric disturbances, and problems associated with an assumption that coarse-grained age-of-onset data can illuminate which condition came first, even when the prodrome of the conditions is known to develop insidiously, often over a span of years (56).

Fortunately, some twin and adoption paradigm research has clarified the issue of shared genetic and environmental predispositions toward antisocial behavior and the problems associated with drug dependence (57 ,58). In addition, an indirect randomized, controlled trial has been completed to evaluate a new developmentally sensitive modality of drug prevention programming and to shed new light on the suspected causal influence of early deviance, aggression, and rule breaking. A detailed description of the indirect randomized, controlled trial is beyond the scope of this chapter and can be read elsewhere (59 ,60). Nevertheless, in brief, the research design involved a repetition of the Woodlawn Project recruitment of a large sample of first-graders (*n* = 2,311), but with random assignment of the children to a "good behavior game" condition, which involved a teacher-led classroom-based intervention designed to improve the behavior and rule abidance of children and promote their social interactions, versus control conditions (either the standard curriculum or a "mastery learning" curriculum designed to improve reading achievement). The children assigned to the experimental interventions were kept in the same primary school classrooms and the same conditions for 2 years, during which they received increasing "doses" of the behavior and reading curriculum. The children assigned to the "standard-setting" or control classrooms also were kept together for 2 years and received just the usual and customary curriculum of the local public school system.

Follow-up assessment of the children who grew up and went to school in this urban public school system occurred on an annual basis from grades 3 to 4 of primary school to grades 7 to 8 of middle school. These assessments involved private face-to-face interviews with each child, in which standardized survey research methods with blinding (assessors did not know which children had received which intervention) and teacher ratings were used. Once the children were old enough, they were allowed to mark their answers on an answer sheet that could not be read by the assessor and was sealed in an envelope for later data entry. The assessments also involved ratings by the teachers in these later grades; the middle school teachers knew that the children had been in a prevention experiment, but they did not know which of the three conditions the child might have received during the first 2 years of primary school.

Life table and regression analyses of the follow-up teacher ratings and self-reported age at first use of tobacco provided evidence consistent with the preventive hypotheses; (a) boys who had received the good behavior game intervention were rated as better-behaved than their counterparts in the other study conditions ($p < .05$), and (b) the risk of starting to smoke tobacco by age 13 or 14 years was substantially greater for boys in the "standard-setting" control classrooms than in those who had spent first and second grades in the "good behavior game" classrooms (RR = 2.0; $p < .05$). Consistent with the observational evidence suggesting that deviant or aggressive behavior is a stronger determinant of drug use for boys than for girls, the "good behavior game" effect was less pronounced among the girls (59). Current continuing follow-up of these study participants into their young adult years, supported by the National Institute of Mental Health and the National Institute of Drug Abuse, will reveal whether the apparent intervention effects are long-lasting and influence the risk for the use of other drugs and the development of drug dependence.

Whereas an indirect randomized, controlled trial of this type is a challenge and requires follow-up over spans of time that exceed typical durations of National Institutes of Health grant awards, this type of experimental investigation of the suspected causal link of early deviance or aggression to later drug use and dependence is indispensable when the task is causal inference. Random assignment of the children to different intervention conditions helps to bring into balance an array of suspected confounding variables. Thereafter, careful measurement and regression modeling help to constrain what randomization has not constrained. Although it is not possible to make a random assignment of children to higher or lower levels of rule breaking and aggressive behavior, it is possible to assign them at random to interventions designed to reduce these levels.

Of course, no single indirect randomized, controlled trial will settle the outstanding issues about this form of psychiatric comorbidity. The case for causal inference will depend on completion of more indirect trials along these lines, with each replication adding strength to the chain of inference and web of causation.

Other forms of "comorbidity" with drug dependence have come under scrutiny in epidemiologic research, most recently an observed co-occurrence involving the anxiety disorders, especially phobic disorders (61). One can expect a more rapid acceleration of epidemiologic attention to the link of anxiety disorders to alcohol or other drug dependence, with time from the first nonexperimental observations to the first indirect randomized, controlled trial measured in years rather than in decades, as was the case for the link of childhood deviance and antisocial behavior to drug dependence. In this context, it may be important to note another feature of the Woodlawn Project findings, which drew attention to the combination of shyness and aggression

or rule breaking among boys. The Woodlawn Project report noted an interaction of shyness and aggression, directing attention mainly to the excess risk for heavy drug use among boys who were rated in first grade as being both shy and aggressive. However, careful inspection of the Woodlawn Project study data indicated that the observed interaction depended heavily on a quite low occurrence of drug use among the boys who were shy but not aggressive. In other words, in the absence of aggression, being shy and not having many friends may help protect an inner city youth against the risks of illicit drug use. The link to current anxiety disorders and comorbidity research involves the prominence of phobias in the observed association with alcohol and other drug dependence, and the Woodlawn Project measurement of shyness as a trait that encompasses not having very many friends, being socially withdrawn, and staying on the fringes of or outside social groups (54).

Before we leave the rubric of causes, several recent studies merit special mention because of their pertinence in the genetic epidemiology of drug dependence. The Vietnam Veteran twin study is especially noteworthy because it is seeking to partition genetic, shared and nonshared environmental influences across a sequence of transitions leading to drug dependence. Unique to this study is its attention to the transition from before to after the first exposure to opportunities to try drugs (62). The importance of this transition in etiologic research on drug dependence is discussed in the next section, under the heading of causal mechanisms.

The work of Kendler and colleagues (63 ,64) is noteworthy for its initial focus on female twins and its spotlight on gene–environment interactions. This work is leading us to a better understanding of how genetic predispositions may have an important influence on entry into risk-laden environments, where exposure to drugs and drug taking becomes more likely, over and above any influence of inherited characteristics on responses to drug exposure. In a related line of work on parent–child interactions, Kendler et al. (65) have recently added new evidence that parental coldness or aloofness may affect the occurrence of alcohol or other drug dependence, but the evidence is not generally supportive of an influence of active parenting styles (e.g., authoritarianism). Of course, evidence to the contrary exists, including some new evidence on how children shape the parenting behaviors displayed by their mothers and fathers (66). Soon, results will be available from indirect randomized, controlled trials in which interventions have been used to increase the aspects of parenting behavior suspected of being most influential in early drug involvement (e.g., supervision and monitoring). Here, the causal inference is supported by a fairly solid body of observational evidence contributed by many different research groups (67 ,68 ,69 ,70 and 71). Nonetheless, as in the link between sociopathy and drug dependence, replications from indirect randomized, controlled trials are apt to provide the most definitive evidence regarding these issues of causal inference. In time, indirect randomized, controlled trials with large epidemiologic samples will probably be performed, possibly with specific targets identified and characterized through elaborations of the human genome project. For example, one can imagine research on parental influences on drug taking that includes measurement of parenting behaviors in addition to inherited determinants of persistent drug use, such as the alleles controlling the cytochrome P-450 enzyme, which is important in nicotine metabolism (72).

RUBRIC 4, MECHANISMS: “HOW DO SEQUENCES OF CIRCUMSTANCES, CONDITIONS, AND PROCESSES LEAD TO DISEASE?”

Part of "109 - Epidemiology of Drug Dependence "

Epidemiology as a discipline places emphasis on studies of the “natural history” of disease, in part because of its early confluence with clinical medicine, bacteriology, and virology. Here, natural history may be understood as the outward manifestations of an evolving causal process and the expression of causal mechanisms that lead toward the fatal or nonfatal resolution of the condition under study. In the study of diseases, “clinical course” can be differentiated from “natural history” once clinical attention can make a fundamental difference. Before then, what we see is natural history. Once effective treatment maneuvers have been started, what we see is the clinical course, or natural history modified by clinical attention.

Until recently, when the concept of natural history was applied in the epidemiology of drug dependence, most attention was given to observable “stages” and “developmental sequences.” For example, Robins (73) and Winick (74) advocated decomposition of the addiction process into stages. They specified a pre-initiation stage that involved first exposure to an opportunity to try a drug. Thereafter, some presented with an opportunity go on to try the drug, whereas others do not. Among those who actually try the drug, the drug-using stage may or may not be followed by another stage—transition into drug dependence. Some users actually “mature out” of stages of very serious drug use (e.g., see ref. 74).

In the work of Kandel and Davies (75), the natural history of drug involvement is conveyed as a stage developmental sequence in which different drugs are tried, first legally available beer or wine, then hard liquor or tobacco, then marijuana as the first “illicit” drug in the sequence, then other illicit drugs. The last development in Kandel’s sequence is use of prescription psychotherapeutic medicines (Fig. 109.5) (85); others have confirmed this position for prescription drug use (86).

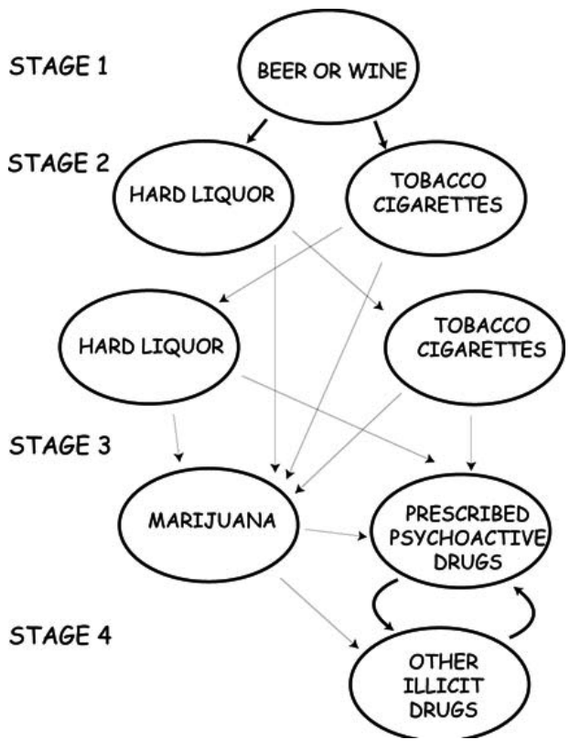

FIGURE 109.5. Stages in the developmental sequence of adolescent drug involvement. (Adapted from Kandel DB, Yamaguchi K, Chen K. Stages of progression in drug involvement from adolescence to adulthood: further evidence for the gateway theory. *J Stud Alcohol* 1992;53:447–57, with permission.)

Nonetheless, some observers have argued that this “gateway description” of sequences from drug to drug may rest solely on different levels of availability or opportunity to use different drugs. Other investigators have challenged the stage transition concept as applied to drug dependence and youthful tobacco smoking (77). They have advocated an

analysis of levels of drug involvement in terms of a hybrid concept that allows for discrete stage transitions, but with dimensional movement within each stage (e.g., see ref. 27). Statistical methods for studying this hybrid transition progression model are being developed for epidemiologic research (e.g., see refs. 78 , 79).

A recent development has been epidemiologic research on the natural history and clinical course of the various clinical features of alcohol dependence (e.g., see refs. 80 , 81 and 82). Separate lines of clinical and epidemiologic research on the natural history of dependence on drugs other than alcohol have also been initiated (e.g., see refs. 83 , 84).

RUBRIC 5, PREVENTION AND CONTROL: “WHAT CAN BE DONE TO PREVENT, REDUCE, OR AMELIORATE THE ADVERSE IMPACT?”

Part of "109 - Epidemiology of Drug Dependence "

The central position of prevention in epidemiology already has been mentioned in this chapter, although many epidemiologists’ careers are devoted to observational studies, with little attention to intervention research. “Control” is also a key concept in epidemiology, referring to maneuvers such as quarantine or the effective treatment of active cases to limit spread to other persons.

During the evolution of epidemiology in the nineteenth century, a new type of professional emerged—a public health officer equipped with newly found knowledge of epidemiology and armed with police powers necessary to protect the larger population from the threat of infectious diseases. In twentieth century efforts to mount an effective societal response to drug dependence, the police authority was split from the public health authority. As a result, when most people now think of the prevention of drug dependence, what comes to mind are health education classes for young people of school age or mass media campaigns to publicize the hazards one faces once drug use starts. We do not tend to think of the international, federal, state, and local laws or police actions as societal instruments for prevention. Nor do we tend to think of early interventions for drug-dependent cases, tracing of secondary contacts who may be sources of sustained outbreaks, or effective treatment of active cases as a means of preventing new cases. Indeed, in some quarters, the opinion has been expressed that concepts of epidemiology and public health should not be applied to drug dependence because these concepts are tied inherently to coercive actions, such as quarantine (85).

Notwithstanding these concerns, during the past quarter-century, some epidemiologists have directed attention to the evaluation of laws and regulatory activities thought to prevent and control drug dependence and associated hazards. Starting in the 1960s, de Alarcon (86) and Hughes et al. (87) refined methods of tracing secondary cases and of street outreach to curb urban outbreaks of heroin dependence. Figure 109.6 shows the pattern of spread of heroin injection that was central to de Alarcon’s work on epidemiology and the prevention of heroin epidemics.

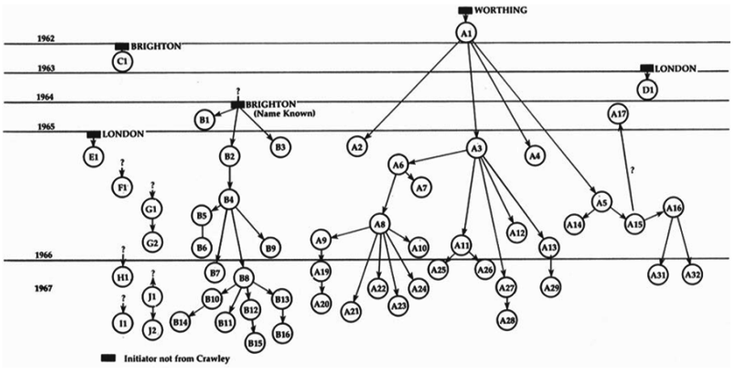

FIGURE 109.6. The person-to-person spread of heroin injection across time and space in the United Kingdom in the 1960s. (From De Alarcon R. The spread of heroin abuse in a community. *Community Health (Bristol)* 1969;1:155–161, with permission.)

It may come as a surprise that epidemiologists have not been the ones to sustain this work or build on it. For example, the most advanced efforts to evaluate drug policy have come from systems research models that make use of epidemiologic data but are based more on econometrics and operations research than on epidemiologic principles, concepts, and methods (e.g., see refs. 88 , 89 and 90). Indeed, more epidemiologic attention and evaluative research have been devoted to community mobilization to prevent HIV infection and AIDS than to the prevention and control of drug dependence, although a new impetus for community mobilization is coming from drug treatment researchers (e.g., see refs. 91 , 92).

Noteworthy exceptions to this generalization about drug prevention research do exist. As examples, the work of Pentz and Perry and their colleagues (93 ,94 ,95 ,96 and 97) involves the mobilization of communities to shape policy and procedures, with a core of interventions directed toward young persons of school age. Gutman and Clayton (98) have recently urged that greater attention be paid to “upstream” prevention maneuvers that affect large aggregations of communities, such as state, federal, and even international policy initiatives. In alcohol and tobacco research, some noteworthy examples can be found of the evaluation of “upstream” interventions

(e.g., see refs. 99 , 100 , 101 and 102), in addition to evaluations of “downstream” maneuvers, such as limiting tobacco sales to minors (103).

Recently, interest has been renewed in “multilevel” statistical models that take into account different levels of organization, from the community at large to the local neighborhood to the household or individual, and in models of “dependent happenings,” such as are seen when innovations (e.g., drug use) diffuse from one person or group to the next (104 ,105 and 106). A carryover into the domain of prevention research has been expressed in recent articles and a textbook (107). These developments, coupled with a greater appreciation of gene–environment transactions or reciprocities, rather than gene–environment competition, promise to transform and sharpen the focus of prevention research during future decades as the human genome project yields new targets (108 ,109 and 110).

CONCLUSION AND FORECAST

Part of "109 - Epidemiology of Drug Dependence "

It is possible to make an optimistic forecast regarding the application of epidemiology to the study of drug dependence. Under the rubric of “quantity,” sustained growth in the number of cross-sectional “prevalence surveys” that estimate the frequency of drug dependence in various populations and subpopulations of the world is apparent. Diagnostically oriented national surveys, such as the National Comorbidity Survey and the National Household Survey on Drug Abuse in the United States, will continue to be at center stage. The “World Mental Health 2000” surveys, organized by Professor Ronald Kessler of Harvard University and Dr. Bedirhan Ustun of the World Health Organization, will enlarge these national perspectives and offer epidemiologic data on the prevalence of drug dependence in more than 15 different participating countries. Because of the greater difficulty and complexity of the Epidemiologic Catchment Area studies, it is less likely that we will see similar growth in prospectively derived estimates of the incidence of drug dependence and the risk for becoming drug-dependent. Most likely, we will have to make do with approximate estimates of risk based on retrospective data from the cross-sectional surveys.

The sustained attention given to determining the prevalence of drug dependence within the context of more general surveys of psychiatric disturbances essentially guarantees a raft of new findings on the location of cases and “psychiatric comorbidity” within the populations of the world. We are likely to see more and more data on the male excess in drug dependence cases, although in some countries, because of the use of psychotherapeutic medicines, a female excess may be shown for some drug categories. Similarly, the excess occurrence among 15- to 44-year-olds in comparison with other age groups may prove to be a general rule via exceptions,

such as the high prevalence of heroin or opium dependence among elderly persons living in the opium-growing regions of the world. Nonetheless, it seems that new findings from these cross-sectional surveys will be most useful in confirming past observations. One may hope for transformative evidence, but the work is not likely to be ground-breaking.

Under the rubric of “causes,” the intersection of epidemiology intersects with the human genome project provides a basis for optimism. As discussed elsewhere, epidemiology has a special capacity to discover environmental circumstances, conditions, and processes that modify inherited predispositions. To the extent that epidemiologic studies are able to incorporate measurements of genetic polymorphisms and to characterize participants as heterozygotes and homozygotes, they will disclose variations in the expression of risk. These variations, linked to environmental conditions or processes, will clarify the webs of causation leading to drug dependence.

The capacity of epidemiology to yield definitive evidence regarding macrosocial causes of drug dependence, such living within an inner city community or being of low socioeconomic status (e.g., see ref. 111), is less of a reason for optimism. The definitive quality of research on these topics will remain limited without a truly massive investment in prospective studies within urban areas, and without levels of subject cooperation and participation far in excess of what is now achieved in these areas.

Under the rubric of “mechanisms,” the above-mentioned statistical advances will bear fruit once investments have been made in longitudinal studies designed to make the measurements required to characterize the hybrid sequences of transitions and progressions. Linked with advances in human genetics and the measurement of environmental conditions and processes, these longitudinal studies promise advances in our understanding, but as a “basic science” initiative, the clinical application of this new understanding is not immediately clear.

Under the rubric of “prevention and control,” we will begin to see long-term results from rigorous drug prevention research during the first decade of the twenty-first century. This evidence should help us to clarify central issues, such as whether preventing the onset of illicit drug use in the early teenage years will be followed by a reduced risk for drug dependence in later adolescence and early adulthood. One may hope for an intersection of etiologic research and prevention research, but any new gains in understanding the genetics of drug dependence may not yield practical preventive interventions for a half-century or more.

The recently developed systems research models suffer mainly from inadequate epidemiologic and law enforcement data (e.g., see ref. 90). However, having forged these systems research models, the policy analysts should provoke epidemiologists to improve the data, and it is hoped that the societal investment in improved data will lead to more compelling evaluations of drug policies and societal responses to drug dependence and illicit drug use.

Under this same rubric, a ray of light has begun to shine forth from the National Institute of Drug Abuse in the United States, where a new unit has been established to promote research on community mobilization and efforts at the community level to curb outbreaks of drug taking and drug dependence. Coupled with continuing progress in the ongoing evaluation of school-based prevention programs and mass media campaigns, this initiative represents an important step in the next generation of progress in epidemiologic research on drug dependence.

ACKNOWLEDGMENT

Part of "109 - Epidemiology of Drug Dependence "

Some of the material in this chapter overlaps with material and ideas presented in other review articles and chapters written by the author. For example, the concepts associated with the rubrics of epidemiology originally were presented in a chapter by Anthony and Van Etten (6); concepts on the hybrid transition–progression model were presented by Anthony and Helzer (27). The appropriate work has been cited, and the editors have been notified of the circumstances.

A. R. Childress, Teresa R. Franklin, J. Listerud, Paul D. Acton, and Charles P. O'Brien: Addiction Treatment Research Center, Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.

Cocaine craving is a cardinal feature of addiction to the drug and is clinically significant because of its potential link to relapse. Addicted patients describe the craving as a powerful, “must-have” pull that causes them to risk, and sometimes lose, their relationships, families, money, possessions, jobs, and even their lives. “Anticraving” medications are greatly needed, but despite intensive research efforts since the mid-1980s, such agents have remained elusive (1 ,2). This dilemma is in part a consequence of our inability to define or measure cocaine “craving” clearly. Diversity in measurement may well account for some of the variability in the data collected, as described below. In part, the problem is our nascent understanding of which brain substrate(s) an “anticraving” medication should address. Until recently, the activity of the brain during cocaine craving was a matter of inference rather than direct observations. The increased availability of powerful tools for brain imaging *in vivo* has thrust research on drug craving forward into a new era. Several laboratories have begun to measure brain activity during cocaine-craving states directly. This chapter reviews current findings, offering a framework for the results and a discussion of their theoretic and treatment implications.

IS THERE MORE THAN ONE KIND OF COCAINE CRAVING?

Part of "110 - Neuroimaging of Cocaine Craving States: Cessation, Stimulant Administration, and Drug Cue Paradigms "

Despite sophisticated tools for brain imaging, the study of cocaine craving is complicated by the fact that desire for the drug can be reported under dramatically different conditions, and measurement is carried out with a range of different scales. For example, craving may be reported in association with *cocaine cessation* (3), but also in association with *cocaine administration* (4) and *cues signaling cocaine* (5 ,6). Brain substrates may differ across these conditions. Interestingly, changes in the mesolimbic dopamine (DA) systems of the brain have been implicated in all three conditions, but the direction of change is not the same in all three. A possible (tonic) decrease in mesolimbic (nucleus accumbens) DA has been proposed in the case of cessation/functional depletion (7 ,8 and 9), whereas an (episodic) *increase* in DA has been hypothesized in the case of cocaine administration (10) and response to cocaine cues (11 ,12). Of course, these differing DA-related states are not mutually exclusive and may interact in important ways; for example, a dose of cocaine or a cocaine-related cue may have a different brain impact in early versus late cessation, depending on the dynamic re-regulation of the affected substrates. The possible “duality” (too much DA vs. too little DA) of cocaine craving has implications not only for the design of imaging studies but also for the treatment of cocaine craving (2). If the *same* brain substrates are responsible for the craving associated with DA deficiency and the craving associated with DA excess, how can either of these craving states be treated without worsening the other? We will return to this question after a review of the neuroimaging evidence for craving across the conditions.

Neurotransmitter systems other than DA are likely to be involved in cocaine reward and motivation (13 ,14). For example, serotonin (15 ,16), glutamate (17), corticosteroids (18 ,19 and 20), and opioids (21 ,22) have each received substantial cocaine-related research attention. However, in the *neuroimaging*

of cocaine craving, many of the studies have used a DA-related framework for their hypotheses, interpretations, or both. The emphasis on a dopaminergic system reflects not only a long literature on DA involvement in stimulant reward and motivation (23 ,24 and 25) but also the availability of DA-related neuroimaging tools for humans (26). Imaging studies testing the role of other neurotransmitters and neuromodulators in cocaine craving will be a welcome addition to the field. The only currently available study in this category is included in the current review (27).

The neuroimaging studies of cocaine craving discussed below are categorized according to whether their primary focus is *cessation, stimulant administration*, or *drug cue paradigms*. In studies in which the paradigms may overlap (e.g., patients in early cessation viewing cocaine cues), this is noted, as it may be helpful in the final integration of craving results across studies and paradigms.

IMAGING OF CRAVING DURING COCAINE CESSATION

Part of "110 - Neuroimaging of Cocaine Craving States: Cessation, Stimulant Administration, and Drug Cue Paradigms "

Hypotheses

Early in the cocaine epidemic, investigators hypothesized that the long-term use of cocaine resulted in a functional depletion of brain DA (9) in regions critical for the regulation of mood, motivation, thought, and concentration. Acute cocaine administration to laboratory animals or to humans elevates levels of synaptic DA (and other monoamines) by reuptake blockade (28 ,29). However, brain measurements in long-term users (or laboratory animals maintained on cocaine) have revealed differences from controls, such as reduced DA synthesis (30), reduced cocaine uptake (31), down-regulation of postsynaptic DA sites (32 ,33), and altered responses in the endogenous opioid system (34 ,35 and 36), differences that may reflect the homeostatic attempts of the brain to cope with a cocaine-induced flood of synaptic DA. DA transporters (DATs) in the long-term user of cocaine may also be dysregulated, although the direction of observed change varies across studies (35 ,37 ,38 ,39 and 40), potentially reflecting the oscillating nature of re-regulation (see also refs. 31 , 41). The DA dysregulation observed in cocaine users following cessation is supported by numerous animal studies. These studies have found alterations in accumbens DA levels (7), the threshold for rewarding brain self-stimulation (42), the metabolism of reward-relevant regions (43), DA synthesis (44), and postsynaptic DA receptors (44). Thus, on cocaine cessation, the DA systems of some cocaine users may be in a neurologically adapted, dysregulated state. The lowered mood, energy, and concentration experienced by some cocaine patients during abstinence may be related, at least in part, to a dysfunction in brain DA systems. According to this general view, the *craving* that arises during abstinence may also reflect DA system dysregulation (8). Do neuroimaging studies support this hypothesis?

Data

The results of several neuroimaging studies are consistent with the notion of DA dysregulation in cocaine cessation; we review here the studies that have also included craving measures.

Early Cessation (1 Week or Less post Cocaine)

Volkow et al. (45) found a higher rate of metabolism by positron emission tomography (PET) with ^{18}F-fluorodeoxyglucose in cocaine users in early cessation (≤1 week post cocaine) than in controls in two major regions of DA projection, the orbitofrontal cortex and the basal ganglia. In this study, craving (“none,” “mild,” “moderate,” or “severe”) during the week before the scan was positively correlated with (both relative and absolute) metabolic rates in the orbitofrontal cortex, and with (absolute but not relative) metabolic rates in another major mesocortical DA projection region, the prefrontal cortex.

Malison et al. (39) studied DATs with single-photon emission computed tomography (SPECT) and B-CIT, a tracer that binds to dopamine and serotonin transporters, in patients abstinent from cocaine for 96 hours or less to determine whether they exhibited the transporter elevations predicted by a neuroadaptive hypothesis. DAT increases of approximately 20% in comparison with controls were indeed detectable, although they were more modest than the DAT increases found in postmortem studies of cocaine users (37 ,38). An inverse relationship was noted between DAT level and depression scores, but no relationship of DAT level to craving scores (on the Cocaine Craving Scale) was found (3).

Early and Later Cessation

Long-term cocaine use can alter μ-opioid binding (34 ,35 and 36), which indicates an interaction of DA and endogenous opioid systems. Given the role of endogenous opioids in mood modulation, up-regulated μ-opioid receptors may contribute to dysphoria or craving in cocaine cessation. Zubieta et al. (27) used PET and ^{11}C-carfentanil (a high-affinity μ-opioid agonist tracer) to image μ-opioid-receptor binding in cocaine patients at 1 to 4 days, and then at 4 weeks post cocaine. In comparison with controls, the cocaine patients showed up-regulation of μ-opioid receptors in the caudate, thalamus, anterior cingulate, frontal, and temporal brain regions; these changes persisted for 4 weeks in all but the temporal region. On the early cessation scan, craving (Minnesota Craving Scale on the prior evening, 100-mm visual analogue scale just before the PET, or both) was positively correlated with μ-opioid binding in the amygdala and the anterior cingulate, frontal, and temporal cortex. These four regions all receive significant DA projections, consistent with DA–opioid interactions. Scores on the Beck Depression

Inventory did not correlate with μ-opioid-receptor availability, which indicates that the early cessation craving was not simply a depressed mood. None of the correlations of craving with μ-opioid binding were significant for the later, 4-week scan.

Later Cessation

In abstinence extending beyond a week (imaging at 1 to 6 weeks, and again at 3 to 4 months post cocaine), neuroimaging studies from the laboratory of Volkow et al. (46) have shown that frontal metabolism is decreased in the brains of cocaine users in comparison with that in controls. Although craving (averaging 3 ± 1 on a scale of 0 to 7) was assessed as a subject characteristic in this study, no correlations with metabolic rates were reported. In a further study of the same patient sample, reductions in orbitofrontal cortex and cingulate metabolism were particularly profound, and these reductions were correlated with reductions in (striatal) DA D2-receptor availability (33). However, craving (on a scale of 0 to 10) during the week of the study did not correlate with striatal D2-receptor availability; correlations of craving with metabolic rates were not reported.

Paralleling the metabolic findings of Volkow, Childress et al. found the resting regional cerebral blood flow (rCBF) to be significantly lower in the anterior cingulate (47) and left medial orbitofrontal cortex (gyrus rectus) (48) of cocaine patients at an average of 13.5 days after cessation in comparison with controls. However, neither baseline cocaine craving nor withdrawal (self-rated on a scale of 0 to 9) at the time of the scan correlated with rCBF in these regions.

Summary of Cessation Studies

The neuroimaging data clearly show a number of differences between the brains of cocaine patients undergoing cessation in comparison with controls not using drugs. The observed differences often are clearly linked to brain DA systems. However, the relationship of these brain indices to “cessation craving” has been variable. At this time, correlative evidence from studies in early (≤1 week) cessation, but not from those conducted at longer intervals post drug, indicates a relationship between craving and brain responses (orbitofrontal and prefrontal cortex metabolism, μ-opioid binding).

Because the “early” and “late” cessation studies were often conducted in separate populations, and with important differences across studies (e.g., monitoring of abstinence, inpatient vs. outpatient population), any conclusions must be drawn with caution. Powerful within-subject designs, including frequent scans and subjective measures across a period of prolonged abstinence, would be helpful in clarifying cessation–brain–craving relationships. If such longitudinal studies were to confirm a lack of a relationship between craving and later resting *hypo*activity (by metabolism and rCBF) in DA projection areas, such findings would have implications for both theory and treatment. For example, if low DA tone is not associated with craving, then enhancing DA activity might not help craving, and could even be problematic (49).

Even if unrelated to craving, the differences between cocaine patients and controls that are evident at both early and later time points (e.g., in DA D2 and μ-opioid receptors) may still be very important. They may reflect other functional consequences of cocaine use, or group differences that possibly predate cocaine use or even predispose subjects to such use. The latter possibility has received very recent support. In a study of Volkow et al. (50), initial liking for intravenous methylphenidate (a stimulant also acting by inhibition of reuptake of DA) in normal persons was *inversely* related to D2-receptor availability. The D2-receptor levels for normal subjects who liked methylphenidate were significantly lower than those for normal subjects who did not like the drug, and they were strikingly similar to those of long-term cocaine users in earlier studies by the same investigators (51). Reduced D2 receptors may thus be a marker for vulnerability to stimulant misuse in addition to, or perhaps even instead of, a possible consequence of misuse.

IMAGING OF CRAVING DURING STIMULANT ADMINISTRATION

Part of "110 - Neuroimaging of Cocaine Craving States: Cessation, Stimulant Administration, and Drug Cue Paradigms "

Hypotheses

Administering cocaine in the laboratory is a reliable and robust trigger of cocaine desire (4), and cocaine users complain that the first dose (“taste”) of cocaine in a binge rapidly elicits profound craving, drug-seeking behavior, and a second dose. Almost two decades ago, Eikelboom and Stewart (52) modeled this behavior in rats, showing that small drug “primes” could motivate drug seeking and reinstate extinguished responding for drug. According to the priming hypothesis, the initial drug effect always precedes the full drug effect and comes (through classic conditioning) to trigger a druglike brain state. The state has powerful positive incentive properties, “pulling” the organism back to the drug.

Koob (53) has proposed a different way in which the first dose of cocaine might lead to the next. In this “opponent process” view, the brain responds to cocaine with homeostatic processes, some of which are the hedonic opposite of the direct effect of the drug, euphoria. The opponent response (i.e., dysphoria) emerges as the direct effects of the drug dissipate and motivates drug seeking to reduce discomfort. Clinically, patients do complain about the jittery offset of the cocaine high, and they recognize that taking another dose of the drug will alleviate this state.

So, is the craving associated with human cocaine administration more closely related to a brain state that occurs at the *onset* or at the *offset* of the drug response? Although the question is posed as a choice, these possibilities (unfortunately

for the task of developing medications) are not mutually exclusive. Craving of the positive, appetitive, “primed” variety may map onto brain responses associated with the initial effect of the drug and be followed shortly thereafter by the dysphoric craving of offset, which may map onto a later set of brain responses that are *opposite* in direction to those of drug. The exquisite temporal sensitivity of functional magnetic resonance imaging (fMRI) allows these possibilities to be examined directly, as discussed below.

What are the likely neuroanatomic and neurochemical features of the craving state(s) associated with cocaine administration? More than two decades of animal research (see refs. 25 , 54 , 55 and 56 for review) support the involvement of the mesolimbic and mesocortical DA systems of the brain in cocaine reinforcement and motivation. Thus, *a priori* neuroanatomic predictions include the familiar projections of the DA cells in the ventral tegmental area of the midbrain to the ventral striatum (nucleus accumbens), amygdala, basal forebrain, orbitofrontal cortex, and medial prefrontal/anterior cingulate cortex. And, although recent animal (13) and human (57) research leaves room for the contribution of other brain systems, DA neuronal elements (DATs, postsynaptic D2 receptors) have also been initial neuroimaging targets.

Data

Several laboratories have now imaged cocaine users during stimulant administration, but some of these studies either did not obtain a craving measure (58 ,59 ,60 and 61), did not analyze the craving item (62), or analyzed a craving item but did not attempt to relate it to the brain measure under study (63). The remaining four studies discussed below have been published since 1997.

Breiter et al. (64) used temporally sensitive fMRI technology with a BOLD (blood oxygen level-dependent) scan to map the brain circuitry activated during a period 5 minutes before, and 13 minutes after, cocaine (0.6 mg/kg, maximum dose of 40 mg) versus saline infusion in cocaine subjects abstinent a minimum of 18 hours. Subjective ratings (“rush,” “high,” “craving,” and “low”) were taken each minute throughout the experiment. “Rush” and “craving” (defined as wanting more cocaine) ratings were later correlated with the group-averaged temporal pattern of signals from each brain region meeting specified threshold and extent criteria for differential activation by cocaine. “Craving” ratings increased steadily from the onset of the cocaine infusion, peaking at approximately 12 minutes post cocaine. No activity in any single brain region precisely echoed the onset and late peak of “craving” ratings. However, significant positive correlations were obtained with regions having early-onset (during euphoria) but *sustained* activations. These included the nucleus accumbens/subcallosal cortex and some paralimbic sites (a section of the parahippocampal gyrus, a section of the posterior insula, and a section of the anterior cingulate). Signal change in the amygdala during cocaine administration was initially reported as heterogeneous (some patients showed increases and others showed decreases), not correlated with rush, and negatively correlated with craving ratings. However, in a follow-up study with cardiac gating of the fMRI signal (see below), the direction of signal change in amygdala was positive for all subjects.

In contrast to “craving” ratings, “rush” ratings peaked quickly (at 3 minutes) after infusion and then declined rapidly. Although the brain regions that correlated with “craving” and “rush” overlapped substantially, a clear dissociation was also noted. “Rush,” but not “craving,” correlated with early maximal, short-duration signals from the ventral tegmental area and basal forebrain (and sections of the cingulate). On the other hand, “craving,” but not “rush,” correlated with an early-onset but sustained signal from the nucleus accumbens/subcallosal cortex. All the activated regions showed early onset to cocaine. Thus, the primary difference between “craving” and “rush” (euphoria) substrates was not a matter of which regions were activated, but of how long. Put another way, a full orchestra is playing from the outset of cocaine administration. As the “rush” wanes, some instruments drop out. “Craving” corresponds to the strains of those that play on.

How do these data fit with the “priming” and “opponent process” hypotheses of craving in response to cocaine? Unfortunately, the fit is not completely straightforward for either view. “Craving” mapped onto the activity of structures (nucleus accumbens/subcallosal cortex) with an early but sustained signal. At the first level of examination, this finding seems consistent with a priming effect; the signal occurs very early and therefore looks like a direct drug effect. However, according to the priming hypothesis, “craving” should map better onto the brain correlates (ventral tegmental area and basal forebrain) for the direct effects of “rush” and euphoria. In terms of clear evidence for a simple opponent process view, no later-occurring activations *opposite* to the direction of the “direct” drug effects in ventral tegmental area/basal forebrain, nucleus accumbens/subcallosal cortex, or other brain regions were identified. However, because the direct drug effect was a positive signal change in virtually all brain areas, detecting opposite direction effects would necessitate the detection and interpretation of fMRI signal decreases (“negative signal change”). Because of the physiologic basis of the BOLD signal, the meaning of “negative signal change” is an ongoing research challenge for fMRI.* Until this issue is resolved, PET in combination

with a ^{15}O bolus performed during and after cocaine administration offers sufficient temporal resolution (^{15}O has a half-life of 128 seconds) that it can be used to sort out “early/direct” from any “later/opposed” effects of cocaine. Another possible complication in detecting “opposed” drug effects is that opponent processes can be conditioned; during the course of thousands of cocaine administrations, a response may “move back in time” so that it becomes nearly engaged at drug onset and persists. In experienced users (the only subjects who can be given cocaine in human studies), distinguishing “direct” from “opposed” effects could be very difficult. Animal research mapping the temporal correlates of brain response to cocaine and its signals during the course of initial and repeated administrations could clarify these relationships; of course, such experiments cannot ethically be conducted in humans.

The other three neuroimaging experiments involving stimulant administration to cocaine users and measures of craving have been conducted by the Volkow team at Brookhaven Laboratories. In one of these experiments, cocaine was used as the stimulant probe; in the other two, methylphenidate was used. In the cocaine study, cocaine users were given intravenous cocaine in doses of 0.3 to 0.6 mg/kg (a dose range known to induce euphoria), administered together with a tracer dose of ^{11}C-cocaine to measure DAT occupancy (29). Subjective self-ratings were taken every minute for the first 20 minutes post infusion, and then at 10-minute intervals for the next 40 minutes. The ratings of cocaine “high” and “rush” were positively correlated with DAT occupancy, but “craving” (the desire for cocaine, rated on a scale from 1 to 10) and “restlessness” were not. Thus, as in the earlier study of Breiter et al. (64), “craving” did not map onto precisely the same substrate as “rush” and “high.” This variability among studies may be a consequence of differences in the way craving was measured in each study.

The results from studies of methylphenidate administration suggest that a simple DA hypothesis of stimulant effects (including craving) may be insufficient. One study compared the subjective and brain DA response of cocaine users (3 to 6 weeks post cocaine) with that of controls after an injection of methylphenidate, which (like cocaine) blocks DA reuptake (51). An intravenous injection of 0.5 mg of methylphenidate per kilogram was followed by an injection of ^{11}C-raclopride, a dopamine D2 ligand sensitive to competition by endogenous DA. Regions of interest were the striatum, thalamus, and cerebellum (as a comparison region devoid of D2 receptors). Subjective measures were taken 5 minutes before and 27 minutes after methylphenidate. “Craving” in response to methylphenidate was much greater in the cocaine users than the controls and was correlated with an enhanced response (reduced raclopride binding) in the thalamus. “High” did not correlate with either thalamic or striatal raclopride binding, but a possible correlation may have been compromised by taking the subjective measures at 27 minutes, when the high had waned. Interestingly, both the “high” and the DA response to methylphenidate (measured by raclopride binding) in the striatum were greater in the *controls* than in the cocaine users, as though the cocaine users’ response to methylphenidate had been blunted.

In a second study of cocaine users (abstinent on average for 14 days), two sequential doses (0.5 and 0.25 mg/kg) of methylphenidate were administered 90 minutes apart, after which metabolism (measured by PET and ^{18}F-fluorodeoxyglucose), D2-receptor availability (measured by ^{11}C-raclopride), and subjective responses (27 minutes after each infusion) were determined (66). The actions of methylphenidate on brain metabolism showed substantial variability across subjects that correlated with striatal D2-receptor availability; the stimulant increased metabolism in subjects with a high level of D2-receptor availability and reduced it in subjects with a low level of D2-receptor availability. Although methylphenidate induced metabolic increases in several areas (cingulate, thalamus, cerebellum), it increased right orbitofrontal and right striatal metabolism *only* in the subjects who experienced cocaine craving (“desire for cocaine and perception of loss of control over cocaine”). This observation indicates a possible (lateralized) role for these regions in stimulant-induced craving, but it also shows that an increase in DA secondary to reuptake blockade is not in itself sufficient to induce the metabolic increases in the frontal regions. As in the prior study, ratings of “high” at 27 minutes post methylphenidate did not correlate with the effects of the drug on metabolism or D2-receptor availability.

Summary

The only fMRI study performed during cocaine administration showed widespread brain activation, including activation of the classic mesolimbic–mesocortical circuitry often implicated in the reinforcing and motivational effects of cocaine. Although several brain regions were commonly activated by both craving and rush, rush-associated ventral tegmental area/basal forebrain signals rapidly declined while the craving-associated signals in the nucleus accumbens/subcallosal cortex persisted. This partial dissociation suggests at least some independence of substrates for these two states. The early onset of brain activation in cocaine-induced craving is consistent with the priming hypothesis; the partial dissociation with rush/euphoria is not. The lack of apparent “offset” activations correlated with craving is inconsistent with a simple opponent process view, but conditioned opponent effects could occur very early in highly experienced users, so that their origins would be obscured.

Studies that use a priming dose of cocaine necessarily image both the direct effects of the drug on the system being measured (e.g., DA system) and simultaneously any cognitive–affective–craving brain activity related to the cocaine cue. This dual time course of effects may account for some of the variability or inconsistency in effects reported.

With regard to which dopaminergic neuronal elements

are involved in the craving response, the results are mixed. Cocaine-induced craving was unrelated to DAT occupancy. However, methylphenidate-induced cocaine craving was correlated with right striatal and right orbitofrontal increases in metabolism and with an enhanced response (indexed by ^{11}C-raclopride) in the thalamus in comparison with controls. These findings could support a postulated DA dysfunction in the striatal–thalamic–orbitofrontal circuit in cocaine addiction (33 ,67). One similarity between the craving findings in early cocaine cessation (reviewed earlier) and the craving results in stimulant administration is a positive correlation with orbitofrontal activation. As discussed in the final section, the orbitofrontal cortex is thus far the only region linked to craving in all three paradigms: (early) cessation, stimulant administration, and exposure to drug-related cues.

Based on the neuroimaging data during stimulant administration, a role of transmitters other than DA in methylphenidate-induced effects (both high and craving) seems likely. Methylphenidate alone was insufficient to increase frontal metabolism, and in other studies by the Brookhaven team, significant levels of DAT occupancy by intravenous methylphenidate did not always result in a subjective high in healthy controls (craving was not probed) (68). The studies needed to determine whether these variable effects are also likely for cocaine (namely, giving pharmacologic doses of cocaine to healthy controls) cannot be performed; primate studies offer an important alternative.

IMAGING OF CRAVING DURING COCAINE CUES

Part of "110 - Neuroimaging of Cocaine Craving States: Cessation, Stimulant Administration, and Drug Cue Paradigms "

Hypotheses

A guiding hypothesis of much of the research in cue reactivity is that the powerful craving and arousal responses to drug-related cues are based on simple classic conditioning (5 ,6). According to this view, cocaine cues trigger cocaine-related subjective and physiologic responses, including craving, because they reliably predict the arrival of the direct effects of the drug. As both the animal and human literature has shown, however, “simple” classic conditioning is often anything but simple. Drug-related conditioning can result in both responses similar to those produced by the drug itself (“druglike”) and responses *opposite* to those of the drug (“drug-opposite”) (69), likely reflecting a conditioned compensatory response to drug onslaught. Both kinds of responses may be of motivational significance. Druglike responses to cues reminiscent of the drug (“Wow… It’s like I’m feeling it already… and I haven’t even had any yet! I can’t wait!!”) may act as a powerful positive incentive, pulling the user back to the drug. If drug-opposite responses to the cues are uncomfortable (in opiate users, these include tearing, yawning, sweating, and nausea), they may also prompt drug seeking.

Is cue-elicited cocaine craving more “druglike” or “drug-opposite”? Do the multiple cues surrounding the cocaine experience become linked predominantly to the brief, intense, orgasmic euphoria… or to the jittery, sometimes uncomfortable, offset effects of this very short-acting drug? Both links seem possible, but they would yield opposite predictions for neuroimaging and pharmacotherapies. If craving to common external (paraphernalia, other users, drug-buying locations, drug talk) or internal (e.g., drug dreams, recurrent memories of “high”) cues is predominantly druglike, we would expect that some elements of the mesolimbic–mesocortical DA system activated by cocaine itself are also activated during cue-induced craving. In animals, cues for cocaine can indeed trigger mesolimbic DA overflow in nucleus accumbens and amygdala (70) and can activate c-*fos* (an immediate early gene) in the cingulate (71 ,72), amygdala (72), and nucleus accumbens (71). Patients often describe cocaine-like effects in response to cues, including heart pounding, ear ringing, head buzzing, stomach “flipping,” mild euphoria, a “taste” of cocaine in the back of the throat, even the “smell” of cocaine in the room… and, of course, profound desire. But what do the brains of cocaine users say about the nature of cue-induced cocaine craving?

Data

As shown in Table 110.1 , the first neuroimaging study in which drug cues were used to induce craving was presented in 1992 (73 ,74). It tested whether video-induced cocaine craving might increase endogenous DA, as indexed by competition with a D2 ligand, ^{123}I-iodobenzamide, in SPECT. The low signal-to-noise ratio of ^{123}I-iodobenzamide, the low resolution of SPECT, and timing of the cue activation (after uptake of the tracer) likely undermined the ability of this early study to detect increased DA release in response to cocaine cues. After this initial effort, imaging studies addressed the neuroanatomic rather than the neurochemical substrates of cue-induced craving.

Laboratory	Imaging Technology	Cocaine Population	Days of Cessation	Cue Description	Results[a]
U. Pennsylvania					
Childress et al., 1992 (73,74)	SPECT, ^{123}I-IBZM competition	Treatment-seeking (n = 10; 10 controls)	Range, 6–51	15′ personalized audio followed by 10″ video (separate days for drug/nondrug)	^{123}I-IBZM not displaced from striatum

[a]Results legend: +, activated; 0, no difference; —, deactivated; ^, positive correlation with cocaine craving; ^(–), negative correlation with cocaine craving. When controls were studied, the summary reflects significant difference between groups for the drug cue vs. nondrug cue conditions. When no controls were studied, the effects are only for drug cue vs. nondrug cue condition in cocaine users. Because of space constraints, results are summarized and "no difference" regions are presented only as relevant to discussion in the text. Please refer to the original articles for a complete listing of neuroanatomic regions studied.

TABLE 110.1. BRAIN IMAGING OF CUE-INDUCED COCAINE CRAVING

At least six additional laboratories (Childress et al., Volkow et al., Kilts et al., Grant et al., Garavan et al., Wang et al., Maas et al.) have conducted imaging studies with cocaine cues since 1992. These studies cover a range of imaging technologies (PET with ^{15}O bolus, PET with ^{18}F-fluorodeoxyglucose, fMRI) and include several variations on the method of presenting drug cues to induce craving. The variations are useful because results obtained in only one laboratory, or with one method of cue presentation, may be more related to the specifics of the laboratory or stimuli than to the psychological state of interest (cueinduced cocaine craving). Conversely, any replication and convergence of findings across multiple laboratories and methods are very encouraging.
A survey of the data in Table 110.1 reveals several convergent findings and suggests that brain activation in response

to cocaine cues often occurs in a particular subset of regions activated by cocaine itself (summarized above). Because of the number of studies, the findings reviewed below are organized according to the anatomic structures that have frequently been activated during cue-induced craving.

Limbic-Related Structures

Several of the structures activated during cue-induced craving are parts of an interconnected rostral limbic system, important in motivation and affective experience. Devinsky et al. (75) describe the rostral limbic system as including "the *amygdala* and septum, and *orbitofrontal*, anterior *insula*, and *anterior cingulate* cortices, the ventral striatum including the *nucleus accumbens*, and several brainstem motor nuclei including the periaqueductal gray." We also include findings for the hippocampus, part of the caudal limbic system in Devinsky's organizational scheme. Several of these limbic structures (e.g., amygdala, anterior cingulate and orbitofrontal cortex) comprise subdivisions of functional significance, but most *in vivo* neuroimaging studies refer to the structures in their entirety because of limited spatial resolution.

Amygdala

The amygdala, located in the medial aspect of the temporal lobe, is interconnected with the other rostral limbic regions and with the hippocampus. The amygdala is critical in signal learning for biologically significant (pleasant or unpleasant) events (76 ,77) and has been activated by cue-induced craving in virtually all the studies able to visualize it. In the first PET study of craving, predicted increases in amygdala rCBF (measured with ^{15}O-water as the perfusion tracer) were found in cocaine patients viewing videos that induced craving (averaging 4.5 on a scale of 0 to 9 for "craving or desire for cocaine") (47 ,78 ,79) versus nature videos. This effect was not evident in controls without a cocaine history. Interestingly, baseline rCBF in the amygdala of cocaine users tended to be lower than in controls, such that increased rCBF in response to the cocaine cues did not exceed the amygdala rCBF in control subjects under the same conditions. Activation of the amygdala in this study was initially documented by a region-of-interest (ROI) analysis and has recently been confirmed by statistical parametric mapping (SPM) of the group data (Fig. 110.1 , *top image*). The amygdala activation to cocaine video cues documented with fMRI (Fig. 110.2) has recently been replicated in an ongoing study (Listerud et al., *unpublished data*). In other PET studies, Schweitzer et al. (81) and Kilts et al. (82) found amygdala activation during memory of cocaine-induced craving ("How strong was the urge to use cocaine, on a scale of 0 to 10?") induced by guided drug imagery, and Grant et al. (83) found a positive correlation of medial temporal lobe activation with video- and paraphernalia-induced craving ("… craving or urge to use cocaine, on a scale of 0 to 10"). A recent fMRI study by Garavan et al. (84) found differential activation of the temporal pole, a region surrounding the ventral amygdala, in response to cocaine versus nature video. The PET camera used in the recent ^{18}F-fluorodeoxyglucose study by Wang et al. (85) did not

permit adequate resolution of the amygdala, and susceptibility artifact in the region of the amygdala prevented reliable imaging in an earlier fMRI study by Maas et al. (86).

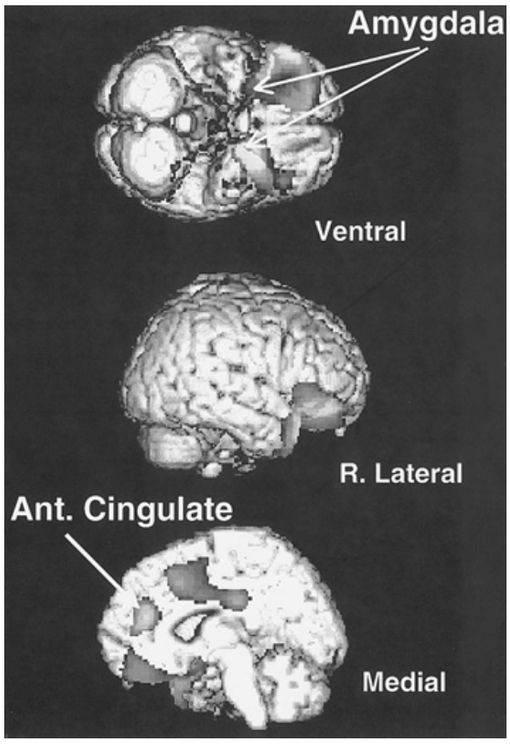

FIGURE 110.1. Amygdala and anterior cingulate activations during craving triggered by cocaine cues. Statistical parametric map (SPM 96) shows differential activation of brain regions by a cocaine video and a nondrug (nature) video; p <.05, corrected. See color version of figure.

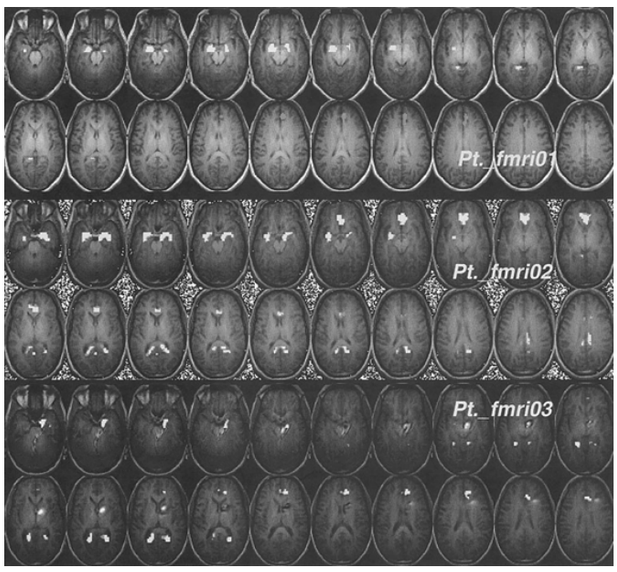

FIGURE 110.2. Functional magnetic resonance imaging of cocaine versus nature video. Individual difference maps show amygdala and anterior cingulate activation in three pilot cocaine patients. See color version of figure.

Anterior Cingulate

The anterior cingulate is located in the dorsomedial prefrontal cortex and is interconnected with other rostral limbic structures, including the amygdala and nucleus accumbens. Multiple roles of the anterior cingulate include selective attention and emotional reactivity to significant stimuli (75 ,87). In parallel with the amygdala findings, the anterior cingulate was differentially activated during video-induced cocaine craving in our initial PET study with ^{15}O bolus (by ROI analysis and later confirmation by SPM analysis of the group data) (Fig. 110.1 , *bottom image*). As with the amygdala effect, the cue-induced rCBF increase in anterior cingulate was from a resting baseline that was hypoactive relative to the baseline of controls. Unpublished fMRI data (Listerud et al.) support the anterior cingulate activation in response to cocaine versus nature cues. Studies by Maas et al. (86), Kilts et al. (82), and Garavan et al. (84) have confirmed anterior cingulate activation during cocaine cues. These studies used fMRI (84 ,86) and PET with ^{15}O bolus (82), imaging techniques that provide good temporal resolution. Studies by Grant et al. (83) and Wang et al. (85) did not detect increased anterior cingulate activation during cocaine cues. They both used PET with ^{18}F-fluorodeoxyglucose; because of its low temporal resolution, this technique may be insensitive to a relatively brief or nonhomogeneous activation of the anterior cingulate.

Nucleus Accumbens/Subcallosal Cortex; Striatum

The nucleus accumbens is located in the forebrain, in the ventral part of the striatum. It is a prominent terminal region for DA cells projecting from the ventral tegmental area, and much animal research points to this mesolimbic–nucleus accumbens pathway as a critical substrate for the reinforcing effects of natural rewards (88), cocaine, and other drugs of abuse (89). In humans, the size of the nucleus accumbens is about 5 mm. Thus, the nucleus accumbens falls at (or often below) the threshold of reliable detection for many early PET cameras, but it often can be localized with the precise anatomic co-registration of fMRI. The 1997 fMRI study of cocaine administration by Breiter et al. (64) contained an "unintentional" cue paradigm (Table 110.1). Subjects given a (double-blinded) infusion of saline solution in the fMRI magnet showed clear activation of the nucleus accumbens if they had previously received an infusion of cocaine in this novel environment. The nucleus accumbens signal to the infusion environment had the same "early-onset, sustained" pattern as the signals to actual cocaine administration. This striking finding suggests that a druglike response to cocaine cues can be established with a single trial.

Other striatal findings in cue paradigms are mixed. In the study performed with PET and ^{15}O bolus, the overall response of the basal ganglia to cocaine versus nature videos was an unpredicted *decrease* in rCBF, but the larger dorsal striatum (which receives primary projections from the substantia nigra) was not parsed from the smaller ventral (nucleus accumbens) portion, which receives projections from the ventral tegmental area (47 ,78 ,79). Garavan et al. (84) found activation of the dorsal striatum (caudate) with fMRI, but did not report on nucleus accumbens. Kilts et al. (82) found nucleus accumbens activation in response to guided cocaine imagery, but the activation was inversely correlated with craving self-reports.

Orbitofrontal Cortex

The orbitofrontal cortex is located in the ventromedial region of the frontal lobes. The orbitofrontal cortex is richly interconnected with DA-related regions involved in reward and stimulus–reward learning (90). Three studies (64 ,83 ,85) found orbitofrontal cortex activation in response to cues; two did not (47 ,82). The remaining two studies, in which fMRI was used, did not report on the orbitofrontal cortex response (84 ,86) (ventral orbital regions are often difficult to image with fMRI because of artifact introduced by air in the sinus cavities). In the three studies finding an orbitofrontal cortex response to cues, the subjects were in early cessation (ranging from 18 hours to 7 days); in the two studies finding no orbitofrontal cortex activation to cues, the patients had been abstinent for longer periods. In the earlier "cessation" section of this chapter, we mentioned that the literature suggests that orbitofrontal cortex hyperactivity in early cocaine cessation is correlated with selfreported craving, whereas (later) orbitofrontal cortex hypoactivity is unrelated to craving. One interpretation that integrates the earlier observations with those in the explicit cue paradigms is that orbitofrontal cortex hyperactivity is associated with enhanced responsivity to cues, whether naturally occurring or presented by a laboratory experiment. Orbitofrontal cortex hypoactivity, on the other hand, clearly does not prevent cue-induced craving and may represent a different vulnerability (see summary below).

Insula

The insular cortex is located interior to the lateral sulcus. It is interconnected with several other regions activated by cocaine cues, including the amygdala and the cingulate and orbitofrontal cortex; it also reflects input from the viscera (autonomic nervous system) and sensory systems. Three laboratories have reported activation of the insula in response to cocaine-related cues, but the effects vary. Wang et al. (85) reported activation of the left insula but found a correlation of craving only with the right insula. Breiter et al. (64) reported activation of the right insula in response to the cocaine infusion environment; no correlation with craving was reported for the small subgroup in this experimental condition. Kilts et al. (82) reported activation of the left insula (in response to guided imagery), but a negative correlation with craving. Given the disparate findings, additional studies will be needed to sort out the nature and direction of cue effects in the insula.

Hippocampus

The hippocampus is located in the medial temporal lobe, posterior to the amygdala. It was not differentially activated by the cocaine videos in our PET study with ^{15}O bolus, and activation has not been reported by the other investigations. This suggests that cue paradigms generally do not make demands on explicit, declarative memory and factual recall, functions closely associated with the hippocampus (91). This is in contrast to the common finding of amygdala activation across several cue studies. Although proximal to the hippocampus and interconnected to it, the amygdala is not activated by explicit memory demands; rather, it supports functions of implicit, emotional memory (92).

Other Structures

Dorsolateral Prefrontal Cortex

The dorsolateral prefrontal cortex, best known for its role in working memory, was not differentially activated by the uninterrupted, narrative cocaine videos in our PET study (47), although craving was robust. Similarly, it was not activated by the paradigm of Kilts et al. (82) with guided imagery, by that of Wang et al. (85) with cocaine theme interviews, or by that of Garavan et al. (84) with an uninterrupted, unrepeated 4-minute video clip.

The paradigm of Maas et al. (86) did activate the dorsolateral

prefrontal cortex; it featured brief alternating exposures to a nondrug and a cocaine video, modified from the tapes of Childress et al. (the faces were blurred to protect the patients' identities). These alternating conditions may have engaged working memory in the cocaine subjects because the same cocaine users reappeared in an ongoing drug scenario that was interrupted by the nondrug video segments. Controls are generally less engaged by cocaine stimuli and therefore would also be expected to show less engagement of working memory. A similar explanation may account for activation of the dorsolateral prefrontal cortex in the paradigm of Grant et al. (83), which featured several repetitions of the same brief cocaine video clip during the period of ^{18}F-fluorodeoxyglucose uptake. In an ongoing fMRI study (Listerud et al., *unpublished data*), activations by uninterrupted versus alternating cocaine videos are being compared within the same cocaine patients. This study will directly test the hypothesis that dorsolateral prefrontal cortex activation in cocaine users is related to the mode of stimulus presentation rather than to cue-induced craving *per se*.

Cerebellum

The cerebellum, important in motor coordination and retention of simple motor schemas, was not activated in our PET study with ^{15}O bolus in which videos were used to induce craving for cocaine (47). Similarly, it was not activated by the cues of Maas et al. (86), Kilts et al. (82), or Garavan et al. (84). The cerebellum was differentially activated in the study of Wang et al. (85), which featured a cocaine theme interview and handling of paraphernalia during the period of ^{18}F-fluorodeoxyglucose uptake. The (highly ritualized and overlearned) handling of cocaine paraphernalia may have triggered motor memories and schemas, a cerebellar function. In support of this notion, the study of Grant et al. (83) also featured handling of paraphernalia as part of the stimulus complex during the period of ^{18}F-fluorodeoxyglucose uptake, and a correlation was found between craving and cerebellar activation. This correlation would occur if handling of paraphernalia acted both as a potent conditioned cue for drug craving and as a trigger for motor memories/highly practiced motor schemas related to cocaine preparation.

Sensory/Association Cortex

In addition to the regions discussed, one imaging study has shown differential activation of visual association areas (peristriate) by cocaine cues (83), and two studies have shown differential activation of the inferior parietal lobe (83 ,84), which is sometimes implicated in working memory. As additional neuroimaging studies accrue, it will be easier to determine whether less common activations such as these reflect a feature of the paradigms used or a feature of the target state.

Summary

The involvement of seven laboratories in neuroimaging cue-induced craving has generated a useful database for drawing preliminary conclusions about the substrates of the state and, importantly, for generating new hypotheses that will help to refine the emerging picture. Despite the variability in imaging techniques, analysis techniques, the abstinence/treatment status of the subjects, and the varied methods used to induce cocaine desire, several convergent findings for regions of activation have been obtained. The most commonly activated regions during cocaine cues, across the laboratories, were the amygdala and anterior cingulate. Two studies that parsed the ventral (nucleus accumbens) from the dorsal striatum showed activation by cocaine cues in the ventral region; the fMRI signal from the nucleus accumbens for a "cocaine-associated environment" (the fMRI magnet!) was strikingly similar to that for cocaine itself. The insula has been activated in at least three cue studies, although the correlations with craving vary in direction. The orbitofrontal cortex was also activated by cues in the (three) studies of cocaine subjects in recent cessation.

The hippocampus was not regularly activated by cocaine cues, which suggests that the cue-induced state does not depend on declarative memory/factual recall. The dorsolateral prefrontal cortex was not activated in most of the cue studies but was activated by cocaine cues that were intermittent or repeated; this activation may be relatively independent of any direct connection to cue-induced craving. The cerebellum was not activated in most cue studies, although it was activated in two paradigms in which paraphernalia handling could have triggered motor memory schemas.

The brain regions activated by cocaine cue paradigms (amygdala, anterior cingulate, nucleus accumbens, insula) do substantially overlap those activated by cocaine itself in the fMRI study of Breiter et al. (64). This is consistent with the druglike phenomena (autonomic arousal, mild euphoria, sense of a cocaine "taste" or "smell") that often accompany cue-induced craving. Most cue paradigms, even those in which fMRI is used, have not yet described the temporal pattern of the signals from these regions during cues; such information would permit a more detailed comparison of cue effects with the multiple effects of cocaine (e.g., "craving" vs. "rush" substrates). No studies have yet examined the ventral tegmental area or basal forebrain in response to cues.

The orbitofrontal cortex deserves special mention in the discussion of craving and drug motivation. Orbitofrontal dysfunction in other disorders has been associated with difficulties in modulating rewarded or punished behavior (e.g., reversing or switching behavior in response to a change in contingencies) (93), impaired somatic/emotional response in anticipation of the consequences of a decision ("future insensitivity") (94), and perseverative, compulsive behaviors (67). Clinically, some of these same difficulties have been

noted in substance abusers, which raises the possibility of a core deficit in some patients (95). Long-term users of amphetamine are impaired on a decision-making task that places demands on ventromedial prefrontal (orbital) function (96), and long-term administration of stimulants clearly erodes orbitostriatal inhibitory function in primates (93). Whether such orbitofrontal cortex deficits predate drug use in humans, predispose to it, or are a consequence of it, the news for long-term cocaine users is not good; they may be at a particular disadvantage in managing their craving for the drug. Interestingly, the reviewed studies link increases in orbitofrontal cortex activity to craving in all three paradigms: (early) cessation, stimulant administration, and response to cues (during early cessation from cocaine). A future challenge is to understand how such activations in a potentially dysfunctional orbitofrontal cortex differ (or not) from normal activation of the orbitofrontal cortex during advantageous decision making (97).

DISCUSSION

Part of "110 - Neuroimaging of Cocaine Craving States: Cessation, Stimulant Administration, and Drug Cue Paradigms "

Theoretic Implications

The neuroimaging of craving states is at a very early stage, and most findings should be replicated before they are taken as either a confirmation or a challenge to theories of addiction and drug motivation. With this caveat kept in mind, some findings from the paradigms reviewed may have implications for current theories.

From the *cessation* paradigms, the preliminary imaging data provide little support for the proposition that craving (drug desire) during cessation arises primarily from a state of prolonged DA depletion or deficiency. Although the DA systems of cocaine patients do differ from those of controls, craving did not show a good relationship to these changes beyond the first week of cessation.

The *drug administration* paradigms show that DA-related regions are activated during stimulant-induced craving, but the temporal pattern of activation fits neither a simple priming (“substrates for craving are the same as the substrates for high”) nor a simple opponent process (“substrates for craving are the opposite of the substrates for high”) view. Studies of craving during methylphenidate administration indicate the possible contribution of non-DA (in addition to DA) systems.

The *cue* paradigms suggest that the regions activated during cue-induced craving often overlap the regions activated by cocaine itself (i.e., the substrate is substantially “druglike”). Of course, these early findings do not preclude “drug-opposite” brain responses or conditioning in response to cocaine cues. The cue data simply suggest that across several laboratory environments (as in patients’ descriptions from the natural environment), cocaine craving with a “druglike” substrate is likely to be evoked.

Interestingly, the current neuroimaging paradigms offer little support for the notion of a “sensitized” substrate, sometimes proposed as a potential mechanism for stimulant drug craving/incentive motivation. Beyond the first week of cessation, cocaine patients often exhibit resting hypoactivity in limbic and frontal regions in comparison with controls. Exposure to cocaine cues or to a stimulant can produce a significant activation in these affected brain regions, but the absolute level of brain response is often no greater than in controls, and may even be less. Of course, the appropriate test for sensitization would require comparing the current responses of cocaine patients with their own initial responses to the drug. This design is unfortunately not feasible. It does, however, highlight a limitation of all our neuroimaging studies in cocaine patients; we usually do not know their baseline before addiction on the brain variables of interest. The discovery of Volkow et al. (50) of striking baseline differences in the availability of D2 receptors in controls (based on liking vs. not liking an initial dose of methylphenidate) is fair warning that the brains of cocaine users who proceed to addiction may differ from those of (some) controls, even before cocaine use begins.

Treatment Implications

Imaging data from the stimulant administration and cue paradigms suggest that craving is often associated with relative increases in the activity of the same brain DA systems that may otherwise be hypoactive in cocaine users. Finding an “anticraving” agent that can modulate the periodic increases in DA in response to cues or drug primes, without worsening symptoms that may be related to chronic hypoactivity (e.g., depressed mood, low levels of energy), poses a particular challenge. Classic DA antagonists (typified by the older antipsychotics) are poor candidates for this modulatory role because they could worsen symptoms related to low levels of DA; they also carry a significant risk for extrapyramidal side effects and tardive dyskinesia.

Partial DA agonists may offer an appealing solution in the future (2 ,98 ,99). These compounds act as agonists under conditions of low DA tone (as may occur in cessation), but as antagonists when the DA concentration increases (as in response to cues or drug primes). The “chameleon-like” nature of partial agonists may possibly offer the cocaine patient a moment-to-moment regulation of the DA system. Unfortunately, for now, no partial agonists (D1, D2, or D3) are approved for humans, although considerable animal research has been done and preliminary safety trials are under way.

Another promising category of DA modulators are the γ-aminobutyric acid type B ($GABA_B$) agonists (100 ,101 ,102 and 103). These compounds may gently modulate the DA system by reducing ventral tegmental area cell firing, thereby reducing DA release in terminal regions. Roberts and colleagues (100 ,101) were the first to demonstrate the blunting of cocaine motivation by the $GABA_B$ agonist baclofen (Fig. 110.3). In

subsequent cocaine-related studies by Dewey et al. (104), the GABA transaminase inhibitor γ-vinyl-GABA also showed promise; its cocaine-related effects are reversible by a $GABA_B$ antagonist. Unpublished preliminary data from Childress et al., testing the ability of baclofen to blunt both subjective and brain responses to cocaine cues by measuring rCBF with PET and ^{15}O bolus, suggest that baclofen, although it has a relatively short half-life, may indeed confer protection against cue-induced craving and the accompanying limbic activation. These data are important because the craving/imaging paradigm is being used to test an "anticraving" medication.

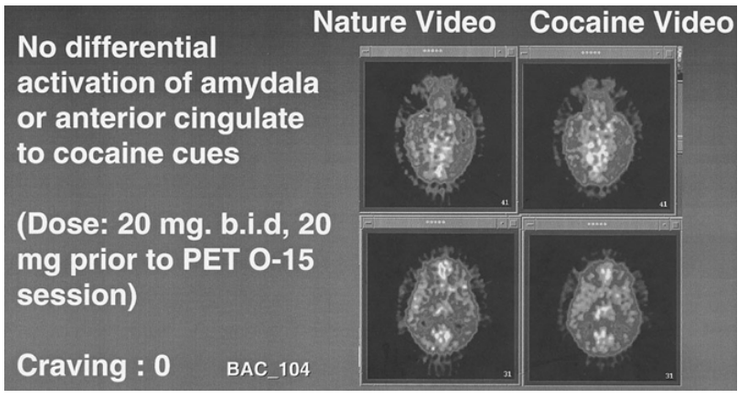

FIGURE 110.3. Baclofen, a γ-aminobutyric acid type B agonist, may blunt limbic activation and craving in response to cocaine cues. See color version of figure.

Future Directions

The neuroimaging studies of cocaine craving reviewed in this chapter will soon be viewed as the "early" stage of our understanding; the imaging field is growing rapidly, as is the sophistication of the tools and their users. Advances in spatial and temporal resolution of imaging devices, and advances in image analysis, will allow the formulation of more precise hypotheses regarding craving substrates. As shown in this review, the future answers are likely to be found within temporal as well as regional patterns of activation. Although DA has played a strong role in shaping the early neurochemical hypotheses, interacting neurotransmitters and neuromodulators will soon be tested as the critical ligands become available. Until then, the combination of pharmacologic probes with neuroanatomic imaging may offer a powerful alternative.

Designs of increased rigor, with attention given to homogeneity of samples (e.g., number of days of cessation, nicotine status, treatment status, urine toxicology status, genetic status, drug use history) and careful characterization of controls, will enhance the replicability of findings across laboratories. Asking for more than one subjective response or "craving item," and asking for these at the optimal time for the paradigm, will ensure a clear test of the relationship between brain activity and subjective state. Characterizing brain activity during other, nondrug states of arousal (e.g., anger, anxiety) will help to determine the specificity of the signature of the brain for cue-induced craving. This is important because the brain structures activated in cueinduced cocaine craving are not "reserved" for this state; rather, they participate in many other states that are not related to cocaine. In this regard, measurement of the brain response during other, nondrug appetitive states (e.g., sexual desire) in subjects who do not use drugs may provide a "positive control" for cocaine craving, which is so often described in sexual terms. Imaging of the craving states for heroin, nicotine, and other drugs of abuse will also provide informative comparisons; these studies have already begun (105).

Although the path ahead is clearly challenging, finding the brain substrates of desire, both for drugs of abuse and for natural rewards, is now a matter of time and effort; the tools are increasingly available. Only a decade ago, and for all of prior human history, brain activity during subjective states was largely a matter of inference. Now, and in the future, these states can be the subject of direct measure. This represents a dramatic paradigm shift, one that enables states such as "desire" and "craving" to be the subject of rigorous scientific research. This research is a critical prerequisite to the rational, and vastly improved, treatment of disorders of desire (i.e., the addictions).

ACKNOWLEDGMENTS

Part of "110 - Neuroimaging of Cocaine Craving States: Cessation, Stimulant Administration, and Drug Cue Paradigms "

We thank V. Mikhalovsky, A. Meyer, and G. Robinson for cyclotron operations and preparation of ^{15}O; S. Riggins, K. Kilroy, D. Dines-Meehan, and C. Herman for PET operations;

W. McElgin for physics consultation; J. Fitzgerald, S. McDonald, J. D. Gray, and A. Fornash for research assistance; and M. Bromwell for editing. This research was supported by research grants NIDA RO1 10241 to Dr. Childress and Core of NIDA P-60 Center to Dr. O'Brien, and by the Medical Research Division of the Philadelphia Department of Veterans Affairs Medical Center.

* fMRI is extremely vulnerable to movement artifact. Signals from the amygdala and other structures near the base of the brain can be affected by the slight movement, at each heartbeat, of blood entering the brain through large vessels, and unreliable or uninterpretable data can result. Cardiac gating of the fMRI signal allows the fMRI scanner to be controlled by the heartbeat, and images are collected in the intervals between beats. Under these controlled conditions, the direction of change in the amygdala was positive for all subjects (H. C. Breiter, *personal communication*).

Section XI
Impulsive and Compulsive Disorders

Eric Hollander

Impulsive and Compulsive Disorders - Introduction

The current edition of *Psychopharmacology: the Fifth Generation of Progress* is unique in including a section on impulsive and compulsive disorders. This is genuinely a novel approach to the characterization of a complex, evolving, and rich area of psychopathology and suggests that compulsive and impulsive phenomena may be alternative phenotypic expressions of similar underlying mechanisms. The section focuses on core symptom domains that cut across impulsive and compulsive disorders and links these clinical phenomena to their fundamental neurobiology, as manifested by genetic factors, neurotransmitter/peptide functioning, and neurocircuitry. This approach is of particular clinical interest in leading the clinician to targeted psychopharmacologic approaches to the core symptom domains. In addition, it has important implications for future categoric classification systems such as the Diagnostic and Statistical Manual and the International Classification of Diseases, which eventually must integrate rapidly emerging genotype and neurocircuitry findings with the core phenomenology of impulsive and compulsive disorders.

Rasmussen and Eisen emphasize how the identification of more homogeneous subtypes via factor-analytic, tic-related, or immune phenomena may have important implications for understanding the course of illness and behavioral phenotype. Pauls and colleagues describe how studying genetic marker (and gene product) data together with data characterizing phenotypic expression in the context of specific environments should allow a more complete examination of the simultaneous contribution of genetic and nongenetic factors in obsessive-compulsive disorder. Rosenberg and MacMillan describe how sophisticated brain imaging studies of obsessive-compulsive disorder may help to delineate specific endophenotypes, discriminate between sporadic and familial forms (reducing genetic heterogeneity), and facilitate an understanding of the developmental neurobiologic underpinnings of obsessive-compulsive disorder. Hollander and Pallanti describe the role of targeted pharmacotherapy and other experimental and somatic treatments in modulating the intensity and frequency of repetitive thoughts and behaviors in obsessive-compulsive disorder. Future approaches will need to integrate our understanding of genotype, neurocircuitry, and subtypes and alternative expressions of the behavioral phenotype into experimental therapeutic strategies for obsessive-compulsive disorder.

Smith and Geary describe how greater attention to the microstructure of the behavior of eating has led to advances in the behavioral neuroscience of the controls of eating. Kaye and Walsh describe psychopharmacologic approaches to the clinical eating disorders and their impact on aberrant feeding behaviors and perception of body image. Swerdlow and Leckman describe efforts to link the clinical phenotype of Tourette syndrome to advances in neuropathology, neuroimaging, genetic linkage, and informative animal models, and the use of endophenotypes for a full understanding of the functional relevance of genes for Tourette syndrome.

Olivier and Young describe how new developments in molecular biology, used to generate inducible and brain region-specific mutants, have provided novel tools with which to study the role of genes, the environment, and their interaction in the causation of aggression, and the neural substrates that mediate this behavior. Coccaro and Siever describe how a better understanding of the role of serotonin and other neuromodulators

in the regulation of aggression has led to a more rational approach to the psychopharmacology of impulsive aggression in humans. Potenza and Hollander describe the neurobiology and treatment of the impulse control disorders and pathologic gambling, disorders linked by a failure to resist urges to engage in pleasurable but ultimately self-destructive behaviors. Stein and colleagues explore a broad range of self-injurious behaviors, ranging from anxiety-reducing compulsive to pleasurable impulsive variants. They draw parallels with animal stereotypies and propose neuropsychopharmacologic approaches derived from an understanding of the neural contributions to these behaviors.

The Course and Clinical Features of Obsessive-Compulsive Disorder

Steven A. Rasmussen

Jane L. Eisen

Steven A. Rasmussen: Brown University, Butler Hospital, Providence, Rhode Island.

Jane L. Eisen: Department of Psychiatry and Human Behavior, Brown Medical School, Providence, Rhode Island.

Twenty years have passed since the landmark National Epidemiology Catchment Area Survey first demonstrated the prevalence of obsessive-compulsive disorder (OCD) in the general population to be 50 to 100 times greater than had been previously believed (1). This unexpected finding was instrumental in the renewed interest in and rapid growth of our understanding of the clinical features, pathophysiology, and treatment of OCD. Epidemiologic studies in different cultures have confirmed the findings that up to 1% to 2% of the general population worldwide suffer from the disorder at any given time (2). Widespread attention in the media, in addition to growing recognition of the disorder among health care professionals, has resulted in improvements in the diagnosis and treatment of large numbers of patients with OCD who would not even have presented for treatment before 1980.

Knowledge of the clinical features of the disorder has also expanded significantly in the last 10 years. Treatment centers specializing in OCD have succeeded in enrolling large cohorts of patients, so that a more sophisticated analysis of the heterogeneity and comorbidity of OCD and the relationship of these variables to treatment outcome has been possible. Prospective observational studies of the longitudinal course of OCD have contributed further insights into the clinical characteristics and prognosis of the illness (3). Improvements in methodology, including the development of structured interviews with proven reliability and validity, the application of survival analysis and other statistical techniques to assess longitudinal variables, and more sophisticated database management systems, have been instrumental in these advances.

Epidemiologic studies have consistently shown that 2% to 3% of the general population in the United States meet lifetime DSM criteria for OCD (4). In a World Health Organization study that determined the leading causes of mortality and morbidity in developed countries, OCD was found to be the eighth leading cause of disability for any medical or psychiatric condition for ages 15 through 44 (5). Total costs of the disorder in the United States have been estimated at $8 billion in 1990, including $2.1 billion in direct costs and $5.9 billion in indirect costs related to lost productivity (6).

However, despite the increased recognition of the public health significance of OCD during the last decade, surprisingly little is known about the long-term course and prognosis of the disorder. Most studies conducted thus far suggest that OCD is chronic and lifelong. For several reasons, however, questions have been raised about the validity of these findings. Previous studies have been hampered by a number of methodologic limitations, including a lack of standardized assessments, small numbers of subjects, and a sample bias toward more severely ill patients. The introduction of effective treatments for OCD in the last 10 years also raises the question of the relevance of course studies conducted in a pretreatment era.

Obsessive-compulsive disorder spans the life cycle. It has been described in children as young as age 2 (7) and also in the very elderly (8). Evidence supports the hypothesis that OCD is a heterogeneous disorder with multiple causes (9). Neurobiologic studies have demonstrated abnormalities in frontostriatal–basal ganglia circuitry (10). Like any organ system, these neural circuits are susceptible to a variety of pathologic processes, including those associated with autoimmune, infectious, developmental/genetic, and aging processes. Identifying homogeneous subgroups of patients with OCD should help in unraveling its neurobiologic pathogenesis and developing more specific and effective treatment strategies.

This chapter reviews data related to the clinical features

and course of OCD during the lifespan. It focuses on the heterogeneity and comorbidity of the disorder in relation to its course, and points to a new wave of studies that should complement neurobiologic and genetic studies of the pathogenesis of OCD, lead to fuller recognition of its impact on society, and help to measure the effectiveness of behavioral and pharmacologic treatment strategies that have been developed during the past two decades.

SUBTHRESHOLD SYMPTOMS

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

It is generally agreed that it is the frequency of obsessions and compulsions, in addition to the degree with which they interfere with function, that distinguishes normal from abnormal. A patient must have had an hour of obsessive-compulsive symptoms daily for a period of 6 months that interfere with social or occupational function to meet DSM-IV criteria for the disorder (11). This requirement has traditionally been thought to translate to a score of 16 or higher on the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS). Like symptoms of anxiety, obsessive-compulsive symptoms are present to some degree in most people. Rachman and Hodgson (12) found that a high percentage of the normal population report some obsessions and compulsions. Similarly, after screening 861 Israeli military recruits at 16 years of age, Apter et al. (13) concluded that obsessive-compulsive phenomena appear on a continuum, with few symptoms and minimal severity at one end and many symptoms and severe impairment on the other. The receiver operating characteristics that would best distinguish the clinical from the subthreshold syndrome of OCD have yet to be delineated. Using Angst's longitudinal follow-up sample, Degonda et al. (14) found a weighted lifetime prevalence for subthreshold obsessive-compulsive symptoms at age 30 of 5.5%. Goodman (15) screened 958 college students and identified 23 subjects with subclinical OCD. At follow-up 1 year later, 87% continued to have significant symptoms. It has been recognized for many years that most normal children go through developmental stages characterized by obsessive-compulsive or superstitious behavior (16). Determining where the clinical syndrome begins and ends is important for pharmacologic and genetic studies. For example, the multicenter collaborative studies of the selective serotonin reuptake inhibitors (SSRIs) in OCD noted a higher rate of response to placebo in patients with Y-BOCS scores between 16 and 20, a finding that prompting some investigators to suggest that patients with Y-BOCS scores below 20 be excluded from controlled trials (17). Family genetic studies have shown a higher risk for both subthreshold and clinical OCD in OCD probands (18).

Most adult patients who meet DSM criteria for OCD remember subthreshold symptoms in childhood. The clinical significance of subthreshold symptoms in childhood continues to be poorly understood. The risk carried by children of parents with OCD for subsequent development of the disorder is poorly defined. No data are available that would make it possible to predict this transition. Similarly, almost no data are available relating the effect of continuing subthreshold symptoms during a period of remission to the likelihood of relapse in adults. Prospective quantitative longitudinal assessment of probands with subthreshold symptoms is needed in child and adult populations.

DEVELOPMENTAL PSYCHOPATHOLOGY

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

Little systematic study of the developmental antecedents of OCD has been carried out since Janet. In his *Obsessions and Psychasthenia*, Janet (19) postulated that obsessions and compulsions are the most severe stage of an underlying prodromal state that he called *psychasthenia*, a syndrome characterized by feelings of incompleteness and imperfection. He hypothesized that all patients in whom obsessions and compulsions develop pass through a prodromal stage of psychasthenia. His clinical descriptions of the temperamental features of psychasthenics coincide remarkably well with our preliminary findings of the prodromal symptoms of patients with OCD. His description of the patient who "finds on the stairway the word that needed to be said in the parlor" is an astute clinical description and close analogue of the independent variable chosen by Kagan et al. (20) to measure behavioral inhibition (i.e., speech latency in a novel social situation). It is worth noting that Janet included three of the five elements of DSM-III compulsive personality disorder in his description of the psychasthenic state: perfectionism, restricted emotional expression, and indecisiveness. Previous studies have shown that a considerable portion if not the majority of patients with OCD do not meet the DSM-III-R criteria for compulsive personality disorder. The European diagnostic schema for anacastic personality is more directly related to Janet's original definition of psychasthenia and is consistent with the idea of an obsessive spectrum that ranges from normal obsessional behavior through obsessional personality to OCD.

A retrospective study of 90 of our OC probands in which a semistructured format was used was designed to elicit prodromal personality traits or temperamental factors commonly found in OCD (22). During this study, we identified 10 factors commonly found in our adult OC probands as children (Table 111.1). These traits tended to vary minimally during the childhood and adolescent years.

Separation anxiety
Resistance to change or novelty
Risk aversion
Submissiveness (compliance)
Sensitivity
Anacastic
Perfectionism
Hypermorality
Ambivalence
Excess devotion to work

TABLE 111.1. BEHAVIORAL INHIBITION

The developmental antecedents of OCD overlap significantly with the behavioral inhibition syndrome in children that Kagan et al. (20) described. Four of the developmental traits appear to be shared by patients with OCD and those with other major anxiety disorders: separation anxiety, resistance to change or novelty, risk aversion, and submissiveness. Four of the traits are more specific to OCD: perfectionism, ambivalence, excess devotion to work, and

excessive morality. The overlap of the developmental antecedents of panic disorder, social phobia, and OCD is consistent with Janet's original conception of the psychasthenic syndrome and adds credibility to the hypothesis that an element of genetic vulnerability is shared among the anxiety disorders. The relationship of adult personality characteristics and clinical subtypes to developmental antecedents awaits further analysis. It appears that some traits are more commonly seen in particular phenomenologic presentations (e.g., incompleteness in perfectionism and the need for symmetry and precision; abnormal risk assessment in high levels of anxiety). It is probable that temperamental factors such as behavioral inhibition increase the risk for the development of a number of psychiatric syndromes. It would be informative to determine the relative risk for development of each of the major anxiety syndromes by following a group of children with behavioral inhibition longitudinally. The environmental and genetic factors that predispose a given individual to the development of a specific anxiety disorder are unknown. It is also worth noting that a significant minority of patients with OCD do not manifest risk-aversive tendencies as children. Further prospective study of the developmental antecedents of OCD and prospective longitudinal evaluation of children at risk should be an important area for future research.

AGE AT ONSET

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

In most studies of the course of illness, *age at onset* refers to the time that symptoms become severe enough that they meet full DSM criteria for the disorder. The reliability of retrospective recall is an inescapable problem. It is safe to assume that reliability decreases as the years between ascertainment and onset increase. In the Brown cohort drawn from an adult OCD clinic, the mean age at onset of significant OCD symptoms was 20.9 ± 9.6 years, with males having a significantly earlier onset of illness, 19.5 ± 9.2 years, than females, 22.0 ± 9.8 years (p <.003) (212). The illness developed before the age of 25 years in 65% of cases, sometimes as early as 2 years. It developed after age 35 in fewer than 15% of obsessional patients (Fig. 111.1). A significant increase in incidence appeared at puberty. Most adult patients remembered having minor obsessive-compulsive symptoms that did not significantly interfere with their ability to function and that did not cause significant distress before the onset of symptoms meeting DSM-III-R criteria for the disorder. Although male patients noticed minor symptoms earlier than female patients, the difference did not reach statistical significance. Most of the patients described a gradual or insidious onset of illness. Emerging data suggest that a considerable percentage of patients with an early, prepubertal onset have an acute attack followed by an episodic course (22). These patients frequently suffer at the same time from multiple tics and other movement disorders, including choreiform movements and behavioral dysregulation. Swedo et al. (23) systematically characterized 50 children with this cluster of symptoms, which they call *pediatric autoimmune neuropsychiatric disorder* (PANDAS). A diagnosis of PANDAS is made if the following criteria are met: (a) the presence of OCD, a tic disorder, or both; (b) prepubertal onset of symptoms; (c) episodic course with

varying symptom severity; (d) dramatic exacerbation of symptoms following a group A ß-hemolytic streptococcal infection; and (e) association with neurologic abnormalities. In these children, the average age at onset was 6.3 years for tics and 7.4 years for obsessive-compulsive symptoms. The longitudinal course of children with PANDAS and how they differ from patients in whom OCD develops but who do not meet the criteria for PANDAS is unclear.

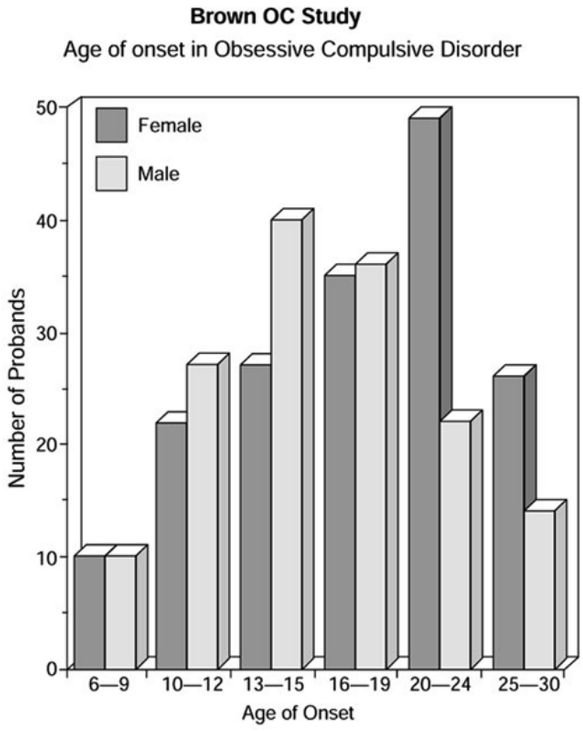

FIGURE 111.1. Age at onset in obsessive-compulsive disorder in the Brown study. (From Jenike MA, Baer L, Minichiello WE. An overview of obsessive-compulsive disorder. NATURAL HISTORY AND COURSE OF ILLNESS

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

DSM-IV describes the course of OCD as typically chronic with some fluctuation in the severity of symptoms over time. The numerous retrospective and prospective follow-up studies of patients with OCD support this description. However, many of the earlier phenomenologic and follow-up studies of OCD suffered from a number of methodologic limitations, including the following: retrospective study design, small sample size, lack of standardized criteria to determine diagnosis, hospital-based samples not representative of the spectrum of the disorder found in the general population, biases in inclusion and exclusion criteria, chart review rather than personal interview, absence of structured interviews, and lack of consensus regarding the definition of relapse, remission, and recovery. Because of these flaws in design, the earlier studies of OCD may have included subjects who would not meet today's criteria for the diagnosis. In particular, clear distinctions between OCD and compulsive personality disorder were often not made, and obsessions and compulsions occurring in the context of other disorders (e.g., psychosis, eating disorders) may have been included as OCD.

Despite these methodologic shortcomings, several more recent prospective follow-up studies, in which a prospective design, standardized criteria to assess diagnosis, and structured interviews with direct patient contact were used, have also shown that most patients continue to meet either all or some of the criteria for the disorder at follow-up. Relatively few patients experience complete remission. Retrospective and prospective follow-up studies of the course are reviewed in detail below.

Retrospective Follow-up Studies

In retrospective studies, fluctuations in the severity of psychiatric symptoms and impact on functioning over time are ascertained primarily on the basis of subjects' recall. Results of these studies are summarized in Table 111.2 . In most of them, patients were selected based on chart review and were subsequently assessed at the time of the study, either in person or through questionnaire. In the earliest longitudinal study of OCD, a relatively good outcome was observed by Lewis (24), who followed 50 patients with OCD (most of whom received some psychotherapy) at least 5 years after initial assessment; 37% were "quite well," 14% were "much improved," but 46% were minimally improved, unchanged, or worse. Only 10% had had an episodic course marked by later recurrence after remission. Pollitt (25) followed 67

nonleucotomized patients for a mean of 3.4 years; 24% were symptom-free (similar to the results with psychotherapy), 36% had mild symptoms and were functioning well, and 12% were improved but with impaired functioning. Only 25% had symptoms that were unchanged or more severe than at baseline. This study was somewhat unusual because most of the patients were selected from an outpatient practice. The results of this study illustrate how outcome is influenced by the baseline severity of the obsessive-compulsive symptoms of the cohort selected. A longer duration of illness at initial evaluation was associated a with poorer outcome with respect to severity of symptoms at follow-up, as might be expected. Duration of illness was also a predictor of course of illness in a study of 29 inpatients with obsessional symptoms followed for 6 years by Ingram (26). In this study, 72% were minimally improved but functioning poorly, unchanged, or worse, and 21% of the patients were much improved. One conclusion that can be drawn is that chronicity at entry appears to predict chronicity at follow-up.

TABLE 111.2. RESTROSPECTIVE FOLLOW-UP STUDIES OF OBSESSIVE-COMPULSIVE DISORDER

Study (Ref.)	No. Patients	Mean Years of Follow-up	Well (%)	Minimally Improved, Unchanged or Much Improved (%)	Worse (%)	Comments

Lo, 1967 (28)	88	3.9	23	50	27	Inpatients and outpatients diagnostic heterogeneity

[a]One patient not leucotomized; five patients leucotomized.
OCD, obsessive-compulsive disorder.

In a study characterized by a long follow-up period, Kringlen (27) found that at 13 to 20 years after initial contact, 42% of patients were unimproved or had worsened symptoms, only 24% were much improved, and 34% described slight improvement in OC symptoms. The patients included in this study were all hospitalized for their first contact, which may contribute to the poorer outcome in this study.

Lo (28) interviewed 88 patients in whom OCD had been diagnosed with a mean follow-up of 3.9 years and found that 23% were symptom-free and 50% had symptoms that were much improved. More than half the patients had distinct obsessions and compulsions. However, 10% had prominent affective symptoms, and 31% were described as having “phobic and ruminative symptoms,” with minimal compulsions. Therefore, some of the patients described as being in remission at follow-up may have had major depression with obsessional or ruminative thinking during their index episode. In reviewing these early follow-up studies, Goodwin et al. (29) concluded that the course of OCD is usually chronic, but variable, with fluctuations in the severity of symptoms.

In follow-up studies conducted since 1980, the course of illness has been evaluated according to criteria different from those used in the earlier studies described above. Patients have been retrospectively assigned to categories of “continuous,” “waxing and waning,” “deteriorative,” and “episodic with full remissions between episodes.” Rasmussen and Tsuang (30) conducted a study in 1986 in which patients were selected based on current enrollment in an outpatient OCD clinic. The course of OCD was described by most patients as chronic or “continuous” (84% of 44 patients); six subjects (14%) had a deteriorating course, and only one (2%) had an episodic course. The average duration of illness at the time of assessment was more than 15 years, which again suggests that the chronicity of the disorder may have been influenced by the sample. Because these subjects were acquired through the process of clinic referral and prospective follow-up was not conducted, no former OCD patients who had already recovered and remained well were included.

Coryell (31) observed some improvement at follow-up in 55.6% of a hospitalized cohort of patients with OCD. However, this cohort was significantly less likely to experience remission after discharge (22%) than the comparison cohort of depressed patients (64%).

Synthesizing methodologically varied studies, some of which present an optimistic picture, others a pessimistic one, may require more careful examination of reported outcomes. It is particularly important to separate the best possible outcome (“full remission” or “symptom-free”) from what is described as “much improved” or “improved,” which may indicate persistent symptoms in the abatement phase of a chronic illness that waxes and wanes. The episodic pattern of full remission (and sometimes later occurrence), when it is clearly identified as such, appears to occur in about 10% to 15% of patients with OCD, although this proportion may increase somewhat as follow-up is extended for several years and may also be greater in childhood OCD (12), in which improvement can be rapid even without treatment (32). In most studies, a smaller proportion of patients (6% to 14%) seem to follow a deteriorating course. Most follow a course marked by chronicity, with some fluctuation of symptoms over time but without clear remissions or deterioration.

Prospective Longitudinal Studies of Course

During the past decade, several prospective longitudinal studies of the course of OCD have been carried out; these are summarized in Table 111.3 . Although studies of adults have supported the hypothesis that OCD is a chronic, lifelong disorder, child and adolescent studies have found a surprisingly high percentage of patients with an episodic course. Flament et al. (33) completed a 2-year follow-up study of 59 adolescents in whom OCD, subclinical OCD, or compulsive personality disorder had been identified in an epidemiologic study of high school students, most of whom had not sought clinical treatment. Of 12 patients who had met the criteria at baseline for OCD, only five still met the full criteria at follow-up. Four patients with subclinical manifestations of OCD at baseline did meet the full criteria for OCD at follow-up. In another 5-year prospective follow-up study, of an OC adolescent cohort seeking treatment at a tertiary clinic, Flament et al. (34) concluded that patterns of course are not easily predicted from baseline variables (34). Some patients with subthreshold symptoms at baseline were severely ill at follow-up, whereas others classified at baseline as severely ill no longer had

clinical levels of symptomatology at follow-up. This finding was substantiated in a recent study by Valleni-Basile et al. (35). When they screened a community sample of 3,283 adolescents with a self-report instrument followed by the Schedule for Affective Disorders and Schizophrenia (SADS), they found 1-year incidence rates of OCD and subthreshold OCD of 0.7% and 8.4%, respectively. Interestingly, transition probabilities demonstrated a pattern of moving from more severe to less severe categories in subsequent years. Of the patients with OCD at baseline, 17% had OCD at follow-up. Only 1.5% of those with subclinical OCD had progressed to OCD that met syndromal criteria. In contrast, in a Danish follow-up study of 23 adolescents presenting with OCD to a community clinic, half of the subjects retained an OCD diagnosis at follow-up. One-third of the subjects had had an episodic course, and two-thirds had had a chronic course (36). Berg et al. (37) reported a 2-year follow-up of 59 high school students with DSM criteria for OCD who were identified as part of an epidemiologic survey. Most of the subjects had never sought treatment. The course of illness was much more variable than had originally been predicted. Some patients with subthreshold symptoms at baseline were severely ill at follow-up, whereas others classified as severely ill at baseline no longer had clinical levels of symptomatology at follow-up. Although these studies have given us our first prospective glimpse of the early course of OCD, they also suffer from significant methodologic limitations. Follow-up was at a single point, an average of 4.8 years from baseline. Interim data about remissions and relapses during the study period were not obtained. However, the evidence suggests that the course of illness may be much more variable and episodic in child and adolescent samples than was previously believed.

Study (Ref.)	Treatments	No. Patients	Mean Follow-up (ys)	Remained in Episode (%)	Partial Remission (%)	Full Remission (%)	Comment
Children and adolescents							
Berg et al., 1989 (37)		12	2	42	17[a]	8	17% had compulsive personality traits
Leonard et al., 1993 (43)	SSRIs, BT, psychotherapy, family therapy	54	3.4	43	46	11[b]	70% on medication at follow-up
Adults

TABLE 111.3. PROSPECTIVE FOLLOW-UP STUDIES OF OBSESSIVE-COMPULSIVE DISORDER

In a three-site prospective longitudinal study of adult patients with OCD conducted by Eisen et al. (38), data were collected on the course of illness in 78 subjects for 2 years. Two instruments with proven reliability and validity were used to evaluate severity of symptoms: the Y-BOCS (39) and the Psychiatric Rating Scale for OCD (PSR-OC) (40). On the PSR-OC, scores ranged from 6 for patients who were severely symptomatic and unable to function at work or socially to 0 for patients who had no obsessive-compulsive symptoms and used no avoidance. Follow-up measures were obtained at 3, 6, 12, and 24 months after baseline assessment.

The probability of achieving at least partial remission during the 2-year study period was 47%. However, if more stringent criteria were used to define remission, in which patients had only occasional or no obsessions and compulsions for 8 consecutive weeks (PSR-OC score ≤2, which is equivalent to a Y-BOCS score ≤8), the probability of achieving remission was only 12%. Once a patient was in remission, the probability of subsequent relapse (defined as returning to a Y-BOCS score ≥16 and a PSR-OC score >4 for any length of time) was 48%. Of the 22 patients who achieved partial remission, 10 relapsed and 12 remained in partial remission throughout the study.

In another prospective study, 107 clinic patients with OCD were followed for up to 5 years after intake (41). The probability of full remission for at least a 2-month period was 22% at 5 years, and the probability of partial remission was 53%. Although outcome in this study was assessed with

a 3-point rating scale, the results are comparable with those in the study of Eisen et al. (38), in which a 6-point PSR-OC and the Y-BOCS were used.

Skoog and Skoog (42) recently described a 40-year follow-up study of 144 patients with OCD who were identified as inpatients in the late 1940s and early 1950s. Two-thirds were improved within a decade after the onset of OCD, and most of the patients reported an intermittent course, with at least two remissions during that time period. However, a chronic course was more common in the later follow-up period, and 20% showed either no improvement or a deteriorative course during the 40 years. Although the length of follow-up in this study was remarkable, methodologic flaws limit the conclusions that can be drawn. First, the sample consisted of psychiatric inpatients hospitalized in the 1940s. The baseline severity of obsessive-compulsive symptoms was unclear because of the lack of scales with proven reliability and validity. It seems likely that patients with a primary diagnosis of major depression were included. Finally, the study was conducted before the widespread availability of the SSRIs and behavioral treatments.

In summary, only a handful of prospective studies of the course of illness in OCD are available. A significantly greater degree of episodic illness is seen in child and adolescent samples than in the adult population. A number of methodologic considerations may account for some of these inconsistencies. The earlier retrospective studies were completed before the introduction of standardized diagnostic criteria, standardized ratings of symptom severity, and effective pharmacologic and behavioral treatment strategies. In addition, because until recently patients with OCD were reluctant to seek treatment, patients with more debilitating symptoms may have been overrepresented in these earlier studies, so that the results are biased toward a worse prognosis. In our pilot study, patients were followed who were already enrolled in our clinic, a factor that potentially contributed to the chronic course noted in many of the subjects. A prospective longitudinal study of the course of 400 patients with OCD is currently in progress.

Effect of Treatment on Course of Illness

Effective pharmacologic and behavioral treatments for OCD became available in the late 1980s in the United States. A follow-up study of children with OCD was conducted by Leonard et al. (43) to determine outcome after standardized short-term treatment with clomipramine (a medication known to be effective in OCD). Fifty-four children and adolescents were re-interviewed 2 to 7 years after participation in a controlled trial of clomipramine and a variety of interim interventions. Obsessive-compulsive symptoms were more severe in only 10 of the subjects at reassessment, so that as a whole, the cohort had improved at follow-up. However, only three subjects (6%) were considered to be in true remission (defined as no obsessions or compulsions and no medication), and 23 subjects (43%) still met full criteria for OCD. Most of the patients were taking medication at follow-up. It is worth noting that the patients who made up this sample were referred to a tertiary research center and were severely ill with a more chronic course than is seen in most childhood samples of OCD.

The results of a 1994 study conducted by Orloff et al. (44) are a greater cause for optimism than those of the studies described above. Most of the 85 subjects assessed 1 to 3 years after baseline evaluations were much improved at follow-up based on chart review. The mean follow-up Y-BOCS score of 9.3 was in the range of mild to minimal obsessions and compulsions that do not interfere with functioning. This improvement in obsessive-compulsive symptoms in comparison with baseline symptomatology was attributed to the current availability of effective behavioral and pharmacologic treatments for OCD (techniques of exposure–response prevention and SSRIs). In fact, 99% of subjects had received at least a 10-week trial of an SSRI and 45% had received some behavior therapy. Most patients were still taking medication at the time of follow-up. Relapses were common in those patients who discontinued medication, which suggests that continued treatment may be required to maintain an improvement in OC symptoms over time.

The effect of treatment on the course of illness in OCD was also evaluated in the prospective study conducted by Eisen et al. (38), described above, in which 77 adults meeting DSM criteria for OCD were followed with frequent interim assessments for more than 2 years. Pharmacologic data gathered included doses of medications and duration of treatment. Patients had to have received a maximum dose of at least one SSRI for a minimum of 12 weeks to be considered to have received adequate pharmacotherapy for OCD. Information obtained on behavior therapy included amount of time spent in sessions, time spent doing homework, whether the patient practiced exposure–response prevention, and imagined homework. Patients were considered to have received adequate behavior therapy if they reported undergoing behavior therapy with a therapist who used exposure–response prevention and if they spent at least 20 hours practicing exposure–response prevention homework assignments. Fifty-five subjects (84% of the total sample) received an adequate trial of at least one SSRI during the study period, and 12 patients (18%) received adequate behavior therapy. The probability of partial remission for those patients who received an adequate trial of at least one SSRI was 51% during the 2-year study period.

The mean Global Assessment of Function (GAF) and Y-BOCS scores at intake and at 2 years were similar for those subjects who received an adequate trial of an SSRI and those who did not receive adequate pharmacotherapy. However, the mean GAF

scores at intake of patients who subsequently underwent adequate behavior therapy during the course of the study were lower than the mean GAF scores of patients who did not undergo behavior therapy. The change in GAF score at 2 years was significantly greater in the group of patients who received behavior therapy, so that these patients in effect “caught up”; their final GAF scores were similar to the scores of the patients who did not undergo behavior therapy.

Although this study was conducted at a time when current behavioral and pharmacotherapies were available, the results again support the findings that for the majority of patients, the course of illness in OCD is continuous with fluctuations in severity rather than episodic with clear periods of remission between periods of exacerbation of symptoms.

QUALITY OF LIFE

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

No longitudinal follow-up study of OCD has systematically measured psychosocial functioning and quality of life over time. Most treatment outcome studies have primarily focused on symptomatic relief. Also, no attempt has been made to examine the relationship between symptom severity and psychosocial functioning over time. For a significant percentage of OCD patients, impairment in function and quality of life is severe (45). It is the only major psychiatric disorder for which neurosurgery continues to be a treatment option. It will be important in future studies to gather prospective information on levels of psychosocial impairment during periods of remission when subjects no longer meet full criteria for a diagnosis of OCD. In the National Collaborative Study of Depression, even subsyndromal symptoms were associated with significant dysfunction in multiple areas (46). Similarly, preliminary data from Eisen et al. (38) suggest that psychosocial functioning continues to be impaired during partial remission despite symptomatic improvement; for example, after 1 year of follow-up, 29% of subjects in partial remission continued to miss work much of the time or were virtually incapable of carrying out activities at their jobs (38).

PREDICTORS OF LONG-TERM COURSE OF ILLNESS

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

Although a number of studies have examined predictors of outcome in OCD, the results have been inconsistent. Most have focused on identifying predictors of short-term outcome following pharmacologic or behavioral treatment. None of the existing studies has examined predictors of remission or relapse rates. These studies have been methodologically compromised by small sample size, inclusion or exclusion criteria that led to sample bias, and inadequate duration of follow-up. Characteristics such as age at onset of OCD, duration of illness, severity of illness at baseline, and phenomenologic subtype have not been associated with outcome in a consistent way. More recently, emerging data have clarified that OCD is a heterogeneous disorder and have begun to point to the existence of discrete subtypes of illness. It will be important to determine whether these “subtypes” influence the likelihood of remission or relapse. The most likely prediction variables are reviewed below.

One subtype of OCD is associated with a family or lifetime history of tic disorders. Although variation between studies is considerable, it is generally accepted that approximately 20% of patients with OCD have a lifetime history of tics, and that 5% to 10% have a lifetime history of Tourette disorder (47 ,48). Family and genetic studies have demonstrated that OCD patients with a family or lifetime history of multiple tics are more likely to have first-degree family members affected by OCD or Tourette syndrome than are OCD probands without tics (49 ,50) They are also significantly more likely to have onset of illness at an early age. OCD patients with tics appear to be less likely to respond to SSRIs, and their OCD symptoms respond differentially to augmentation of an SSRI with a neuroleptic (51). Certain OCD symptoms have been shown to develop more commonly in this subgroup, including the need for symmetry, ordering, arranging, and hoarding (52). The presence of a tic disorder predicted more severe symptoms of OCD at follow-up in children (47). The predictive power of a personal or family history of multiple tics in regard to remission and relapse rates should be investigated.

The role of personality disorder in outcome also has not been explored prospectively, although the relationship has been investigated in a number of acute treatment studies with inconsistent findings. In the study of Jenike et al. (53), schizotypy was a negative predictor for outcome after pharmacologic and behavioral treatment. In a study by Baer et al. (54), the presence of any single personality disorder was not related to improvement on any outcome measure in a 12-week placebo-controlled trial of clomipramine in OCD. However, a larger number of personality disorders was consistently related to poorer outcome, as was the presence of a DSM-III cluster, a personality diagnosis. A subsequent single-site study of the effect of a personality disorder on the response to fluoxetine failed to confirm that a cluster A diagnosis is a negative predictor of outcome (55).

The DSM-IV field trial of OCD established that a significant percentage of patients with OCD have poor insight (56). The validity of this new diagnostic category is still in question. Data pertaining to the effect of poor insight or overvalued ideation on behavioral treatment response have been inconsistent (57 ,58). Eisen and Rasmussen (59) retrospectively assessed the course of illness in four subgroups of OCD: OCD and schizophrenia, OCD and schizotypal personality disorder, OCD with poor insight, and OCD without psychotic features. A deteriorative course was noted in 82% of the patients with coexisting schizophrenia, 69% of those with

coexisting schizotypal personality disorder, 17% of those with poor insight, and only 8% of those without psychotic features. This study was hampered by the lack of a valid and reliable scale to measure poor insight and by the retrospective assessment of the course. We have recently published data on the reliability and validity of a new scale, the Brown Assessment of Beliefs Scale (BABS), that has demonstrated excellent sensitivity to change with short-term treatment (60). Eisen et al. (61) assessed change in BABS scores in patients with OCD who participated in the first phase of a double-blinded relapse study of sertraline in OCD. They found no significant correlation between degree of insight as measured by the BABS and outcome after 16 weeks of sertraline. The role of insight in remission and relapse deserves further scrutiny.

Obsessive-compulsive disorder has been linked to alterations in neurologic function involving the basal ganglia after head trauma, encephalitis, and birth events (62). Hollander et al. (63) described a subset of patients with OCD who had an increased number of neurologic soft signs and neuropsychological abnormalities in comparison with a control group matched for age, sex, and handedness. The examination of soft signs involved fine motor coordination, involuntary movements, sensory function, and visuospatial tasks. Soft signs were correlated with severity of obsessions. Receiver operating characteristic analysis found that a cutoff of three or more signs yielded the minimum number of combined errors of sensitivity and specificity in blindly distinguishing OCD subjects from controls. When these criteria were used, 25 of 40 subjects were considered to have soft neurologic signs. A second study of OCD adolescents found a high frequency of age-inappropriate synkinesias and lateralization of deficits to the left side of the body (64). In a nonblinded study in which a clinical neurologic examination was performed in childhood and adolescent OCD subjects, most of the patients had abnormal neurologic findings, including choreiform movements, nonspecific neurodevelopmental signs, and left hemisyndrome (65). Significantly more signs of central nervous system dysfunction were observed in the OCD group, manifested by abnormalities in fine motor coordination, involuntary movements, and abnormal sensory and visuospatial function. Some evidence was found of an increased number of left-sided signs that were suggestive of right-sided dysfunction. The hypothesis that this subgroup is etiologically distinct requires further validation in a study of predictive outcome.

Another important area of investigation is symptom subtype in OCD. Thus far, specific obsessions and compulsions have not predicted outcome in the vast majority of follow-up studies. In a preliminary analysis of 544 patients from a multicenter trial of acute clomipramine, the authors failed to find any significant correlation between symptom subtype, identified by the Y-BOC Symptom Checklist, and outcome (66). Recent work in which factor analysis was used to cluster groups of obsessions and compulsions suggests that certain symptom clusters may identify subtypes of OCD (67 ,68). Data obtained with positron emission tomography (PET) have shown that regional activation of the prefrontal cortex varies according to factor (69), and emerging genetic data suggest that familial loading varies according to factor (70). Symmetry and certain obsessions, such as aggressive and sexual obsessions, are more frequent in patients with OCD and chronic tics (71). One family study suggests that the rate of OCD is higher in first-degree relatives of probands with aggressive obsessions (49). The analytic technique used to identify factors from the Y-BOC Symptom Checklist may be fruitful in predicting the course of OCD. Evidence is increasing that patients in whom hoarding is a primary obsessive-compulsive symptom are resistant to traditional behavioral and pharmacologic interventions (72 ,73 and 74). In addition, hoarding was the only compulsion associated with a lower probability of remission in our pilot study.

The data regarding early onset and outcome of OCD are quite inconsistent. In a number of studies, an earlier age at onset of OCD was associated with a worse prognosis. In the study of Ravizza et al. (75), the age at onset of patients who failed to respond to a trial of an SSRI was earlier than that of responders. Thomsen (36) reported that attainment of puberty by the time of referral predicted a better prognosis than a prepubertal onset. In a reanalysis of the multicenter efficacy and safety data for clomipramine, Ackerman et al. (76), using stratification and logistic regression techniques to identify multiple prognostic factors and control for confounds, found a later age at onset to be a strong predictor of response. Skoog and Skoog (42) reported that onset of OCD before age 20 was related to a poorer outcome, especially in men. In other studies, age at onset did not predict severity of illness at follow-up. Adolescents in the study of Berg et al. (37) had an extremely variable course. In our sample, the onset of major obsessive-compulsive symptoms before age 14 predicted a higher likelihood of remission.

The severity of OCD symptoms at baseline was not predictive of long-term outcome in most studies (77 ,78 ,79 ,80 and 81), although the truncated pretreatment range of severity makes such a relationship difficult to demonstrate. It seems likely that more severe symptoms are associated with a greater degree of functional impairment and a greater number of comorbid conditions, although this hypothesis remains to be tested. However, in the only study we could locate that examined level of functioning in OCD, pretreatment functioning did not predict follow-up outcome (73). Duration of symptoms was not predictive in any study (78 ,79 ,81 ,82), although it is possible that chronicity accompanied by comorbidity may worsen prognosis. Type of ritual (washing vs. checking) was not predictive in two studies (11 ,79) and predicted erratically in others (77 ,83), a finding that argues against any consistent relationship of symptom type to outcome.

PHENOMENOLOGIC SUBTYPES AND THEIR STABILITY OVER TIME

The beginning clinician is often struck by the diversity of the clinical presentations of OCD. However, this initial impression is soon replaced by the realization that the obsessions and compulsions are remarkably limited in number and stereotypic. During the last 15 years, we have characterized the phenomenologic and clinical features of more than 1,000 patients with OCD. The basic types and frequencies of obsessive-compulsive symptoms have been found to be consistent across cultures and time (84). Why particular symptom patterns develop in given persons remains unknown. The most common obsessions include contamination, pathologic doubt, aggressive and sexual thoughts, somatic concerns, and the need for symmetry and precision. The most common rituals are checking, cleaning, and counting.

Aside from a relatively gross analysis of the course in terms of variation in overall intensity of symptoms, finer analyses of variations in symptom focus or symptom mix have not been attempted. Nevertheless, in their study of childhood OCD, Swedo and Leonard (22) reported that 90% of patients experienced some change in symptom pattern over time, often starting with a solitary ritual without associated obsessive thoughts (notably uncommon in adults), then later adding new symptoms that sometimes became predominant over earlier ones. More work is needed to delineate the frequency and magnitude of the cyclic variations in intensity and focus of obsessive-compulsive symptoms.

COMORBIDITY

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

Biological markers and neuropharmacologic challenge studies depend on the selection of homogeneous clinical populations that reduce the variance. In studying a disorder like OCD, the presence of other axis I disorders is a serious obstacle for researchers wishing to obtain homogeneous subgroups. The majority (57%) of OCD patients presenting to our clinic have at least one other DSM-III-R diagnosis. To complicate matters further, OCD is a chronic illness, and an even higher percentage of our patients have a lifetime history of another axis I disorder. Distinguishing primary from secondary diagnoses can often be difficult, if not impossible.

Studies examining the coexistence of OCD and other psychiatric disorders can be divided into two groups: (a) those examining the coexistence of other psychiatric disorders in a clinically defined population of patients with OCD and (b) those primarily focused on recording the incidence of obsessive-compulsive symptoms in other diagnostic groups. The coexistence of other anxiety states, depression, and psychotic symptoms with obsessive-compulsive symptoms was well documented in the early literature. However, few systematic clinical psychopathologic studies had been completed before 1985. Earlier studies were retrospective and failed to utilize standardized diagnostic criteria or reliable structured instruments.

The dispute about the relationship between OCD and schizophrenia has been of central interest. Controversy centers on whether a psychopathologic continuum exists for the two disorders. Some investigators have suggested that obsessions are a preliminary sign of schizophrenia, whereas others have claimed that obsessional thoughts are a neurotic defense against psychotic decompensation. Most current researchers feel that the two disorders are different entities without any true relationship. If OCD was closely related to schizophrenia, one would expect that schizophrenia would develop in a significant percentage of OCD patients. However, follow-up studies have shown that the incidence of progression to schizophrenia in primary OCD probands is low, between 1.0% and 3.3%. Rosen (85), in a retrospective chart review of 850 inpatients with schizophrenia, found that approximately 10% exhibited prominent obsessive-compulsive symptoms. This finding was replicated by Fenton and McGlashan (86), who found that 10% of schizophrenics in a Chestnut Lodge (Rockville, Maryland) follow-up study exhibited prominent obsessive-compulsive symptoms. These obsessive-compulsive schizophrenic patients tended to have a more chronic course and a greater frequency of social or occupational impairment in comparison with a matched sample of schizophrenics without obsessive-compulsive features. Recently, Eisen et al. (87) interviewed 77 patients who met SADS criteria for schizophrenia and found that 7.8% met DSM-III-R criteria for OCD. The average Y-BOCS score for those meeting the criteria for OCD was 22.3 ± 5.2.

The relationship between obsessions, compulsions, and depression was the subject of several early studies. These were primarily retrospective and failed to use diagnostic criteria or structured interviewing. Thus, many aspects of the association between depression and OCD remain unclear. One aspect that deserves further study is whether the affective episodes in OCD are primary or secondary. Dividing depressed obsessional patients into these two categories (i.e., primary and secondary) was originally advocated by Lewis (24). No systematic study of the frequency of obsessions and compulsions in a sample of depressed patients existed until recently. Although a great deal of interest has been shown in the question of whether compulsive personality increases the risk for development of a major depression, the results remain inconclusive, with wide variations in percentages across studies possibly caused by the lack of standardized diagnostic criteria.

The phenomenologic and biological evidence relating OCD to affective disorder has been reviewed by Insel (88). It has been noted that obsessive-compulsive features are rarely, if ever, seen in mania. We reported a case of OCD

in a patient with bipolar disorder whose obsessions and compulsions worsened in direct proportion to the severity of his depression and totally disappeared when he became manic (89). Although preliminary evidence suggests that OCD is rarely seen in mania, no systematic data on the frequency of obsessive-compulsive symptoms in a bipolar population were available until recently. Kruger et al. (90) and Chen and Dilsaver (91) reported on the frequency of OCD in bipolar and unipolar populations. Chen et al. found that 21% of patients with bipolar disorder, 12.2% of patients with unipolar depression, and 5.9% of patients with other disorders had OCD in the National Epidemiology Catchment Area Survey sample. Kruger et al. found that 35% of patients with both bipolar and unipolar depression had an obsessive-compulsive syndrome. Many of these depressed patients suffer from obsessions, which are at times difficult to differentiate from ruminations.

In our subsample of 250 patients who met DSM-III criteria for OCD, only 25% denied depression on admission (72). The majority admitted to feelings of inadequacy and hopelessness, and only one patient gave a history of euphoria. During the course of their illness, most reported that depression developed after the obsessive-compulsive symptoms; therefore, the patients were classified as having secondary depression. A minority (8%) of patients had a simultaneous onset of obsessive-compulsive symptoms and depressive episodes.

Kringlen (27) reported that more than 50% of 91 obsessional patients in his series had phobic symptoms. Among the 104 depressed obsessional patients of Videbach (92), 42 (40%) described phobic symptoms. In contrast, Welner et al. (93) found associated phobias in only 7 (5%) of 150 patients with severe OCD. Additional evidence supporting a shared vulnerability to OCD and other anxiety disorders is the high incidence of childhood phobias reported by obsessional patients. Lo (28) reported that 21 (35%) of his 59 obsessional patients had had significant phobias during childhood. Videbach (92) observed the same in 52 (50%) of his 104 depressed, ruminative patients. Similarly, Ingram (26) reported that 22 (25%) of 89 OCD patients had had significant phobias in childhood. During the last 5 years, several studies have examined the association of OCD with other anxiety disorders. In a study of 60 patients with panic disorder in which the SADS-LA and personal interviews were used, Breier et al. (94) found that 17% met the DSM-III criteria for OCD. Subsequent studies by Mellman and Uhde (95) and Barlow (96) confirmed these initial findings of the overlap between panic and OCD. Insel (88) pointed out the importance of the distinction between primary and secondary anxiety disorders. For example, it is often difficult to distinguish a primary social phobia with obsessive features from primary OCD that is centered on obsessing about having to complete a ritual in public. The finding of a high frequency of current and lifetime anxiety disorders suggests that OCD patients are vulnerable to virtually all types of anxiety. The high prevalence of anxiety states in these patients may be a consequence of common developmental/temperamental traits whose phenotypic expression is secondary to shared genotypic and psychosocial factors. Of particular interest in this regard is the high lifetime prevalence (12%) of separation anxiety in this group of patients (97), a finding that has also been well documented in panic disorder (20).

Table 111.4 summarizes the common axis I disorders associated with OCD in the Brown cohort. Two-thirds of obsessive-compulsive patients have a lifetime history of a major depression, and one-third have a major depression at the time of first evaluation. The majority (85%) have a mood disorder secondary to their OCD, and 15% appear to have a concurrent unipolar recurrent depression. A significant overlap is also seen with the other axis I anxiety disorders, including panic disorder, panic disorder with agoraphobia, social phobia, generalized anxiety disorder, and separation anxiety disorder. Other comorbid conditions

that appear more frequently than one would expect include eating disorders, Tourette syndrome, and schizophrenia. Comorbid axis I conditions can influence the course of illness and affect choice and order of treatment.

TABLE 111.4. COEXISTING AXIS I DIAGNOSES IN PRIMARY OBSESSIVE-COMPULSIVE DISORDER

Diagnosis	Current Semistructured (*n* = 100) (%)	Lifetime Semistructured (*n* = 100) (%)	From SADS (*n* = 60) (%)
Major depressive disorder	31	67	78
Simple phobia	7	22	28
Separation anxiety disorder	—	2	17
Social phobia	11	18	26
Eating disorder	8	17	8
Alcohol abuse (dependence)	8	14	16
Panic disorder	6	12	15
Tourette syndrome	5	7	6

SADS, Schedule for Affective Disorders and Schizophrenia.
Adapted from Jenike et al., with permission.

Special attention has been focused recently on patients with tics and OCD. Approximately 20% of patients with OCD have a lifetime history of multiple tics, and 5% to 10% have a lifetime history of Tourette syndrome (82). The age at onset in this subgroup is earlier, and they have family pedigrees loaded for both Tourette syndrome and OCD (49). Miguel et al. (98) studied similarities and differences in the clinical symptoms of 15 outpatients with OCD but not tics and 12 adult patients with Tourette syndrome but not OCD. All patients with OCD reported that some cognition preceded their compulsions, whereas only 2 of 12 patients with Tourette syndrome reported any cognition. In contrast, all patients with Tourette syndrome reported that sensory phenomena preceded their repetitive behaviors; no OCD patients reported such sensations (97).

Considerable interest has been shown in the overlap of OCD with eating disorders, particularly anorexia nervosa. In the study of Thiel et al. (99), 37% of 93 women who met criteria for anorexia or bulimia nervosa also met DSM-III-R criteria for OCD and had a score of 16 or higher on the Y-BOCS. Rastam et al. (100) also reported a high rate of OCD in a sample of 16-year-old girls in whom anorexia nervosa had been diagnosed.

Axis II conditions in OCD are covered extensively elsewhere in this volume. The most commonly encountered diagnoses are dependent, avoidant, passive–aggressive, and compulsive. Schizotypal, paranoid, and borderline personalities are found less commonly in OCD but appear to be associated with a poor outcome.

RELATIONSHIP OF HETEROGENEITY TO COMORBIDITY

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

We have become increasingly interested in developing a model for subtyping patients with OCD according to what we see as the three core features of the disorder: abnormal risk assessment, pathologic doubt, and incompleteness. These features cut across phenomenologic subtypes, such as checking, washing, or the need for symmetry, although some subtypes are more closely associated with one core feature than another.

Like most phobics, persons with OCD continually worry that if there’s a one in a million chance that something terrible will happen, it will happen to them. If there’s a one in a million chance that the elevator cable will snap, the phobic patient is certain that it will snap when he is in the elevator. In the same way, many of the thoughts of the patient with OCD are dominated by improbable events that most of us would not think twice about. Many checkers suffer from “what if?” What if I don’t unplug the coffee machine and there’s a fire? The patients with sexual or aggressive obsessions also worry. What if I do pick up the knife?

On the opposite side of the spectrum are the patients with OCD who experience little or no anxiety that something terrible will happen. Janet observed that many patients with OCD are tormented by an inner sense of imperfection. Their actions are never completely achieved to their satisfaction. Many of our patients describe an inner drive that is connected with a wish to have things perfect, absolutely certain, or completely under control. When they achieve such perfection, they describe a curious sensation that they can compare to no other feeling. Janet called it the “occasional brief appearance of sublime ecstasy.” This absolute feeling of certainty or perfection is rarely attained, and therefore the patients experience a feeling of incompleteness.

Feelings of going exactly through the middle of a door, of having both shoelaces tied to exactly the same tension, of having ones hands perfectly clean, of saying ones prayers exactly right, or of having one’s hair parted precisely down the middle are clinical examples. Most of us can relate to the feeling of wanting to have something just so or perfect and the feeling of accomplishment when we finally get it that way, and to feelings of frustration and incompleteness when it’s not that way. But for the obsessive, this feeling becomes attached to an action that would hold little significance for most of us, just as most of us do not think about the one in a million chance that something will go wrong. Patients with trichotillomania or Tourette syndrome also describe a feeling of incompleteness with continued tension until they have finished pulling out an entire patch of hair or completed a sequence of tics to their satisfaction. Both say that it is impossible to stop in the middle of a compulsive action despite the consequences.

The core features appear to relate both to the clinical features of OCD and to the comorbid disorders. In patients with abnormal risk assessment, high levels of anxiety are associated with symptoms. They are also likely to have comorbid axis I generalized anxiety disorder or social phobia, avoidant and dependent personality features, and a family history of an anxiety disorder. In contrast, patients with incompleteness are likely to manifest low levels of anxiety, comorbid multiple tics or habit disorders (e.g., trichotillomania, onychophagia), and compulsive personality features. Empiric validation of these subgroups may have important implications for diagnosis and treatment. Some evidence has already been found that patients with treatment-resistant OCD and tic spectrum disorder are particularly responsive to dopaminergic antagonists. These patients are also more likely to exhibit incompleteness.

Baer et al. (67) applied principal component analysis to 107 patients with OCD who completed the Y-BOC Symptom Checklist and examined the correlations between the factor scores and the presence of comorbid tic or personality disorders. Three factors, symmetry/hoarding, contamination/cleaning,

and pure obsessions, best explained the variance. Only the first factor was significantly related to OCPD (obsessive-compulsive personality disorder) or a lifetime history of Tourette syndrome.

COMMENT

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

During the past 15 years, significant advances have revolutionized the way we conceptualize and treat OCD. Epidemiologic studies have confirmed that OCD is an underrecognized common major psychiatric disorder with a lifetime prevalence of 2% to 3% in the general population, and they have been instrumental in focusing the attention of researchers, clinicians, and the media on OCD. Studies of the clinical features and course of the disorder and associated comorbid conditions have appeared in the literature since the turn of the twentieth century and have been the subject of numerous prospective and retrospective studies of its course, reviewed here.

Finally, future studies will continue to benefit from further refinement of our thinking about the heterogeneity and comorbidity of OCD and the search for homogeneous subtypes. The identification of an OCD–tic subtype has already led to important new genetic and biological studies and has been directly relevant to treatment. The recent effort to characterize pediatric autoimmune neuropsychiatric disorders and their relationship to genetic vulnerability to streptococcal infection offers a promising lead for furthering our understanding of the pathophysiology of OCD. It is possible that we will increase our understanding of predictions of remission and relapse related to possible homogeneous subtypes of illness. A review of these studies suggests that the course of OCD, long thought to be chronic, may be more episodic than previously believed, particularly in children and adolescents. It also appears that in some subjects, pharmacologic and behavioral treatments may alter the natural course of illness. However, a long-term prospective follow-up study of a large number of patients with OCD is needed to confirm these observations. In addition, the effectiveness of these treatments in routine practice are not known.

SUMMARY

Part of "111 - The Course and Clinical Features of Obsessive-Compulsive Disorder "

The prevailing notion that the course of OCD is chronic and deteriorating has not been consistently borne out by the evidence, particularly in children followed prospectively. Furthermore, the natural course of this disorder appears to have been altered by the availability of effective pharmacologic and behavioral therapy. In their review of follow-up studies, Goodwin et al. (29) found that the course of OCD can be categorized as (a) unremitting and chronic, (b) phasic with periods of complete remission, or (c) episodic with incomplete remission that permits normal social functioning. Although the results of studies varied considerably in regard to the percentage of patients in each category, the majority of patients in each study were always in the last group, and the course of about 10% of patients was marked by progressive deterioration. These figures are consistent with our own study of patients meeting DSM-III criteria for OCD (Table 111.3). Although previous descriptive studies found a chronic waxing and waning course in 85% of patients, no attempt was made in previous studies to subdivide the waxing and waning course into predictable patterns or subtypes. More recent studies in which a prospective design and standardized criteria were used have shown that the episodic form of this disorder (clear periods of remission while the patient is off medication) is uncommon. The periodicity, duration, and severity of episodes in patients with OCD vary considerably. Once established, obsessions and compulsions usually persist, although the content, intensity, and frequency of the symptoms change over time.

The introduction of the SSRIs has led to a significantly improved prognosis for patients with OCD during the last decade. In a follow-up study by Orloff et al. (44) of a cohort of 83 OCD patients assessed 1 to 3 years after initial evaluation, 64% had a decrease of more than 50% in Y-BOCS score, and 33% had a decrease of more than 75% in Y-BOCS score at follow-up. These results are at odds with those of two other prospective longitudinal observational studies of the course of OCD that have recently been initiated at our site. Eisen et al. (38) examined 68 obsessive-compulsive outpatients evaluated at the Yale–Brown clinics and followed them prospectively during a 2-year period. Of the 51 patients who started the study meeting full criteria, 57% still met full criteria after 2 years. Survival analysis revealed a 47% probability of achieving at least partial remission during the 2-year study period. In another prospective study, by Steketee et al., 107 clinic patients with OCD were followed for up to 5 years after intake. The probability of partial remission for at least a 2-month period was 53%, and for full remission (no longer meeting criteria) at 5 years it was 22% (41).

The Pathophysiology and Genetics of Obsessive-Compulsive Disorder

David L. Pauls

Emanuela Mundo

James L. Kennedy

David L. Pauls: Child Study Center, Yale University School of Medicine, New Haven, Connecticut.

Emanuela Mundo and James L. Kennedy: Department of Psychiatry, University of Toronto, Toronto, Canada.

Multiple converging lines of evidence suggest that neurobiology plays a significant role in the etiology of obsessive-compulsive disorder (OCD). During the past decade, there has been considerable progress in the identification of neuroanatomic substrates involved in the expression of OCD. The brain areas most frequently identified by *in vivo* neuroimaging studies as potentially involved in the manifestation of OCD are the orbitofrontal cortex (OFC), the anterior cingulate area (ACA), and the head of the caudate nucleus (1). Furthermore, pharmacologic and neurobiological studies have implicated several central neurotransmitter systems in the pathophysiology of OCD and related conditions. The strongest pharmacologic evidence concerns the serotonergic system and the well-established efficacy of potent serotonin reuptake inhibitors in the treatment of OCD (2 ,3); however, other systems have also been implicated. A growing body of evidence suggests that the pathophysiology OCD is complex and that, despite the fundamental role played by serotonin (5-HT) in the pathogenesis of obsessions and compulsions, a serotonergic dysfunction may explain no more than 50% of the variability of the disease. The most widely accepted alternative neurochemical theory for OCD suggests that the dopamine (DA) neurotransmission system also may be important in the pathophysiology of some cases of OCD (3 ,4 ,5 and 6). Specifically, the DA hypothesis has been proposed for those cases of OCD that appear to be related to Gilles de la Tourette syndrome (GTS) or other tics disorders, and/or those that occur with schizotypal personality disorder and/or poor insight. There is also a new etiologic hypothesis for OCD involving an autoimmune mechanism, particularly relevant for early-onset cases.

At the same time, there has been considerable research that has documented the familial nature of OCD (7). These family data, when taken together with twin studies, suggest that genetic factors are important in the manifestation of this illness. Segregation, linkage, and association studies have begun and the results are similar to those observed for other major psychiatric disorders: The mode of transmission within families is complex and the precise genetic mechanism is not known.

In this chapter the main pathophysiologic findings for OCD are reviewed as well as the evidence that genetic factors are of etiologic importance. Finally, the findings from studies examining candidate genes proposed as the result of several lines of investigation that implicate both the serotonergic and dopaminergic neurotransmitter systems are summarized.

THE PATHOPHYSIOLOGY OF OCD

Part of "112 - The Pathophysiology and Genetics of Obsessive-Compulsive Disorder "

The Serotonin Hypothesis

Historically, the serotonin (5-HT) hypothesis has its basis in the pharmacology of OCD. In the late 1960s it was observed that clomipramine, the only tricyclic antidepressant with potent 5-HT reuptake blocking properties, had antiobsessional activity (8 ,9). Subsequently, several studies have shown that clomipramine and several other selective serotonin reuptake inhibitors (SSRIs) are effective antiobsessional agents. In fact, results were taken as evidence that serotonin plays a fundamental role in the pathogenesis of OCD (10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 and 18). These observations have led to the examination of the serotonin system and its function in OCD patients. Peripheral markers for the 5-HT system and a number of parameters of the 5-HT function have been investigated. These include CSF 5-hydroxyindoleacetic acid (the major metabolite of serotonin) (19 ,20 ,21 and 22), whole blood levels of 5-HT (23 ,24 and 25), platelet 5-HT concentrations (26),

and platelet imipramine binding (thought to be reflective of 5-HT uptake) (27 ,28 ,29 and 30). The results of these studies, although not definitive, suggest that a 5-HT dysfunction is present in OCD. More detailed information has come from pharmacologic challenge studies in which compounds were administered that, acting presynaptically or postsynaptically, stimulate 5-HT transmission. In these studies behavioral and neuroendocrine responses in OCD patients were assessed after challenges with meta-chloro-phenyl-piperazine (mCPP) (20 ,31 ,32 ,33 ,34 ,35 and 36), intravenous clomipramine (37 ,38), the 5-HT precursor tryptophan (39 ,40), the 5-HT releasing agent fenfluramine (41 ,42 ,43 ,44 and 45), ipsapirone (46), buspirone (47), and sumatriptan (48 ,49). These studies have also yielded conflicting results, similar to those derived from the challenge studies employing the 5-HT antagonist metergoline (50 ,51) and tryptophan depletion (53). Overall, about 50% of the OCD patients challenged acutely with proserotonergic compounds experienced a transient worsening of obsessive symptoms. These results suggest that for some OCD patients there would be a basal hyperactivity of the 5-HT neurotransmission system, owing either to a hypersensitivity of the postsynaptic receptors or to a hypoactivity of the presynaptic ones, which usually provide self-regulation (54). This could explain both the worsening of OCD symptoms after acute 5-HT stimulation and the clinical efficacy (i.e., improvement of OCD symptoms) after chronic administration of proserotonergic compounds (37 ,38).

The chronic administration of clomipramine or SSRIs induces an enhanced 5-HT release in the orbitofrontal cortex, probably as a consequence of the desensitization of the terminal 5-HT autoreceptors, and this has been hypothesized to be the neurobiological substratum for the effects of SSRIs in the treatment of OCD. The involvement of the presynaptic desensitization as a key step for the neurobiological mechanism of the antiobsessional response to proserotonergic compounds is also suggested by both the long latency of clinical efficacy (6 to 8 weeks, longer than the latency for the antidepressant response induced by the same compounds) and the high doses required (54).

Nevertheless, the fact that not all OCD patients respond to clomipramine or SSRIs and approximately 40% of them have no clinical improvement (55 ,56) may reflect the biological heterogeneity of the OCD phenotype already suggested by the variability of the response to acute 5-HT challenges. Thus, consideration of more homogeneous subgroups of OCD patients defined by response to biological challenges or different symptom subtypes could lead to clarification of the pathogenesis of the disease and the role of alternative hypotheses to the serotonergic one.

The Dopamine Hypothesis

There is now considerable evidence that some forms of OCD are etiologic related to GTS (57). GTS appears to be predominantly dopaminergically mediated, as evidenced by the well-documented clinical response to haloperidol and other dopamine antagonists (58), by the exacerbation with L-dopa and central nervous system stimulants (such as amphetamines) (59 ,60), and reports of lower CSF levels of the dopamine metabolite homovanillic acid (HVA) (61). Moreover, OCD patients with comorbid tic disorder or GTS are usually resistant to conventional pharmacotherapy with proserotonergic compounds, and may benefit from adjuvant treatment with dopamine (DA) or DA/5-HT blockers (6 ,55 ,56 ,62 ,63). This body of evidence suggests that there is an involvement of DA in at least some OCD patients.

With respect to the peripheral markers of the DA transmission, normal CSF levels of HVA have been reported (19 ,64), whereas the administration of fenfluramine produced increased inhibition of HVA secretion (33 ,65). The DA involvement has been assessed by measures of growth hormone response to apomorphine (66 ,67), and challenge with *d*-amphetamine (68) and methylphenidate (69), with conflicting results.

The serotonin and dopamine systems interact extensively, particularly in the basal ganglia (31), an area that has been implicated in the pathogenesis of obsessive-compulsive phenomenology by several studies (1 ,70 ,71 and 72). Indirect support for the involvement of both transmitter systems includes the observation of the emergence of *de novo* OC symptoms in patients on clozapine or risperidone, atypical antipsychotics with both D2 and 5-HT2 blocking properties (73 ,74 and 75), together with the demonstrated antidopaminergic activity of two antiobsessional agents, clomipramine and fluoxetine (76 ,77).

Other Neurobiological Hypotheses

Alternative neurobiological mechanisms have been proposed for OCD but they are in need of further confirmation. As already reported, functional neuroimaging studies have demonstrated dysfunction in the orbitofrontal cortex, basal ganglia and striatum, which normalize with successful treatment (78 ,79). Neuroendocrine mechanisms were implicated in the pathogenesis of obsessions and compulsions, based on studies employing oxytocin, vasopressin, and somatostatin (64 ,80 ,81 and 82). These studies also need further replication.

The Autoimmune Hypothesis

Allen, Leonard, and Swedo first proposed the intriguing autoimmune hypothesis of OCD (83) after a thoughtful review of the literature. An association was drawn between infection with group A B-hemolytic Streptococcus (as well as other agents, including viruses), and the onset or the exacerbation of OCD in some children. The observation of an association between Sydenham’s chorea (an involuntary

movement disorder related to group A B-hemolytic Streptococcus-induced autoantibodies reacting with the basal ganglia) and OCD led to the characterization of the “pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections” (PANDAS) by Swedo and colleagues (84 ,85), including OCD. Similar links between group A B-hemolytic Streptococcus and GTS have been observed (86 ,87). A monoclonal antibody that identifies B-lymphocyte antigen (D8/17) has been shown to be a marker for susceptibility to rheumatic fever, PANDAS, and early-onset OCD in general (88 ,89). Moreover, D8/17 levels have been found to follow a segregation pattern most consistent with autosomal recessive inheritance in rheumatic fever families (89 ,90). There is evidence that PANDAS is familial, with dramatically increased rates of clinical and subclinical OCD observed in parents of children with PANDAS (91).

The importance of this hypothesis cannot yet be determined, however, because it is not known how many childhood-onset cases of OCD are associated with this autoimmune process. It is possible that inherited genetic factors interact with the autoimmune mechanisms, making a subject more or less susceptible to the cross reaction created by the infection. Genetic variants in the human leukocyte antigen (HLA) system may be interesting candidates to examine in this group of OCD subjects.

THE GENETICS OF OCD

Part of "112 - The Pathophysiology and Genetics of Obsessive-Compulsive Disorder "

There has been considerable controversy regarding the inheritance of OCD. This is surprising since the familial nature of OCD has been documented since the 1930s and twin studies have provided evidence for the importance of genetic factors in the manifestation of OCD.

Twin Studies

In 1986, Rasmussen and Tsuang (92) reviewed the literature on OCD twins and found 32 of 51 (63%) MZ twins were concordant for OCD. Furthermore, when those twins where zygosity was in doubt were eliminated from the sample, 13 of 20 (65%) were concordant for OCD. These MZ concordance rates are similar to those reported for affective and anxiety disorders. However, the results need to be interpreted with caution because no data from DZ twins were available for comparisons.

This shortcoming was addressed by Carey and Gottesman (93) who studied a consecutive series of 15 MZ and 15 DZ twins ascertained from the Maudsley Twin Register. The index twin in each pair had received a psychiatric diagnosis of obsessional neurosis, obsessional personality, or phobic neurosis at local hospitals during a 32-year interval (1948 to 1979). Each twin pair was followed-up by personal interview and assessment of psychiatric status. The hospitals’ notes on the index cases and family members were also used to assign diagnoses. When a diagnosis of obsessive symptoms was used, these investigators found that 87% of the MZ twins were pair wise concordant compared to 47% of DZ twins, yielding a heritability estimate of approximately 80%.

In a more recent study, Torgersen (94) investigated the concordance of anxiety disorders (including obsessive-compulsive disorder) in the co-twins of 32 MZ and 53 DZ same-sex Norwegian twins. The sample consisted of all twins born between 1910 and 1955 who were admitted for treatment of neurotic or borderline psychotic disorders at any time before 1977. After ascertainment each twin was interviewed using a structured psychiatric interview that recorded lifetime occurrence of psychiatric symptoms; this information was then combined with the hospital records to make DSM-III lifetime diagnoses. A group of six DSM-III anxiety disorders was examined: panic disorder, agoraphobia with and without panic, social phobia, OCD, and generalized anxiety disorder (GAD). No twins were found to be concordant for the same anxiety disorder. Thus, the author examined concordances in the larger context of an “anxiety spectrum.” When the category that included only panic disorder, agoraphobia, social phobia, and OCD was, a statistically significant difference in concordance rates was seen: 45% in MZ pairs compared to 15% in DZ pairs (P <.02). This difference was not seen when considering GAD alone, nor when a combined proband diagnostic category including GAD was used.

Two important aspects of these studies critically limit their usefulness. The first limitation is the lack of standardized diagnostic criteria across studies. It is difficult to interpret results when different diagnostic criteria are used in the different studies being compared. The second limitation is the lack of blindness in evaluating the twins. The investigators doing the evaluations of the co-twin, knew the diagnosis of the index case. The lack of any procedural blind for obtaining diagnostic information or for making the actual diagnoses of a co-twin is a serious source of bias that could lead to spurious results.

Two studies were completed that used twins ascertained through twin registries. Furthermore, the evaluations of the twins were done blindly. Clifford (95) and Clifford and associates (96) analyzed data collected from 419 pairs of unselected twins who had been given the Eysenck Personality Questionnaire (EPQ) and the 42-item version of the Leyton Obsessional Inventory (LOI). Multivariate analyses provided separate heritability estimates of 44% for obsessional traits (as defined by the 10-item “Trait Scale” of the LOI) and 47% for obsessional symptoms necessary for a diagnosis of OCD (as defined by the 32-item “Symptom Scale” of the LOI). In a separate study using twins from the Australian Twin Registry, Andrews and associates (97) administered structured psychiatric interviews to 186 MZ and 260 DZ twin pairs. Ascertainment was not based on psychiatric caseness. Lifetime data for OCD, GAD, panic

disorder, social phobia, and major depressive disorder were obtained. The findings were similar to those of Torgersen in that, no differences in MZ/DZ concordances were observed when individual disorders were examined. However, when the diagnoses were combined into a single category of “neuroticism,” the MZ correlations were significantly higher than for the DZ twins; (0.58 versus 0.31) for female twins and (0.44 versus 0.27) for male twins.

In summary, all twin studies to date are consistent with the hypothesis that genetic factors are important for the expression of OCD and the specific symptoms necessary for a diagnosis of OCD. Furthermore, the two most recent studies (94 ,97) suggest that some of the same genetic factors may be important for the manifestation of some other anxiety symptoms.

Family Studies

Data from the majority of family studies completed over the past 60 years suggest that OCD is familial (7); however, rates of illness among relatives vary from study to study. Many of the studies completed prior to 1990 are difficult to interpret because of differences in diagnostic criteria and assessment methodologies and the lack of control samples or reliable estimates of population prevalence. Some of the shortcomings of this early research were addressed in six recent studies (57 ,98 ,99 ,100 ,101 and 102). All of these studies demonstrate that OCD and related conditions are familial.

Lenane and colleagues (98) studied families of 46 children and adolescents and found that 17% of the parents had OCD (25% of fathers and 9% of mothers). In a second study of the families of children and adolescents, Leonard and co-workers (99) found that 13% of first-degree first-degree relatives of OCD probands met DSM criteria for OCD. Bellodi and associates (100) reported that 3.4% of the relatives in 92 families had OCD. Although this rate is somewhat lower than other studies, it nevertheless represents a twofold increase over available population prevalence estimates. Of note is that when probands were separated on the basis of age at onset, the morbid risk for OCD among relatives of early onset (before age 14) probands was 8.8% compared to 3.2% among the relatives of later onset probands. A shortcoming of these three studies is that none included a control sample. However, assessments in all of them were done using structured interviews that were used in epidemiologic surveys. The best estimate of the population prevalence for OCD from the most recent epidemiologic study (103) is 2.3 ±0.3% in Baltimore (both of the Lenane and Leonard studies were done at the NIH in Washington, DC). Using this estimate of prevalence, the relative risk (γ) (the ratio of illness among relatives to the population prevalence) (103) for these two studies ranged between 4.4 and 10.2.

The three remaining family studies included control samples. Black and colleagues (101) studied families of 32 adult OCD probands. First-degree relatives over the age of 18 of 32 probands with OCD and 33 controls were systematically interviewed using the Diagnostic Interview Schedule (DIS). Altogether, 249 relatives (nearly 60%) were directly interviewed. Although the prevalence of OCD was not significantly increased among relatives of OCD probands, the results support the concept of an OCD spectrum. In particular, there was an increase in the rate of “subclinical” OCD among parents of OCD probands when compared to parents of controls. The following caveat should be noted when interpreting these findings. In most studies of psychiatric disorders, direct interviews, family history data, and medical record data are used to make “best estimate” diagnoses (104). In this study, Black and colleagues used only data collected from direct interviews of the relatives about themselves to assign diagnoses. Given the secrecy of many OCD patients and their tendency to hide their illness, it is possible that some family members denied symptomatology on direct interview. As noted in the report, family history data were collected by Black and colleagues but were not used in the diagnostic assignment reported. When those family history data are included, the recurrence risk among first-degree relatives is 9.8%; a rate not significantly different from recurrence risks reported in other studies. Using this estimate for the risk to relatives, the γ ranges between 1.8 and 12.1.

In 1995, Pauls and colleagues (57) reported the results of a study of 466 first-degree relatives of 100 OCD probands and 113 control subjects. The age corrected rate of OCD (10.3%) was significantly higher in the relatives of OCD probands when compared to controls (1.9%). A familial relationship has been reported between OCD and GTS and chronic tics (CT) (105) and it has been speculated that familial OCD is that type that is related to GTS. Although the rates of GTS and chronic tics were also significantly higher among relatives of OCD probands than among controls in this study, the patterns within the families suggested that much of OCD is not related to GTS; the majority of OCD individuals did not have a personal or family history of GTS or tics; however, many did have a positive family history of OCD. Thus, some forms of OCD that appear to be unrelated to tics or GTS are familial.

Finally, in the most recent and methodologically sound family study of OCD, Nestadt and colleagues (102) reported that 11.7% of 326 first-degree relatives of 85 OCD probands met DSM-III-R criteria for OCD compared to only 2.7% of controls. The methods used in this study were essentially identical to those used in the Pauls and associates (57) study. That is, the investigators directly interviewed all available first-degree relatives and obtained family history data for all first-degree relatives. Best estimate procedures were used in assigning diagnoses. The difference between the Pauls and Nestadt study is that, the latter was able to interview many more first-degree relatives than the former. Nevertheless, it is remarkable that the estimates of recurrence

risk obtained in the two studies were not significantly different. Using available population prevalence estimates from each site and the recurrence risks reported for first-degree relatives, the estimated γ ranges between 3.4 and 27.8.

Clinical Heterogeneity and Its Relationship to Familiality

Although the assessment and diagnosis of OCD is highly reliable and valid, it has also become clear over the last decade that there is considerable variability of symptomatology across individuals who have a diagnosis of OCD. Given this variability, a number of investigators have begun research to explore the possibility that subtypes/components of OCD might be distinguished on the basis of some features of the disorder. Several analyses have been completed to determine whether more homogeneous groups of OCD patients could be identified that were also more likely to be familial. One way of grouping individuals that has helped identify heritable subtypes in other conditions has been to examine age at onset. Analyses of age at onset of OCD indicate that early-onset OCD is more likely to be familial (57 ,102). However, there is still considerable familial heterogeneity within this group because a substantial proportion of early-onset OCD cases are not familial (7).

Another approach that has proven useful in identifying components of the phenotype rather than subtypes of patients is factor analysis. A number of investigators have completed factor analyses on at least four independent samples of individuals with OCD (106 ,107 ,108 and 109). In all of these analyses similar factors emerged that accounted for a substantial amount of the variance in each data set. One factor was best characterized by aggressive, sexual, religious, and somatic obsessions and related checking behavior (in the most recent set of analyses, this factor appeared to split into two separate factors). Another factor was characterized by the need for symmetry or exactness, repeating rituals, counting compulsions, and ordering/arranging compulsions. Another factor was characterized by contamination obsessions and washing/cleaning compulsions. And a final factor was characterized by hoarding obsessions and compulsions.

Preliminary analyses have been undertaken to examine whether any of these factors are related to family risk patterns (110). One of the samples included in the factor analyses reported by Leckman and associates (107) consisted of the probands for the family study of OCD reported by Pauls and co-workers (57). Additional factor analyses of the family data, which included all first-degree relatives, demonstrated that the relatives showed the same factor structure as the probands. Further analyses suggested that there were different recurrence risks for OCD among relatives of probands with different combinations of factors scores. The age-corrected recurrence risk among relatives of probands who had positive scores on the factor characterized by aggressive, sexual, religious and somatic obsessions and related checking behavior was 23.6% compared to only 13.9% among relatives of probands who had negative scores on that factor ($x^2 = 7.57$, $P < .006$). For the factor characterized by the need for symmetry or exactness, repeating rituals, counting compulsions and ordering/arranging compulsions, the age-corrected recurrence risk among relatives of probands who had positive scores was 22.7% compared to 13.5% among relatives of probands who had negative scores on that factor ($x^2 = 7.57$, $P < .019$). There was no relationship between risk to relatives and proband factor scores for the other factors. As discussed, results of complex segregation analyses that incorporated these factors scores suggested that there were different patterns of transmission within families that were related to the factor scores of the probands. Unfortunately, the number of affected relatives for whom it was possible to generate factor scores was too small to allow meaningful analyses designed to determine whether the factor scores of affected relatives were correlated with the factor scores of the probands.

Family patterns demonstrate that OCD is a complex disorder with different familial patterns being associated with different clinical characteristics of OCD. Given these familial patterns, it is likely that several genes contribute to the manifestation of the disorder. It is quite plausible that unique genes could be involved in the expression of different domains of symptomatology. Separately examining these component parts of the phenotypic spectrum with regard to their transmission within families and the possible role of genetic factors could facilitate the identification of the genes involved in the manifestation of OCD.

Segregation Analyses

Together, the family and twin study data provide compelling evidence that some forms of OCD are familial and genetic. Furthermore, segregation analyses reveal that the patterns within families are consistent with genetic models that include genes of major effect. Nicolini and colleagues (111) performed segregation analyses on data collected from 24 OCD families and Cavallini and co-workers (112) completed complex segregation analyses with data from a sample 107 families ascertained through an OCD proband. In both studies, the most parsimonious result suggested that the mode of transmission within families was most similar to an autosomal dominant pattern; however, other major gene solutions could also adequately explain the observed familial patterns.

More recently, complex segregation analyses were completed (110) on the family study data reported on by Pauls and associates (57). Analyses were done using the computer program POINTER (113). One hundred families with 466 first-degree relatives composed of 191 parents (95 fathers and 96 mothers), 217 siblings (105 brothers and 112 sisters),

and 58 offspring (39 sons and 19 daughters) were included in the analysis.

Analyses were performed on: (a) the complete data set; (b) a subset of clearly familial families; and (c) family subsets based on the previously described symptom factor structure in order to explore the possibility that these factors represent homogeneous heritable components of OCD.

Using the entire data set, only the model of no transmission could be rejected ($x^2_{(4)} = 135.49$, $P < 10^{-6}$). No specific genetic models could be ruled out. The lack of definitive results with the total sample could be due to the fact that approximately half of the families in this sample did not have any relatives affected with OCD. This pattern of familiality has also been observed in at least three other studies: Nicolini and associates (111) reported that 11 of 24 probands in their study did not have a family history of OCD; Eapen and co-workers (114) observed that approximately half of the probands in their study were isolated cases; and Cavallini and colleagues (112) reported that 54 of their 107 probands were sporadic cases.

Given these findings, the next analyses included only the subset of families in which there were at least two individuals (the proband and one other first-degree relative) affected with OCD. A total of 52 families were included in these analyses. Because OCD in another family member was a criterion for inclusion of a family, one of the affected first-degree relatives in each family was randomly assigned as a secondary proband and the analyses were appropriately corrected for this ascertainment. In these analyses, all transmission models could be rejected except a multigenic model that included both a gene of major effect and polygenic background.

Finally, these investigators divided all families on the basis of four dichotomous classification schemes that were derived from the probands' factor scores obtained from the factor analyses described in the preceding (107). For the analyses performed on families whose probands had positive scores for hoarding obsessions and compulsions, contamination obsessions and compulsions, or aggression/checking obsessions and compulsions, only the hypothesis of no transmission could be rejected. That is, there was no genetic model that could be identified as the most parsimonious. On the other hand, analyses of families whose probands had positive scores on the factor characterized by symmetry (counting obsessions and compulsions) yielded results consistent with a model that included genes of major effect.

The results of these segregation analyses demonstrate that the transmission of OCD is generally difficult to model (at least within the confines of current methods for complex segregation analysis). In most cases, no single genetic model provided the most parsimonious solution to the patterns of transmission. This could be owing to the fact that OCD is etiologically heterogeneous with only half of the cases representing familial forms. It is noteworthy that when analyses were limited to those families in which the disorder was clearly familial (i.e., families in which there are at least two individuals with OCD), the most parsimonious explanation of transmission was that it was multigenic, with at least one gene of major effect on a polygenic background.

OCD is clinically heterogeneous and most likely is also genetically heterogeneous. Although it is possible that there is at least one locus that has an appreciable impact on the manifestation of OCD, it is highly likely that it is not a single-gene disease. The familial transmission patterns are not consistent with single-gene inheritance. As reviewed in the section on pathophysiology, it appears that there are several different neurochemical pathways that are involved in the expression of OCD. Thus, it is likely that there are a number of different molecular paths to the behavioral outcome; each influenced by a different gene or genes.

In summary, there is compelling evidence from twin, family, neuroanatomic, and neurobiological studies that biological/genetic factors are important in the expression of OCD. A more complete understanding of the genetic basis and of the interactions between relevant genotypes and relevant environmental factors will be important for eventual clarification of the etiology and pathogenesis of this complex disorder. Results from all segregation analyses suggest that the underlying genetic mechanisms for OCD involve genes of major effect. The next necessary step in our goal of understanding the genetics of OCD is to localize and characterize the genes that confer susceptibility.

MOLECULAR GENETIC STUDIES

Part of "112 - The Pathophysiology and Genetics of Obsessive-Compulsive Disorder "

Genetic linkage has long been recognized as one of the methods useful in clarifying the role of genetic and environmental factors in the expression of complex disorders like OCD. Historically, the method has had limited applicability because of the small number of sufficiently polymorphic genetic markers available for study in humans. With the sequencing of the human genome, this situation has changed dramatically. Theoretical and empirical work suggests linkage studies can identify the location and thereby verify the existence of genetic loci important in the expression of these disorders; however, multiple strategies need to be employed in the study of complex non-mendelian disorders (115 ,116). Although the sib-pair approach has been available for some time, only recently has it become evident that its application is increasingly important in the genetic study of disorders where there may be genetic heterogeneity and where the mode of inheritance is complex (116). An important advantage in the use of sib-pairs is that no prior assumptions regarding specific genetic model parameters are required. Furthermore, with the increasing number of polymorphic markers available, association studies may prove feasible in the search for susceptibility genes (117).

Given the family patterns observed and the findings from

segregation analyses regarding the mode of transmission of OCD, a methodologic approach that does not require specification of a particular genetic model should be more efficacious in identifying some of the OCD susceptibility genes. Furthermore, as discussed by Pauls (118) exclusive reliance on large multigenerational families for the detection of linkage is not indicated when the disorder is common and the most likely mode of transmission is multigenic.

At the present time, there are no published linkage studies of OCD. Thus, the remainder of this chapter focuses on association studies of candidate genes.

Association Studies

Genes of the Serotonergic System

Gene testing in OCD has begun, focusing on candidates derived from the hypothesized etiologic importance of the serotonin and dopamine systems. With respect to the serotonin system, the serotonin transporter gene (SLC6A4) has been implicated in OCD as the site at which SSRIs initially exert their effects. Lesch and co-workers (119) evoked considerable interest in the transporter gene by demonstrating an association between the short allele of the 44bp insertion/deletion polymorphism in the promoter region and the anxiety-related personality traits of Neuroticism and Harm Avoidance in 505 individuals. This polymorphism has been shown to affect gene function *in vitro;* the longer allele (*l*) is associated with threefold increases in gene expression (120). Furthermore, the *l* allele of this polymorphism has been associated with elevated blood SLC6A4 levels in a sample of 70 OCD subjects (121). The first study of the promoter polymorphism revealed a trend toward increased homozygosity (*l*/*l* and *s*/*s*) in OCD patients, but the overall results were indeterminate (122). Subsequent investigation of OCD trios revealed significantly increased transmission of the *l* allele to OCD probands (123).

The 5-HT2A-receptor gene has been investigated in an association study, including 67 OCD patients (124) with inconclusive results. Kim and associates sequenced the 5-HT2B-receptor (125). One single nucleotide polymorphism was found in intron 1 of the gene, but no evidence for a functional mutation was found. Finally, another association study by Cavallini and colleagues (126) of a 5-HT2C polymorphism in 109 OCD subjects and matched controls also gave negative results.

Very recently, an association between OCD and a polymorphism of the 5-HT1DB receptor gene has been reported (127). This result appears to be particularly interesting with respect to the pathogenesis of OCD and surely deserves further investigation. The 5-HT1DB receptor is a terminal autoreceptor involved in the regulation of 5-HT transmission, and challenge studies with selective ligands (i.e., sumatriptan) (48) showed an acute worsening of OC symptoms, whereas chronic treatment with the same compound can induce improvement in OCD patients resistant to conventional pharmacotherapy (128).

Genes of the Dopaminergic System

Turning to dopamine system genes, two early case–control studies showed a lack of association with polymorphic sites in the dopamine D2 and D3 receptor genes (129 ,130). These negative results also have been replicated (124). The most promising gene in the dopamine system appears to be the D4 receptor gene. Preliminary investigations have shown a positive association between a 48-bp VNTR polymorphism and OCD (131); Cruz and co-workers (132) reported an association between the seven-repeat variant of the same polymorphism and the subtype of OCD with comorbid tic disorders.

Additional Genes

There are preliminary investigations of two enzymes involved in the metabolism of biogenic amines, catechol-*O*-methyltransferase (COMT) and monoamine oxidase A (MAO-A). Camarena and associates (133) found increased frequency of the low activity MAO-A allele in females, among a total sample of 41 OCD patients and controls. COMT modulates dopaminergic and noradrenergic neurotransmission via inactivation of catecholamines. Support for involvement of this gene derives from observations of an association between velo-cardio-facial syndrome, a rare congenital malformation associated with a microdeletion on chromosome 22q11, and obsessive-compulsive symptoms (134 ,135). Of significant interest, the COMT gene maps to this region. Two studies by Karayiorgou and colleagues (136 ,137) have shown an association between susceptibility to OCD in males and a common functional COMT allele that leads to a reduced enzyme activity. In an attempt to replicate this finding, Alsobrook and associates (138) completed family based association studies in 50 OCD trios and found no significant association in the total sample or in male probands; however, these investigators found an association in female probands (P = 0.051). Schindler and colleagues (139) have found evidence for association between homozygosity of either COMT allele and OCD. In sum, these COMT results are difficult to understand at this point. It is possible that genetic heterogeneity and population stratification may be contributing to the complexity of the findings.

CONCLUSION

Part of "112 - The Pathophysiology and Genetics of Obsessive-Compulsive Disorder "

The identification and characterization of genes important in the expression of OCD will be a major step forward in understanding the genetic and biological risk factors important for the expression of this disorder. In addition, this

work will allow the potential identification of other nongenetic factors associated with the manifestation or amelioration of the symptoms of the disorders. On the one hand, the identification of a linked marker will permit the design of much more incisive studies to illuminate the physiologic/biochemical etiology of OCD by examination of the gene product and its impact on the development of the disorders. On the other hand, by controlling for genetic factors, through the genetic case-control research paradigm, it will be possible to document more carefully the environmental and nongenetic factors important for the expression of OCD and other possibly related conditions. Studying genetic marker data together with data characterizing phenotypic expression in the context of specific environments should allow a more complete examination of the cocontribution of genetic and nongenetic factors.

Imaging and Neurocircuitry of OCD

David R. Rosenberg

Shauna N. MacMillan

David R. Rosenberg and Shauna N. MacMillan: Wayne State University School of Medicine, Detroit, Michigan.

> The history of the living world can be summarized as an elaboration of ever more perfect eyes, within a cosmos in which there is always something more to be seen.
>
> --(Pierre Teihlard de Chardin, *The Phenomenon of Man*)

Once considered a rare condition, obsessive-compulsive disorder (OCD) is now recognized as a severe and often chronically disabling illness that affects 1% to 3% of the world's population (1 ,2 ,3 ,4 and 5). The condition is characterized by intrusive ritualistic thoughts, ideas, and behaviors (obsessions and compulsions, respectively) over which the person has little if any control. Recent investigation further suggests that the illness has its onset in childhood and adolescence in at least 80% of all cases, although it often goes undiagnosed until adulthood (6).

In recent years, neuroimaging studies have begun to bridge the gap between our understanding of the neurobiologic underpinnings of OCD and the development of effective clinical assessment measures and treatments for the illness. This is critical because even as use of the selective serotonin reuptake inhibitors (SSRIs) and cognitive behavioral therapy (CBT) has become routine in the treatment of OCD, at least one-third of OCD patients do not respond at all to currently available treatments (7). Many patients who respond to treatment do so only partially; continued functional impairment is the rule. It is the rare patient who experiences complete remission of his or her symptoms. A clearer understanding of the neuropathophysiologic mediation and expression of OCD may result in the identification of new and more effective treatments for this chronic and often crippling illness.

Indeed, this view is supported by many other neurologic and medical conditions for which treatment includes psychosocial and medication interventions acting on specific somatic substrates. Up until the 1930s, epilepsy was considered more a psychiatric than neurologic condition (8 ,9). Indeed, in the Middle Ages, persons with epilepsy were often believed to be possessed by the devil. Epilepsy carried considerable stigmata and was often a cause for shame; its victims were often considered to be "crazy" and in need of psychiatric treatment. This reflected, in part, a lack of knowledge about the neurobiologic substrates underlying epilepsy. With the advent of the EEG, it became evident that electrical abnormalities in the brain underlie various epileptiform conditions. The EEG also helps guide choice of treatment intervention (10); for example, different medications are used for persons suffering from temporal lobe epilepsy (e.g., carbamazepine) versus those suffering from grand mal seizures (e.g., phenobarbital). Treatment for other medical conditions such as diabetes, rheumatoid arthritis, and asthma also includes psychosocial and medication interventions acting on specific somatic substrates. Although we have not achieved comparable understanding of neuropsychiatric disorders such as OCD, 10 years from now we may have identified 10 different subtypes of OCD characterized by specific neurobiologic abnormalities that may, in turn, necessitate individualized treatment interventions (11). Neuroimaging allows for precise measurement of brain structure, chemistry and function, which can be correlated with both baseline and clinical outcome measures (e.g., Yale-Brown-Obsessive-Compulsive Scale, SSRI, CBT treatment) (12). This very powerful approach is answering hypothesis-driven investigations regarding pathophysiology, psychobiology, and treatment response in psychiatric disorders such as OCD. Brain imaging techniques in conjunction with advances in neuroscience and neuropsychopharmacology can contribute a great deal to the outstanding questions in child psychiatry relevant to enhanced diagnostic rigor and treatment development (13).

In this chapter, the authors review: (a) current neurocircuitry models of OCD that have converged to implicate abnormalities in cortical-striatal-thalamic-cortical circuits (14 ,15 ,16 ,17 ,18 ,19 and 20); (b) the relevant neuroimaging techniques utilized in investigating the neurocircuitry of OCD; and (c) neuroimaging studies conducted in OCD patients. The developmental

implications of these investigations are then discussed and a new clinical neurodevelopmental model of OCD is described as it may relate to treatment development.

NEUROCIRCUITRY OF OCD: CORTICOSTRIATAL CIRCUIT THEORIES

Part of "113 - Imaging and Neurocircuitry of OCD "

Basal Ganglia

As early as 1931, von Economo (21) described postmortem globus pallidus abnormality in OCD associated with postencephalitic parkinsonism. OCD behaviors are also increased in other basal ganglia disorders, including Huntington disease, Tourette syndrome, pediatric autoimmune neuropsychiatric disorders associated with group A ß-hemolytic Streptococcal infections (including Sydenham's chorea), neuroacanthocytosis, and progressive supranuclear palsy (17 ,22 ,23 ,24 ,25 ,26 ,27 ,28 and 29). Aberrations in basal ganglia–frontal cortical networks may play an especially critical role in the emergence of OCD symptoms (14 ,16).

Frontal Cortex

Fronto-striatal abnormalities have been hypothesized to represent the core pathology in OCD (15 ,16 ,30 ,31 ,32 ,33 and 34). Ventral prefrontal cortical regions, particularly anterior cingulate and medial orbital frontal cortex and their striatal target fields, have been most consistently implicated in the pathogenesis and maintenance of OCD (16 ,31 ,35 ,36 ,37 ,38 ,39 ,40 ,41 and 42). This may, in part, reflect the critical role of anterior cingulate and medial orbital frontal cortex in regulation of affect and motivation (31 ,35 ,36 and 37). Lesions to these brain regions results in the inability to inhibit context inappropriate responses and inappropriate impulse modulation and behavior. Indeed, neuropsychological studies suggest that a deficit in response inhibition abilities may represent a core deficit in OCD (43 ,44 ,45 ,46 ,47 and 48). Neurosurgical lesions (e.g., cingulotomy) have also been demonstrated to be effective in reducing OCD symptoms in treatment-refractory patients (49). In contrast, evidence for abnormalities in other frontal lobe regions (e.g., dorsolateral prefrontal cortex) are much less compelling.

The anterior cingulate and medial orbital frontal cortex and their striatal target fields in ventral striatum receive dense projections from mesiotemporal lobe, particularly the amygdala and hippocampus (31 ,50). Mesiotemporal structures including the amygdala and hippocampus play an especially important role in processing and responding to the emotional valence of affective stimuli (30 ,51 ,52 ,53 ,54 and 55). In fact, animal studies have demonstrated that serotonin reuptake inhibitors known to be effective in the treatment of OCD have particularly potent effects on receptors in the amygdala (56 ,57 ,58 and 59). Wise and Rapoport (60) have hypothesized that excess activity in mesial temporal-orbitofrontal and anterior cingulate regions and their striatal target fields could disinhibit particular regions of the thalamus leading to OCD behaviors.

Thalamus

The thalamus is a highly evolved sensory and motor gateway to the cortex that serves as the final subcortical input to frontal cortex and plays a critical role in consciousness, perception, and integration of information (32 ,61). The thalamus is an important component of frontal and limbic circuits; thalamic lesions result in neuropsychological and behavioral disturbances similar to deficits observed in OCD patients (17 ,31 ,62). In fact, "frontal lobe"-type syndromes frequently appear indistinguishable from vascular and degenerative disorders of the thalamus (17). The thalamus serves as a filter in integrating information before it reaches the cortex—a task facilitated by its many cortical and subcortical connections.

When released from the inhibitory influence of the striatum, the thalamus stimulates cortical output. This has led to descriptions of "direct" and "indirect" pathways modulating frontal cortical output to ensure context-appropriate responses (31 ,32 and 33). Although the "direct" pathway releases the inhibitory tonic influence of the striatum, thereby stimulating thalamic stimulation of the cortex so that instinctual and protective hard-wired behaviors are enhanced, the "indirect" pathway facilitates the cortex in shifting sets and responding to new situations on the basis of the particular circumstance and prior stored information by inhibiting the thalamus. Baxter and associates (32) have hypothesized neural hyperactivity in the direct versus indirect pathways and that this imbalance may result in obsessive and compulsive behaviors characteristic of the illness.

Preclinical investigation has demonstrated that compulsive behaviors can be provoked by altering thalamic function (63 ,64), whereas thalamic stimulation can result in compulsive behaviors in humans (65). This is particularly intriguing because neurosurgical lesion of the thalamus (e.g., partial thalamotomy) has actually been reported to reduce OCD symptoms in treatment-refractory OCD patients (49).

In summary, neurobiologic studies from preclinical and clinical laboratories have consistently implicated a cortico-striato-thalamo-cortical network in the pathogenesis of OCD (15 ,16 ,32 ,60 ,66). Advances in neuroimaging (discussed in the following) provide an unprecedented opportunity for developing a mechanistic understanding of the developmental neurobiology of OCD as it relates to the behaviors that characterize the illness. These methods allow for the direct, *in vivo* and noninvasive "biopsy" of the brain at levels of spatial and temporal resolution heretofore possible only in animal or postmortem human studies. Neuroimaging studies also facilitate our taking advantage of advances in neuroscience and applying them directly to clinical neuropsychiatric conditions such as OCD. Such an approach

may ultimately result in new diagnostic and therapeutic approaches with the identification of surrogate neurobiological markers predicting treatment response (or lack, thereof) (66 ,67 and 68). Although a detailed review of brain imaging methodology is beyond the scope of this chapter, a brief review is presented in the following. For more detailed descriptions, the reviewer is referred to relevant textbooks on brain imaging (69 ,70).

BRAIN IMAGING TECHNIQUES

Part of "113 - Imaging and Neurocircuitry of OCD "

Neuromorphometry

Newer noninvasive neuroimaging procedures permit measurement of changes in regional brain anatomy, chemistry, and function. Pioneering work in psychiatric neuroimaging has already resulted in findings of critical relevance to psychiatric disorders despite the brief period during which these techniques have been in use (71). For example, less than 15 years ago, measurement of structural abnormalities in neuropsychiatric disorders was limited to postmortem brain studies (70). Understandably, many were (and some remain) skeptical about applying brain imaging to neuropsychiatric disorders such as OCD. This may, in part, reflect the lack of sensitivity of earlier neuroimaging techniques (e.g., skull x-ray and ventriculogram) (70). The emergence of computerized tomography (CT) ushered in a new era of brain research during which evaluation of living tissue would become routine.

Moreover, although many discounted Johnstone and colleagues' (72) CT finding of cerebral ventricular abnormalities in schizophrenia, these currently represent some of the most replicated and best-established findings in psychiatry (69).

Quantitative CT and the more recent emergence of magnetic resonance imaging (MRI), which allows for enhanced three-dimensional (3D) acquisitions, tissue differentiation without putative ionizing radiation risks have revolutionized our ability to conduct precise, *in vivo* and noninvasive quantitative neuromorphometric studies of regional brain anatomy. These studies are critical because the volume of a brain region of interest in neuropsychiatric disorders has been demonstrated to reflect that region's function (73 ,74). Volumetric neuroimaging studies are also critical to guide functional, metabolic, and neurochemical studies and can also help characterize neurodevelopmental and degenerative effects of neuropsychiatric disorders (75). Interpretation of functional neuroimaging studies is, therefore, predicated on controlling for volumetric differences between patients and controls as well as psychotropic medication-induced volumetric changes (76 ,77 and 78).

Functional Neuroimaging

Although quantitative measures of brain volume are critical, newer and more sophisticated functional neuroimaging techniques may be more sensitive in identifying subtle brain abnormalities in neuropsychiatric disorders (79). Positron emission tomography (PET) and single photon emission computerized tomography (SPECT) permit measurement of cerebral blood flow, metabolism, neurochemistry, and receptor function. These techniques have been instrumental in elucidating the pathophysiology of OCD. Both SPECT and PET techniques use ligands labeled with radiation. These putative radiation risks limit their viability in pediatric populations and in longitudinal repeated studies assessing neurodevelopment and neurodegenerative effects. For example, many institutional review boards preclude PET studies in healthy control children. This may, however, become more feasible with advances in methodology including 3D PET, which may reduce radiation exposure significantly. Although radiation risks associated with SPECT are considerably lower than PET, the decreased resolution of SPECT limits its usefulness.

The recent advent of magnetic resonance spectroscopy (MRS) and functional MRI (fMRI) represent powerful approaches for the direct, *in vivo* and noninvasive measurement of brain chemistry and function without ionizing radiation risks. Recent investigation in OCD suggests that these techniques are very sensitive in identifying brain abnormalities not evident even with sophisticated morphometric MRI (79). In contrast to PET, fMRI allows for enhanced temporal resolution of brain function rather than focusing on measurement of brain activity during a single brief time interval (67). Event-related fMRI allows for second-to-second temporal resolution (80). Newer techniques including magnetoelectroencephalography (MEG) or electroencephalography (EEG) with fMRI studies allow acquisition and analysis brain activity in real-time with a spatial resolution in millimeters and a temporal resolution of milliseconds (81). Although not currently available, this is an active area of investigation and expected to be available in the very near future.

In summary, previous *in vivo* investigation of neuropsychiatric disorders such as OCD was limited by measures that provided only a peripheral index of brain function. Direct assessment of brain was limited to postmortem neuropathologic study or *in vivo* study in animal models. The aforementioned neuroimaging techniques provide an unprecedented opportunity to measure brain anatomy, chemistry, and function to elucidate the neurobiologic underpinnings of neuropsychiatric disorders such as OCD, which may translate into the development of new assessment procedures and treatments. In the following section, we discuss a series of neuroimaging studies that have consistently implicated regional changes in cortico-striatal-thalamic-cortical neural circuitry (66) being involved in the pathogenesis and maintenance of OCD.

NEUROMORPHOMETRY OF OCD (TABLE 113.1)

Italics indicate studies in the pediatric age-range.
[a]Studied patients with pediatric autoimmune neuropsychiatric disorders associated with Group A β-hemolytic streptococcal infection.
[b]Study by Peterson et al. included both pediatric and adult subjects. Putamen and globus pallidus were increased in patients with obsessive-compulsive disorder and attention deficit hyperactivity disorder who had increased antistreptolysin O and antideoxyribonuclease B antibody titers.

TABLE 113.1. STRUCTURAL NEUROIMAGING STUDIES IN OBSESSIVE-COMPULSIVE DISORDER

Global Changes of Ventricles, Cerebral Volume, and Atrophy

Although total brain volume has not been found to differ between OCD patients and controls (76 ,82 ,83 ,84 ,85 ,86 ,87 and 88), Behar and associates (89) reported significantly increased ventricular brain ratio (VBR) in adolescent OCD patients compared to controls. Rosenberg and co-workers (87) observed significantly increased third ventricular volumes in 19 treatment-naive, pediatric OCD patients compared to 19 age- and sex-matched controls but no differences in lateral ventricular volume as measured by volumetric MRI. In contrast, Insel

and colleagues (90) observed no significant differences in VBR between adult OCD patients and healthy comparison subjects. Examination of cortical gray and white matter has, however, demonstrated increased gray-white matter ratios in adult OCD patients (83 ,84). Such abnormalities could be owing to aberrations in prenatal programmed cell death or postnatal reductions or delays in myelination (84). Recent investigation has suggested abnormalities of postnatal myelination in pediatric OCD patients (91 ,92).

Striatum

Despite the striatum being posited as a primary site of pathology in OCD (30), structural neuroimaging studies of the caudate nucleus in adult OCD patients have revealed contradictory findings. Scarone and colleagues (93) reported increased right caudate size in OCD patients compared to controls, whereas Robinson and co-workers (85) found bilateral reductions in caudate volume in OCD patients. Four MRI studies have reported no significant differences in caudate size between OCD patients and controls (79 ,82 ,94 ,95). Investigation of the other components of the basal ganglia, including the putamen and globus pallidus, has not demonstrated volumetric differences between adult OCD patients and controls (84 ,94 ,96 ,97). These studies were potentially confounded by several factors including illness chronicity, past treatments, heterogeneity of OCD, and differences in imaging methodology used. Structural imaging studies in children may prove especially instructive because they allow for examination of neurodevelopmental factors and repeated studies for longitudinal assessment.

Nonetheless, structural neuroimaging studies in pediatric OCD patients have not been entirely consistent. Behar and associates' (89) observation of increased VBR in adolescent OCD patients is consistent with reductions in striatal volume (information on striatal volumes was not provided). More recently, Luxenberg and co-workers (96) reported bilateral reductions in caudate volume in adolescent men with OCD compared to controls using quantitative CT. Using volumetric MRI, two recent investigations (87 ,98) found no significant differences in caudate volume between treatment-naive pediatric OCD patients and age- and sex-case matched controls. Localized reductions in putamen volume associated with OCD symptom severity but not illness duration, however, were observed in pediatric OCD patients compared to controls (Fig. 113.1). Reduced putamen volumes have been reported in Tourette syndrome (99), a condition frequently associated with OCD symptoms. Putaminal lesions associated with OCD also have been reported in isolated case reports (100 ,101) and pediatric OCD patients have antibodies directed at the putamen at rates significantly greater than in healthy pediatric comparison subjects (102).

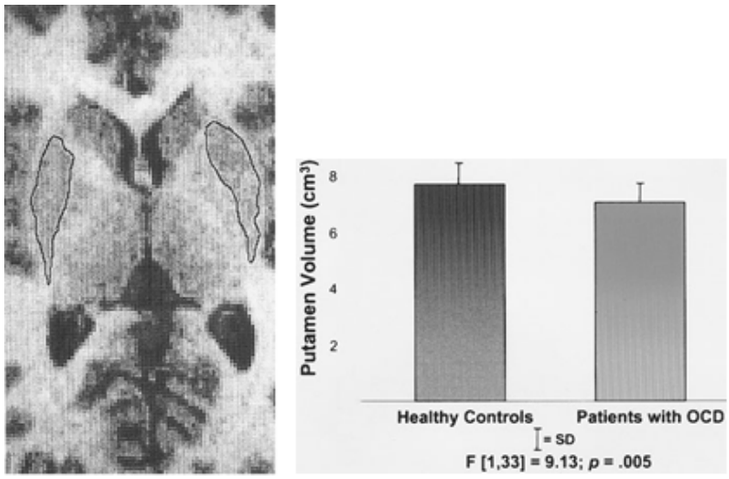

FIGURE 113.1. Measurement of putamen in the axial plane using a manual tracing technique *(left)*. Putamen volume by group *(right)*. OCD, obsessive-compulsive disorder. Adapted from Rosenberg DR, Keshavan MS, O'Hearn KM, et al. Frontostriatal measurement in treatment-naive children with obsessive-compulsive disorder. *Arch Gen Psychiatry* 1997;54:824–830.

In this regard, it is important to point out that Giedd and associates (24 ,26) have reported increased volumes in caudate, putamen, and globus pallidus in children with OCD or tics associated with group A ß hemolytic streptococcal (GABHS) infections and pediatric patients with Sydenham chorea and associated OCD and tic behaviors compared to healthy children. These conditions are now referred to as pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) (103 ,104) and may represent discrete subtypes of OCD and tic disorders. Increased basal ganglia volumes may be consistent with hypothesized antibody-mediated inflammation of the basal ganglia in poststreptococcal or OCD or tic disorders (103 ,104). Giedd and colleagues (24 ,26), however, did not observe an association between basal ganglia size and symptom severity of OCD or tics, suggesting an indirect relationship between basal ganglia size and the pathophysiology of the condition. Allen and associates (104) observed plasmapheresis to be dramatically effective in PANDAS patients in reducing OCD and tic symptom severity.

In fact, Giedd and colleagues (25) conducted serial MRI scans and observed a striking relationship among basal ganglia volume, OCD symptom severity, and treatment with plasmapheresis in an adolescent with autoimmune OCD (PANDAS) (Fig. 113.2). Recently, Peterson and colleagues (27) reported that higher antistreptolysin O antibody titers were associated with larger basal ganglia volumes in OCD patients with chronic or recurrent streptococcal infections. This finding was not specific to OCD; however, as higher antibody titers were also associated with enlarged basal ganglia volumes in attention deficit hyperactivity disorder (ADHD) patients with chronic or recurrent streptococcal infections (Fig. 113.3 ; Table 113.2). In fact, Peterson and colleagues (27) found robust associations between diagnosis of ADHD and titers of antistreptolysin O and antideoxyribonuclease B titers, whereas no such association was seen between antibody titers and a diagnosis of OCD or chronic tic disorders. We also do not know the impact of chronic or recurrent streptococcal infections on basal ganglia volume in children who do not develop OCD, tic disorders, or ADHD. Further study is clearly warranted.

Multivariate analysis of variance assessing the strength of the association of diagnosis-by-antibody interactions with basal ganglia volumes.

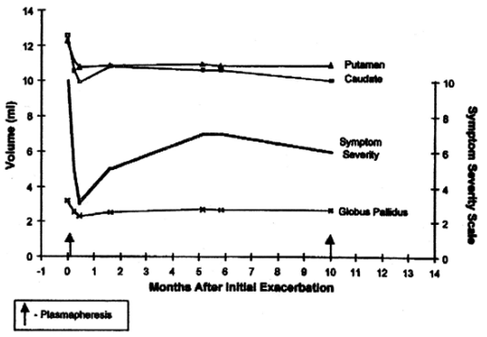

FIGURE 113.2. Sequential magnetic resonance imaging of basal ganglia volumes in a male adolescent undergoing plasma exchange for infection-related obsessive-compulsive disorder. Reprinted from Giedd JN, Rapoport JL, Leonard HL, et al. Case study: acute basal ganglia enlargement and obsessive-compulsive symptoms in an adolescent boy. *J Am Acad Child Adolesc Psychiatry* 1996;3S(7):913–915.

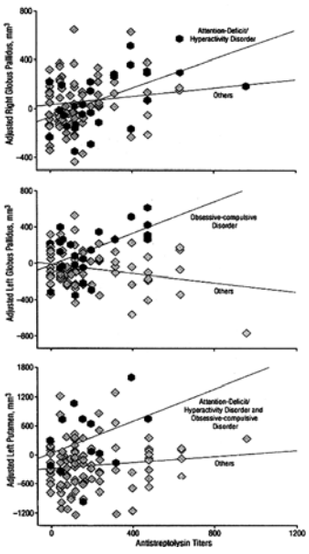

FIGURE 113.3. Association of titers, diagnoses, and basal ganglia volumes. The interaction of antistreptolysin 0 titers with attention-deficit/hyperactivity disorder and obsessive-compulsive disorder diagnoses are presented graphically. Basal ganglia volumes are adjusted for the effects of all independent variables in the multivariate analysis of covariance (Table 113.2); hence, the residuals of the volumes after the adjustment can be positive or negative. These volume residuals are plotted against the raw antistreptolysin 0 values for each of the relevant diagnostic groups. Titers are plotted in dark circles for the noted diagnostic group and in lighter diamonds for all other subjects. Reprinted from Peterson BS, Leckman JF, Tucker D, et al. Preliminary findings of antistreptococcal antibody titers and basal ganglia volumes in tic, obsessive-compulsive, and attention deficit/hyperactivity disorders. *Arch Gen Psychiatry* 2000;57:364–372.

Taken together, these findings underscore the need for standardization of research studies in patients with OCD and controlling for potential confounds of comorbidity, treatment effects, and illness duration. It also illustrates how brain imaging is exploiting advances in developmental neurobiology with important implications for neurodiagnostic assessment and treatment development. A neurodevelopmental perspective is equally critical as illustrated in the following.

Prefrontal Cortex

Morphometric MRI measurement of the prefrontal cortex has also yielded conflicting findings. Total prefrontal cortical volumes have not been found to differ between adult OCD patients and controls (84 ,85 ,105). Jenike and associates (84) did observe increased opercular volumes in OCD patients. Grachev and co-workers (105) reanalyzed the 10 adult female OCD patients and matched controls studied by Jenike and associates (84) using a sophisticated topographic parcellation method (106) and found an increase in six right frontal and four left parcellation units in OCD patients. Anterior cingulate, orbitofrontal, and opercular cortical volumes did not differ significantly between OCD patients and controls. Grachev and associates (105) also noted a significant correlation between increased volume of right inferior frontal pars triangularis and right midfrontal cortical volumes and poor cognitive performance on nonverbal immediate recall testing. More recent investigation (107) found localized reduced bilateral orbital frontal volumes in OCD patients versus healthy comparison subjects. Superior frontal gyrus and anterior cingulate volumes did not differ between OCD patients and controls.

Consistent with findings in adults, Rosenberg and colleagues (87) reported no significant differences between treatment-naive pediatric OCD patients and controls in total prefrontal cortical volume; however, a neurocognitive study of a similar sample of pediatric OCD patients (44) revealed a selective deficit in the core prefrontal cognitive function, neurobehavioral response inhibition, with no abnormalities in working memory (delayed response) or preparatory set (Fig. 113.4). Monkey studies and human clinical studies suggest that ventral prefrontal cortex plays a critical role in mediating the suppression of context inappropriate responses (17 ,108 ,109 ,110 ,111 ,112 ,113 ,114 ,115 and 116), whereas dorsal prefrontal cortex may play a more specific role in mediating delayed response and preparatory set (117 ,118). Subsequent investigation demonstrated increased corpus callosal area in treatment-naive pediatric OCD patients compared to controls,

particularly in the regions of the genu and splenium (91). The corpus callosum connects the cerebral hemispheres so that the genu connects ventral prefrontal cortex and the striatum, whereas the splenium connects temporal lobe regions (119 ,120).

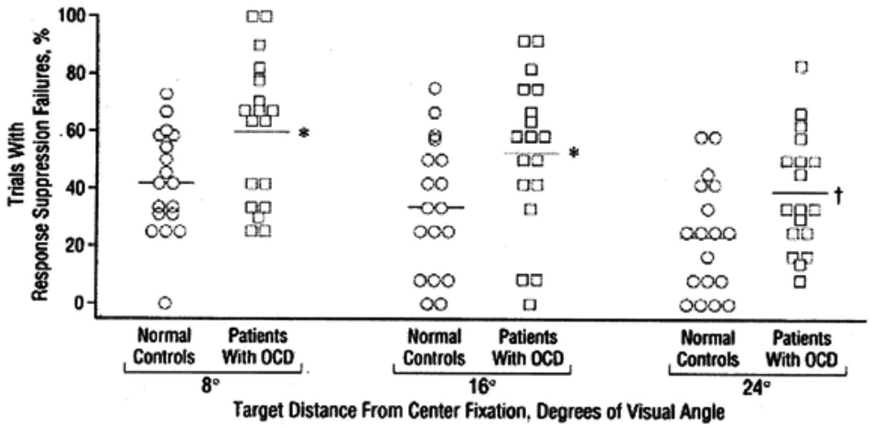

FIGURE 113.4. Mean response suppression failures for nondepressed, psychotropic medication-naive pediatric patients with obsessive-compulsive disorder (OCD) and normal controls performing the antisaccadic task. Lines through distributions represent the mean value. Asterisks indicate *P* = .01; dagger, *P* = .02. Reprinted from Rosenberg DR, Averbach DH, O'Hearn KM, et al. Oculomotor response inhibition abnormalities in pediatric obsessive-compulsive disorder. *Arch Gen Psychiatry* 1997;54:831–838.

Rosenberg and associates (91) also noted that the age-related increase in corpus callosal area in healthy children and adolescents was absent in OCD patients (Fig. 113.5A). Controls achieved comparable corpus callosal areas to their age-matched OCD counterparts between 16 and 18 years of age, which is consistent with prior findings of no significant differences in corpus callosal area between adult OCD patients and controls (83 ,84). Postnatal reduction or delay in myelination in OCD has been hypothesized to be involved in the pathogenesis of OCD (84). In support of this hypothesis, MacMaster and colleagues (92) reported increased signal intensity localized to the genu region of the corpus callosum in pediatric OCD patients

compared to controls. Increased genu area in pediatric OCD patients could be related to excess myelin sheath thickness (92). An alternative explanation is abnormal pruning or reduction of neural elements within the corpus callosum. This may be less likely because neuronal apoptosis occurs very early in development (121), whereas myelinization takes place during the peak periods of onset of pediatric OCD (122).

Adapted from Gilbert AR, Moore GJ, Keshavan MS, et al. Decrease in thalamic volumes of pediatric obsessive-compulsive disorder patients taking paroxetine. *Arch Gen Psychiatry* 2000;57(5):449–456. Jenike MA, Breiter HC, Baer L, et al. Cerebral structural abnormalities in obsessive-compulsive disorder. A quantitative morphometric magnetic resonance imaging study. *Arch Gen Psychiatry* 1996;53:625–632.

Subsequent investigation has revealed significantly increased ventral prefrontal cortical volumes in anterior cingulate cortex in 21 treatment-naive pediatric OCD patients compared to age and sex case-matched controls (88) (Fig. 113.5B). Increased anterior cingulate volumes were inversely correlated with reduced striatal volumes in OCD patients. Oculomotor response inhibition abnormalities also correlated with increased anterior cingulate volumes and reduced striatal volumes in pediatric OCD patients (Fig. 113.5C). No significant differences were observed in posterior cingulate or dorsolateral prefrontal cortical volumes between pediatric OCD patients and controls (88). Thus, prefrontal cortical abnormalities in pediatric OCD may be localized to ventral prefrontal anterior cingulate circuits, particularly in younger patients.

Temporal Cortex

The temporal limbic structures, comprising the amygdala and hippocampi are critically involved in regulating emotion in both health and disease (123 ,124 and 125). This function undergoes striking changes throughout childhood, adolescence, and early adulthood (126 ,127). Medial orbital frontal cortex, anterior cingulate cortex, and ventral striatum receive dense afferent projections from limbic regions, including the amygdala and hippocampus (31 ,128).

Initial MRI investigation in adult OCD patients and healthy controls revealed no significant differences in mesiotemporal lobe brain structures (84 ,95 ,105). More recent investigation by Szesko and colleagues (107) using criteria from postmortem histologic analysis (129) with a semiautomated computerized system (130) demonstrated bilateral reductions in amygdala volume in OCD patients as compared to healthy controls. No significant differences between OCD patients and controls were observed in the hippocampus.

Recent investigation in pediatric OCD patients has also implicated the amygdala (87 ,91). Specifically, Rosenberg and associates (87) reported reduced putamen but not caudate volumes in treatment-naive pediatric OCD patients. The putamen receives more projections from the amygdala than the caudate and reduced putamen volumes are observed after temporal lobe lesions (131). In pediatric OCD patients, a positive correlation was observed between putamen and amygdala volumes but not amygdala and caudate volumes (87). Subsequent investigation also revealed significant differences between pediatric OCD patients and controls in the size of the splenium, the region of the corpus callosum that connects temporal-limbic regions (91). However, direct measurement of whole temporal lobe, amygdala, and hippocampal and superior temporal gyrus volumes failed to reveal any significant differences between pediatric OCD patients and age- and sex-matched controls (88). Perhaps, volumetric abnormalities of the amygdala only become apparent later in development. Alternatively, our methods may not have been sensitive enough to distinguish subtle abnormalities in this circuitry. It should be noted that it is often difficult to distinguish the amygdala and hippocampus even at the histologic level (132).

Thalamus

Volumetric abnormalities in ventral prefrontal cortex and the striatum in pediatric OCD patients led to our studying the thalamus, the final subcortical input to frontal cortex. Jenike and co-workers (84) reported no significant differences in thalamic volume in adult OCD patients, many of whom had been treated with psychotropic medication and had long-term illness duration. In contrast, Gilbert and co-workers (76) demonstrated significantly increased thalamic volume as measured by volumetric MRI in 21 treatment-naive, pediatric OCD patients compared to 21 age- and sex-matched healthy controls (Fig. 113.6). As in the corpus callosum and anterior cingulate cortex, volumetric abnormalities in the thalamus were particularly pronounced in younger patients with OCD (Fig. 113.5D). After monodrug therapy with the SSRI, paroxetine, thalamic volumes decreased to levels comparable to those observed in healthy children. Reduction in thalamic volume was positively correlated with reduction in OCD symptom severity with increased pretreatment thalamic volume predicting better response to paroxetine treatment (Fig. 113.7). In contrast, thalamic volume did not decrease after 12 weeks of CBT in 11 treatment-naive pediatric OCD patients who received no adjunctive medication treatment (133). No significant changes were observed in total brain volume, the striatum, or anterior cingulate cortex with either CBT or paroxetine treatment. In view of serotonin's critical role in thalamocortical development and activity (134), thalamic volumetric reductions in pediatric OCD patients may be specific to SSRI treatment as opposed to a generalized treatment response or spontaneous resolution of symptoms.

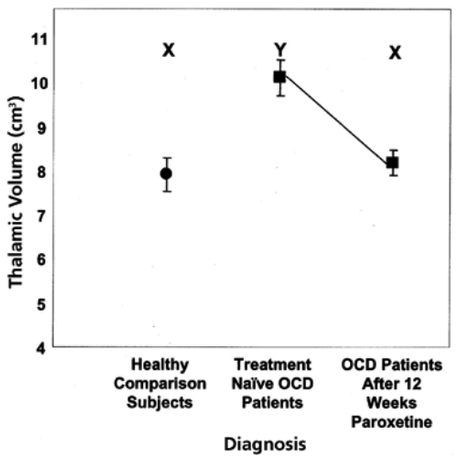

FIGURE 113.6. Thalamic volume by diagnostic and treatment condition. Groups not sharing the same letter are significantly different at $P < .05$. Adapted from Gilbert AR, Moore GJ, Keshavan MS, et al. Decrease in thalamic volumes of pediatric obsessive-compulsive disorder patients taking paroxetine. *Arch Gen Psychiatry* 2000;57(5):449–456.

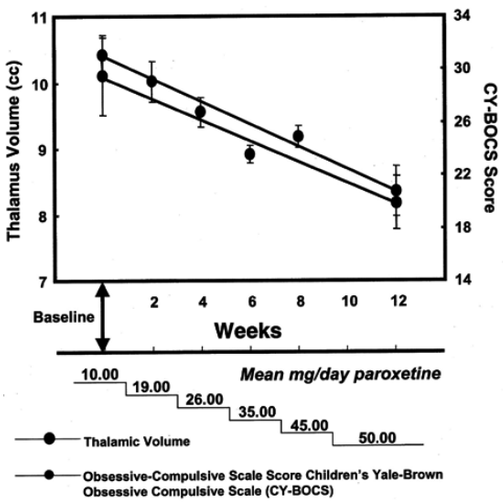

FIGURE 113.7. Decrease in thalamic volume associated with reduction in Obsessive-Compulsive Score of the Children's Yale-Brown Obsessive-Compulsive Scales. Reprinted from Gilbert AR, Moore GJ, Keshavan MS, et al. Decrease in thalamic volumes of pediatric obsessive-compulsive disorder patients taking paroxetine. *Arch Gen Psychiatry* 2000;57(5):449–456.

It should be noted that the techniques utilized in these investigations were unable to discriminate specific subdivisions of the thalamus. Thus, we were unable to localize changes to specific thalamic target fields. The dorsomedial

nucleus of the thalamus has been most implicated in the pathogenesis of OCD (15 ,31). Morphometric analysis of regional subdivisions of the thalamus is currently an active area of investigation in our laboratory.

In summary, although not entirely consistent, structural neuroimaging studies implicate abnormalities in cortico-striato-thalamo-cortical circuits. The neural network dysplasia of reduced striatal volumes and increased ventral prefrontal and thalamic volumes in treatment-naive pediatric OCD patients is especially intriguing. Rosenberg and Keshavan (88) have hypothesized that a dysplasia in postnatal synaptic pruning may be involved resulting in excess pruning in the striatum and reduced or delayed pruning in ventral prefrontal cortex and the thalamus in pediatric OCD,

which may be owing to abnormalities in glutamatergic–serotonin neurotransmission. Although morphometric brain imaging studies are instructive, functional neuroimaging studies that actively drive the system and can measure brain chemistry and receptor function may be more sensitive in their ability to detect more subtle and localized abnormalities in brain circuitry (79).

FUNCTIONAL NEUROIMAGING STUDIES OF OCD

Part of "113 - Imaging and Neurocircuitry of OCD "

Functional Neurocircuitry of OCD

Although structural neuroimaging studies measure the brain in the resting or neutral state, functional neuroimaging procedures including PET, SPECT, and fMRI allow for localized measurement of dynamic rather than static brain function by measurement of regional cerebral blood flow, glucose metabolism, and brain activation (135). To date, most studies have assessed function over a period of seconds to minutes during single session studies so that the temporal dimension has been relatively unexplored. Recent advances are beginning to permit “real-time” analysis of brain function in response to differential stimulation and diagnostic and treatment conditions. This allows for a connectionist approach to brain circuitry and not simply monitoring whether a certain region of interest activates but when and for how long. Such an approach is especially promising for repeated longitudinal assessment of OCD patients before, during, and after treatment intervention.

PET and fMRI studies suggest excess activity in the caudate nucleus, orbitofrontal cortex, thalamus, and amygdala in OCD (38 ,42 ,66 ,136 ,137 ,138 ,139 ,140 and 141). Symptom provocation of OCD symptoms using individually tailored noxious stimuli in adult OCD patients results in an increase in regional cerebral blood flow and activation in these regions (42 ,140 ,141) (Fig. 113.8). It is not entirely clear, however, whether increased activity in these circuits is specific to OCD or

represents a nonspecific finding generalized to all anxiety states (142). For example, increased regional cerebral blood flow in frontal cortex has been found to be associated with anxiety in OCD patients (143 ,144). In healthy adult volunteers, cholecystokinin induces anxiety with increased regional cerebral blood flow in anterior cingulate and the amygdala, whereas anticipation of an anxiety-provoking stimulus has been associated with increased activation of orbital frontal cortex (145). Therefore, Rauch and associates (146) reviewed pooled data from their PET symptom provocation studies of patients with OCD, simple phobia and posttraumatic stress disorder in an effort to determine which patterns of activation were specific to OCD and which were generalized across different anxiety disorders. They found that activation of paralimbic circuits, including posterior medial orbital frontal cortex, anterior cingulate, and temporal limbic regions were associated with all anxiety conditions and not specific to OCD. In contrast, activation of anterior orbital frontal cortex and the caudate nucleus were specific to OCD, suggesting that these regions may be primary loci of abnormality in the illness (Fig. 113.9).

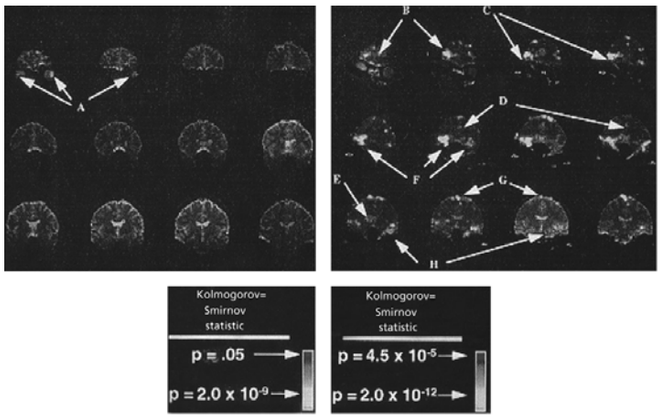

FIGURE 113.8. Results for one normal subject (left) and one patient with obsessive-compulsive disorder (right) (normal subject 2 and patient 9 [trial B]), juxtaposed for comparison. The gradient echo functional data are shown as a - log (p) map (Kolmogorov-Smirnov statistic) in color, superimposed over a T_2-weighted high-resolution instascan image in gray tone, for anatomic reference. Twelve contiguous slices are shown for each subject. The threshold for the control subject is at a lower level to emphasize the absence of activation, while the patient's threshold is at a more stringent level ($P < 10_{-7}$, approximating Bonferroni-corrected $P < .01$). A, eye movement; B, middle frontal cortex; C, inferior frontal cortex; D, cingulate cortex; E, caudate nucleus; F, orbital frontal cortex; G, superior frontal cortex; H, temporal cortex. Reprinted from Breiter HC, Rauch SL, Kwong KK, et al. Functional magnetic resonance imaging of symptom provocation in obsessive-compulsive disorder. *Arch Gen Psychiatry* 1996;53:595–606. See color version of figure.

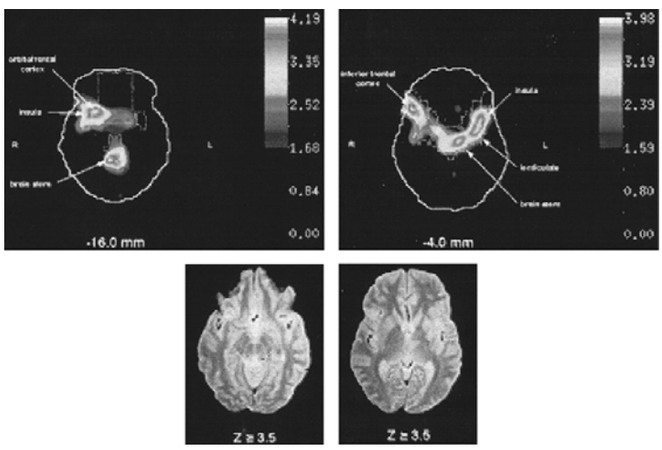

FIGURE 113.9. Positron emission tomography (PET) statistical parametric map of provoked minus control conditions for pooled data from three anxiety disorders. Horizontal slices from the statistical parametric map, at 16 and 4 mm inferior to the anterior commissure-posterior commissure plane respectively, are oriented according to neuroimaging convention (*top*, anterior; *bottom*, posterior; *right*, left; *left*, right), and each is displayed in two ways. In the upper panels, Z-score values are illustrated via a Sokoloff color scale. White dashed outlines reflecting the boundaries of brain regions of interest, as defined via a digitized version of the Talairach atlas, are superimposed for anatomic reference; solid lines demarcate the boundaries of the whole brain slice. In the lower panels, contiguous pixels exceeding a Z-score threshold of 3.5 (corresponding to approximately $P < .05$, corrected for multiple comparisons) are shown in red. The findings are superimposed over a structural (T2-weighted) magnetic resonance image transformed to Talairach space for approximate anatomic reference. The magnetic resonance reference image is from a nominally normal subject, who did not participate in these PET studies. Reprinted from Rauch SL, Savage CR, Alpert NM, et al. The functional neuroanatomy of anxiety: a study of three disorders using positron emission tomography and symptom provocation. *Biol Psychiatry* 1997;42(6):446–452. See color version of figure.

Functional Neuroimaging Studies in OCD: Implications for Treatment Development

Recent investigation suggests that differential baseline patterns of brain activity in OCD patients may predict differential response to specific treatment interventions (e.g., CBT,

SSRI) (147). For example, PET scans performed before and after 10 weeks of treatment with either CBT or the SSRI, fluoxetine have identified significant and comparable reductions in right caudate glucose metabolism associated with reduction in OCD symptom severity (38 ,148) (Fig. 113.10). Pathological correlations among orbital frontal cortex, the caudate nucleus and the thalamus were observed in pretreatment OCD patients but not in healthy volunteers. These pathologic correlations were eliminated after effective treatment with either SSRI or CBT. Subsequent analysis of this data (38 ,148) has demonstrated that specific patterns of metabolic activity in left orbital frontal cortex predicted response to CBT and the SSRI, fluoxetine (68). Specifically, decreased left orbital frontal-to-hemisphere metabolic ratios at baseline predicted better response to fluoxetine, whereas increased left orbital frontal-hemisphere metabolic ratios at baseline predicted better response to CBT. Saxena and colleagues (147) has extended this finding in OCD patients treated with paroxetine noting significant decreases in glucose metabolism in right anterior orbital frontal cortex and the right caudate nucleus in treatment responders but not in nonresponders (Fig. 113.11). Decreased metabolic activity in the left and right orbital frontal cortex predicted better response to paroxetine with greater reduction in OCD symptom severity (Fig. 113.12).

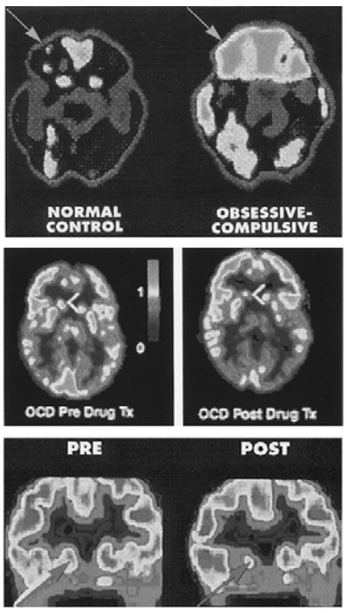

FIGURE 113.10. Positron emission tomography studies demonstrating increased right caudate glucose metabolism in a patient with obsessive-compulsive disorder compared to a healthy volunteer *(top)*. Note the significant decrease in right caudate glucose metabolism after pharmacotherapy *(middle)* and cognitive behavioral therapy *(bottom)*. Reprinted from Schwartz JM. *Brain lock*. New York: HarperCollins, 1996. Baxter LR, Schwartz JM, et al. Caudate glucose metabolic rate changes with both drug and behavior therapy for obsessive-compulsive disorder. *Arch Gen Psychiatry* 1992;49:681–689. See color version of figure.

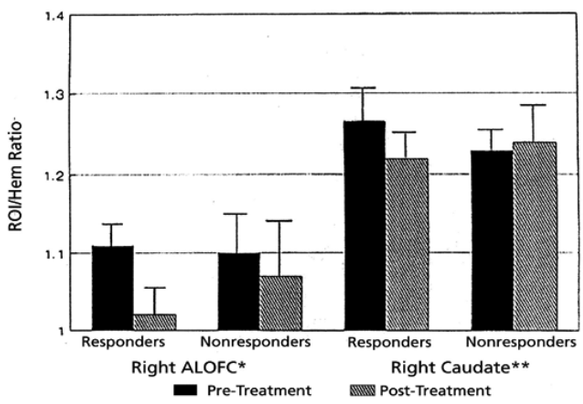

FIGURE 113.11. Mean pretreatment and posttreatment metabolic ratios (± SD) in right anterior lateral orbital frontal cortex (ALOFC) and right caudate, normalized to ipsilateral hemisphere (ROI/Hem), in responders versus nonresponders to paroxetine. There was a significant difference in the magnitude of change in right ALOFC/Hem between responders (1.11 ± .05 pretreatment to 1.02 ± 0.05 posttreatment) and nonresponders (1.10 ± .06 pretreatment to 1.07 ± .08 posttreatment). Mean right Cd/Hem decreased significantly in treatment responders (1.27 ± .06 to 1.22 ± .05) but not in nonresponders (1.23 ± .04 to 1.24 ± .05). *P = .04; **P = .01). Reprinted from Saxena S, Brody AL, Maidment KM, et al. Localized orbitofrontal and subcortical metabolic changes and predictors of response to paroxetine treatment in obsessive-compulsive disorder. *Neuropsychopharmacology* 1999;21:683–693.

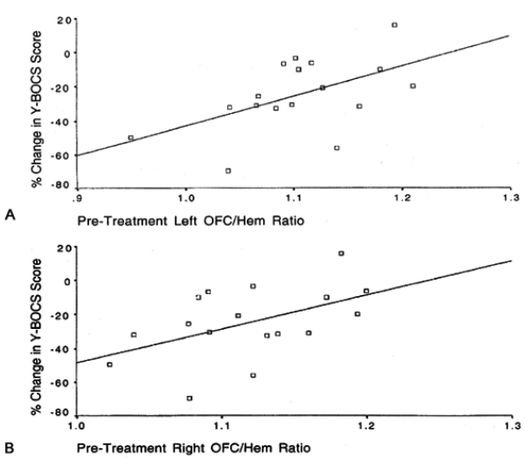

FIGURE 113.12. A: Scatter plot of pretreatment glucose metabolic rate in left orbitofrontal cortex, normalized to ipsilateral hemisphere (left OFC/Hem), and change in Y-BOCS score after paroxetine treatment (Kendall's tau = -.39, P = .01); **B:** Scatter plot of pretreatment glucose metabolic rate in right orbitofrontal cortex, normalized to ipsilateral hemisphere (right OFC/Hem), and change in YBOCS score after paroxetine treatment (Kendall's tau = -.35, P = .02). Reprinted from Saxena S, Brody AL, Maidment KM, et al. Localized orbitofrontal and subcortical metabolic changes and predictors of response to paroxetine treatment in obsessive-compulsive disorder. *Neuropsychopharmacology* 1999;21:683–693.

It should be noted, however, that functional imaging data sets have not been entirely consistent in OCD patients studied before and after treatment intervention. Benkelfat and colleagues (149), for example, observed a significant decrease in caudate and anterior orbital frontal glucose metabolism but only the decrease in caudate metabolism was associated with reduction in OCD symptom severity. In contrast, Swedo and co-workers (150) reported no change in caudate metabolic activity after 2 months of clomipramine treatment in OCD patients with childhood onset of

illness. Decreased baseline right orbitofrontal and anterior cingulate metabolic rates, however, did predict better response to clomipramine treatment. Rubin and associates (151) also observed no caudate metabolic changes before and after SSRI treatment but found that decreased metabolism in orbitofrontal cortex before treatment predicted greater reduction in OCD symptom severity.

Strikingly, there have been no published functional neuroimaging studies in children or adolescents with OCD. Techniques such as fMRI may be especially relevant to the study of childhood populations because there are no putative ionizing radiation risks facilitating repeated study for longitudinal follow-up with a neurodevelopmental perspective. This is an active area of investigation in our laboratory where preliminary symptom provocation modeling investigation of adult OCD patients (42 ,141) has demonstrated increased activation in ventral prefrontal–striatal circuitry (unpublished data). This is especially relevant in view of recent clinical neurodevelopmental models of OCD (88).

Taken together, functional neuroimaging studies are already beginning to integrate and translate advances in neuroscience into treatment development so that specific neural network activations might help predict patients more (or less) likely to respond to a particular treatment (e.g., CBT or SSRI) (147). Recent advances allowing for the noninvasive real-time measurement of brain activity provide an unprecedented window of opportunity for unlocking the mechanisms underlying the pathogenesis of OCD with important implications for treatment development.

NEUROCHEMICAL STUDIES IN OCD

Part of "113 - Imaging and Neurocircuitry of OCD "

Neuronal Viability

To our knowledge, there have only been four neuroimaging studies directly measuring brain chemistry in OCD. Proton magnetic resonance spectroscopy (1-H MRS), which can measure compounds including the neuronal marker, *N*-acetyl-aspartate (NAA) (152), cytosolic choline containing compounds (Cho), glutamatergic compounds including glutamate, glutamine and GABA (Glx), creatine/phosphocreatine (Cr), and myoinositol (mI). Like fMRI, there are no ionizing radiation risks, making it a particularly child-friendly technique facilitating longitudinal monitoring of patients before and after treatment intervention.

Prior investigation in adult OCD patients and those with epilepsy has found that 1-H MRS NAA measurement may be a more sensitive method for identifying neuronal dysfunction than morphometric MRI assessment (79 ,153). Reduced striatal NAA levels without striatal volumetric differences were observed in OCD patients compared to controls, suggesting that 1-H MRS NAA measurement can detect neuronal loss at a magnitude undetectable by morphometric MRI (79). Ebert and colleagues (154) also reported reduced NAA/Cr levels in the striatum and anterior cingulate cortex but not parietal white matter of adult OCD patients. Volumetric data for the regions of interest were not provided.

Fitzgerald and co-workers (155) compared 11 treatment-naive pediatric OCD patients and 11 age- and sex-case-matched healthy comparison subjects and found localized

functional neurochemical marker abnormalities in right and left medial but not lateral thalamus. Reduced NAA/Cho +Cr levels associated with OCD symptom severity were observed in OCD patients compared to controls (Fig. 113.13). This is intriguing because the dorsomedial nucleus of the thalamus has been especially implicated in the pathogenesis of OCD (15).

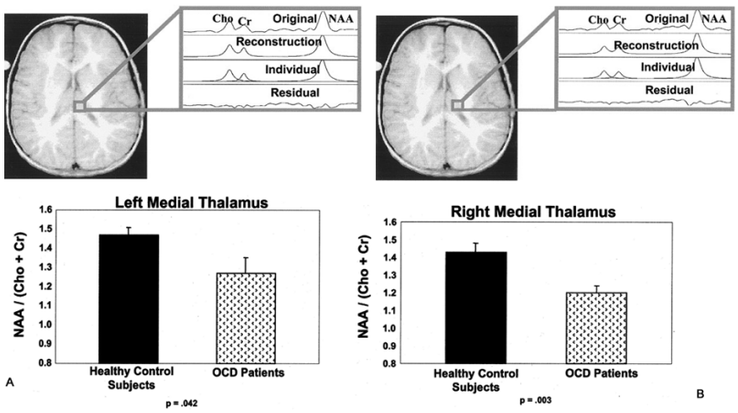

FIGURE 113.13. Sample spectra for voxels *(top)* placed in the left medial thalamus *(A)* and left lateral thalamus *(B)*. Individual peaks for choline compounds (Cho), creatine/phosphocreatine (Cr), and *N*-acetylaspartate (NAA) were resolved from the original spectrum, leaving a residual. NAA/(Cr + Cho) metabolite ratios by group *(bottom)* for left *(A)* and right *(B)* medial thalamus. OCD, obsessive- compulsive disorder. Adapted from Fitzgerald KD, Moore GJ, Paulson LD, et al. Proton spectroscopic imaging of the thalamus in treatment-naive pediatric obsessive-compulsive disorder. *Biol Psychiatry* 2000;47:174–182.

Neuronal dysfunction or loss in specific fronto-striatal-thalamic circuits in OCD could be related to excess brain activity measured in this circuitry with functional neuroimaging (154). Moreover, reduced NAA levels in fronto-striatal-thalamic regions may result from increased glutamatergic afferent projections to the thalamus and striatum (79 ,156). Excess glutamatergic afferent input could be neurotoxic to fronto-striatal neurons and, thereby, result in reduced NAA levels.

Glutamatergic Dysfunction in OCD

Rosenberg and Keshavan (88) hypothesized that anatomic and functional abnormalities in cortico-striatao-thalamo-cortical networks may result from disruptions in glutamatergic modulation of serotonin neurotransmission. The majority of axon terminals in the basal ganglia are glutamatergic afferents (31 ,157 ,158), with the caudate nucleus receiving an especially massive glutamatergic innervation from ventral prefrontal cortex (15 ,159 ,160). Ablation of frontal cortex results in a dramatic reduction in caudate glutamate concentrations (159 ,161). Becquet and associates (160) have shown that glutamate exerts a potent inhibitory effect on serotonin release in the caudate nucleus. Conversely, serotonergic neurons can modulate glutamate release (160) with stimulatory 5-HT2a receptors on GABAergic interneurons inhibiting glutamatergic projections from ventral prefrontal cortex to the striatum and thalamus (158). Increased glutamatergic afferent input from ventral prefrontal cortex to the striatum and thalamus, therefore, may be consistent with increased activation in this circuitry as measured by functional neuroimaging (141) and be related to the pathogenesis and maintenance of OCD. Chronic treatment with SSRIs results in a marked increase in 5-HT release in orbital frontal cortex of guinea pigs (162). SSRI treatment may, therefore, stimulate 5-HT2a receptors with consequent alterations in serotonergic release from cell bodies

in frontal cortex, which would alter cortico-striato-thalamic glutamate projections (Fig. 113.14).

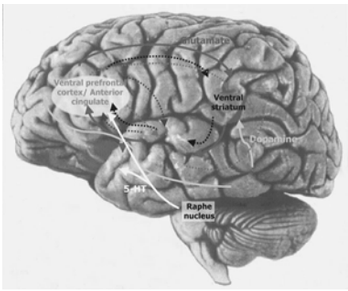

FIGURE 113.14. Illustration of cortico-striato-thalamo-cortico network in obsessive-compulsive disorder. Neurotransmitters: Glu, Glutamate; GABA-gamma-aminobutyric acid; DA, dopamine; 5-HT, serotonin. Brain regions: AC, anterior cingulate; RN, raphe nucleus; SN, substantia nigra; Thal, thalamus; TLC, temporal lobe cortex; VPFC, ventral prefrontal cortex; VS, ventral striatum; VT, ventral tegmentum. Adapted from Rosenberg DR, Keshavan MS. Toward a neurodevelopmental model of obsessive-compulsive disorder. *Biol Psychiatry* 1998;43:623–640.

Rosenberg and co-workers (98) recently reported significantly increased glutamatergic concentrations in the caudate nucleus but not occipital cortex of 11 treatment-naive pediatric OCD patients compared to 11 age- and sex-matched healthy controls (Fig. 113.15). After 12 weeks of monodrug therapy with paroxetine, a significant decrease in caudate but not occipital glutamatergic concentrations was observed (Fig. 113.16). Decrease in caudate glutamatergic concentrations was associated with reduction in OCD symptom severity so that higher pretreatment caudate glutamatergic concentrations predicted better response to paroxetine (Fig. 113.17). An active area of investigation in our laboratory involves comparisons of the impact of CBT, SSRI, and combination therapy on glutamatergic concentrations in the caudate and other brain regions as well as measuring the long-term stability of these changes (e.g., do changes persist after medication is discontinued?).

Reprinted from Moore GJ, MacMaster FP, Stewart C, et al. Case study: caudate glutamatergic changes with paroxetine therapy for pediatric obsessive-compulsive disorder. *J Am Acad Child Adolesc Psychiatry* 1998;37(6):663–667.

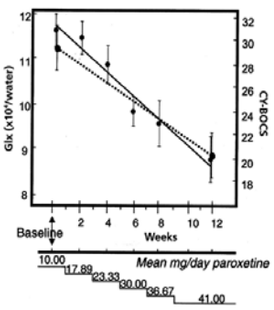

FIGURE 113.17. Decrease in left caudate glutamatergic concentrations associated with reduction in obsessive-compulsive score of the Children's Yale-Brown Obsessive-Compulsive Scales (CY-BOCS) (CY-BOCS, —; Glx [glutamate/glutamine/GABA], ·····). Reprinted from Rosenberg DR, Hanna GL. Review of genetic and imaging strategies in obsessive-compulsive disorder. Potential implications for treatment development. *Biol Psychiatry* 2000;48:1210–1222.

Findings of increased caudate glutamatergic concentrations that decreased after paroxetine treatment are consistent with functional neuroimaging studies that have reported increased metabolic rates, regional cerebral blood flow, and brain activation that decreased after SSRI treatment (38 ,147). Glutamatergic afferent terminals influence brain glucose metabolism so that regional brain glucose metabolism parallels glutamatergic activity (163). Serotonin agonists have also been shown to reduce glucose metabolism (164). Taken together, these data suggest a reversible glutamatergically mediated dysfunction in cortico-striato-thalamo-cortico circuitry.

Serotonergic Role in OCD

Perhaps the most compelling evidence for a serotonergic role in OCD comes from investigation that has consistently found serotonin reuptake inhibitors to be effective in reducing OCD symptoms, whereas medications affecting norepinephrine and dopamine appear to be less effective (165). Indirect support for the serotonin hypothesis of OCD comes from a plethora of platelet, cerebrospinal fluid (CSF), and pharmacologic challenge studies suggesting a serotonergic role in OCD. Platelet 3-H imipramine binding sites are considered to be putative markers of 5-HT function and are quite similar to those on presynaptic 5-HT neurons (166). Although a number of studies have reported decreased 5-HTPR in platelets of medication-free OCD patients (166 ,167 ,168 ,169 and 170), there are contradictory reports (171 ,172 ,173 and 174).

Studies of the serotonin metabolite, 5-hydroxy-indole acetic acid (5HIAA) have also found increased 5HIAA levels in OCD patients compared to controls (172 ,175), although contradictory reports exist (176). Swedo and colleagues (177) reported that higher pretreatment CSF 5HIAA levels were correlated with increased OCD symptom severity and predicted better response to clomipramine. In contrast, Asberg and co-workers (178) noted that OCD symptom severity was associated with lower pretreatment CSF 5HIAA levels, although higher pretreatment 5HIAA levels did predict better response to clomipramine. Blood and CSF serotonin measures can be influenced by a person's height, diet, season of the year, activity level, and menses (179), thereby limiting the reliability of these markers as indices of brain serotonin function.

5-HT receptor subtypes are localized to different areas of the brain (180). In order to better elucidate regional abnormalities of serotonin function that might contribute to OCD, Hollander and co-workers (181) combined pharmacologic challenge with functional neuroimaging. They used SPECT to measure the impact of the mixed 5-HT agonist–antagonist, meta-chlorophenylpiperazine (mCPP) in seven OCD patients. mCPP is a metabolite of trazodone, which acts most strongly at the postsynaptic 5-HT-2C receptor. Its administration results in exacerbation of OCD symptoms (181 ,182 ,183 ,184 ,185 ,186 ,187 and 188), although contradictory findings have been reported (189 ,190). Hollander and associates (181) noted a significant global increase in cortical blood flow in OCD patients that was associated with mCPP symptom exacerbation. Ho Pian and co-workers (190), also using SPECT, were unable to confirm this finding and, instead, reported decreased blood flow in the frontal cortex, striatum, thalamus, and cerebellum as well as global decreased blood flow in seven OCD patients with no mCPP response. The advent of more specific probes of serotonin synthesis and receptor function may help clarify putative serotonin dysregulation in OCD.

Recent PET investigation using the probe, α-C-11-methyl-L-tryptophan (AMT), an analogue of tryptophan may be especially instructive. Tryptophan is the amino acid precursor to serotonin so that AMT is converted to α-C-11—methyl serotonin. α-C-11-methylserotonin is a 5-HT variant that is not degraded by monoamine oxidase; therefore, AMT-derived serotonin is effectively “kept” in serotonin neurons making it measurable by PET (191). In healthy volunteers, Chugani and associates (191) used AMT PET studies and found high regional AMT uptake in frontal cortex, the striatum, thalamus, and temporal lobe, regions that receive dense serotonergic projections from the raphe nuclei in the midbrain. More recently, Chugani and colleagues (192) reported reduced AMT uptake, suggestive of decreased serotonin synthesis in the frontal cortex and thalamus in autistic boys 4 to 11 years old. The repetitive, ritualistic thoughts and behaviors of autism can be similar to those in OCD. SSRIs sometimes can be beneficial in treating compulsive behaviors observed in autistic patients such as head banging and other rituals (193).

Pilot AMT PET studies in our laboratory have compared AMT uptake in pediatric OCD patients, 8 to 17 years old

as compared to their unaffected siblings (194). Decreased uptake of AMT in the caudate nucleus and a trend for decreased uptake of AMT in anterior cingulate cortex was observed in the OCD patients. Because of the putative radiation risks associated with PET, we are not able to study healthy children as a comparison group. The radiation risks also make repeated studies in the same subjects less viable. Recent study has also suggested that the AMT tracer may be more reflective of free tryptophan than of serotonin synthesis (195). This is currently an active area of investigation in our center.

Other ligands such as 18F-altanserin, a 5-HT2a postsynaptic receptor antagonist may be relevant to the study of OCD. Goldman and associates (196) reported consistent 5-HT2a associations in two independent populations in two countries, implicating 5-HT2a in anorexia nervosa and OCD. Kaye and co-workers (197) have studied anorexic and bulimic women after long-term recovery with regular menstrual cycles and normalized eating and weight and found significantly reduced 18F altanserin binding in bilateral orbital frontal regions but not in other brain regions as compared to healthy female controls. The authors hypothesized that increased extracellular 5-HT could compete with 18F altanserin binding at 5-HT2a receptors and, thereby down-regulate 5-HT2a postsynaptic receptors. Anorexia nervosa and bulimia share certain characteristics with OCD and both conditions can also benefit from SSRI treatment (198).

This ligand as well as others being developed and in the pipeline may ultimately clarify more precisely the role of serotonin in OCD.

CONCLUSION

Part of "113 - Imaging and Neurocircuitry of OCD "

Advances in brain imaging and neuroscience are making the brain mechanisms involved in the pathogenesis and maintenance of OCD accessible as never before. Indeed, the time is now ripe to use brain imaging to exploit advances across several disciplines. For example, sophisticated brain imaging studies may facilitate more informed genetic studies and vice versa. Rauch (67) has argued persuasively that brain-imaging studies may help delineate specific endophenotypes for genetic studies in OCD. Such an approach might help discriminate between familial and sporadic OCD, thereby clarifying some of the genetic heterogeneity of OCD (11). To our knowledge, no prior study has employed both genetic and neuroimaging approaches in the same population, although there is precedent for such an approach in the study of ADHD (199). Obviously, costs of such an endeavor prohibit routine use of both techniques. It will be critical to delineate areas of maximum utility where these techniques are likely to provide the best yield and, therefore be most cost effective (67). For example, identified candidate serotonin or glutamatergic genes might be integrated into specific neuroimaging paradigms (11). Neuroimaging studies may also help clarify the role of established susceptibility genes as well as facilitating an enhanced understanding of the developmental neurobiologic underpinnings of OCD. Combination of these approaches may be especially effective in the identification of meaningful surrogate neurobiologic markers predictive of treatment response (or lack thereof). Ample evidence exists across various medical disciplines that increased understanding of the biologic mechanisms underlying an illness inevitably translates into critical advances in diagnosis and treatment (200).

UNIQUE ASPECTS OF OCD PHARMACOTHERAPY

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Obsessive-compulsive disorder (OCD) is a chronic disorder with substantial impact on quality of life (1) that affects 2% to 3% of the US population (2,3). Previously believed to be refractory to treatment, the symptoms of OCD are substantially reduced with the use of medications having potent effects on blocking the serotonin (5-HT) transporter. The response to serotonin reuptake inhibitors (SRIs) in OCD is somewhat unique compared to that in other mood and anxiety disorders, in that higher doses and a longer lag-time to therapeutic effect of SSRIs may be required, and a lack of response to other antidepressant/antianxiety agents in OCD is evident. Nevertheless, SRIs do not cure patients, and 30% to 50% remain treatment nonresponders; therefore, other pharmacologic approaches, augmentation strategies, and especially cognitive-behavioral treatments may become necessary. Recently, other more invasive treatment options have been studied in the refractory population as well. This chapter highlights the psychopharmacology of OCD, including the current state of the art and future directions. Cognitive behavioral treatments for OCD, which are also highly effective, are not extensively reviewed here.

DIFFERENTIAL DIAGNOSIS AND COMORBIDITY: IMPLICATIONS FOR THERAPEUTICS

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Although the diagnosis of OCD is usually straightforward, presenting with classic obsessive and compulsive symptoms, sometimes OCD presents with atypical features. Conversely, other disorders may present with symptoms reminiscent of OCD. For example, the ruminations of depression, intrusive thoughts, or delusions of psychotic disorders, and stereotyped behaviors of developmental disorders, may mimic OCD. Thus, comprehensive clinical evaluation and careful differential diagnosis are essential.

Psychiatric comorbidity is the rule rather than the exception in OCD. Up to two-thirds of all patients with OCD have lifetime comorbidities (3 ,4). These comorbid conditions not only serve to cloud the diagnostic picture, but also can influence the selection of optimal treatments.

The prevalence of obsessive-compulsive symptoms in schizophrenic patients has been estimated to range from 7.8% to 46.6% (5 ,6 and 7). A recent paper reported that in the early phase of the disorder, 14% of schizophrenic patients fulfilled criteria for a diagnosis of OCD (8). Atypical neuroleptics have been associated with both new onset and exacerbation of obsessions and compulsions, with numerous reports for clozapine (9) and less for risperidone. Treatment of OCD symptoms in schizophrenic patients may take into account this possible effect of atypical neuroleptics, and dosage reduction and/or SRI augmentation may be recommended (10).

The prevalence of OCD in patients with bipolar disorder has been estimated to be around 30% (11 and 12), half of whom had one or two other associated anxiety disorders (13); therefore, previous manic or hypomanic episodes and subthreshold hyperthymic characteristics should be evaluated and treated accordingly (14). Because SRIs may sometimes precipitate hypomanic or manic episodes in adults (15 ,16 and 17) and adolescents (18) without previous manic episodes, low initial doses, gradual dose elevation, and addition of mood stabilizers may be required.

IMPACT OF COMORBIDITY/SUBTYPES, OUTCOME MEASURES, AND RESPONDER CRITERIA

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

In evaluating treatment response in OCD, the patient population under study and measurement of response can significantly

impact findings. For example, OCD patients who fail to respond to prior SSRI therapeutic trials may have only a 25% chance to respond to an additional SSRI trial (19). Likewise, patients with comorbid tics (20), delusional symptoms, or schizotypical personality disorder (21) may not respond to SSRIs, and may require neuroleptic augmentation strategies. OCD patients with neurological soft-signs may be poorly responsive to SSRIs (22). Also, specific OCD subtypes, such as hoarders, may be poorly responsive to SSRIs. Finally, related or OCD spectrum disorders share important features with OCD and may be comorbid with OCD, influencing treatment outcome (23).

TREATMENT RESPONSE

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

The degree of symptom resolution in response to treatment determines the need for dosage adjustment, augmentation, or switching to an alternative treatment. Treatment response may be assessed qualitatively via periodic clinical interviews or the regular use of validated scales such as the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) to quantify the ongoing severity of OCD symptoms. Approximately 60% of patients treated with SRIs experience at least a 25% to 35% decrease in symptoms in Y-BOCS (24), which is typically operationalized as a criterion for response.

Although the Y-BOCS score generally is an excellent gauge of symptomatic improvement, the overall change in quality of life also must be considered. The Y-BOCS does not reflect these quality of life issues, and may not be sensitive to subtle changes, such as going from 8 to 2 hours per day of rituals. The criteria set for response (i.e., 25% or 35% reduction in Y-BOCS, CGI improvement of 1 or 2, or a combination of the two) may markedly impact percentage of subjects who are considered responders in various trials, and thus studies that utilize different response criteria might yield very different response rates.

SEROTONIN AND DOPAMINE FUNCTION IN OCD

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Evidence for serotonergic and dopaminergic function in OCD is discussed in detail elsewhere (see Chapter 112). Extensive research documenting the efficacy of SRIs has indicated that the antiobsessional properties of these drugs may be related to their 5-HT reuptake inhibition properties. Peripheral and central marker abnormalities have generally supported a proposed 5-HT hypothesis (25). Of note, in a subgroup of OCD patients, increased levels of CSF 5-hydroxyindoleacetic acid (5-HIAA) have been observed and a correlation has been found between response to treatment and a reduction of both 5-HIAA levels and platelet 5-HT concentration (26-27). The partial serotonin 5-HT2C agonist *m*-chlorophenylpiperazine (*m*-CPP) has been found to acutely exacerbate symptoms in a subgroup of OCD patients in some (28 ,29) but not all studies (30), and has generally demonstrated neuroendocrine blunting in these patients as compared to normal controls (29 ,31). Treatment with clomipramine or fluoxetine leads to cessation of this behavioral exacerbation and normalization of the neuroendocrine findings in response to repeat *m*-CPP challenge (32 ,33). There is some evidence for linkage disequilibrium of the 5-HT1DB receptor gene and OCD, with preferential transmission of the G allele to affected subjects (34). To date, a specific abnormality of the 5-HT system in OCD has not been identified and the strongest evidence in support of the serotonin hypothesis remains the preferential response to SRIs.

There is a debate regarding the nature of the SRI-induced changes to the 5-HT system. Administration of the SRIs results in an immediate inhibition of the 5-HT transporter, with the effect of increasing synaptic 5-HT; however, the full clinical response may not be seen for up to 8 to 12 weeks of SRI treatment. An understanding of the neuroadaptive changes that take place with treatment is helpful in clarifying the mechanism of action involved. It has been reported that desensitization of 5-HT-2 receptors is implicated in the antiobsessional effect of SRIs (35). Alteration of serotonin release in the orbito-frontal cortex has been found to occur only after 8 weeks of treatment (36). These adaptive changes seem to involve a reduction in the number of receptors and altered responsivity of second messengers (37). There are many subtypes of 5-HT receptors, each having a distinct pattern of brain localization, with those expressed in basal ganglia and orbitofrontal regions of particular interest in the etiology of OCD (38).

There are complex structural and functional interactions between dopamine (DA) and 5-HT in the brain. Evidence implicating DA in the neurobiology of OCD is derived from a number of areas. In animal models, amphetamines have been shown to induce stereotypies that are viewed as compulsive behaviors (39). An association of postencephalitic Parkinson syndrome with obsessive-compulsive symptoms has been found (40). The comorbidity of Tourette syndrome and OCD is well described (41), as well as the association of a variety of other basal ganglia disorders with OCD. There is also evidence of DRD2 and DRD3 receptor gene polymorphisms in OCD (42).

SEROTONIN REUPTAKE INHIBITORS: ACUTE TRIALS

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

SRIs include clomipramine (Anafranil), fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), and citalopram (Celexa). Of these, fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram are “selective serotonin-reuptake inhibitors” (SSRIs), characterized by minimal affinity or pharmacologic action at receptor sites other

than the serotonin transporter. Clomipramine, on the other hand, is a tricyclic antidepressant (TCA). Thus, although clomipramine's serotonin-reuptake-blocking properties are similar to those of the SSRIs, it also has pharmacologically significant affinity for cholinergic and adrenergic receptors, thereby influencing its side-effect profile.

Although all SRIs block reuptake of serotonin presynaptically, there are other pharmacologic characteristics that distinguish these agents from one another, including differences in metabolism, half-life, protein binding, and effects on other neurotransmitter systems (43 ,44 and 45). All SRIs undergo hepatic metabolism and renal excretion. SRIs may be divided into those with active and those with inactive metabolites. For clomipramine, fluoxetine, and sertraline, which have active metabolites, the half-life of the daughter compound must be considered when estimating duration of effect after dosing. In general, measuring serum levels of SRIs and/or their metabolites has not been useful in determining effective dosage or predicting clinical response. Protein binding may influence levels of available drug in at least two ways: (a) if the patient is on other highly protein-bound medicines, competition can produce elevated levels of the SRI and/or the other agent, and (b) hypoproteinemia, as seen in chronic medical illness, malnutrition, or advanced age, can lead to higher concentrations of unbound SRI (i.e., the active form). There are subtle differences in the relative affinities of the various SRIs for monoaminergic reuptake sites, and more prominent differences between clomipramine and the SSRIs with respect to anticholinergic and antiadrenergic postsynaptic effects. These pharmacologic distinctions do not appear to have major consequences in terms of differential efficacy, but they do influence side-effect profile.

Case reports first suggested that obsessions might be successfully treated with clomipramine 30 years ago (46). Since then, controlled trials demonstrated clomipramine's efficacy in OCD. In the past decade, the introduction of the SSRIs has greatly increased treatment options (Table 114.1) (47 ,48 ,49 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 and 65).

TABLE 114.1. CONTROLLED TRIALS OF SEROTONIN REUPTAKE INHIBITORS THERAPY FOR OBSESSIVE-COMPULSIVE DISORDER IN ADULT PATIENTS

Studies (Ref.)	Conditions	Results
Clomipramine (CMI) vs Placebo or Non-SRIs		
Karabanow, 1977 (47)	CMI vs placebo	CMI superior to placebo
Montgomery, 1980 (48)	CMI vs placebo crossover	CMI superior to placebo

Jenike et al., 1990 (84)	Setraline vs placebo	Sertraline superior to placebo
Greist et al., 1992 (70)	Setraline vs placebo	Sertraline superior to placebo
Tollefson et al., 1994 (74)	Fluoxetine vs placebo	Fluoxetine superior to placebo
Montgomery et al., 1993 (78)	Fluoxetine vs placebo	Fluoxetine superior to placebo
CMI vs SSRIs		
Den Boer et al., 1987 (61)	CMI vs fluvoxamine	Comparable efficacy
Freeman et al., 1994 (103)	CMI vs fluvoxamine	Comparable efficacy
Pigott et al., 1990 (62)	CMI vs fluoxetine	Comparable efficacy
Koran et al., 1996 (63)	CMI vs fluvoxamine	Comparable efficacy
Lopez-Ibor et al., 1996 (102)	CMI vs fluoxetine	Comparable efficacy
Zohar et al., 1996 (64)	CMI vs paroxetine	Comparable efficacy

The tricyclic SRI clomipramine, and the four selective serotonin-reuptake inhibitors fluoxetine, fluvoxamine, sertraline, and paroxetine, are currently approved by the FDA for the treatment of OCD in adults; three, clomipramine, fluvoxamine, and sertraline, are approved for treatment of OCD in children and adolescents. SRIs have also been found to be effective in treating other obsessive-compulsive spectrum disorders (23 ,66 ,67).

Although 65% to 70% of OCD patients have a clinically meaningful response to their first SRI treatment (68), with sequential trials as many as 90% of OCD patients may ultimately respond (69). Nevertheless, most patients are left with notable residual symptoms, perhaps with a 25% to 60% improvement (69). Although this improvement is clinically significant, patients may remain significantly impaired. These five SRIs have been demonstrated to be effective and well tolerated in OCD in short-term large multicenter controlled trials (52 ,70 ,71 ,72 and 73). There is also evidence regarding long-term treatment response for some of these agents (71 ,74 ,75).

Clomipramine

Clomipramine is a tricyclic antidepressant that, in addition to being an SRI, is a potent norepinephrine (NE) inhibitor and has moderate dopamine (DA) receptor-blocking properties. It was the first medication found to be effective in the treatment of OCD and its efficacy has been firmly established over the past 30 years. The first two multicenter randomized controlled trials of clomipramine in the treatment of adult OCD were conducted in 1991 (52). CMI was administered in doses up to 300 mg per day for 10 weeks and resulted in reductions of 38% and 44% in OCD patients' total YBOCS scores compared to 3% and 5% in the placebo groups. These treatment effects were apparent at 6 weeks, and the YBOCS scores continued to improve over the course of the trial. Patients in the clomipramine versus placebo group were more likely to experience adverse events and discontinue treatment. Two notable adverse events on clomipramine were seizures (0.4%) and elevated aminotransferase levels (6.9%).

Fluoxetine

Fluoxetine, an SSRI, and norfluoxetine, its principal metabolite, have notably long half-lives. Early open trials suggested efficacy of fluoxetine in OCD (76 ,77). A large, double-blind placebo-controlled 8-week study of fluoxetine at three fixed doses (20 mg per day, 40 mg per day, and 60 mg per day) showed that the fluoxetine groups, combined, were superior to placebo in efficacy (72 ,78). Individually, the 40- and 60-mg dosage groups (but not the 20-mg group) were superior in efficacy to the placebo group. Fluoxetine was well tolerated and the dropout rate was low (<6%). In the multicenter study, which led to FDA approval, the same three doses of fluoxetine for 13 weeks were all significantly more effective than placebo in improving OCD (72). Defining response as a 35% improvement in total YBOCS score, response rates were 32.1%, 32.4%, and 35.1% for the 20-, 40-, and 60-mg groups, respectively, and 8.5% for placebo. Both obsessions and compulsions were found to respond to fluoxetine treatment independent of any antidepressant effect. Outcome on fluoxetine is unrelated to plasma levels of fluoxetine, norfluoxetine, or their sum (79).

Fluvoxamine

Several double-blind controlled studies have shown fluvoxamine to be effective in treatment of OCD (80 ,81 and 82). Perse and colleagues (80) reports on a multisite study that found fluvoxamine (100 to 300 mg per day) to be superior to placebo. In this study, 43% of patients receiving fluvoxamine

treatment responded after 6 weeks compared to 12% receiving placebo (defining response as much or very much improved on the improvement item of the Clinical Global Impression Scale). Of special interest, Goodman and associates (83) demonstrated the selective efficacy of SSRIs in OCD because fluvoxamine (up to 300 mg per day) was significantly more effective than the norepinephrine reuptake inhibitor desipramine in the reduction of obsessive-compulsive symptoms in an 8-week double-blind trial.

Sertraline

Although one early study did not find sertraline to be superior to placebo in the treatment of OCD (84), several subsequent studies have demonstrated its efficacy in OCD. Chouinard and associates (85) found sertraline (up to 200 mg per day) to be more effective than placebo on all outcome measures in an 8-week trial. A large 12-week, multicenter, placebo controlled, double-blind trial of sertraline in three fixed doses (50, 100, or 200 mg per day), found sertraline at 50 and 200 mg per day to be significantly more effective than placebo, but the 100-mg dose was not more effective than placebo. Clinical outcome was not correlated with sertraline plasma levels (86).

Paroxetine

A large multicenter placebo controlled study of paroxetine in three fixed doses (20, 40, and 60 mg per day) found that the 40- and 60-mg doses were significantly more effective than placebo, but the lower dose (20 mg) was not more effective than placebo (71). There was a suggestion of a dose–response relationship, and paroxetine was well tolerated in the acute dose study phase.

Citalopram

Citalopram, the most selective of the SSRIs, has not been granted FDA approval in OCD. In a 24-week open pilot study of 29 OCD patients treated with citalopram, 76% had reduction in Y-BOCS scores of more than 50% compared to baseline, with most doses between 40 and 60 mg per day (87). In a 10-week single-blind study of 30 patients with OCD who underwent randomized treatment with fluvoxamine, paroxetine, or citalopram, there were no significant differences found between the three treatments, although the study was underpowered to detect significant differences between active treatments (88). Recent controlled treatment trials suggest efficacy in OCD (89).

Zimeldine

Although early research with zimeldine in OCD was promising, it has been withdrawn from use owing to several reports of Guillain-Barre syndrome occurring during treatment.

Venlafaxine

Venlafaxine, a serotonin/norepinephrine reuptake inhibitor, has not been systematically studied in controlled trials in OCD, but open pilot data suggest potential efficacy and the need for controlled trials (90).

SEROTONIN REUPTAKE INHIBITORS: SIDE EFFECTS AND DRUG INTERACTIONS

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Side Effects

Efficacy must be balanced against side effects in choosing treatment options, and side-effect profile is magnified in OCD because the treatment is likely to be chronic. All SRIs can cause side effects attributable to their serotonergic action. Clomipramine, a TCA, is most apt to cause anticholinergic and antiadrenergic side effects, whereas SSRIs tend to cause fewer side effects mediated via nonserotonergic receptor systems (43 ,44 and 45 ,91 ,92 ,93 ,94 and 95).

TCAs such as clomipramine have a quinidine-like antiarrhythmic effect that slows intracardiac conduction (95). Although generally an issue only in patients with known cardiac disease, occasional adverse effects may be seen in patients with no documented pre-existing condition. Furthermore, in overdose, the cardiac conduction effects of TCAs lead to much greater toxicity than the SSRIs. This is important, because there is an increased rate of suicide attempts in OCD, especially when associated with comorbid disorders. TCAs have anticholinergic effects that can cause tachycardia, blurred vision, constipation, urinary retention, and confusion (44). Orthostatic hypotension may occur as a result of alpha$_1$-adrenergic antagonism (44). Last, clomipramine lowers seizure threshold (94).

SSRIs are relatively safe compared to TCAs. Few, if any, deaths have been reported following overdose with SSRIs. Although side effects are generally less severe, one may see agitation, anxiety, nausea, headaches, weight gain (over time), and sexual dysfunction (43). Although any of these side effects can contribute to noncompliance, sexual dysfunction is seen in as many as one-third of patients (92) but may not be readily reported unless the clinician specifically inquires about it. There are little systematic data on the treatment of SSRI-induced sexual dysfunction, but case reports and clinical practice have shown that effective interventions may include lowering the dose of SSRI or adding yohimbine (an α_2-adrenergic antagonist), amantadine (a dopamine agonist), methylphenidate, cyproheptadine (an antihistaminic/antiserotonergic agent), buspirone, or sildenafil (69). There also exists a clinically significant discontinuation syndrome that occurs on abrupt discontinuation of an SSRI with short half-life (71).

Drug Interactions

Patients treated for OCD often take concurrent medications; therefore, potential drug interactions should be considered when selecting an antiobsessional agent. In addition to well-established drug interactions known to occur with clomipramine and other TCAs, individuals may also experience idiosyncratic reactions (91 ,93 ,95 ,96 ,97 ,98 and 99). Some medications interact with clomipramine by influencing its plasma concentration, whereas others potentiate clomipramine's side effects via synergy at relevant receptor sites. The hypotensive effects of clomipramine can be exacerbated by α-methyldopa, ß-adrenergic blockers, clonidine, diuretics, and low-potency antipsychotics. Quinidine and other class Ia antiarrhythmics as well as thioridazine, mesoridazine, and pimozide may add to cardiotoxic effects of TCAs. Common medications that have anticholinergic effects can synergize with TCAs to produce anticholinergic toxicity, including antihistamines, antiparkinsonians, low-potency antipsychotics, over-the-counter sleeping pills, and antispasmodics or antidiarrheals. Conversely, TCAs such as clomipramine can potentiate the effects of warfarin or block the effects of guanethidine.

SSRIs can participate in drug interactions as a consequence of effects on the hepatic cytochrome P-450 system (96 ,97 and 98). As each SSRI is metabolized by one or more isoenzymes of cytochrome P-450, they may either inhibit or induce the corresponding enzymatic activity, thereby affecting the metabolism of other drugs. Conversely, other medications can inhibit or induce the P-450 system, thereby modulating the metabolism of SRIs. There is tremendous individual variation in P-450 effects. In addition, because SSRIs are highly protein-bound, this can lead to drug interactions

that do not involve the cytochrome P-450 system per se. For example, SSRIs can compete with warfarin, carbamazepine, and valproate for protein-binding sites, leading to increased levels of these agents, with accompanying adverse effects. In general, these interactions do not represent absolute contraindications to coadministration, but may require necessary adjustments to the dose of SRIs or other medications.

COMPARATIVE STUDIES OF THE SRIs

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Efficacy

Although metaanalyses have suggested that clomipramine is more effective than the SSRIs, head-to-head comparisons of clomipramine and SSRIs show no particular edge in efficacy to any of these medications. Three metaanalyses consisting of comparisons of previously published data sets found clomipramine superior to SSRIs in OCD treatment efficacy (24 ,100 ,101). In the Greist metaanalysis, the three SSRIs fluoxetine, fluvoxamine, and sertraline, were found to have similar efficacy, whereas clomipramine was found to be significantly more effective. It is important to realize that the studies on which these metaanalyses were based did not include head-to-head comparisons and patient samples for clomipramine may have differed from those for the SSRIs. The clomipramine studies, which were generally conducted in an earlier time period, included SRI naive patients, while the SSRI studies included patients who had previously failed to respond to clomipramine or fluoxetine trials; thus, the SRI trials were likely to include more treatment-refractory patients.

A few studies have evaluated the relative efficacy of the SSRIs in double-blind, head-to-head comparisons. No difference was found in the rate of response to fluoxetine (40 mg per day) compared to clomipramine (150 mg per day) when response was defined as a 35% reduction in total YBOCS scores (102) but fluoxetine was found to be better tolerated. Two comparisons of fluvoxamine and clomipramine have found then to be equally effective and, again, the SSRI was better tolerated (103 ,104). A comparison of paroxetine and clomipramine also found equal efficacy with superior tolerability for the SSRI, which also had a lower discontinuation rate (105). Additional comparative studies would be helpful because these had small sample sizes that were underpowered to show significant differences between two active medications, and did not include comparisons among the SSRIs.

Tolerability

In the studies noted in the preceding, the SSRIs were seen to have somewhat fewer side effects than clomipramine, but this did not necessarily impact compliance; however, in the CMI trials, there were no other alternatives available, which might have impacted discontinuation rates. Clomipramine has α-adrenergic, anticholinergic, and histaminergic effects and has quinidine-like cardiac properties that can increase the QTc interval. These effects can be a particular problem for OCD treatment, because it often requires doses higher than needed to treat depression. In a retrospective study comparing clomipramine and fluoxetine in the treatment of OCD, Jenike and colleagues (106) reported clomipramine treatment was associated with greater adverse events. For clomipramine, patients reported higher rates of sedation, dry mouth, nausea, dizziness, constipation, sweating, headache, and blurred vision. The adverse events reported for fluoxetine treatment were generally mild and transient. A metaanalysis of four large multicenter trials (52 ,70 ,72 ,86) found no difference in dropout rates owing to side effects: 8% for clomipramine, 10% for sertraline, 12% for fluoxetine, and 15% for fluvoxamine (24). Looking at the withdrawal rate for all causes, clomipramine had significantly fewer dropouts than the SSRIs despite having a greater rate of adverse events. However, as noted, this may be owing to the sample differences across studies discussed earlier, and lack of alternative treatment during the CMI trial. Typical tricyclic adverse effects were reported in the clomipramine collaborative study (52): dry mouth (80%), tremor (53%), dizziness (53%), sedation (49%), and male sexual dysfunction (41% of men). Fluoxetine was generally well tolerated in its multicenter study (72). The most commonly reported adverse effects were headache, nausea, insomnia, rhinitis, anorexia, dry mouth somnolence, anxiety, tremor, and diarrhea. There were significantly greater adverse effects with greater fluoxetine doses. In the sertraline study (24), the following adverse effects were reported significantly more frequently by the sertraline than the placebo group: diarrhea, insomnia, decreased libido, nausea, anorexia, ejaculation failure, tremor, increased sweating, and increased weight. Overall, 93% of the sertraline patients reported adverse effects with a correlation noted between higher dose and frequency of side effects; 77% of patients on placebo reported adverse effects. In the fluvoxamine study (70), the following adverse events were significantly more likely to be reported for fluvoxamine that placebo: insomnia, nausea, somnolence, asthenia, delayed ejaculation, nervousness, dry mouth, tremor, and anorexia. A recent review comparing controlled trials suggested that when compared with clomipramine, the SSRIs have equivalent efficacy and superior tolerability and lack anticholinergic side effects particularly (107).

Studies that compared clomipramine and an SSRI in double-blind, head-to-head comparisons, found the SSRIs to be better tolerated: Fluoxetine (40 mg per day) was better tolerated than clomipramine (150 mg per day) (102), as were fluvoxamine (103 ,104) and paroxetine, which also had a lower discontinuation rate (105). Efficacy and tolerability of clomipramine (100 to 250 mg per day) and fluvoxamine (100 to 300 mg per day) were compared in a double-blind, parallel group, randomized study (104). Both groups

showed steady improvement throughout the study; no differences were observed between the groups for any efficacy variable at any time and both clomipramine and fluvoxamine were equally effective in reducing OCD symptoms; they displayed differences in the profiles but not severity of the side effects.

LONG-TERM TREATMENT AND DISCONTINUATION

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

OCD is a chronic disorder; therefore, long-term treatment is often required. Although this research has methodologic limitations, data on long-term SSRI treatment (fluoxetine, sertraline, and paroxetine) suggests that efficacy is maintained and sometimes increases over time. Still more information is needed on the long-term efficacy and safety of SRIs in OCD treatment. SRIs have been proved effective in the acute treatment of OCD; double-blind substitution trials with clomipramine have shown that symptoms frequently recur after discontinuation of treatment (108 ,109).

A retrospective follow-up study of 85 patients with OCD reported that most of the patients treated with SSRIs for 1 to 3 years had maintained or increased symptom improvement (110). Two double-blind and/or placebo-controlled long-term SSRI continuation studies have reported continued efficacy and tolerability (74 ,75). Although valuable, these studies had no effective control group for the maintenance phase: Because only responders to an acute trial continued into long-term maintenance, there were only a handful of placebo patients in maintenance and there was no other control group. To date, no long-term, double-blind substitution trials have been published. An open-label discontinuation trial (111) followed 130 responders to 6 months of acute treatment with an SRI: clomipramine, fluoxetine, or fluvoxamine. This occurred for 2 years of treatment (or until they experienced a recurrence) with the same medication at the same dose, the same medication at half the dose, or no treatment. The study showed a superior therapeutic effect for both medication conditions compared to discontinuation of pharmacotherapy. One controlled, long term, double-blind substitution trial (71) has shown that paroxetine is superior to placebo in preventing OCD relapse during a 6-month discontinuation trial (which followed 12 weeks of acute treatment in a double-blind placebo-controlled paroxetine dose finding trial and 6 months of open-label paroxetine treatment). In addition, treatment effects appeared to be sustained and may have even increased over the time of the trial. In addition, following the double-blind discontinuation phase, subjects switched to placebo had a significantly greater rate of relapse, and time to relapse was significantly shorter on placebo versus paroxetine (71). One study suggested that long-term maintenance therapy might be provided with lower dosages of antiobsessional drugs, with a clear advantage for tolerability and compliance (112).

SRIs IN CHILDHOOD AND ADOLESCENT OCD

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

The clinical presentation of OCD in children and adolescents resembles that observed in adults (113). There has been increasing awareness of the frequency with which children and adolescents suffer from OCD (114). Clomipramine has been well studied in the treatment of OCD in this population. An 8-week multicenter double-blind study (115) found clomipramine to be effective and superior to placebo (mean Y-BOCS scores decreased by 37% versus 8%). These findings led to FDA approval of clomipramine for the treatment of OCD in children and adolescents. The side-effect profile in this sample included anticholinergic, antihistaminic, and α-adrenergic effects such as dry mouth, tremor, sedation, dizziness, sweating, and insomnia. No serious adverse events were reported; however, some patients were withdrawn owing to hepatic enzyme elevations and cardiac palpitations. Electrocardiographic monitoring should be undertaken because tricyclic antidepressants have the potential for being cardiotoxic (116).

Fluvoxamine is an FDA-approved SSRI for the treatment of pediatric OCD. In an 8-week open-label trial of fluvoxamine with adolescents (100 to 300 mg per day), the majority of patients showed significant improvement in their OCD symptomatology (117). The side-effect profile was similar to that reported in adults, including hyperactivity, anxiety, sedation, dizziness, headache, tremor, and nausea. A large (*N* = 120) double-blind placebo-controlled 10-week study of fluvoxamine (50 to 200 mg per day) with children and adolescents (ages 8 to 17) found the drug to be significantly superior to placebo (118). Side effects were described as mild; those that were more commonly reported in the fluvoxamine group included insomnia, agitation, hyperactivity, somnolence, and dyspepsia.

There have been four small prospective studies investigating the efficacy of fluoxetine in pediatric OCD. Three of these were open design (119 ,120 and 121). Riddle and co-workers (122) conducted a double-blind crossover trial of fluoxetine (*N* = 14; mean age 11.8; 20 mg per day, fixed daily dosing) and reported it to be superior to placebo as measured by CGI scores for global improvement. The most commonly reported adverse effects included insomnia, motor activation, fatigue, and nausea. In general, the side effects were reasonably well tolerated and did not result in withdrawal from the study, except for a 13-year-old boy who developed suicidal ideation in the third week of fluoxetine treatment. There were no significant changes in laboratory studies, EKG, weight, pulse, or blood pressure. Major limitations of the study were the small sample size and the fixed dosage.

In a retrospective chart review by Geller and colleagues (123), fluoxetine led to moderate to marked improvement in OCD symptoms in 74% of patients (*N* = 38); mean age 12.3). Relatively high doses of the drug were required, on average 50 mg per day (1.0 mg/kg per day). Long-term

efficacy was sustained over the follow-up period of, on average, 19 months. Fluoxetine was generally well tolerated and adverse effects were less marked than those associated with clomipramine. Despite this apparent tolerability of high doses, it has been recommended that, for children, an appropriate starting dose of fluoxetine is 10 mg per day or less (122).

The FDA has also approved sertraline for the treatment of child and adolescent OCD, which has been shown to be safe and effective in this population (124). In a randomized, double- blind, placebo-controlled trial, 107 children aged 6 to 12 years and 80 adolescents aged 13 to 17 years were randomized to receive either sertraline titrated to a maximum of 200 mg per day (53 children, 39 adolescent) or placebo (54 children, 41 adolescents). After 12 weeks, 42% of the patients receiving sertraline and 26% of those receiving placebo were very much or much improved on CGI ratings. The incidence of side effects was similar to that reported in adults; sertraline appears to be a safe and effective antiobsessional agent in children and adolescents.

In an open-label trial, the adverse effects and potential clinical efficacy of citalopram (10 to 40 mg) were examined in 23 children and adolescents (aged 9 to 18 years). After 10 weeks, over 75% of these youths showed a moderate or marked improvement and adverse effects appeared to be minor and transient, suggesting that citalopram might be well tolerated in children and adolescents (Table 114.2) (128).

Study (Ref.)	Conditions	Results
Flament et al., 1985 (125)	CMI vs placebo	CMI superior to placebo
Devaugh-Geiss et al., 1992 (115)	CMI vs placebo	37% decrease Sx on CMI 8% decrease Sx on placebo
Rapoport et al., 1980 (126)	CMI vs DMI vs placebo	No differences
Leonard et al., 1988 (127)	CMI vs DMI	CMI superior to DMI
Leonard et al., 1991 (109)	CMI substituted with DMI in 50%	18% on CMI relapsed
Riddle et al., 1992 (122)	Fluoxetine vs placebo	Fluoxetine superior to placebo
March et al., 1998 (124)	Sertraline vs placebo	Sertraline marked improved 42% vs 26% placebo
Riddle et al., 2001 (124a)		

TABLE 114.2. CONTROLLED TRIALS OF SEROTONIN REUPTAKE INHIBITOR THERAPY FOR OBSESSIVE-COMPULSIVE DISORDER IN CHILDREN AND ADOLESCENTS

Recent reviews on the treatment of children and adolescents with OCD suggest that adjunctive interventions including parent case management education and specific cognitive-behavioral should be considered in the majority of cases.

BEHAVIOR THERAPY AND PHARMACOTHERAPY

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Prolonged exposure coupled with response prevention is a key element of behavior therapy for OCD. Exposure involves prolonged confrontation with stimuli that provoke obsessional thoughts or compulsive behaviors. Patients agree not to engage in their usual ritualistic behavior or cognitions and to remain in the situation until their discomfort wanes. Homework is generally prescribed outside the therapist contact. Success rates vary from 50% to 80% (129). Some studies suggest that up to 90% of patients have achieved clinically significant benefits from behavior therapy (130). Generally, 70% to 80% of these patients maintain their acute gains at 1-year follow-up (131).

Intensive behavior therapy over 3 weeks has produced promising results, even in a very symptomatic group. Foa and colleagues (132) reported that 51% of patients experience at least a 70% drop in symptoms, with 35% experiencing a 31% to 69% reduction. These gains are generally (75%) maintained at 12-month follow-up. It is often difficult to arrange such extensive exposure in an outpatient setting, however. Recent results in one trial suggest that providing this treatment in a group setting may be effective and cost effective (133). Relapse prevention programs have proved beneficial in maintaining the gains of acute treatment (134).

Comparisons

A metaanalysis comparing behavioral treatments and SSRIs in OCD involved 77 studies in 4,641 patients. Effect sizes for behavior therapy were not significantly different from those of the SSRIs. There were also no significant differences between the SSRIs, although CMI appeared to have some increased efficacy but not sufficient enough to warrant favoring it over other SSRIs given its side-effect spectrum and the dangers associated with overdose (135). The choice between these two modalities is often dominated by the relatively limited availability of behavioral therapists and by patient preference. Up to 25% of individuals refuse behavioral therapy, whereas others prefer a nonpharmacologic treatment. A computer program offering behavior therapy via 12 computer-controlled interactive phone calls was found effective in over two-thirds of the patients (136).

In clinical practice, a combination of pharmacotherapy and behavioral therapy is often employed, although available research is not yet clear on potential benefits of combined medication and behavior therapy, either on response or relapse prevention.

TREATMENT-RESISTANT OCD: CLINICAL AND BIOLOGICAL PREDICTORS OF NONRESPONSE

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

It has been recommended that a minimum of 12 weeks of SRI treatment is needed to evaluate treatment response. Long-term trials have also noted continued improvement beyond this period.

The relationship between plasma levels of the SSRIs and treatment outcome in OCD is unclear. Studies on fluoxetine and sertraline indicated that plasma levels correlated with dosage but there was no evidence of a concentration—response relationship (75 ,137). It was reported that brain levels of fluoxetine and fluvoxamine reach steady state after 6 months and 1 month, respectively, and correlate with plasma levels (138). Current research is investigating the connection between brain steady-state levels and treatment response.

The response of OCD to drug treatment is frequently partial and incomplete. Poorer outcome has been associated with the presence of compulsions, the chronicity of the illness, and a continuous as opposed to fluctuating course (139) as well as the coexistence of borderline, schizotypal, or avoidant personality disorders (140). Depression is the most common comorbid diagnosis with OCD. The presence of concurrent depression at the start of treatment was not found to predict whether SRIs were effective in reducing obsessive-compulsive symptoms (100). Hollander and associates (141) reported that select measures of serotonergic function may be useful in predicting response to SRI treatment in OCD. They found that nonresponders to SRIs were likely to experience worsening of OCD symptoms and to have a blunted prolactin response on being challenged with the partial 5-HT agonist *m*-chlorophenylpiperazine (*m*-CPP). Further work is needed in this area. Also, OCD patients with increased neurologic soft-signs, a measure of subtle neurologic dysfunction, had a worse response to SRIs (22).

AUGMENTATION STRATEGIES

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Augmentation strategies play an important role in OCD pharmacotherapy for SRI partial and nonresponders, as 40% to 60% of patients with OCD will not respond to an adequate treatment trial of an SRI. Augmentation agents added to SRIs include both serotonin enhancers and agents involving other neurotransmitter systems, which may contribute to the pathophysiology of OCD.

Serotonergic Enhancers

Pharmacologic agents with serotonergic properties have shown varying utility in augmentation of SRIs.

Buspirone

Buspirone, a 5-HT1A agonist, has been reported effective in treating OC symptoms in augmentation to fluoxetine in some open-label studies (142 ,143) but not in a controlled study (144). A 10-week double-blind trial of buspirone addition to ongoing clomipramine treatment reported no significant further clinical improvement in OC symptoms (145). In a double-blind, placebo-controlled study adding buspirone to fluvoxamine-refractory OCD, buspirone was not found to be significantly better than placebo in reducing OCD symptoms (146).

Fenfluramine

D-L-Fenfluramine, an indirect 5-HT agonist, added open-label to ongoing SRI treatment led to improvement in OC symptoms in six of seven patients (147). D-Fenfluramine also has been cited as potentially effective in augmenting clomipramine in OCD (148); however, these agents have been removed from the market because of side-effect issues.

Tryptophan

Tryptophan, a 5-HT precursor, has shown varying degrees of effectiveness in case reports of SRI augmentation in OCD (68 ,149), but has been removed from the market because of side effects. 5-HTP has been reported helpful in anecdotal case reports.

Lithium

Lithium, which is thought to enhance presynaptic 5-HT release in the brain (150) and influence second messenger systems coupled to 5-HT receptors, was reported to improve OC symptoms in three out of four patients treated with open-label addition to ongoing fluoxetine treatment (151). However, in a 4-week double-blind study of lithium augmentation to 16 OCD partial responders on clomipramine, there was no further decrease in OC symptoms reported after lithium (152). In two double-blind, placebo-controlled trials of lithium, addition to ongoing fluvoxamine treatment in OCD nonresponders (2-week study [20 points] and 4-week study [10 points]), only a small statistically significant reduction in OCD symptoms was reported from the 2-week trial, but not from the 4-week trial (153).

Clonazepam

Clonazepam, a benzodiazepine with unique serotonin properties, has been efficacious in augmentation to SRIs in the patients with OCD in case series (154) and in a double-blind, controlled augmentation trial with fluoxetine or clomipramine (155).

Trazodone

Trazodone, a 5-HT2 and α-adrenergic blocker with weak 5-HT reuptake properties, which has *m*-CPP as a minor metabolite, was recently reported effective in augmentation to various SRIs in five cases of refractory OCD (156).

Pindolol

Pindolol is a B-adrenergic blocker with 5-HT1B and 5-HT1A receptor antagonist activity. Recent reports indicate that adjunctive pindolol may shorten the latency to antidepressant response to SRIs (157); however, data in OCD patients are mixed. One study of pindolol augmentation to paroxetine in resistant OCD resulted in mild improvement (158), whereas another report found that pindolol did not shorten the latency of fluvoxamine antiobsessional response (159). Thus, the utility of pindolol in non-depressed OCD patients is in doubt.

Dopaminergic Agents

The dopamine system has also been implicated in the pathophysiology of OCD; therefore, it is potentially useful in augmentation studies. Dopamine antagonist/SRI combinations have been reported to be effective in OCD.

Haloperidol

In a double-blind, placebo-controlled study of OCD patients on fluvoxamine monotherapy, haloperidol augmentation was found to be significantly more effective than that of placebo, and 100% of patients with a concurrent chronic tic disorder (8/8) responded to ongoing fluvoxamine-haloperidol treatment (160).

Pimozide

Open case series have shown the effectiveness of pimozide/SRI combinations in OCD patients with and without comorbid tic-related disorders (161).

Risperidone

In an open trial of risperidone/SRI combination treatment, 87% (14/16) of patients with refractory OCD had substantial reduction in OC symptoms (162). In another open trial, after the addition of risperidone, seven out of 14 patients had clinical improvement after failing to respond to SSRI treatment alone (163). Other cases of risperidone augmentation reported effectiveness in reducing OC symptoms in patients who had failed SRI trials (164 ,165). A chart review, including eight OCD patients treated with the combination of an SRI and risperidone, reported three (37.5%) patients much or very much improved in OCD symptoms (166).

Olanzapine

Case series (167 ,168) and open-label trials (169) have reported benefits of adding titrated doses of olanzapine (10 or 15 mg per day) to an SSRI in refractory OCD patients. Thus, olanzapine might also be considered in the augmentation of severe forms of OCD, although careful monitoring of the potential interaction with SSRIs is suggested because this combination may produce idiosyncratic effect on plasma levels.

GABA/Second Messenger Systems

Gabapentin, a γ-aminobutyric acid (GABA) analogue, was reported to improve OC symptoms in 5/5 partial responders in a 6-week pilot study of fluoxetine augmentation within 2 weeks of treatment (170). In an open-label augmentation trial of SRIs with inositol, a precursor in the phosphatidyl-inositol cycle, 3/10 refractory OCD patients reported clinically significant responses on the CGI improvement scale (171); therefore, agents affecting other neurotransmitter or second messenger systems may play a role in augmentation strategies.

NOVEL PHARMACOTHERAPIES

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Some individuals with OCD remain refractory even to augmentation strategies. For them, alternate pharmacotherapy may provide relief.

Intravenous Clomipramine

Intravenous clomipramine was first reported successful in treating obsessive symptoms in 1967 (46). A review of the literature found over 100 cases of successful treatment with intravenous clomipramine (172). In a double-blind, placebo-controlled trial of intravenous versus oral pulse loading of clomipramine in 15 OCD patients, six of seven patients treated with intravenous clomipramine were responders compared to one of eight patients with oral clomipramine (4.5 days after pulse loading), suggesting greater immediate improvement with intravenous pulses (173). This may be owing to avoidance of the first-pass liver metabolism of clomipramine, resulting in a greater clomipramine/desmethyl clomipramine ratio, more potent central 5-HT effects,

and fewer side effects. The superiority of the intravenous route compared to the oral one has been reported in a placebo-controlled study (174). After 1 month of intravenous clomipramine (doses up to 250 mg per day) 58% of 21 patient nonresponders to oral administration randomized to receive intravenous clomipramine showed a marked clinical improvement rated by both CGI and Y-BOCS, without serious adverse events.

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors (MAOIs), which block the catabolism of serotonin as well as norepinephrine and dopamine, have been reported successful for refractory OCD in some but not all studies. Case reports of successful treatment are available for iproniazid (175) and most substantially for phenelzine, which was one of the first pharmacologic agents tried for OCD. These reports primarily combined phenelzine with other medications (176 ,177 and 178). However, in a 10-week placebo-controlled comparison trial of fluoxetine versus phenelzine in 54 patients with OCD, patients treated with fluoxetine significantly improved more than those in the phenelzine or placebo groups, except for a subgroup of patients with symmetry obsessions who responded to phenelzine (179).

Serotonergic Agents

Buspirone monotherapy was reported to be ineffective in an 8-week open trial of 14 OCD patients (180) and Hewlett's survey found seven reported successes and 21 reported failures (172). Trazodone has been found successful in both cases and open trials of comorbid depression with OCD (181 ,182 and 183); however, it was found ineffective in reducing OC symptoms in a double-blind, placebo-controlled trial (184). The first treatment response to tryptophan was described in seven patients with OCD (185), with no further controlled studies. The role of other serotonergic agents in treating OCD including 5-HT3 agonists (ondansetron) and 5-HT2 agonists requires further research.

Noradrenergic Agents

The noradrenergic system has also been explored as a novel individual pharmacotherapy in OCD. A case report of clonidine, an α2-agonist, documented improvement in OCD (186). Intravenous clonidine was reported to markedly reduce obsessions in six OCD patients (187). However, in a double-blind controlled crossover trial of clomipramine, clonazepam, and clonidine in 28 OCD patients, clonidine was found ineffective in reducing OCD symptoms (188).

Stimulants and Dopamine Releasers

Although most attention has focused on the blockade of dopaminergic receptors in OCD, there are also reports that agents that release dopamine and dopamine receptor agonists may also have efficacy in OCD. Insel and associates (189) reported that two patients treated with amphetamines (10 to 20 mg) achieved a "persistent benefit" for a period of several weeks. He reported an additional two patients treated with "low-dose" amphetamines for several months who reported a decrease in obsessional symptoms. Ceccherini-Nelli and Guazzelli (190) described three cases of OCD with concurrent depression responding to the dopaminergic agonist bromocriptine (15 to 30 mg). These reports must be reconciled with reports that chronic administration of methylphenidate and amphetamine may induce ritualized behaviors and other OCD-like symptoms (191 ,192).

There are seven cases of reported improvement and one reported failure on chronic dopaminergic agonists. In a survey by Hewlett (172), five of 28 subjects (19%) achieved a good response with chronic amphetamine. Neither of these two patients treated with bromocriptine had any improvement. Bupropion, which inhibits dopaminergic reuptake, was associated with 15 failed treatments.

The OCD-like behaviors induced by chronic amphetamine may represent stereotypies, or complex tics, rather than compulsions that are performed to reduce anxiety. Clomipramine is a potent inhibitor of dopamine uptake and is antiobsessional. Conceivably, the response to low-dose neuroleptics in OCD may stem from their effects on blocking presynaptic dopamine D2 receptors, increasing dopamine release (190).

Benzodiazepines

Case reports of clonazepam have also shown its efficacy (172 ,193). In a double-blind crossover trial, 40% of the patients who had failed clomipramine treatment had clinically significant responses to clonazepam treatment, and clonazepam was significantly more effective than clomipramine during the first 3 weeks of treatment (188). However, a double-blind multicenter placebo-controlled trial of clonazepam demonstrated no efficacy (194). Other benzodiazepines, such as alprazolam, have also not shown efficacy in treating OCD (195).

Anticonvulsants

There are three case reports of significant response to nonbenzodiazepine-related anticonvulsants (two of whom had clinical epilepsy) all with carbamazepine, and 23 treatment failures (172). Two patients with OCD and clinical epilepsy responded to clonazepam treatment (196); however, clinical experience with anticonvulsants may be more positive. Two of 12 patients (17%) at two sites had successful trials of carbamazepine, and six of 26 patients (23%) at three sites had positive outcomes with sodium valproate (172).

Gonadal Steroids

There have been six reported cases of improvement associated with antiandrogen treatment, four of which were menstrually related, and one menstrually related improvement with an anovulatory medication (172). Only one antiandrogen failure has been reported, and one failure of estrogen treatment alone. An open trial with flutamide, an androgen receptor antagonist, in eight OCD patients, demonstrated a lack of response (197). None of the OCD centers has reported using this modality in treating OCD. As such, this treatment has not been well studied. In practice, the feminizing effects of these treatments in males limit their use in this population. In females, it is unclear whether treatment efficacy, if present at all, is limited to specific phases of the menstrual cycle. This treatment is unlikely to become a mainstream therapy for OCD.

Second Messenger System Agents

Agents that affect second messenger systems may also be effective in OCD. In a 6-week double-blind controlled crossover trial of inositol versus placebo in 13 OCD patients, YBOCS scores with inositol treatment were significantly lower than scores when on placebo (198).

Peptides

The role of peptide hormones has been studied in OCD. In one study, elevated CSF levels of oxytocin were found in a subtype of OCD patients compared to Tourette syndrome patients and controls, and levels were correlated with OCD severity, suggesting a possible role for oxytocin in the neurobiology of OCD (199). Oxytocin is a hormone released by the posterior pituitary that regulates uterine and lactiferous duct contraction. It has been implicated in certain ritualized behaviors and the extinction of active avoidance behavior in animals (200). In all, there have been three reported cases of improvement with chronic intranasal oxytocin and 12 failures
(172 ,173 ,174 ,175 ,176 ,177 ,178 ,179 ,180 ,181 ,182 ,183 ,184 ,185 ,186 ,187 ,188 ,189 ,190 ,191 ,192 ,193 ,194 ,195 ,196 ,197 ,198 ,199 ,200 and 201). There have been no reports of improvement with vasopressin; however, this medication has not been administered chronically. None of eight patients at two OCD sites improved with oxytocin treatment. Although experience is limited with this modality, it does not appear to be a promising treatment.

Opiates

Warneke (202) reported that oral morphine in doses of 20 to 40 mg every 5 to 8 days produced marked benefit in five very severe cases of OCD. In contrast, naloxone has proved unsatisfactory and controversial (203 ,204). Tramadol, an analgesic that binds to opioid receptors and inhibits the reuptake of norepinephrine and serotonin, has been reported to produce a significant decrease in Y-BOCS scores in a 6-week open-label study in seven treatment refractory OCD patients (205). Controlled trials are required, although it has low abuse potential, low physical dependency, and mild tolerance.

AUTOIMMUNE TREATMENTS

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Autoimmune mechanisms may also play a role in at least a subtype of patients with OCD, particularly those who manifest a sudden onset of OCD symptoms following infection by group A B-hemolytic streptococci. Studies with oral penicillin were not found to be effective in such patients (206). Plasmapheresis and intravenous immunoglobulin (IVIG) have been reported effective in case studies (207). Recently, both IVIG and plasma-exchange groups were associated with significant improvement at 1 month in 30 children with infection-triggered exacerbations of OCD or tic disorders who received IVIG, plasma exchange, or placebo (208).

INVASIVE PROCEDURES

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

Finally, novel nonpharmacologic treatments may also play a role in treating some OCD patients. Right prefrontal repetitive transcranial magnetic stimulation has been shown to significantly decrease compulsive urges, compared to nonsignificant increases in urges with stimulation to midoccipital (control) areas and a nonsignificant reduction of urges in left lateral prefrontal areas (209). Further studies are warranted. Recent work with vagal nerve stimulation, deep brain stimulation, and various forms of neurosurgery suggest promise, but require controlled trials.

Patients who have failed all pharmacologic and behavioral treatments (and probably ECT) may be candidates for neurosurgical treatments of OCD (210). Various procedures in intractable cases have been successful, with 25% to 30% of patients experiencing significant benefit without undue side effects. The most common current neurosurgical procedure is cingulotomy, either performed via craniotomy or with the γ-knife procedure. In a United States trial, 18 patients underwent cingulotomy. At follow-up 2 years later, 28% met conservative criteria as responders, with 17% more meeting criteria as partial responders (210). Neurosurgery should be considered for a small percentage of truly refractory patients.

OCD SPECTRUM DISORDERS

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

An OCD spectrum has been proposed, consisting of various disorders that overlap with OCD in several features, including clinical symptoms (repetitive thoughts and behaviors),

course of illness, comorbidity, family history, neurobiology, and treatment response (selective efficacy of SSRIs) (25).

Three key clusters of disorders have been identified: (a) disorders with preoccupation with body image, body weight, or body sensations; (b) impulsive disorders in which repetitive behaviors are driven by pleasure; and (c) neurologically based disorders with repetitive behaviors. Clusters 2 and 3 are dealt with elsewhere in the volume. Here we focus on one disorder from the first cluster where there exist double-blind controlled pharmacologic data.

Body dysmorphic disorder (BDD), the distress of imagined ugliness, is a somatoform disorder in which patients are obsessed with an imagined imperfection or deformity in their appearance, and repeatedly check their appearance in mirrors or engage in cosmetic surgery to change their appearance. There is often poor insight or delusional conviction, and secondary depression and social phobia.

A recent double-blind crossover trial compared the SRI clomipramine to the noradrenergic reuptake inhibitor desipramine (DMI) (8 weeks of each phase) in 40 BDD patients (211). Desipramine, the active control, was chosen to control for nonspecific antidepressant and antidepressants, and because it has a similar side-effect profile to CMI, enhancing the blind. The SRI CMI resulted in significantly greater improvement in all primary outcome measures of BDD severity than did DMI, and also improved measures of functional impairment to a significantly greater extent than did DMI. Subjects with delusional conviction regarding body defect improved on CMI but not DMI, and severity of delusional conviction improved with CMI. Thus, BDD, like OCD, but in contrast to other mood or anxiety disorders, demonstrates a selective efficacy to SRIs, but not to NRI treatment. The delusional conviction in BDD appears secondary to obsessive preoccupation, and also responds to SRI treatment.

CONCLUSION

Part of "114 - Current and Experimental Therapeutics of Obsessive-Compulsive Disorder "

In summary, SSRIs and the tricyclic antidepressant clomipramine are currently the first-line treatment for OCD, with the SSRIs' side-effect profile being more favorable than that of clomipramine. However, 40% to 60% of patients with OCD may not respond to an adequate treatment trial of an SRI. Furthermore, not all patients tolerate SSRIs, and there is often a time delay in seeing a full therapeutic response. Thus, other pharmacologic approaches to treating OCD have been investigated, and certainly combinations of pharmacotherapy and cognitive behavioral therapy are considered the treatment of choice. Augmentation and novel monotherapy strategies have been explored in refractory patients, with serotonergic enhancers, dopamine/serotonin antagonists, enhancers of second messenger systems, and GABAergic agents, with varying efficacy. Recently, immunomodulatory and invasive procedures have been explored as well, but require further study.

The Behavioral Neuroscience of Eating

Gerard P. Smith

Nori Geary

Gerard P. Smith and Nori Geary: Department of Psychiatry, Weill Medical College of Cornell University, New York-Presbyterian Hospital, Westchester Division, White Plains, New York.

Clinical syndromes stimulate basic science by providing unexpected combinations or dissociations of phenomena that basic science did not predict or cannot explain. That clinical eating disorders in which abnormally large meals can occur in patients with low, normal, or high body weight contradicts the assumption that the only function of eating is to provide energy intake for nutritional homeostasis. In the past decade the basic science of eating has responded to this problem in such a fundamental way that it has undergone a paradigm shift. Instead of seeking the neurobiological mechanisms of eating solely in the molecular transformations of energy homeostasis, eating is now seen as a problem in behavioral neuroscience. This shift promises for the first time an adequate basic science of eating because the new view includes genetic and sexual vulnerabilities, learning, and a coherent neural system composed of peripheral feedbacks and central integrations that use amines, peptides, and steroids. The shift has been driven by the recent progress in a "top-down" analysis of meals, the functional unit of eating (1). This analysis has included the application of molecular genetics that revealed a central cascade of neuropeptides, the recognition that the neurology of eating was a system that integrated peripheral feedback and central information to turn a central pattern generator for oromotor movements on and off, the realization that learned controls of eating developed rapidly and acted frequently, and a renewed attack on the mechanisms by which estrogen inhibits eating. We review these areas in this chapter.

MOLECULAR GENETICS AND CENTRAL NEUROPEPTIDE CASCADE

Part of "115 - The Behavioral Neuroscience of Eating "

Although peptides have been implicated in the control of eating since 1957 (2) and more than 20 peptides had been shown to have effects before 1990, the use of molecular genetic techniques to discover agouti protein in 1993 and leptin in 1994 galvanized an intensive search for new brain peptides relevant to the control of food intake and metabolism. The search succeeded (Table 115.1).

TABLE 115.1. CHRONOLOGY OF PEPTIDE EFFECTS ON FOOD INTAKE AFTER CENTRAL OR PERIPHERAL ADMINSTRATION

Peripheral	Central
1957 Glucagon	1974 Opioids
1973 Cholecystokinin	1977 Thyrotropin-releasing hormone
1979 Bombesin	1979 Cholecystokinin, insulin
1980 Insulin	1981 Bombesin
1981 Somatostatin	1982 Neurotensin
1983 Neurotensin	1983 Corticotropin-releasing factor
1984 Calcitonin gene-related peptide	1984 Calcitonin gene-related peptide, somatostatin
1987 Tumor necrosis factor	1985 Neuropeptide Y
1988 Enterostatin	1986 Galanin, alpha melanocyte-stimulating hormone
1989 Interleukin 1-beta	1988 Interleukin-1 beta, tumor necrosis factor alpha
1991 Amylin	1991 Amylin, enterostatin
1992 Apolipoprotein AIV	1992 Tumor necrosis factor beta
1998 Glucagon-like peptide -1	1993 Apolipoprotein AIV
	1994 Agouti protein
	1995 Leptin
	1996 Urocortin, Glucagon-like peptide 1, melanin concentrating hormone
	1997 Agouti related protein
	1998 Orexins, cocaine and amphetamine regulated transcript

The year listed is the first report of the effect according to a search of the literature using Pub Med in 1999 and references in the reviews that accompanied this article. Smith GP. Introduction to the reviews on peptides and the control of food intake and body weight. *Neuropeptides* 1999;33:323–328.
Reproduced from Smith GP. Introduction to the reviews on peptides and the control of food intake and body weight. *Neuropeptides* 1999;33:323–328, with permission of the publisher.

Of the new peptides, leptin was the most intensively investigated because it was hoped that it was the long sought negative-feedback signal synthesized from and released by adipose tissue that was hypothesized by Kennedy in 1953 to be the crucial link between food intake and energy storage (3). The hyperphagia and obesity that occurred in mice that had a genetic deficit in leptin production (*ob/ob*) or in leptin receptors (*db/db*) apparently substantiated the importance of leptin as a negative-feedback signal. However, the euphoria evaporated when it was discovered that circulating leptin was abnormally high, rather than low, in almost all obese humans as well as in mice and rats that became obese on a high-fat diet.

The nature of this leptin "resistance" is under intensive investigation. It appears to involve decreased transport into the brain and decreased intracellular signal transduction after leptin binds to its receptor (4). Its common occurrence shows that the negative-feedback effect of leptin is easily overcome by diets that increase eating. This is a compelling demonstration of a central theme in behavioral neuroscience: Reinforcement frequently overcomes regulation.

Although leptin was not a "magic bullet" for the treatment of obesity, a crude idea driven by commercial hopes rather than scientific knowledge, the analysis of its inhibition of food intake and increased metabolism has stimulated an enormous amount of work that can be summarized briefly. (See refs. 4 and 5 for extensive reviews.) The arcuate nucleus in the ventromedial hypothalamus is a nodal point for leptin's action. Leptin stimulates a lateral population of proopiomelanocortin (POMC) neurons and inhibits a medial population of neurons that express neuropeptide Y (NPY), a potent stimulant of eating, and agouti-related peptide (AGRP), an antagonist of melacortin (MC) receptors, especially MC_4, that also stimulates eating. The MC_4 receptor

is necessary for leptin's inhibition of food intake because the effect of leptin is abolished when an antagonist blocks MC_4. Furthermore, MC_4 knockout mice are hyperphagic and obese despite high circulating leptin. The endogenous agonist for the MC_4 receptor is α-melanocyte-stimulating hormone (MSH), a translational product of the POMC neurons. The roles of other peptides, such as orexin A, cocaine and amphetamine-regulated transcript (CART), glucagon-like peptide-1 (GLP-1), apolipoprotein-IV, melanin concentrating hormone (MCH), and mahogany protein in the physiologic control of eating, and their relationship (if any) to leptin's action remain to be determined.

Identification of these peptides sparked anatomic investigations that used immunocytochemical techniques to trace connections from NPY-AGRP neurons to orexin neurons in the lateral hypothalamus, and projections of NYP-AGRP neurons and POMC neurons to the paraventricular nucleus in the anteromedial hypothalamus and to the hindbrain, especially to the region of the nucleus tractus solitarius (NTS). Discussion of these results has attempted to extract their meaning from the medial and lateral hypothalamic syndromes. This is not illuminating because those syndromes never clarified the normal control of eating and the extent of the anatomic damage was not determined; they were problems, not explanations.

The current status of this work on central neuropeptides can be described as "a few small islands of scientific understanding surrounded by a vast area of uncertain phenomena" (2). The progress represented by the work with these peptides has been real and has been trumpeted loudly in the scientific literature and lay press. Its limitations have been less emphasized. They include the facts that leptin resistance is a significant problem in dietary-induced obesity and that high-fat diets decrease the potency of a variety of peptides. Furthermore, the central neuropeptide cascade defined by leptin action has been described in the unusual situation of 24 or 48 hours of food deprivation. This makes the relevance of this cascade to the controls of food intake and body weight under more normal conditions problematic. It is particularly important to understand that most of the progress in the field has been horizontal, that is, it has added new peptides to the list that affect energy intake, storage, and expenditure. Relatively little progress has been made in the vertical problems of physiologic function, interactions, and generalizations. Despite their difficulty, the vertical problems must be pursued in order to decipher the meaning of these molecules. To say that a peptide increases or decreases food intake is to pose a problem for scientific investigation rather than to state a conclusion about physiologic function. The physiologic function of a peptide is learned only when we can specify the function of that peptide in the central neural networks that control food intake and body weight.

The example of cholecystokinin makes this point. Cholecystokinin (CCK) released from the small intestine during a meal provides a negative-feedback signal for the control of the size of that meal in animals (6) and humans (7). An important part of the evidence for this was that administration of a specific antagonist of CCK_A receptors produced a significant increase in meal size in rodents, pigs, monkeys, and humans under a variety of conditions. This satiating action of CCK is mediated by CCK_A receptors on vagal afferent fibers that project to the medial and caudal NTS. The disconnected caudal brainstem of the chronic decerebrate rat has sufficient neural complexity to process this visceral information into a stop signal to the central pattern generator (cpg) that controls oromotor movements (8), but in the intact brain, forebrain structures, such as the paraventricular nucleus, are also involved (6). Thus in this case, we know the biological meaning of CCK in the control of food intake because we can define it as one of the stimuli of the peripheral negative feedbacks that control meal size.

The experimental history of the extensive and convergent results required to prove that the satiating effect of CCK was a physiologic function of the peptide is a case study for

those pursuing the meaning of other peptides (9). Behavioral specificity, receptor mechanism, predictable results with reversible antagonists, afferent neural mediation, and the effect of experimental context (genetic, dietary, metabolic, and prior experience) had to be assessed and interpreted. The experience teaches that physiologic meaning is not read out directly from molecular structure or from an increase or decrease of food intake.

NEURAL CONTROL OF EATING

Part of "115 - The Behavioral Neuroscience of Eating "

Because the biological meaning of a peptide for the control of eating is defined by its role in the neural network that integrates peripheral and central stimuli into oromotor output, we now review the important progress that has been made in that area in the past decade.

Although it is common to refer to this area of research as the Neural Control of Food Intake, this is imprecise and misleading because food intake denotes a measurement made by investigators, not a movement made by animals or people. The somatic nervous system controls the oromotor movements of eating; the autonomic nervous system controls movements of the digestive tract through its effects on the enteric nervous system, intraluminal digestion, neuroendocrine release, and metabolic transformations. The sensory stimuli from these efferent effects are integrated in the central nervous system to affect somatic and visceral efferent output. The major advance in the understanding of this vast, complicated neural system has been in the somatic nervous system's control of eating.

Eating consists of rhythmic oromotor movements, such as licking, lapping, and mastication. These movements have a relatively fixed rate. For example, rats make five to eight licks per second (the range in individual rats is less). This is the motor signature of a group of neurons acting as a cpg. The cpg for licking in the rat is in the medial, intermediate, and lateral reticular formation of the medulla (10). A network of premotor neurons extends forward from the caudal brainstem to the region of the substantia nigra (11). Thus, the neural control of eating can be reduced to what turns the cpg on and off (12).

Eating can be initiated by a variety of external stimuli, such as visual, social, olfactory, and auditory. Internal stimuli, such as a slight decrease in plasma glucose (13), a rise in liver temperature (14), and a decrease in basal metabolism (15) are also effective. The efficacy of most, if not all, of these stimuli can be modified by experience. It is important to note that the adequate stimuli for the initiation of eating do not determine the duration or size of the subsequent meal. These aspects of a meal are determined by the mechanisms that maintain eating.

The fact that the initiation of eating does not determine how long eating will continue or how much will be ingested means that eating a meal is not produced by a ballistic control system. Eating, once initiated, is under feedback control. Positive feedback is stimulated by orosensory stimuli and negative feedback is stimulated by gastric and small intestinal stimuli. The positive feedback turns the cpg on and the negative feedback turns it off.

The brain processes these feedbacks within the neural context of other stimuli that are relevant to the control of eating, but are not produced by ingested food stimuli acting on the mucosa of the gastrointestinal tract. A network that compares the relative potency of positive and negative feedbacks analyzes the result of this distributed processing of the peripheral feedback information. Eating is maintained as long as positive feedback exceeds negative feedback; eating stops and the meal ends when negative feedback exceeds positive feedback for a considerable time (Fig. 115.1).

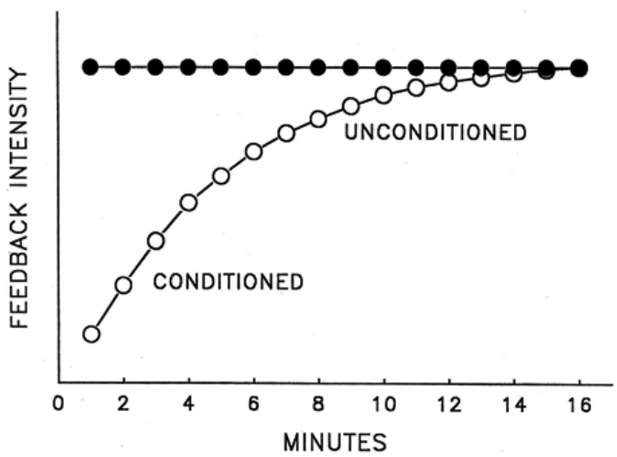

FIGURE 115.1. This depicts the temporal interaction of positive and negative afferent feedbacks produced by ingested carbohydrate solutions during a representative meal. Note that the meal ends when the potencies of the positive and negative feedbacks are judged to be equal by a comparator function(s) of the central networks for the control of ingestion. •, positive feedback; ô, negative feedback. Reproduced from Smith GP. Feeding: control of eating. In: Adelman G, Smith BH, eds. *Elsevier's encyclopedia of neuroscience*. New York: Elsevier, 1999:711–714, with permission of the publisher.

The oromotor output of this continuous integration of positive and negative feedbacks is a sequence of clusters of licks separated by short intervals of nonlicking (16). The number of licks in a cluster is a measure of orosensory positive feedback (palatability). The number of clusters is a measure of the relative potency of the positive and negative feedbacks (1 ,17). The meal ends when the animal no longer reinitiates licking for a relatively long time (15 to 120 minutes in the rat).

There are two important points about these feedback effects: First, the site of action of the adequate stimuli is preabsorptive. In addition to its classic motor and secretory functions, the gastrointestinal tract is a sensory sheet from the tip of the tongue to the end of small intestine. It is peppered with mechanical and chemical receptors; their dispersion

over large areas provides for the effect of stimulus load (i.e., concentration and volume of stimuli).

The second point is that all of the afferent fibers from the mouth, stomach, and small intestine project to the caudal brainstem.

The direct preabsorptive stimulation by the stimuli of ingested food and its digestive products that provide feedback control during a meal is a criterion for distinguishing these feedback controls from all other controls. These feedback controls are direct controls of meal size (Fig. 115.2) and all other controls are indirect controls (Table 115.2).

Categories	Examples
Rhythmic	Diurnal, estrogen
Metabolic	Changes in leptin, insulin, and fatty acids
Thermal	Environmental and fever
Conditioned	Preferences, aversions, and satiations
Cognitive	Social and, in humans, cultural and esthetic
Ecological	Relative densities of predators and foods

[a]The list of categories is neither mutually exclusive nor exhaustive; this is particularly true for conditioned, cognitive, and ecological.

TABLE 115.2. INDIRECT CONTROLS OF MEAL SIZE[a]

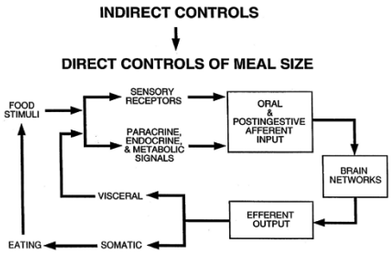

FIGURE 115.2. Flow diagram of the direct controls of meal size stimulated by ingested food acting on preabsorptive receptors of the gastrointestinal tract. Note that food stimuli activate afferent neurons providing positive and negative feedbacks directly and indirectly through effects on paracrine, endocrine, and metabolic signals. The efferent output of the central networks for the control of eating is carried over somatic efferent fibers. Because some of the direct controls are stimulated by ingested food in every meal, indirect controls of meal size exert their effects by modulating direct controls. (See the unidirectional arrow between indirect and direct controls.) Reproduced from Smith GP. Feeding: control of eating. In: Adelman G, Smith BH, eds. *Elsevier's encyclopedia of neuroscience*. New York: Elsevier, 1999:711–714, with permission of the publisher.

This is not an arbitrary classification because it is based on a biological criterion of site of action. The classification also carries neurologic meaning. That meaning comes from experiments in the chronic decerebrate rat. Because the caudal brainstem contains the cpg and all of the projections of the afferent nerves mediating peripheral feedback effects, the decerebrate rat responds to direct controls (18 ,19). In contrast, none of the indirect controls that have been tested affect eating in the chronic decerebrate rat. Because indirect controls require the forebrain to be connected to the caudal brainstem in order to control eating, the reciprocal connections between forebrain and hindbrain are necessary for the modulation of the direct controls by the indirect controls. This theory asserts that indirect controls have no direct action on the cpg during a meal in the absence of direct controls activated by ingested food. Specifying the peptidergic and aminergic connections that mediate an indirect control's effect on the direct controls is the next step and it is the place where the recent advances in central peptides and the neural control of eating converge.

The identification of the importance of the positive and negative feedbacks from the periphery in the direct controls of eating that are modulated by the indirect controls facilitates the investigation of human eating disorders in three ways.

1. The peripheral, preabsorptive sites of action are accessible to controlled stimulation in the conscious human before, during, and after test meals.
2. An increase or a decrease in meal size can be explained by changes in feedback potency (Table 115.3).

Change of Meal Size	Afferent Feedback	
	Positive	Negative
Increase	Increase	Decrease
Increase	Increase	No change
Increase	Increase	Smaller increase
Increase	No change	Decrease
Decrease	Decrease	Increase
Decrease	Decrease	No change
Decrease	Decrease	Smaller decrease
Decrease	No change	Increase

[a]Some changes of afferent feedbacks responsible for increased or decreased meal size. Identification of the mechanisms of a specific change(s) in potency of feedbacks is an experimental problem. (See Table 115.4 for candidates.)
Reproduced from Smith GP. The controls of eating: a shift from nutritional homeostasis to behavioral neuroscience. *Nutrition* 2000;17:10–20, with permission of the publisher.

TABLE 115.3. CHANGES IN POTENCY OF AFFERENT FEEDBACKS THAT DETERMINE CHANGES IN MEAL SIZE[a]

3. Identifying which combination of changes in feedback underlies the change in meal size focuses the search for neurobiological mechanism because the feedbacks have

different mechanisms in the rat and are likely to be similarly differentiated in the human (Table 115.4).

Direct controls	Peripheral	Central
Orosensory	Gustatory and olfactory transducers	Dopamine[a] Opioids[a]
Gastric	CCK[a] at CCK_A vagal mechanoreceptors, other mechanoreceptors, and bombesin-like peptides	Amino acids from gastric vagal afferent terminals in NTS Serotonin[a]
Small intestinal	CCK[a] at CCK_A receptors on vagal mechanoreceptors and chemoreceptors; glucagon,[a] amylin, enterostatin, apolipoprotein IV, and insulin released by nutrient or digestive stimuli through contact with mucosal receptors or by the release of incretins	Amino acids from duodenal and hepatic vagal afferent terminals in NTS Serotonin[a]

NTS, nucleus tractus solitarius.
[a]Indicates that a molecule has been demonstrated to be a physiologic mechanism. The physiologic status of the other molecules is uncertain.

TABLE 115.4. MOLECULAR MECHANISMS OF DIRECT CONTROLS OF MEAL SIZE

An example of the use of this theory of the control of meal size is the recent work concerning the pathophysiology of the abnormally large meals that characterize patients with bulimia nervosa. Since the 1970s there has been evidence that these patients do not feel as full as normal after the same size meal. This has been confirmed more precisely in recent work that showed that bulimics require more food to report equal fullness (20). This suggests a defect in the satiating process (21), specifically a defect in the potency of negative feedback. This hypothesis was strengthened when orosensory positive feedback measured psychophysically did not reveal large increased responses to carbohydrate or fat stimuli (22). Thus, using Table 115.3 , the hypothesized combination was decreased negative feedback and no change in positive feedback. The decreased negative feedback could involve peripheral mechanisms or central modulation. Two peripheral abnormalities have been found: an enlarged stomach capacity (23) and a decreased release of CCK (24). The decreased release of CCK was ameliorated when binge eating stopped in one experiment (25), but further experiments are required to evaluate this phenomenon.

There may also be a defect in the central processing of the decreased peripheral negative feedback information owing to abnormal function of the central serotonin system. If central serotonin function is decreased in bulimia patients, they should be more vulnerable than controls to a further decrease in serotonin function produced by serotonin depletion. This prediction has been confirmed: Acute tryptophan depletion that probably decreased central serotonin activity increased meal size in patients with bulimia (26).

The combination of decreased central serotonergic processing with decreased peripheral negative feedback could be particularly disruptive of satiation because the satiating potency of CCK in rats is synergistic with gastric distension and is reduced by decreased central serotonergic function, particularly at $5\text{-}HT_{2C}$ receptors (6).

In addition to decreased negative feedback, bulimia patients also have an abnormal cognitive indirect control. They eat much larger meals when they are instructed to binge compared to when they are instructed not to binge (27).

LEARNING AND EATING

Part of "115 - The Behavioral Neuroscience of Eating "

Numerous regions of the brain can be implicated in eating by a variety of techniques in animals and humans. This reflects the fundamental biological importance of eating to individual life and reproduction, and the functional requirements of a foraging omnivore. From this viewpoint, it is not surprising that learning and memory are important processes in the control of eating. Three important types of learning have been identified using Pavlovian procedures and theory: conditioned preference, conditioned aversion and avoidance, and conditioned satiation.

Conditioned preferences are formed by flavor–flavor associations or flavor–postingestive associations (28). Once formed, the preferences increase the size of meals. When the postingestive unconditioned stimulus is omitted, the conditioned preference persists for months, but its effect on

intake extinguishes rapidly. The acquisition of a conditioned flavor–postingestive preference requires dopamine acting at D_1 receptors, perhaps in the nucleus accumbens (29). Opioid mechanisms are apparently not necessary.

Conditioned aversions and avoidance are formed by associations between orosensory stimuli (especially gustatory) and aversive postingestive stimuli. Nausea is commonly reported in humans who have conditioned aversions.

The anorexia that accompanies amino acid imbalance may be an example of a conditioned avoidance. It involves a serotonergic mechanism because a 5-HT_3 antagonist abolishes it (30). The same 5-HT_3 mechanism is observed in the conditioned aversions and avoidances observed in cancer patients undergoing chemotherapy (31). The recent report of successful treatment of binge eating with a 5-HT_3 antagonist suggests that conditioned avoidance may also be involved in that eating disorder (32).

Certainly, conditioned avoidance of food characterizes patients with anorexia nervosa. This aversive stimulus appears to be cognitive and part of the morbid fear of fatness. The strong potency of this psychopathological inhibitory control of eating can be appreciated when it is remembered that the low circulating leptin of the emaciated patient (4) disinhibits the central cascade of peptides so that the neurological drive to eat is intense (see section on molecular genetics and central neuropeptide cascade).

The *c-fos* technique has been used to detect changes in the neural network that underlies the acquisition and expression of a conditioned taste aversion (CTA) (33 ,34). The most significant changes occur in the NTS in the hindbrain and central nucleus of the amygdala in the forebrain. The increased C-Fos in the NTS correlates with the acquisition, extinction, and forgetting of the CTA (35). The meaning of this correlation is under active investigation.

The changes in the NTS depend on connections with the forebrain because they are abolished ipsilateral to surgical hemidecerebration at the level of the superior colliculus (36). This is a nice example of how an indirect control, learning, requires connections between the forebrain and hindbrain in order to affect eating. (See ref. 37 for other examples.)

There is evidence that D_1 receptor mechanisms are necessary for the acquisition of a CTA as well as a conditioned preference. Injection of a D_1 antagonist into the lateral hypothalamus blocked the acquisition of a CTA (38).

The third type of learning is conditioned satiation. Like conditioned preference of the flavor–postingestive type, it depends on the association between orosensory stimuli and a postingestive stimulus. Unlike conditioned preferences and aversions, conditioned satiation is hedonically neutral. Its function is to decrease the rate of eating concentrated liquids during the early part of a meal (39). It can be acquired or extinguished within one or two meals. The postingestive stimulus acts in the stomach and beyond the pylorus (40). Increases of plasma glucose are not a sufficient UCS to form a conditioned satiation (41). Nothing is known about the mechanisms that mediate this type of learning.

It is interesting that the way to extinguish conditioned satiation in the rat is to prevent the accumulation of ingested food in the stomach and small intestine by draining the gastric contents out through a chronic gastric fistula. This form of sham feeding leads to a significant increase in meal size owing to the removal of unconditioned negative feedback from the stomach and small intestine. After three to five consecutive sham-meals, conditioned satiation is extinguished and meal size is maximal. If real-feeding meals are given between sham-feeding meals, however, the size of a sham-fed meal is larger than normal, but not maximal, because some conditioned satiation is present (42). These phenomena in the sham-feeding rat (Fig. 115.3) may be relevant

to the abnormally large meals that occur with repetitive bingeing followed by vomiting or purging.

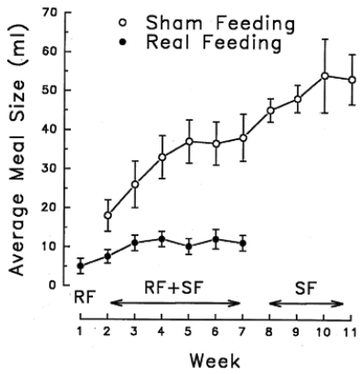

FIGURE 115.3. The potency of learned controls of meal size based on postingestive food stimuli is revealed by the progressive increase in test meal size during repeated sham-feeding trials. During sham feeding, liquid food drains from open gastric cannulas without significant accumulation in the stomach or small intestine, so that learned controls based on gastrointestinal food stimuli extinguish. In this experiment 13 rats were offered a sweet liquid diet once daily, after 3 hours of deprivation of their maintenance diet. During week 1, rats fed normally (real feeding, RF); during weeks 2 to 7, sham-feeding (SF) tests alternated with real-feeding tests, and during weeks 8 to 11, rats were only sham fed. The figure shows the average real and sham meal sizes in each week. During the first sham-feeding test, rats still ate well-defined meals terminated by behavioral signs of normal satiety, indicating that after this short period of food deprivation, pregastric food stimuli can elicit satiety. However, meal size nearly doubled during this test, because of the absence of direct, unconditioned gastric and postgastric controls of eating. Sham meal size doubled during weeks 3 to 7, when sham- and real-feeding tests were alternated, whereas real meal size increased only a small amount, and sham meal size almost doubled a third time during weeks 8 to 11, when there were no real feeding tests. These further increases during the last 4 weeks reflect the extinction of conditioned satiety. Reproduced from Geary N, Smith GP. Appetite. ESTROGEN AND EATING

Part of "115 - The Behavioral Neuroscience of Eating "

Given the high incidence of eating disorders in women and the frequent onset of them when the ovarian rhythm begins, the recent renewed interest in the control of eating by estrogen in rats is most welcome.

Estrogen has two inhibitory effects on eating. The first occurs during the periovulatory phase of the estrus cycle in rats. The decrease in food intake is owing to a decrease in meal size (43). The combination of feedback potencies (Table 115.3) that accounts for the decrease in meal size is no change in positive feedback and increased negative feedback (44). The increased negative feedback is the result of estrogen increasing the potency of endogenous CCK released from the small intestine (Fig. 115.4) (45 ,46). Presumably this synergism is a central action of estrogen changing the processing of the vagal afferent stimulation of the NTS in response to CCK acting on CCK_A receptors of vagal afferent terminals in the upper small intestine, but it is not known where this synergism occurs or where the receptors are that mediate it (47 ,48 and 49).

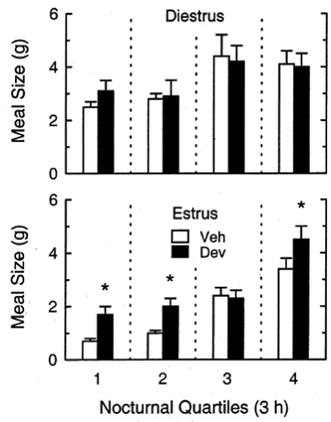

FIGURE 115.4. Antagonism of CCK_A receptors with devazepide (Dev) increased rats' spontaneous meal size throughout the nocturnal period of estrus, but not during diestrus. Thus, an increase of endogenous CCK's satiating potency contributes to the cyclic decrease in meal size during estrus that is mediated by estradiol. Furthermore, endogenous CCK does not appear to contribute to the tonic inhibitory effect of estradiol on meal size because devazepide did not increase meal size during diestrus. Data are mean meal sizes per 3-hour quartile of the nocturnal phase. Note that meal size increased across the dark phase in both estrus and diestrus and that meal size after vehicle (Veh) treatment during the fourth quartile of estrus, when devazepide increased meal size, was as large as control meal size during the first two quartiles of diestrus, so that devazepide's selective effect during estrus was not an artifact of the cyclic differences in meal size. *Nocturnal meal size after devazepide larger than after vehicle, $P < .05$. Reproduced from Eckel LA, Geary N. Endogenous cholecystokinin's satiating action increases during estrus in female Long-Evans rats. *Peptides* 1999;20(4):451–456, with permission of the publisher.

The inhibitory effect of estrogen on food intake during the periovulatory phase has been reported in women (50 ,51). The role of CCK in this effect has not been investigated.

The facts that the ovarian rhythm is disrupted in anorexia nervosa and circulating estrogen is low adds a further disinhibition to the central network that controls eating in these patients.

The second inhibitory effect of estradiol on eating is a tonic inhibition of meal size that acts throughout the ovarian cycle in rats. Release from this inhibition by ovariectomy causes a sustained increase in meal size and obesity. This effect of estrogen, however, does not appear to be mediated by a change in the satiating potency of CCK.

Both effects of estrogen depend on binding to the estrogen receptor α because mice with this receptor knocked out do not show either effect (52).

There are sex differences in the incidence or clinical course of many diseases associated with anorexia as well as in the anorectic response to many immune-system mediators, such as IL-1 and α-TNF. Some of these sex differences appear to be related to estrogenic function. Crohn disease, an inflammatory bowel disease in which anorexia is an early sign (53), is one such. The incidence of Crohn disease is higher in women than men (54) and use of estrogen-containing contraceptives increases women's risk further (55).

Anorexia caused by Gram-negative bacterial infection is also estradiol-sensitive. The effect of estradiol to increase the anorexia produced in rats by intraperitoneal administration of bacterial lipopolysaccharide is expressed by a decrease in meal frequency without a change in meal size (56), indicating that this effect of estrogen is separate from the effects on meal size.

CONCLUSION

Our understanding of the controls of eating in rodents has been transformed in the past 5 years. Although the relationship of eating to nutritional and energetic homeostasis continues to be investigated, particularly in relationship to the new peptides that have been discovered with molecular genetic techniques, the investigation of eating has been broadened in several ways. More attention to behavioral analysis has paid off, especially the microstructure of eating. It has revealed the operation of a cpg as the final common path for the neural control of oromotor movements and provided a continuous measure of the integrated output of the central neural network controlling the cpg during a meal, the functional unit of eating behavior.

The recognition that the size of a meal is under positive and negative feedback controls has been exploited. Specific aminergic and peptidergic mechanisms have been demonstrated to be involved in these feedbacks. The afferent nerves that carry the peripheral information generated along the preabsorptive surface of the gut from the tip of the tongue to the small intestine have been identified. Because some of these peripheral mechanisms are activated in every meal, all controls of eating not related to the food being ingested during a meal act on eating by modulating the central processing of the peripheral feedback stimuli. This has led to a new theory of the controls of eating that is more biological, comprehensive, quantitative, and testable than previous ones (1).

The widely distributed processing of information relevant to the control of eating in the brain reflects the importance and complexity of eating in omnivores such as rodents and humans.

What to eat? Where? When? With whom? These are pressing questions for rodents as well as humans. The ability to answer them with apparent ease requires learning and memory. Recognition of this fact increasingly affects research on eating.

The paradigm shift that the study of eating has undergone, that is, from viewing eating as serving only nutrient and energetic homeostasis to a recognition that the search for the controls of eating is a fundamental problem in behavioral neuroscience (1), makes the basic science more useful for and more relevant to the investigation of clinical eating disorders. Using the similarity in eating behavior, gastrointestinal function, and peripheral visceral afferent neurons as a bridge, the transfer of new information from the laboratory to the clinic should accelerate markedly in the next 5 years.

Psychopharmacology of Eating Disorders

Walter H. Kaye

B. Timothy Walsh

Walter H. Kaye: Western Psychiatric Institute & Clinics, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania.

B. Timothy Walsh: Columbia University College of Physicians & Surgeons, New York, New York.

Anorexia nervosa (AN) and bulimia nervosa (BN) are disorders characterized by aberrant patterns of feeding behavior and weight regulation, and disturbances in attitudes toward weight and shape and the perception of body shape. In AN, there is an inexplicable fear of weight gain and unrelenting obsession with fatness even in the face of increasing cachexia. BN usually emerges after a period of dieting, which may or may not have been associated with weight loss. Either self-induced vomiting, or some other means of inappropriate compensation for the excess of food ingested follows binge eating. The majority of people with BN have irregular feeding patterns and satiety may be impaired. Although current AN is an exclusion for the diagnosis of BN, some 25% to 30% of individuals with BN presenting to treatment centers have a prior history of AN; however, all BN subjects have pathologic concern with weight and shape. Common to individuals with AN or BN are low self-esteem, depression, and anxiety.

In certain respects, both diagnostic labels are misleading. Individuals affected with AN rarely have complete suppression of appetite, but rather exhibit a volitional and often an ego syntonic resistance to feeding drives, eventually becoming preoccupied with food and eating rituals to the point of obsession. Similarly, BN may not be associated with a primary pathologic drive to overeat; rather, individuals with BN, like those with AN, have a seemingly relentless drive to restrain their food intake, an extreme fear of weight gain, and often a distorted view of their actual body shape. Loss of control with overeating usually occurs intermittently and typically only some time after the onset of dieting behavior. Episodes of binge eating ultimately develop in a significant proportion of people with AN (1), whereas 5% of those with BN eventually develop AN (2). Considering that restrained eating behavior and dysfunctional cognitions relating weight and shape to self-concept are shared by patients with both of these syndromes, and that transitions between these syndromes occur in many, it has been argued (3) that AN and BN share at least some risk and liability factors in common.

The etiology of AN and BN is presumed to be complex and multiply influenced by developmental, social, and biological processes (4 ,5); however, the exact nature of these interactive processes remains incompletely understood. Certainly, cultural attitudes toward standards of physical attractiveness have relevance to the psychopathology of eating disorders (EDs), but it is unlikely that cultural influences in pathogenesis are prominent. Dieting behavior and the drive toward thinness are quite commonplace in industrialized countries throughout the world, yet AN and BN affect only an estimated .3% to .7%, and 1.7% to 2.5%, respectively, of women in the general population. Moreover, the fact that numerous clear descriptions of AN date from the middle of the nineteenth century suggests that factors other than our current culture play an etiologic role. Also, both syndromes (particularly AN) have a relatively stereotypic clinical presentation, sex distribution, and age of onset. This supports the possibility that there are significant biologic vulnerabilities to developing an ED.

PHENOMENOLOGY

Part of "116 - Psychopharmacology of Eating Disorders "

Variations in feeding behavior have been used to subdivide individuals with AN into two meaningful diagnostic subgroups that differ in other psychopathologic characteristics (6 ,7). In the restricting subtype of AN, subnormal body weight and an ongoing malnourished state are maintained by unremitting food avoidance; in the binge eating/purging subtype of AN, there is comparable weight loss and malnutrition, yet the course of illness is marked by episodes of binge eating, and/or by some type of compensatory action such as self-induced vomiting or laxative abuse. Individuals with the binge eating/purging subtype of AN are also more

likely to exhibit histories of behavioral dyscontrol, substance abuse, and overt family conflict in comparison to those with the restricting subtype of AN. Personality traits of marked perfectionism, conformity, obsessionality, constriction of affect and emotional expressiveness, and reduced social spontaneity are particularly common in individuals with AN. These traits typically appear in advance of the onset of illness and persist even after long-term weight recovery, indicating they are not simply epiphenomena of acute malnutrition and disordered eating behavior (8 ,9 ,10 and 11).

Individuals with BN remain at normal body weight, although many aspire to ideal weights far below the range of normalcy for their age and height. The core features of BN include repeated episodes of binge eating followed by compensatory self-induced vomiting, laxative abuse, or pathologically extreme exercise, as well as abnormal concern with weight and shape. The DSM-IV has specified a distinction within this group between those individuals with BN who engage in self-induced vomiting or abuse of laxatives, diuretics, or enemas (purging type), and those who exhibit other forms of compensatory action such as fasting or exercise (nonpurging type). Beyond these differences, it has been speculated (12) that there are two clinically divergent subgroups of individuals with BN differing significantly in psychopathologic characteristics: a so-called multi-impulsive type, in whom BN occurs in conjunction with more pervasive difficulties in behavioral self-regulation and affective instability; and a second type whose distinguishing features include self-effacing behaviors, dependence on external rewards, and extreme compliance. Individuals with BN of the multi-impulsive type are far more likely to have histories of substance abuse and display other impulse control problems such as shoplifting and self-injurious behaviors.

Most cases of AN emerge during the period of adolescence, although the condition can be observed in children. Whether or not prepubertal onset of the illness confers a more or less ominous prognosis is not known. Recovery from the illness tends to be protracted, but studies of long-term outcome reveal the illness course to be highly variable: Roughly 50% of individuals eventually have reasonably complete resolution of the illness, whereas 30% have lingering residual features that wax and wane in severity long into adulthood. Ten percent of people with AN pursue a chronic, unremitting course; the remaining 10% of those affected eventually die from the disease.

BN is usually precipitated by dieting and weight loss, yet it can occur in the absence of apparent dietary restraint. The frequency of binge episodes, their duration, and the amount of food consumed during any one episode all vary considerably among patients. Age of onset is somewhat more variable in BN than AN, with most cases developing during the period from mid- to late adolescence through the mid-twenties. Follow-up studies of clinical samples 5 to 10 years after presentation show 50% of patients recovered, whereas nearly 20% to 30% continued to meet full criteria for BN (13). Following onset disturbed eating behavior waxes and wanes over the course of several years in a high percentage of clinic cases. Approximately 30% of remitted women relapse into BN symptoms.

PERSISTENT PSYCHOLOGICAL DISTURBANCES AFTER RECOVERY

Part of "116 - Psychopharmacology of Eating Disorders "

People who have an ED often have a variety of symptoms aside from pathologic eating behaviors. Physiologic symptoms include an abundance of neuroendocrine, autonomic, and metabolic disturbances (see the following). Psychological symptoms include depression, anxiety, substance abuse, and personality disorders. Determining whether such symptoms are a consequence or a potential cause of pathologic feeding behavior or malnutrition is a major methodologic issue in the study of EDs. It is impractical to study EDs prospectively because of their low incidence, early age of onset, and difficulty of premorbidly identifying those who will develop an ED. However, subjects can be studied after long-term recovery from an ED. The assumed absence of confounding nutritional influences in recovered ED women raises a possibility that persistent psychobiological abnormalities might be trait-related and potentially contribute to the pathogenesis of this disorder. A limited number of studies have investigated people who have recovered from AN and BN. Although the definition of recovery from an ED has not been formalized, investigators tend to include people formerly ill with AN after they are at a stable and healthy body weight for months or years and have not been malnourished or engaged in pathologic eating behavior during that period of recovery. For BN, investigators tend to include subjects who have been abstinent from binge eating and purging for months or years. Some investigators include criteria of normal menstrual cycles and a minimal duration of recovery, such as 1 year of time.

Investigators (8 ,9 ,10 and 11) have found that women who were long-term recovered from AN had a persistence of obsessional behaviors as well as inflexible thinking, restraint in emotional expression, and a high degree of self- and impulse-control. In addition, they have social introversion, overly compliant behavior, and limited social spontaneity as well as greater risk avoidance and harm avoidance. Moreover, individuals who are long-term recovered from AN had continued core ED symptoms, such as a drive for thinness, and significant psychopathology related to eating habits. Similarly, people who have recovered from BN continue to be overly concerned with body shape and weight, display abnormal eating behaviors, and report dysphoric mood (14 ,15 ,16 and 17). Recovered AN and BN women have increased perfectionism; their most common obsessional target symptoms are the need for symmetry and ordering/arranging. Considered together, these residual behaviors can be characterized as over-concerns with body image and thinness, obsessionality

with symmetry, exactness, and perfectionism, and dysphoric/negative affect. In general, pathologic eating behavior and malnutrition appears to exaggerate the magnitude of these concerns. Thus, the intensity of these symptoms is less after recovery but the content of these concerns remains unchanged. The persistence of these symptoms after recovery raise the possibility that the disturbances are premorbid traits that contribute to the pathogenesis of AN and BN.

PHARMACOLOGIC TREATMENT OF ANOREXIA NERVOSA

Part of "116 - Psychopharmacology of Eating Disorders "

Most medication trials in AN have been conducted with inpatients in an attempt to accelerate restoration of weight. Some studies also examined the impact of medication on mood or anorectic attitudes. A wide variety of psychoactive medications, such as L-dopa (18), phenoxybenzamine (19), diphenylhydantoin (20 ,21), stimulants (22), and naloxone (23), have been administered to people with anorexia nervosa in open, uncontrolled trials. In many of these trials, medications have been claimed to be beneficial, but none of these observations has been confirmed under double-blind, controlled conditions.

Few studies of medication using rigorous double-blind placebo-controlled trials have been reported in patients with AN. In contrast to the positive claims from open trials, results from double-blind trials have been limited, for the most part. Double-blind studies, at most, report marginal success in treatment of specific problems such as improving the rate of weight gain during refeeding, and disturbed attitudes toward food and body image, depression, or gastrointestinal discomfort.

One problem with determining the efficacy of pharmacotherapy in AN is that often medications have been given in association with other therapies. Thus, it may be unclear whether it was the medication or therapy that resulted in improvement. Furthermore, the primary criterion for improvement has often been weight gain, not a normalization of thinking and reduction in fears of being fat. It is important to emphasize that treatment in structured settings, such as inpatient units, even without medication, succeeds in restoring the weight of over 85% of underweight patients (24). Thus, it may be difficult to prove that an active medication is effective in such a setting. However, relapse within 1 year *after* successful inpatient weight restoration is very common (25). For example, the Maudsley study (26) reported that only 23% of the patients had a good outcome at 1 year after discharge despite intensive outpatient individual or family therapy.

Controlled trials of the neuroleptics pimozide (27) and sulpiride (28) have suggested limited effects in accelerating weight gain or altering anorectic attitudes for some patients for part of the study, but overall drug effect was marginal. Recently, there has been clinical interest in “atypical” neuroleptics for AN because of their notoriety for causing weight gain in other patient populations (29). A recent case report suggested that olanzapine administration was associated with weight gain and maintenance as well as reduced agitation and resistance to treatment in 2 women with AN (30). Several drugs have been tested because of anecdotal reports of their effects on stimulating appetite. Tetrahydrocannabinol (THC) was not useful and, in fact, may have been detrimental because it increased dysphoria in some patients (31). Clonidine was also found to have no therapeutic effect on increasing weight restoration as compared to placebo (32), even with doses that affected hemodynamic parameters.

When underweight, patients with anorexia nervosa have delayed gastric emptying (33), which improves with refeeding. Still, delayed gastric emptying could perpetuate the disorder in some patients by limiting the quantity of food that may be comfortably eaten. Most studies of prokinetic drugs in AN have been limited to parenteral preparations or experiments with small uncontrolled groups of patients (34 ,35 and 36). In a controlled trial, cisapride (37) was no better than placebo in improving gastric emptying, although some subjective measures of distress during meals and measures of hunger improved more in the group on cisapride.

In summary, these medication trials have been of short duration and focused on whether medication produces additive benefit to an established treatment program. Few follow-up studies have examined whether medication treatment produces lasting benefit. A new generation of studies has begun to focus on whether medication can prevent relapse after patients leave to a structured treatment setting.

Use of Antidepressants in AN

There has been controversy as to whether AN and major depressive disorders share a common diathesis; however, critical examination of clinical phenomenology, family history, antidepressant response, biological correlates, course and outcome, and epidemiology yield limited support for this hypothesis (38 ,39 and 40). Still, the high frequency of mood disturbances associated with this disorder resulted in trials of drugs such as amitriptyline (41 ,42 and 43), and lithium (44). Neither medication appears to significantly improve mood compared with the effects of placebo.

For more that 50 years (45), investigators have suggested that AN shares similarities with obsessive-compulsive disorder (OCD). In fact, patients with AN have a high prevalence of obsessive-compulsive symptoms or disorders (46 ,47 and 48), as well other anxiety disorders (49). More over, adult women with OCD have an increased incidence of prior AN (50). Individuals with a past history of AN display evidence of increased serotonin (51) activity that persists after long-term weight recovery. In addition, women who recover from AN continue to have modest, but significant, increases in negative

mood, obsessionality, perfectionism, and core eating disorder symptoms. Similarly (10), personality characteristics associated with AN, such as introversion, self-denial, limited spontaneity, and a stereotyped thinking style, may also persist after weight recovery. Studies in humans and animals suggest that serotonin activity is related to behavioral inhibition. Together, these data raise the possibility that increased CSF 5-HIAA could be associated with inhibition and an obsessive need with exactness and perfectionism. A disturbance of this neurotransmitter system has been implicated in OCD (52) and only serotonin-specific medication has been found to be useful in treating OCD.

There are suggestions that medications that affect the serotonin system may impact the clinical characteristics of patients with AN. Initial reports on cyproheptadine, a drug that is thought to act on the serotonergic and histaminergic system (53), indicated that it might have beneficial effects on weight gain, mood, and attitude in some patients (54 ,55). Cyproheptadine data from comparison trials with amitriptyline and placebo found cyproheptadine to significantly improve weight gain in the restricting subtype of AN, whereas amitriptyline was more effective in those patients with bulimic behavior (56).

Several groups (57 ,58) reported that an open trial of fluoxetine, a highly specific serotonin reuptake inhibitor might help patients with AN gain and/or maintain a healthy body weight. Recently, the Pittsburgh group reported a double-blind placebo-controlled trial of fluoxetine in 35 patients with restrictor-type AN (59). Subjects were started on fluoxetine after they achieved weight restoration (approximately 90% of ideal body weight) during a hospitalization. Patients were randomly assigned to fluoxetine (*N* = 16) or placebo (*N* = 19) after inpatient weight-restoration and then were followed as outpatients for 1 year. After 1 year of outpatient follow-up, 10 of 16 (63%) subjects had a good outcome on fluoxetine, whereas only three of 19 (16%) had a good outcome on placebo (*P* = .006) (Fig. 116.1). Aside from improved outcome, fluoxetine administration was associated with a significant reduction in obsessions and compulsions and a trend toward a reduction in depression. These data suggest that fluoxetine may help prevent relapse in some patients with AN.

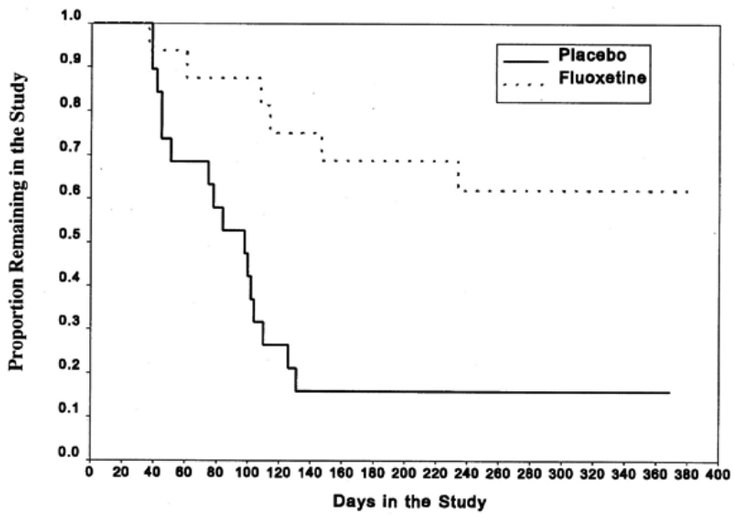

FIGURE 116.1. Survival of subjects with anorexia nervosa treated with fluoxetine or placebo.

It is important to note that SSRIs appear to have little effect on reducing symptoms and preventing hospitalization in malnourished, underweight anorexics (60 ,61). Women with AN, when malnourished and underweight, have reduced plasma tryptophan availability (62) and reduced CSF 5-HIAA (63), the major metabolite of serotonin in the brain. In addition, low estrogen values during the malnourished state may reduce serotonin activity by effects on gene expression for serotonin receptors (64) or the serotonin transporter (65). SSRIs are dependent on neuronal release of serotonin for their action. If malnourished patients have compromised release of serotonin from presynaptic neuronal storage sites and reduced synaptic serotonin concentrations, then a clinically meaningful response to an SSRI might not occur (66). The possibility that fluoxetine is only effective for patients after weight restoration is supported by the fact that a change of serotonin activity is associated with weight gain. For example, CSF 5-HIAA levels are low in underweight anorexics, normal in short-term weight-restored anorexics, and elevated in long-term weight-restored anorexics (67). If CSF 5-HIAA levels accurately reflect CNS serotonin activity, then these data imply that a substantial increase in serotonin activity occurs after weight gain.

The use of serotonin-specific medications in the treatment of AN is promising but many questions remain. First, only one double-blind placebo-controlled study has been completed in a relatively small number of restrictor-type patients. Thus, it will be important to replicate this work

in a larger group of patients. Second, more data are needed to determine if there are differential effects in the restricting of binge eating/purging subtypes of AN. Third, it needs to be determined whether certain features are especially responsive to serotonin-specific medications: core anorexic symptoms, depression, anxiety, obsessionality, or eating behavior.

Guidelines for Clinical Treatment

The first line of treatment for underweight patients with AN should be refeeding and weight restoration. As noted, although difficult, most patients will gain weight in a structured eating disorders treatment program without the use of medication. Weight gain alone tends to reduce exaggerated obsessionality and dysphoric mood in many patients (68). There is limited evidence that fluoxetine and possibly other serotonergic medications help prevent relapse after weight restoration. It is important to emphasize that some physiologic and cognitive alterations persist for months after achieving goal weight, including increased energy needs, menstrual disturbances, several neurotransmitter disturbances, urges to engage in disordered eating patterns, and body image distortions. Thus, treatment should continue for at least 3 to 6 months after achieving goal weight, preferably until there is resumption of menstrual periods, normalization of caloric needs, remediation of any physical complications, and sufficient remission of pathologic eating and body-image distortions so that daily activities are not disturbed. We strongly support use of the recent American Psychiatric Association (APA) guidelines for eating disorders (69), which describe comprehensive treatment of AN.

PHARMACOLOGIC TREATMENT OF BN

Part of "116 - Psychopharmacology of Eating Disorders "

As summarized in *Neuropsychopharmacology, the Fourth Generation of Progress,* a substantial body of work was published during the 1980s and early 1990s demonstrating that antidepressants are more effective than placebo in the treatment of BN (70). In 1996, the FDA approved the use of fluoxetine (71 ,72) for this disorder, the only medication to receive such an official indication to date. Although the notion of using antidepressants for BN emerged because of the high frequency of symptoms of depression and anxiety, the utility of antidepressants does not appear confined to patients with concurrent major depression, suggesting that these medications may exert their effects, at least in part, via alterations in the neural systems underlying the control of appetite. The notion that antidepressants may be useful in BN via mechanisms other than those that are responsible for their antidepressant activity is also suggested by the observations that a higher daily dose of fluoxetine (60 mg per day) appears superior to the standard antidepressant dose (20 mg per day) in the treatment of BN and that the onset of benefit from antidepressant treatment typically is quite rapid (Fig. 116.2).

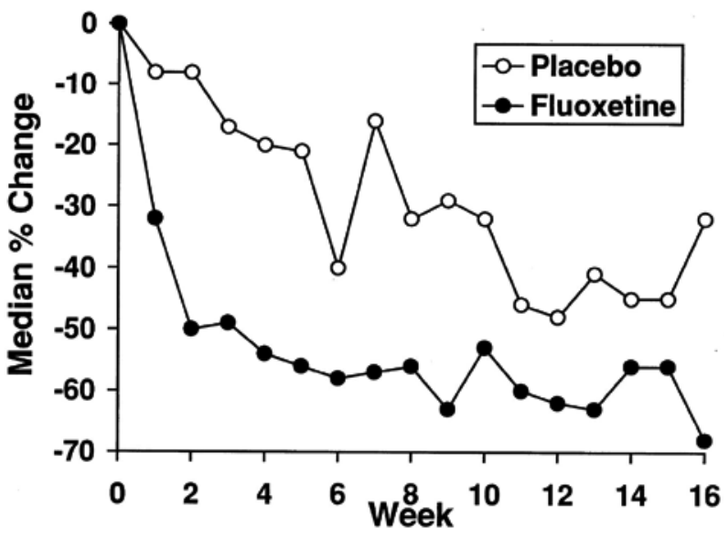

FIGURE 116.2. Median percentage change in the number of binge-eating episodes among patients with bulimia nervosa receiving fluoxetine or placebo.

No trials have been published in which the efficacy of one antidepressant is compared directly to that of another. In the absence of such data, although virtually all classes of antidepressants appear superior to placebo in reducing binge frequency, SSRIs are generally preferred because of their relatively benign side-effect profile; however, aside from fluoxetine, only fluvoxamine has been formally examined in BN. Fichter and colleagues reported a study of novel design in which patients were randomly assigned to fluvoxamine or placebo following successful completion of inpatient treatment (73). Although fluvoxamine was associated with a dropout rate of 38% over 19 weeks compared to 14% on placebo, the active drug was superior to placebo in reducing the re-emergence of bulimic behaviors and attitudes. In light of these results, it is surprising that a large European trial has been reported to find no difference between the response to fluvoxamine and placebo in the initial treatment of outpatients with bulimia (Freeman, personal communication, 1999). Thus, although most clinicians expect sertraline, paroxetine, citalopram, and venlafaxine to be useful, the efficacy and ideal dose of SSRIs other than fluoxetine for the treatment of BN have not been established.

Since the clear recognition of bulimia as a syndrome in 1979, effective psychotherapeutic approaches, have also been developed, most of which utilize cognitive behavioral therapy (CBT). CBT is generally believed to be more effective than a single course of an antidepressant medication (69). This fact, coupled with reasonable evidence of sustained benefit following CBT and the reluctance of many patients to take psychotropic medications, has led to CBTs being generally considered the treatment of first choice for BN. Several studies have examined whether it is beneficial

to combine psychological treatment with antidepressant medication.

The earliest studies of the combination of medication and psychotherapy utilized tricyclic antidepressants. Mitchell and associates (74) found that imipramine was associated with a greater reduction in measures of anxiety and depression than was placebo when combined with an intensive group psychotherapy program; however, imipramine did not augment the impact of the psychological treatment on the salient behavioral symptom, binge eating. Agras and colleagues (75) compared five treatments for BN: individual CBT alone, desipramine alone for 16 or 24 weeks, and CBT plus desipramine for either 16 or 24 weeks. As was also true of the study of Mitchell and colleagues, Agras and co-workers reported that the outcome of psychological treatment alone was clearly superior to that of a course of tricyclic antidepressant. There were a few hints of a small advantage for the combination of medication and CBT, but these were not impressive. Leitenberg and co-workers (76) attempted to compare CBT to a course of desipramine and to a combination, but terminated the study prematurely because of a high dropout rate, primarily caused by medication side effects.

More recent studies have examined the potential advantages of combining an SSRI (fluoxetine) and psychological treatment. The Columbia group has reported the results of a study that compared two forms of individual psychological treatment (CBT and supportive psychotherapy) combined either with placebo or a two-stage medication intervention (77). Patients assigned to receive active medication received desipramine; if desipramine was either ineffective or intolerable, the medication was changed to fluoxetine under double-blind conditions. In this study, CBT was clearly superior to supportive psychotherapy in reducing the key behavioral symptoms of BN. In addition, compared to placebo, active medication added modestly but significantly to improvement in binge eating and depression.

Goldbloom and colleagues (78) compared individual CBT to a course of fluoxetine and the combination. Unfortunately, interpretation of the results is limited by a high dropout rate, which resulted in few significant differences among the three treatments. Beumont and colleagues (79) reported a comparison of fluoxetine versus placebo when combined with nutritional counseling, which presumably included many elements of CBT. The nutritional counseling program was impressively effective, and at the conclusion of treatment, there were no significant differences between the fluoxetine and placebo groups in binge frequency; however, the fluoxetine-treated group exhibited less dietary restraint and fewer concerns about body shape and weight.

Combined, these data suggest that adding medication to structured psychological treatment for BN does provide added benefit, but of small magnitude. Clinically, guidelines to identify patients who are particularly likely to benefit from one treatment approach or another would be extremely useful. Unfortunately, attempts to identify such predictors of treatment response have been impressively unsuccessful. Because those patients who derive the greatest benefit from treatment typically exhibit an early response (80), it may useful to initiate treatment with CBT, for example, and to add another intervention such as medication if the initial response is not satisfactory. Recent data demonstrate that medication can be useful for patients who do not respond adequately to psychological treatment or who relapse following the end of treatment (18).

Despite the progress in developing treatment approaches for bulimia in the last 20 years, a major current problem is the absence of treatments of established efficacy other than CBT and antidepressant medication. Even in the best hands, only about 50% of patients achieve remission with these treatments, and a significant number relapse following the conclusion of the initial intervention. Clinicians and investigators have considered the use of other psychotropic medications that are believed to reduce appetite, such as topiramate, but no controlled data are available to date about its utility in BN. Recently, Faris and associates (82) have reported that the antiemetic medication ondansetron, a 5-HT3 antagonist, was more effective than placebo during a 4-week trial in reducing binge eating and vomiting in a group of chronically and severely ill bulimic patients. More data regarding the side effects of ondansetron and its impact on psychological features of the disorder are required to assess the clinical utility of this agent, but the exploration of novel medication interventions for BN is overdue.

PHARMACOLOGIC TREATMENT OF BINGE EATING DISORDER

Part of "116 - Psychopharmacology of Eating Disorders "

During the development of DSM-IV, interest grew in defining another eating disorder characterized by frequent binge eating but without the recurrent use of inappropriate compensatory behavior required for the diagnosis of BN. Out of these discussions, criteria for binge eating disorder (BED) evolved, and were included in an appendix of DSM-IV as a criteria set for further study. Significant interest in the characteristics and treatment of BED has since developed, and the results of several psychopharmacologic interventions have been published. Although obesity is not required by the criteria for BED suggested in DSM-IV, the studies to date have generally focused on overweight or obese individuals.

Even before the delineation of BED, McCann and Agras (83) reported that desipramine was superior to placebo in reducing binge frequency among a group of “nonpurging bulimics.” Most of the participants were overweight, but neither desipramine nor placebo was associated with significant weight loss in this short-term study. In contrast, Marcus

and associates (84) found that when combined with a behavioral weight loss program, fluoxetine was associated with greater weight loss than was placebo during a 1-year study of obese binge eaters; unfortunately, information on binge frequency was not obtained. In contrast, Alger and colleagues (85) reported that neither imipramine nor naltrexone was more effective than placebo in reducing binge frequency or weight in obese binge eaters.

More recently, studies have focused on patients meeting the criteria of DSM-IV for BED and have examined serotonergic agents. Stunkard and co-workers (86) found that the appetite suppressant *d*-fenfluramine, which has since been withdrawn from the market, was more effective than placebo among 28 obese women with BED in reducing binge frequency; however, surprisingly, not in promoting weight loss. Nevertheless, fluvoxamine compared with placebo was associated with significant reductions in both binge frequency and body mass index among 85 patients with BED (87).

Obesity is a major and growing public health problem in the industrialized world in general and the United States in particular. Approximately one-third of obese individuals presenting to weight loss clinics meet diagnostic criteria for BED; therefore, effective treatments for this disorder may be of widespread clinical utility. Research conducted to date suggests that pharmacotherapy may play a role, but a number of important issues are unresolved. Individuals with BED have disturbances in eating behavior by definition, and are typically overweight and exhibit symptoms of anxiety and depression in clinical samples. Effective interventions should lead to improvements in all three spheres. Yet, it is surprising that the response of these presumably related symptoms to medication is at least somewhat inconsistent, so that patients may report a decrease in binge frequency but no change in weight. A major problem in the development of effective treatment strategies is an impressively high response of binge eating to nonspecific interventions, including placebo. In part for this reason, the effects of medication treatment have been modest in size. Furthermore, the impact of medication in BED appears to fade rapidly once medication has been discontinued. These issues leave the role of pharmacotherapy for BED currently unresolved, and underline the need for additional research, including studies to examine the potential benefits of combining medication with psychological treatment, especially CBT.

Tourette Syndrome and Related Tic Disorders

Neal R. Swerdlow

James F. Leckman

Neal R. Swerdlow: Department of Psychiatry, University of California, San Diego School of Medicine, La Jolla, California.

James F. Leckman: Child Study Center, Yale University School of Medicine, New Haven, Connecticut.

> Each movement is preceded by certain preliminary sensory signals and is in turn followed by sensory impressions at the end of the action. Each movement is the result of a voluntary capitulation to a demanding and relentless urge accompanied by an extraordinarily subtle sensation that provokes and fuels the urge. Successively sharper movements build up to a climax—a climax that never comes (1).

A MODEL NEUROPSYCHIATRIC DISORDER

Part of "117 - Tourette Syndrome and Related Tic Disorders "

Biological models allow investigators to extrapolate from simple to complex systems, to generate and test hypotheses, and to grasp schema that are within range of our intellect, as we reach to conceptualize things beyond this range. Tourette syndrome (TS) is a “model neuropsychiatric disorder” (2 ,3) that seems tantalizing in its simplicity. The genetic basis is stronger than any common neuropsychiatric disorder other than Huntington disease. The age of onset and the sex distribution of TS are strong clues that neurodevelopmental and hormonal processes are causative in TS. Emerging evidence suggests a role of epigenetic (e.g., hypoxia) or “environmental” (e.g., group A streptococcal infections) factors in the origin of at least some cases of TS, again making TS an ideal model for “nature-nurture” interactions in the pathogenesis of brain disorders. The clinical presentation and responsivity to dopamine antagonists provide strong clues that the critical substrates of TS fall within the basal ganglia, a system implicated in an increasing number of neuropsychiatric disorders and perhaps the one most studied and best understood in the neuropsychiatric literature. The familial and phenomenologic links to obsessive-compulsive disorder (OCD) have led many investigators to conceptualize tics in TS as “movement-equivalents” of obsessions and compulsions, and the apparent connections with OCD and attention-deficit/hyperactivity disorder (ADHD) raise hope that by solving the TS “model,” we will understand a family of disorders that collectively affects close to 10% of the population. By all accounts, the TS model should be readily solvable, like a practice question before the really tough questions on an examination. Although we still lack clear answers for many of the complex questions raised by this syndrome, this chapter reviews the current state of progress in understanding the clinical features and neurobiology of TS and related tic disorders.

TICS: MOTOR, PHONIC, AND BEYOND

Part of "117 - Tourette Syndrome and Related Tic Disorders "

The DSM-IV describes tics as “sudden, rapid, recurrent, nonrhythmic, stereotyped movements or vocalizations,” but the self-assessments by Dr. Joseph Bliss (quoted earlier) and others (4) make it clear that tics in TS have a depth and dimension far beyond their motor or vocal components. Tics can be characterized by their anatomic location, frequency, intensity, and “complexity.” Facial and upper torso muscle groups are commonly active in motor tics, but virtually any motor group can be involved, including diaphragmatic muscles, in which rapid contractions can generate sounds by the expulsion of air through the upper airways. *Simple tics* are brief, circumscribed movements or sounds that are fragments or “chunks” of behavior or speech, rather than “self-contained,” meaningful motor sequences or utterances. These may include blinking, facial grimacing, mouth movements, head jerks, shoulder shrugs, and arm and leg jerks. *Complex tics* are more elaborate, sustained actions or linguistically meaningful sounds that often give the appearance of an intentional, “willful” event. Examples include facial gestures and movements such as brushing hair back, possibly in combination with head jerk, and body shrugs. Although most tics can be distinguished from chorea and dystonic movements, this differential diagnosis is not

always easily made, and some patients manifest symptoms across the entire range of involuntary movements. Audible tics may or may not involve the vocal cords, but true vocal tics can range from grunts and barking sounds to complete, grammatically correct phrases. Only about 10% of patients with TS express vocal tics with obscene content, termed *coprolalia* (5).

Tics can often be willfully suppressed for brief periods. Unfortunately, voluntary tic suppression can be associated with a buildup of inner tension, so when the tics are expressed, they are more forceful than they would otherwise be. Tics are also diminished during periods of goal-directed behavior that requires focused attention. Jim Eisenreich, who was a lifetime .300 hitter despite having significant motor tics for his entire professional baseball career, explained, “you only have to concentrate for 5 seconds on each pitch” (6). Tics can also be “suggestible,” activated by a verbal suggestion, or they can mimic or “echo” behavior or sounds from other people or the surrounding environment, analogous to stimulus-dependent behaviors in some posttraumatic or vascular orbitofrontal syndromes.

The degree of impairment associated with particular tics is partly dependent on their frequency, intensity, complexity, and duration. For example, a very frequent simple motor wrist tic may be less impairing than an infrequently occurring, forceful obscene (copropraxic) gesture. Very commonly, functional impairment in TS is strongly related to the severity of associated symptoms, including obsessions, compulsions, and attention deficits, as discussed later.

Many patients with tic disorders report a variety of sensory and mental states associated with their tics. Simple sensory tics, like simple motor or phonic tics, are rapid, recurrent, and stereotyped, and they are experienced as a sensation at or near the skin. The sensations are typically bothersome or uncomfortable, like an “itch” or a “crawling” feeling. Patients may be unusually aware, distracted, and distressed by particular sensory stimuli that most persons would not notice. One patient explained, “you know the scratchy feeling of a tag on your neck when you put on a new shirt? I have tags on every part of every shirt, all the time.” This site sensitization to certain forms of sensory information is a relatively understudied phenomenon that may provide important clues to the neurobiology of this disorder (7). *Premonitory urges* are more complex phenomena, which often include both sensory and psychic discomfort that may be momentarily relieved by a tic (7 ,8 and 9). An extension of the sensory-psychic dimension of tics may include a sense of discomfort or distress if sensory information (typically visual, but also tactile) is not experienced as “just right”; the assessment that something is “just right” can reflect complex stimulus properties, including balance and symmetry, texture, or context. The full elaboration of tics therefore can include sequential experience: (a) a sensory event or premonitory urge, (b) a complex state of inner conflict over whether and when to yield to the urge, (c) the motor or phonic production, and (d) a transient sensation of relief.

Further underscoring the importance of the sensory dimensions of TS, many patients with tic disorders are remarkably sensitive to perceptions arising both from within themselves (of somatic origin) and from the external world. Patients may unconsciously mirror the behavior and speech of others as well as of themselves. A related phenomenon is *triggering perceptions* in which some patients report urges to perform dangerous, forbidden, or simply senseless acts, such as to touch a hot iron, to jump from heights, to put the car in reverse gear while driving down a highway, or to shout in a quiet church service (10).

Diagnosis

The diagnosis of TS is based exclusively on the history obtained from the patient, parents, or other family members and on direct examination. Diagnostic criteria for “Tourette’s disorder” (DSM-IV) (11) and “definite Tourette syndrome” (TS Classification Study Group) (12) differ only slightly: both diagnoses require the frequent occurrence of multiple motor tics and one or more vocal tics, over a continuous interval that involves most of a full year, with the onset of symptoms early in life (before age 18 to 21 years). The controversial requirement that tics cause “marked distress or significant impairment in social, occupational, or other areas of functioning” has been challenged; as currently written in the DSM-IV, this criterion excludes persons who have adjusted well to the presence of tics, because these persons are not considered to have Tourette disorder if the syndrome is not a major source of distress.

The DSM-IV lists two specific tic disorders other than Tourette disorder. The diagnosis of *chronic motor or vocal tic disorder* is made when tics are limited to one or the other domain, but the patient otherwise meets criteria for Tourette disorder. Chronic motor tic disorder is the more common of these two conditions, and both are often viewed as part of the “broader phenotype” of TS. One clue that TS and related tic disorders reflect some aberration in a normal developmental process is that various tics are exhibited at some point in early development by most children. To bridge this gradient of “normal” versus “abnormal” tic behaviors in childhood, and to span the temporal gap between symptom onset and the 1-year “duration” requirement for the diagnosis of Tourette disorder, a diagnosis of *transient tic disorder* can be made if childhood tics, either motor or vocal, are frequent and cause distress, and they last between 1 and 12 months. As many as one in ten children may meet criteria for this diagnosis (13), and thus by extrapolation, in at most 10% of these children will symptoms continue beyond a year, thereby meeting criteria for one of the chronic tic disorders.

Comorbid Conditions

Although some persons experience “pure” tic disorders, functional impairment is often more directly related to the partial or full manifestation of comorbid conditions such as OCD and ADHD. Clinical and epidemiologic studies indicate that more than 40% of patients with TS experience recurrent obsessive-compulsive symptoms (8 ,14). Compared with “pure” TS, patients with comorbid TS and OCD experience more lifetime functional impairment, as rated by standardized scales, and specifically in areas such as employment and social relations. Overall, the level of lifetime impairment in these persons correlates significantly with the severity of OCD symptoms (15). Specific obsessive-compulsive symptoms associated with most impairment in patients with TS include aggressive and sexual obsessions and repeating and counting compulsions. Aggressive and sexual obsessions are also associated with more severe motor and phonic tics, even in patients with TS who do not meet full diagnostic criteria for OCD (15). These relationships underscore the importance of early recognition and treatment of comorbid obsessive-compulsive symptoms in TS.

Studies sharply differ on the rates of ADHD seen among patients with TS. Clinical studies vary according to setting and established referral patterns, but it is not uncommon to see reports of 50% or more of referred children with TS diagnosed with comorbid ADHD (16). In contrast, epidemiologic studies typically indicate a much lower incidence of comorbidity (14 ,16). Similar to the functional impact of comorbid OCD, patients with comorbid ADHD and TS experience significantly greater impairment than patients with “pure” TS. Longitudinal studies confirm that children with comorbid TS and ADHD are at high risk of anxiety and mood disorders, oppositional defiant disorder, and conduct disorder (17 ,18), whereas children who only have TS tend to fare better (17 ,19 ,20). Levels of tic severity are less predictive of peer acceptance than is the presence of ADHD (19 ,20), and rates of subsequent psychiatric morbidity in comorbid TS and ADHD are nearly identical to those seen in prior cross-sectional and longitudinal studies of “pure” ADHD (21 ,22).

Natural History and Epidemiology

Tics typically begin between 3 and 8 years of age. For persons who go on to develop TS, the tics typically follow a waxing and waning course, usually with a progressive pattern of tic worsening. On average, the period of greatest tic severity occurs between 8 and 12 years of age. The onset of puberty is not associated with either the timing or the severity of tics. The early teens are generally followed by a steady decline in tic severity, and by 18 years of age, perhaps as many as 50% of patients with TS are nearly tic free (23). Symptoms in adulthood may typically settle into a more predictable, yet idiosyncratic repertoire, with increases in tic frequency and forcefulness during periods of stress or emotional excitement.

Estimates of the prevalence of TS vary considerably across studies. In studies relying on identified treated cases, prevalence estimates were 0.046 (Minnesota) (24) to 5.2 in 10, 000 (North Dakota) (25). School-based surveys yielded much higher estimates, up to 23.4 in 10,000 (26). Community surveys yielded prevalence rates that range from 2.9 in 10,000 in Monroe County, NY (27) to 299 in 10,000 in the United Kingdom (16 ,28). Thus, although a population prevalence of 5 in 10,000 is commonly cited, considerable evidence suggests that the true prevalence of TS may be considerably greater than this.

NEUROBIOLOGY OF TOURETTE SYNDROME

Part of "117 - Tourette Syndrome and Related Tic Disorders "

Interconnected cortico-striato-pallido-thalamic (CSPT) circuitry has long been implicated in the regulation of movement, thought, and affect; abnormalities within this circuitry have also been proposed to contribute to the pathophysiology of many neuropsychiatric disorders (29 ,30). The “motor” loops of CSPT circuitry are known to be the locus of disease in primary movement disorders such as Huntington disease (31), Parkinson disease (32) and hemiballism (33), and the “limbic” CSPT loops have been proposed as the source of disease in schizophrenia (29), depression (29), OCD (34 ,35), ADHD (36), substance abuse disorders (37), temporal lobe epilepsy (38), and many other seemingly disparate forms of psychopathology (39). Important models have been proposed to account for a wide range of CSPT disorders, based on variations in responses to “generalized” or “epigenetic” early developmental insults, from neonatal hypoxia to bacterial infections. Despite this departure from the notion of discrete, specific “lesions” and circumscribed clinical presentations, the prevailing model in the search for the pathophysiology of TS is perhaps closest to that previously applied to Huntington disease, in which a unique mutation in a single gene causes—by as yet unknown cellular mechanisms—a characteristic disease that leads to a fairly predictable clinical presentation and course. Yet the actual pathophysiology of TS remains quite elusive. The scant tangible evidence of the pathophysiology of TS comes primarily from studies in neuropathology and neuroimaging; supportive evidence comes from other fields of investigation, including neuropsychology and psychophysiology, and from ties between TS and other disorders, such as OCD and ADHD, providing indirect evidence based on what is known about the pathophysiology of these other disorders.

The published literature of TS neuropathology studies now includes seven presumed TS cases; of these, informative clinical and histologic data are available from five cases. Interpretation of the findings from even these five cases is

clouded by issues of diagnostic uncertainty, comorbidity, and potentially confounding neurologic insults. Preliminary findings have identified four different locations of potential pathology within CSPT circuitry: (a) intrinsic striatal neuron abnormalities, including increased packing density of neurons in the striatum (n = 1) (40); (b) a diminished striatopallidal "direct" output pathway, with reduced dynorphin-like immunoreactivity in the lenticular nuclei (n = 5) (41 ,42); (c) increased dopaminergic innervation of the striatum, with increased density of dopamine transporter sites (n = 3);(43); and (d) reduced glutamatergic output from the subthalamic nucleus, based on reduced lenticular glutamate content (n = 4) (44). Thus, in a manner more reminiscent of neuropathologic findings in schizophrenia than, for example, Huntington disease, these preliminary neuropathologic findings in TS do not converge to identify a specific, circumscribed "hole" in CSPT connections, but instead they suggest a range of disturbances or imbalances that affect the "whole" circuit (45). Many other measures of CSPT biology in TS, including amine levels and receptors, have been reported to be normal, also in these preliminary, small studies. Clearly, postmortem studies are hampered by limitations in the nature and number of the brains that have been studied (46). Efforts by the Tourette Syndrome Association (TSA) to secure adequate material for neuropathologic studies are currently under way and should allow a new generation of tissue-based research during the next decade.

Neuroimaging findings may ultimately provide information critically important to our understanding of the pathophysiology of TS. Volumetric imaging studies demonstrate minimal, if any consistent, abnormalities in persons with TS. Among reports of enlarged corpus callosum volume (47), reduced caudate volume (48), or diminished right-to-left asymmetry for the caudate nucleus (49) and left-to-right asymmetry for putamen and lenticular nucleus (48), the magnitude of such changes is small, typically on the order of 5%; furthermore, some reports fail to support even these small abnormalities. The specific cellular or structural processes that may be responsible for these anatomic abnormalities are unknown. Concerns regarding sample heterogeneity, comorbidity, and effects of chronic medication exposure, described earlier in relation to neuropathologic studies, are equally applicable to neuroimaging studies in TS.

Neuroimaging studies of regional perfusion or glucose uptake presumably measure features indicative of neuronal metabolism. In general, these studies in TS report reduced glucose uptake in orbitofrontal cortex, caudate, parahippocampus, and midbrain regions (52), as well as reduced blood flow in the caudate nucleus, anterior cingulate cortex, and temporal lobes (53 ,54 ,55 and 56). Regional glucose uptake patterns may reflect distributed CSPT dysfunction, as suggested by the observed covariate relationships between reduced glucose uptake in striatal, pallidal, thalamic, and hippocampal regions (56). The single greatest consistency across metabolic imaging studies in TS—that of distributed hypometabolism—contrasts sharply with the observed corticostriatal hypermetabolism reported by many groups in patients with OCD (33 ,34). The only suggestion of regional activation in TS comes during active tic suppression, which is associated with increased right caudate neuronal activity, as measured by functional magnetic resonance imaging (fMRI) (57); however, tic suppression is also accompanied by bilaterally diminished neuronal activity on fMRI measures, in the putamen, globus pallidus, and thalamus. The most analogous paradigm in OCD—obsession provocation—is associated with increased metabolic activity at every level of CSPT circuitry (35), in sharp contrast to the pattern observed in TS.

Neurochemical imaging studies have reported relatively subtle abnormalities in levels of dopamine receptors (58), dopamine release (59), and dopamine transporter (60) in the striatum of some patients with TS. Some of these findings have not been replicated (61 ,62), others await replication, even internally (60), and others are evident only in a small subgroup of TS, such as four of 20 patients (58), issues raising concern about their generalizability to the pathophysiology of TS. A potentially important report of 17% greater caudate D2 receptor binding among more symptomatic TS identical twins (63) was based on five twin pairs and reached statistical significance at the $p < .04$ level, by nonparametric analyses. Significant correlations between symptom severity and D2 binding were obtained using aggregate symptom scores from three clinical measures. These latter findings do not directly address the brain mechanisms that distinguish persons with TS from those without TS, but rather, point to the need to understand specific factors that contribute to the heterogeneity of the TS phenotype among affected persons.

Various techniques have been used to demonstrate a wide array of abnormalities in the levels of many major neurotransmitters, precursors, metabolites, biogenic amines, and hormones in blood, cerebrospinal fluid and urine of patients with TS, compared with controls (64 ,65 and 66). Attempts to understand the relation of these abnormalities to the pathophysiology of TS have ranged from a proposed causal role ascribed to a single metabolic abnormality, such as the reported cerebrospinal fluid elevation of the potential excitotoxin kynurenine (67), to models for imbalances in norepinephrine, dopamine, and serotonin (5-HT) systems similar to "imbalance" models proposed for other complex forms of psychopathology. One qualitatively different finding, reported by Singer et al. (68), is that of approximately 40% elevations of serum antiputamen antibodies in children with TS. This finding may have particular importance, based not only on its magnitude and specific linkage to basal ganglia circuitry, but also on converging evidence of autoimmune contributions to at least some forms of TS (see later).

Additional evidence of disorders in CSPT circuitry in

TS comes from neuropsychological and psychophysiologic studies (69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 and 77). Even these findings generally suggest mild deficits, at most: response distributions overlap greatly among patients with TS and control subjects, with most patients with TS performing within the normal range. The most consistently observed deficits occur on tasks requiring the accurate copy of geometric designs, that is, “visual-motor integration” or “visual-graphic” ability (69 ,77); somewhat similar deficits are reported in patients with OCD (78). No compelling evidence links these deficits in TS and OCD with a specific frontal or frontal corticostriatal territory, although visuospatial functions have generally been conceptualized to be regulated by dorsolateral prefrontal cortex and descending cerebrospinal fluid inputs to the head of the caudate nucleus (79). Neurophysiologic studies have documented a reduced cortical silent period after repeated *transcranial magnetic stimulation* (rTMS) in TS (80). This increased cortical excitability could result from impaired inhibition through disinhibited thalamocortical inputs or through abnormalities intrinsic to cortex, or both. Further support for the role of basal ganglia circuitry in TS comes from anecdotal reports of symptom exacerbation or reduction in patients with tumors within, or transections of, CSPT elements, respectively (81 ,82).

GENETICS OF TOURETTE SYNDROME

Part of "117 - Tourette Syndrome and Related Tic Disorders "

TS may be the most clearly inheritable common neuropsychiatric disorder. First-degree relatives of TS probands appear to be 20 to 150 times more likely to develop TS, compared with unrelated persons (83). Concordance rates for TS among monozygotic twins approach 90%, if the phenotypic boundaries include chronic motor or vocal tics, versus 10% to 25% concordance for dizygotic twins, across the same boundaries (84). The mode of inheritance remains elusive, even after more than 15 years of studies. Some segregation analyses have supported transmission through an incompletely penetrant autosomal dominant major locus (85 ,86), but in other studies, more complex models could not be excluded (87). The impact of assortive mating on inheritance may be particularly strong in TS, based on higher-than-predicted rates of bilineal transmission (88 ,89 and 90). Other findings suggest different inheritance patterns for maternal versus paternal transmission (91). Approaches using candidate genes or chromosomal translocations have offered results that were exciting but thus far not generally informative (92 ,93 and 94). Perhaps the most conservative assessment is that susceptibility to TS may be determined by a major gene in some families and by multiple genes of small relative effect in others, with a “dose-effect” of greater susceptibility for individuals homozygous versus heterozygous for these genes.

The TSA International Genetics Consortium completed the first genome-wide scan in an affected sibling-pairs (sib-pair) study. The *sib-pair design* relies on the comparison of the number of alleles at a given locus that are shared by two affected siblings, across all families in the sample. If the number of affected siblings sharing an allele or alleles is significantly higher than that expected by chance, it suggests a gene or genes of etiologic importance for TS. Using 76 affected sib-pair families with a total of 110 sib-pairs, the multipoint maximum-likelihood scores (MLS) for two regions (4q and 8p) were suggestive of high sharing (MLS greater than 2.0). Four additional regions also gave multipoint MLS scores between 1.0 and 2.0 (95). Collection of a second, replication set of approximately 100 sib-pairs is nearly complete, and it will be used to map these broad chromosomal regions more narrowly.

ENVIRONMENTAL FACTORS

Part of "117 - Tourette Syndrome and Related Tic Disorders "

Evidence of nongenetic environmental factors in the genesis of TS supports an interactive role for at least three sets of environmental factors: adverse prenatal and perinatal events, acute and chronic psychosocial stressors, and postinfectious autoimmune mechanisms.

Retrospective studies have identified an association between adverse events during the prenatal and perinatal period and an increased risk for the development of TS. Although the strongest evidence points to chronic mechanisms that influence the supply of nutrients by the placenta (96 ,97), other risk factors have been proposed including severe nausea and vomiting during the first trimester, severe maternal stress during pregnancy, exposure to high levels of androgenic steroids, and chronic or acute hypoxic and ischemic injury (98 ,99 ,100 and 101). Although no specific mechanism is known to connect these early life events and the development of TS, preclinical studies have shown that various neural insults during the prenatal and perinatal period result in the delayed emergence of pathology within interconnected CSPT circuitry and in specific behavioral abnormalities that are also manifested by individuals with TS, such as reductions in sensorimotor gating of the startle reflex (102 ,103 ,104 ,105 and 106). These early insults may also set the stage for a heightened stress response in adulthood and altered immune function (107 ,108 and 109).

As with several other disorders associated with CSPT dysfunction, including OCD, schizophrenia, and affective disorders, increased life stressors are associated with symptom exacerbation in TS. More than 98% of patients with TS report worsening of tic symptoms during periods of stress and anxiety (110). A direct assessment of the relationship between stress and tics revealed that anticipation of a stressful medical procedure, a lumbar puncture, has been shown to produce greater elevations in plasma adrenocorticotropic hormone in patients with TS than in control subjects and an elevated urinary excretion of catecholamines that correlated with symptom severity (66). Patients with

TS also have been reported to have elevated levels of cerebrospinal fluid norepinephrine and corticotropin-releasing factor (66 ,111). Importantly, although stress clearly alters CSPT dynamics and increases symptoms of numerous different neuropsychiatric disorders, no existing data implicate a specific etiologic relationship between stress and TS.

It is well known that *group A ß-hemolytic streptococcal (GABHS) infections* can trigger immune-mediated disease in genetically predisposed persons (112). Acute rheumatic fever (RF) can occur approximately 3 weeks after an inadequately treated GABHS infection. In addition to inflammatory lesions involving the heart (rheumatic carditis) and joints (polymigratory arthritis), rheumatic fever can be accompanied by CSPT disease responsible for the manifestation of Sydenham chorea. Patients with Sydenham chorea frequently display motor and vocal tics, obsessive-compulsive, and ADHD symptoms suggesting the possibility that at least in some instances these disorders share a common origin (113 ,114). As in Sydenham chorea, antineuronal antibodies have been reported to be elevated in the sera of patients with TS (68).

It has been proposed that *pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection* (PANDAS) represents a distinct clinical entity and includes Sydenham chorea and some cases of TS and OCD (115). The most compelling evidence that acute exacerbations of TS and OCD can be triggered by GABHS comes from two independent reports that most patients with childhood-onset TS or OCD have elevated expression of a stable B-cell marker (116 ,117). The D8/17 marker identifies close to 100% of patients with rheumatic fever (with or without Sydenham chorea), but it is present at low levels of expression in healthy control populations. Dr. Susan Swedo and her colleagues reported that in children who met PANDAS criteria, GABHS infection was likely to have preceded neuropsychiatric symptom onset for 44% of the children, whereas pharyngitis (no culture obtained) preceded onset for another 28% of the children. In a minority of cases (31%), neuropsychiatric symptom exacerbations were associated with documented GABHS infection, and in another 42%, they were associated with symptoms of pharyngitis or upper respiratory infection (no throat culture obtained) (115). Although these results are intriguing, they are not compelling with regard to specific immunologic mechanisms linking PANDAS and TS. Clearly, independent replication and systematic study of this intriguing phenomenon may provide a basis for the rational design of therapeutic and preventative interventions. The need for accurate and complete information in this area is underscored by the finding that, based solely on the existing minimal data, parents are actively seeking for their children invasive treatments such as plasmapheresis and intravenous immunoglobulins. With emerging preliminary findings suggesting possible links between streptococcal infections and some aspects of OCD and ADHD, this area of investigation has become a major public health issue.

TREATMENT

Part of "117 - Tourette Syndrome and Related Tic Disorders "

Therapeutic models of TS emphasize the importance of flexible, integrated biopsychosocial strategies. Flexibility is important because the nature of the disorder and its impact on patients and families change dramatically across its course. It is often the case that, when families first present for assessment of TS, confusion, fear, anger, and embarrassment fill an “information void” and are exacerbated by the very public outward manifestations of tics, their deceptive “volitional” appearance, and their sometimes socially unacceptable content. Although parents may worry about a child’s counting rituals or may be exasperated by a child’s continued disruption of a school class, the child’s tics often evoke in them a more intense, visceral sense of desperation. Such reactions reverberate throughout the family and affect the child. The familial nature of the illness means that, almost invariably, when a child first manifests symptoms, close relatives (often parents or siblings) are, or were once, also affected; this sets the stage for a range of “generational” psychological consequences for parents, as painful memories are rekindled.

Education

Initially, much of the distress associated with TS can result from a lack of understanding of the illness. Education about the natural history of TS, emphasizing the involuntary, “no-fault” nature of certain brain-behavior relationships, is an essential part of the early treatment of this disorder. This process can begin in the diagnostic assessment: faced with a set of simple, matter-of-fact questions about tic symptoms, many of which are found in printed, standardized scales such as the Yale Global Tic Severity Scale (118), parents and patients recognize that other people must have had experiences much like their own. As information displaces the “mystery” of a child’s tic behaviors, the urgency to make immediate somatic interventions can diminish.

Physicians, parents, and patients should be aware of the waxing and waning nature of the illness. An initial clinical visit may be precipitated by a recent exacerbation of previously subclinical or tolerable symptoms. Given the cyclic pattern of TS, such periods are often followed by a gradual diminution of symptoms, even in the absence of a specific biological intervention. One danger of rapidly initiating medication treatment in TS is that a “false-positive” response, based on the normal cyclic fluctuation of symptoms, will convince patient, family, or physician that a particular medication is “effective.” This false-positive response, and the false hope that it creates, can result in unnecessary medication exposure and side effects and, ultimately, in heightened

frustration when the illness follows its natural course toward the next phase of exacerbation. Observing the cyclic fluctuations, while the patient is free of medications, can provide a more clear impression of a patients' natural illness course and can thereby be a useful basis for interpreting future medication effects.

The "bigger picture" of the natural history of TS is also critically important: persons with TS can and should be expected to live full, productive lives; as many as half of these persons will be largely symptom free by the time they enter their twenties; and every persons has strengths that must be nurtured and developed and that will ultimately be more significant determinants of life quality and character than are tics or other TS symptoms. Within this broader context, parents and patients should understand that, at present, the benefits of medication treatments of TS are relatively modest, and the potential social, psychological, and biological side effects are not trivial.

Pharmacotherapy

Medications can play an important role in the treatment of TS. Because functional impairment in this disorder is most closely linked to comorbid conditions such as OCD and ADHD, symptoms of these disorders (and even their "subclinical" manifestations) are often the first targets of pharmacotherapy in TS. Effective treatment of these comorbid conditions can often markedly diminish tic severity. The basis for this therapeutic interaction is not well understood, but it may include some or all of the following: (a) simple interactions at a neural level, such as a direct medication effect within multiple or interacting CSPT "open loops," including, for example, those that mediate both obsessions and tics; (b) interactions related to the stressful nature of comorbid conditions; for example, tics are reduced by a diminution of stress that follows successful treatment of OCD or ADHD symptoms; (c) interactions at a level of cognition resources, such as improved volitional "suppressibility" of tics because of improved attentional allocation; and (d) interactions at a symptom level, such as diminished need for repetition or complex rituals that could otherwise make tics more elaborate. Regardless of the mechanism, treatment of comorbid OCD or ADHD (as well as mood disorders, discussed later) should be a high priority because these conditions are responsible for significant functional impairment, they are generally responsive to appropriate pharmacotherapy, and their treatments are relatively free of significant side effects. Even the prolonged use of stimulants in comorbid TS and ADHD, once avoided because of fears of stimulant-potentiation of tics, was shown to be safe and effective in a large TSA-funded study with a 2-year longitudinal design (119). Clearly, close clinical monitoring is important in all pharmacotherapy, particularly in children.

Dopamine Antagonists

When tic-suppressing agents are necessary, the cost-to-benefit ratio differs among medications and across clinical conditions. *Dopamine antagonists*, particularly high potency, D2-preferential blockers such as haloperidol, fluphenazine, and pimozide, are the most potent and rapid-acting tic-suppressing agents that have been studied in controlled trials. These medications may be most useful in patients with severe, intractable tics, but they also have undesired side effects, causing blunting of cognitive skills, mood, and motivation (120 and 121); when discontinued, these high potency D2 blockers can precipitate withdrawal dyskinesia and significant worsening of tics (120). In adults, these drugs are clearly linked to an increased risk of tardive dyskinesia, although in children, this relationship has not been as clearly defined. One newer, "atypical" antipsychotic, risperidone, is a mixed dopamine/5-HT receptor blocker that is proving to be a useful anti-tic medication, with a side effect profile somewhat preferable to that of haloperidol or pimozide (122). Controlled studies of risperidone efficacy in TS are in progress; however, experience suggests that significant, undesired weight gain with this drug is not infrequent. Dopamine antagonists are also useful in conjunction with a primary antiobsessional agent (e.g., selective serotonin reuptake inhibitors) in treatment refractory OCD with comorbid tics; risperidone is frequently used in this capacity. A double-blind trial of ziprasidone in TS yielded encouraging short-term results without the weight gain associated with risperidone (123). The utility of other "atypical" antipsychotics such as olanzapine or quetiapine in the treatment of TS or tic-related OCD is not known.

α_2-Agonists

The α_2-adrenergic agonists, clonidine and guanfacine, are often used as first-line anti-tic agents, both because of their relatively favorable side effect profile and because of some evidence linking these drugs to improved attentional abilities in children with ADHD (124 ,125). These drugs have relatively weaker anti-tic abilities, compared with dopamine antagonists, and their benefit generally evolves more gradually than with dopamine antagonists. Still, there are advantages to prescribing these medications in lieu of antipsychotics; aside from the somatic side effects of neuroleptic agents, it is often not inconsequential for a child when his or her teacher researches these drugs in the *Physician's Desk Reference* and reads "for severe psychotic states only."

Newer Pharmacologic Approaches

Several new therapeutic avenues for TS are being explored in controlled studies. Preliminary studies suggest that one severely impairing feature of some forms of TS—rage attacks—may be sensitive to treatment with selective serotonin

reuptake inhibitors (126). One double-blind trial suggested some anti-tic benefit from low doses of dopamine agonists such as pergolide (127), an effect attributed to “autoreceptor” actions that suppress activity in midbrain dopamine nuclei; other dopamine agonists are also being explored in this capacity. Nicotinic manipulations, ranging from nicotine patches to the nicotinic antagonist mecamylamine, may offer significant anti-tic benefit, if controlled studies replicate the impressive series of case reports with these agents (128 ,129 and 130). Tic reduction after nicotine patches has been reported to be sustained for several weeks after exposure to the patches for only a few hours. The seemingly paradoxical effectiveness of both nicotine and mecamylamine may suggest that nicotine’s beneficial effects in TS reflect a rapid and sustained desensitization of nicotine receptors. Studies in adults suggest that sustained use of the nicotine patch does not increase the liability for nicotine abuse or dependence (131), but relevant studies in children, with intermittent brief patch exposure, have not been attempted. Δ^9-tetrahydrocannabinol was also reported to diminish tic severity in TS, in a large case series (132); controlled studies with this agent are in progress. Obviously, such putative therapeutic effects may provide clues relevant to the pathophysiology of TS. Various other agents, ranging from opiate antagonists to androgen antagonists, have been reported to have beneficial effects on tic symptoms; generally, these effects have been modest (133) or accompanied by a worrisome liability for side effects (134).

Certain intractable and localized tics have also been treated successfully with repeated injections of botulinum toxin. Generally, tic location and type shift across the course of an illness, so such a “peripheral” approach may be effective only for short periods of an illness. Still, substantial case series evidence suggests the utility of this approach for some patients, and even vocal tics have been treated effectively with botulinum toxin (135). At another extreme, *habit reversal therapy* involves the application of cognitive and behavioral therapy principles to TS (136), analogous to the successful use of these therapies in the treatment of OCD. Although studies with habit reversal therapy are only now being completed, initial results appear promising, offering the possibility of a true, “nonpharmacologic” approach to this disorder. Conceptually, once it is effectively learned, habit reversal therapy may be easy to apply over a period of years, to a variety of different types of tics.

One novel approach being studied in TS, as well as OCD and depression, involves the therapeutic use of rTMS. Although clearly at an investigational phase, technical advances in rTMS may ultimately allow localized, stereotaxic-guided activation of frontal and striatal CSPT elements implicated in the pathophysiology of TS. Proponents of rTMS emphasize that the procedure can be administered on an outpatient basis, at relatively low cost, without apparent significant side effects. More heroic efforts for intractable TS and OCD have included psychosurgical interventions, particularly anterior cingulotomy or capsulotomy (80 ,81 and 82). Even this more extreme approach is now being accomplished on an outpatient basis, through the use of a gamma knife. However, the most promising psychosurgical approach may involve high-frequency electrical stimulation after the placement of deep brain electrodes (137).

Alternative Therapies

The void created by a lack of fully effective medication treatments for TS has been filled by *alternative therapies*, as parents and patients use self-experimentation to identify treatment strategies that work for themselves and then share this information with others in the TS community. The dissemination of this information has been greatly facilitated by internet communications. Proponents of alternative approaches, which generally include nutritional and vitamin supplementation, believe that these interventions are natural, safe, and effective and may be targeting a metabolic or biochemical defect that underlies TS, but that has thus far eluded detection by scientific investigations. Just as for conventional therapies, symptom reduction with alternative treatments must be interpreted in the context of the natural waxing and waning course of TS. Perhaps even more so than for conventional therapies, these alternative approaches carry a potential for improvement based on expectation or “placebo” effects. For an individual patient, a placebo effect is not necessarily problematic, but tremendous cost and hardship are created if such treatments are applied on a larger clinical scale and ultimately fail to deliver the promised therapeutic benefit. Nutritional or related interventions may be “natural,” but they ultimately cause biochemical changes in the body and can impart significant side effects. Other “side effects” occur when patients substitute these alternative approaches for treatments that are known to offer some efficacy and that keep them in contact with clinicians who can monitor their overall medical condition. Ultimately, it is critically important for these alternative treatments to be tested in controlled trials, in which their tolerability, safety, and efficacy can be established in an objective manner. Unfortunately, the cost of such studies is often prohibitive, and they are generally not a high priority for funding from the pharmaceutical industry. Clinicians should ask patients and parents whether alternative therapies are being used, particularly if medications are being added or changed, to avoid potentially harmful drug–drug interactions.

Treating Tourette Syndrome and Depression

As is true with most neuropsychiatric conditions, comorbidity of TS with affective disorders deserves special attention, owing to the insidious and often profound morbidity imparted by depression. Comorbid affective illness accompanying TS is generally sensitive to standard pharmacotherapies

for these disorders. These can often be used in combination with anti-tic regimens, but the possibility of iatrogenic depression from dopamine antagonists should always be considered, because this may dictate a reduction in neuroleptic dose rather than the addition of an antidepressant. As with comorbid OCD or ADHD, it appears that *comorbid depression* can often cause a worsening of tics in TS, and there are reports of severe, refractory, mood-dependent tics in comorbid TS and depression that show dramatic sensitivity to electroconvulsive therapy (138 ,139). Whereas more representative epidemiologic data are necessary, the lifetime prevalence of comorbid mood disorders in TS patients seen in specialty clinics may be as high as 70%, comparable to that reported in patients with OCD (140).

FUTURE DIRECTIONS

Part of "117 - Tourette Syndrome and Related Tic Disorders "

Several lines of inquiry are positioned to make major advances in our understanding of the etiology and treatment of TS, based on the tremendous progress that has already been made in each of these areas:

The *clinical "phenotype"* of TS has been particularly well characterized. However, compared with motor and phonic tics, sensory phenomena in TS are relatively less well understood and are more difficult to study. A full understanding of the TS phenotype will clearly enhance research efforts, by permitting stratification in measures from all levels of analysis, from genetics to neuropsychology. Detailed clinical characterization, and the experimental analysis that it facilitates, will also be important in clarifying the potentially critical distinction between the form of TS that undergoes substantial remission by the early twenties and that which is lifelong and unremitting. This issue has tremendous importance, because these two "types" of TS are not generally (and often cannot be) segregated in genetic, neuroimaging, or other biological measures in this disorder. For example, it may not be appropriate to generalize to all forms of TS the biology that is described by neurochemical brain imaging studies, which, because of ethical concerns, exclusively involve adults with TS. At another level, current TS studies that include children will likely involve both "types" of TS, without any clear way to stratify this heterogeneous sample. A full understanding of the TS phenotype may also be of value in developing symptom "clusters" or "factors," like those that provide meaningful segregating strategies in OCD.

Future efforts in *TS neuropathology* will result in the collection of an adequate number of well-phenotyped, optimally prepared brains, to permit meaningful studies. Through the efforts of the TSA Neuropathology Program and the Harvard Brain Tissue Resource Center, approximately three new, optimal TS brains are collected each year, and in 1998, eight TS brains were cut for neurochemical and neuroanatomic studies. A common "library" of matched control tissue is also being collected, to diminish variability across different studies. These systematic efforts, combined with the judicious but timely distribution of brain tissue for studies, should help to overcome many of the limitations of past TS neuropathologic studies. Our ability to utilize this material effectively and to interpret the information that it provides depends entirely on our progress in understanding the complex interconnections within CSPT circuitry. Although we have useful maps of the major thoroughfares within CSPT circuitry, we will need to be equally knowledgeable regarding the detailed input-output relationships of functionally and neurochemically distinct striatal subterritories. Important pathologic findings can be lost if they are unknowingly averaged across heterogeneous anatomic domains.

Neuroimaging efforts in TS will focus on two strategies that have been so informative in studies of OCD: pretreatment versus posttreatment repeated measures and on-line behavioral or psychophysiologic probes in conjunction with functional imaging. Nonpharmacologic treatment effects on regional brain metabolism or brain activation may be studied before and after habit reversal therapy, similar to such studies using cognitive and behavior therapy in OCD (141). Appropriate on-line probes for fMRI studies must be carefully developed. Optimally, these probes should either (a) detect deficits in patients with TS, or (b) in healthy persons, selectively activate relevant brain substrates, including the basal ganglia or frontal circuitries. Event-related fMRI techniques appear especially promising as investigators seek to identify the sequence of neural events that precede and follow tics.

Replication of the initial *genome scan* from the TSA International Sib-Pair Study is in progress, and fine mapping of the most promising regions is planned. Verification and extension of this work within several extended TS families are also anticipated. Parallel efforts will continue in targets of opportunity, including informative chromosomal translocations. Ultimately, genes conferring a risk of TS will be identified and cloned. Experience from similar efforts that are already completed with the Huntington disease gene suggest that identification of the TS genes will be followed by a substantial amount of work designed to understand their normal function and the pathologic impact of their abnormal products.

Even with the most detailed description of the "clinical phenotype" of TS, it is possible that a full understanding of the functional relevance of the "TS genes" will require the *use of endophenotypes*—physiologic or neuropsychological markers of gene function that can be identified in patients with TS and that could also be abnormal in unaffected, first-degree relatives. These markers could greatly enhance the power of linkage analyses, by allowing a "physiologic" parsing of the phenotype of affected and at-risk individuals. A variety of such markers has been explored in TS, including antisaccade measures (74), eyeblink measures of prepulse

inhibition of startle (73) or condition-test paired pulse paradigms (76), and measures of cortical silent periods after rTMS (80). The neural bases of these various measures are consistent with our present conceptualization of CSPT substrates of TS, but the effect sizes of existing measures are small or moderate and thus are suboptimal for use in genetic analyses. This area of work in TS, however, has been relatively understudied.

Until recently, TS research suffered from the relative lack of informative *animal models*. Mutant rodent models may prove useful (142), particularly in understanding the behavioral and physiologic consequences of the selective loss of a specific neural element, such as the dopamine transporter (143). Essentially, such models provide a nonpharmacologic, nonsurgical means of studying the effects of a chronic perturbation in basal ganglia circuitry. Animal models can also be used, however, in guiding the development of candidate endophenotypes; particularly valuable would be measures that can be assessed across species and that can be shown in preclinical studies to have predictive or construct validity for TS.

One animal model that promises to be particularly informative regarding the neurobiology of TS involves the manipulation of the relative activity of medium spiny projection neurons within the striosomal and matrix compartments of the striatum (144). These two compartments differ with respect to their cortical inputs: striosomal neurons receive limbic and prelimbic inputs, and neurons in the matrix receive inputs from ipsilateral primary motor and sensory motor cortices. Dopamine projection neurons from the pars compacta of the substantia nigra serve to “tune” this system as it determines responsivity to certain cues (interoceptive or exteroceptive). As noted by Leckman and Riddle (145), this model may provide a meaningful integration of knowledge drawn from different perspectives that may be directly relevant to certain important clinical issues, including (a) the stress responsiveness of tics, (b) the presence of premonitory sensory urges and “just-right” perceptions, (c) the need to “even-up” sensory and motor stimuli in a bilaterally symmetrical fashion, (d) the reduction of tics when a person is engaged in acts that require selective attention and guided motor action, and (e) the timing of tics and the course of tic disorders. Such a model may also guide hypothesis-driven studies in other areas of TS research. For example, based on the distinct input-output characteristics of neurons in the striatal matrix versus striosomes, it may be useful to determine whether there is a differential involvement of these neurons in Sydenham chorea and postinfectious forms of TS. Even more subtle clinical distinctions within the “TS spectrum” may be predicted to reflect a differential involvement of these striatal components, with more affectively laden symptoms common to “tic-related OCD” reflecting the involvement of striosomal elements and more affectively “neutral” motor and sensory symptoms of “pure” TS reflecting the involvement of the striatal matrix (15).

Although several new therapeutic approaches to TS are being developed, as discussed earlier, there is clearly a significant need to *understand the proposed role of streptococcal infections in the pathogenesis of TS* and to assess the potential role of antistreptococcal or immunosuppressive therapies. Penicillin prophylaxis is gaining increasing use in patients with childhood tic disorders and OCD, without any controlled studies demonstrating efficacy for this approach; an analogous patterns has been seen in the recent rush for unproven, experimental treatments for autism (146). Certainly, repeated injections or even oral treatment with antibiotics can have detrimental consequences in children. Even more concerning is the increasing use of plasmapheresis or intravenous immunoglobulin therapies in affected children, with only preliminary data from controlled studies demonstrating efficacy for these costly and invasive interventions (147). Given the expanding clinical boundaries of streptococcal-associated conditions, controlled, large sample studies of penicillin prophylaxis in TS, and perhaps of other related therapies as well, should be a major priority from a public health standpoint.

SCIENTIFIC HURDLES

Part of "117 - Tourette Syndrome and Related Tic Disorders "

Major obstacles impede the search for the pathophysiology of TS. Serious ethical issues complicate invasive studies in children and affect TS research tools ranging from the use of radioisotopes in neuroimaging studies to the acquisition of meaningful age-matched control samples. The longevity of patients with TS is certainly a blessing, but it also precludes the availability of neuropathologic material for systematic studies. The lifelong interval between diagnosis and study increases the likelihood that the “lesion” will melt into the compensatory milieu of nervous tissue or will be camouflaged by the many other insults that befall an aging brain. The medical care of patients with TS is rarely focused on “end-of- the-life-spectrum” issues, and thus pediatricians and families rarely consider procedures for brain donation. Indeed, the optimal therapeutic approach to TS is often to downplay the notion of TS as a “disorder,” to not “pathologize,” but rather to emphasize the ways to survive and thrive with TS. Neuropathologic material is thus most readily available from persons whose TS has remained severe throughout adulthood and who are identified by family and physicians as being particularly impaired by this disorder. As noted earlier, refractory TS may reflect pathologic features quite distinct from the more common forms of this illness, and thus neuropathologic studies with tissue acquired from elderly patients with TS may not be generally informative about TS and potentially could be scientifically misleading.

Despite these hurdles, with centralized research coordination by the TSA, and increased attention to critical issues of clinical heterogeneity and comorbidity, future studies will

be much better equipped to overcome the obstacles that have left us, to date, with wide gaps in our understanding of the pathophysiology of TS. The formidable hurdles facing TS research are not unique to this disorder, but are equally relevant to conditions that span the range from primary movement disorders (148) to disorders with primary psychiatric manifestations (149). In this manner, the quest to understand the neurobiology of TS does serve as a practice question for more complex disorders, and the strategies developed to overcome challenging scientific hurdles will be invaluable lessons, with applications across a wide range of neuropsychiatric disorders.

ACKNOWLEDGMENTS

Over the past several decades, various animal models have been used extensively to characterize the activity of various drugs and drug classes, and from these results, to anticipate their activity in humans. However, the value of animal models that purport to predict the potential therapeutic value of new drugs is often accepted with considerable reservation and, when the therapeutic objective involves psychiatric disease, is perhaps viewed with outright suspicion.

In general, the animal models most readily accepted as a basis for predicting responses in humans are those that are homologous, that is, those in which both the condition being observed and its origin are similar to those in humans. Examples may include suppression of bacterial infections by antibiotics or hypertension in monkeys. Few, if any, models of psychiatric dysfunction, however, can be considered homologous, if only because the origin of the psychiatric condition is unknown.

In the absence of homologous models, isomorphic models (in which the observed condition is apparently similar even if the cause is not) may be fairly rapidly accepted. An example may be amphetamine-induced psychosis as a putative model for schizophrenia. Finally, there are many models in which neither the condition nor the origin can be clearly linked with the disease being modeled, but in which there is empiric evidence of some predictive validity either for the disease or some aspect of its therapy. In psychopharmacology, the evidence is usually the discovery that agents with known therapeutic activity in humans consistently correlate with some response in an animal model. It can be argued that before animal models are developed for any disorder, the essential features of the disorder should be known. Here researchers run into trouble because the essential features of many disorders in humans are unclear. Pathologic aggression is not a DSM-IV disorder for which criteria are set for determining what is normal or abnormal (1). Moreover, there is little understanding of the biological factors underlying pathologic aggression in humans, so it is difficult to formulate a rational research program. A discussion of the characteristics of pathologic aggression is needed for the development of animal models of this disorder.

Despite the drawbacks adherent to aggression research, there is an increasing knowledge of the effects of psychoactive drugs on aggressive behavior, both in animals and in patients. Thus, two roads are emerging: one studying the fundamental causes of aggression and dysfunctions, the other studying the modification of behavior by pharmacologic interventions.

CLASSIFICATION OF AGGRESSION

Part of "118 - Animal Models of Aggression "

Despite many attempts, a generally acceptable definition of *aggression*, particularly as it applies to individual human behavior, has not yet emerged. This failure arises in part from the following: (a) the varying theoretic or philosophic persuasions of those offering definitions; (b) the inherent difficulty in capturing the essence of a multifaceted behavior; and (c) the attempt to include within the definitions elements of motivation that cannot readily be observed or elicited. However, a generally acceptable working definition from the perspective of animal research is somewhat easier to obtain and could read “any overt behavior that produces aversive or noxious stimuli or harm to another organism.” In this definition, the “motivation” of the behavior is not an essential element, but it may be deduced directly from the stimuli that elicit the behavior and from the overt behavior itself. Different types of animal aggression can be distinguished based on the environmental situations eliciting those behaviors. Moyer was the first to describe such a classification (2), later followed by alternative classifications (3).

All these classifications have their own inherent problems, such as to link the aggression to connotations of offensive and defensive aggression, using the ethology-derived term *agonistic behavior* as an important distinction to classify aggression models.

The distinction of aggression into offensive and defensive models is universal (4), is functional, and seems to be paralleled in brain mechanisms involved in the behavior. *Offensive behavior* is characterized by the initiative of the aggressor and intended damage to the opponent (5 ,6). In contrast, *defensive behavior* lacks active approach (initiative), and the defensive animal (6) inflicts no intentional damage. *Predatory aggression* represents separate classification of aggression that seems to be primarily driven by appetite mechanisms and apparently has a distinct brain system involved.

Neither in humans nor in animals is agonistic behavior pathologic. In the framework of evolutionary theory, these behaviors are understood to encourage survival of the fittest, to disperse populations, to aid adaptation to threatening environments, and generally to improve the probability of individual and species survival. In humans, agonistic behavior is considered acceptable or not based on certain predetermined rules. Although “aggressive” behavior is associated with certain somatic and psychiatric disease states, and such behavior may be considered in establishing a diagnosis, there is no diagnostic category of “aggressive disease” or “offensive syndrome” *per se*. In the clinical literature, such behaviors may be referred to as “violent,” “hostile,” “agitated,” “impulsive,” or “pathologic aggressive.” Although animal models of aggression try to simulate the human conditions as much as possible, this is difficult because we know so little about the underlying mechanisms of aggression in disease states. By studying several paradigms in animals with the expectation that they have at least some predictive validity for human disorders with pathologic aggression, we hope (a) to develop new drugs for treatment of patients and (b) to gain insights into the underlying mechanisms resulting in the disorder. With the emergence of molecular genetic technologies, we increasingly understand the roles of certain genes in aggression, which may ultimately lead to development of novel treatment strategies for pathologic aggression.

Instead of being exhaustive, the present chapter focuses on some selected animal models of aggression with some bearing for human pathologic conditions. Specific examples of drug effects and underlying mechanisms are also discussed.

MODELS OF OFFENSIVE BEHAVIORS

Part of "118 - Animal Models of Aggression "

Several paradigms are used to study offensive aggression, such as isolation-induced offensive behavior (mouse), resident-intruder offensive behavior (rat/mouse/hamster), offensive behavior after electrical stimulation of the brain (rat), maternal offensive behavior (mouse/rat), offensive play-fighting among juvenile rats, and offensive behavior among piglets.

Some of these models are described, and some relevant pharmacology is outlined (benzodiazepines, neuroleptics, psychostimulants, antidepressants, serenics). The putative face, construct, and predictive validity are discussed. In addition, several models providing insights into novel neural mechanisms of aggression as well as interactions between genes and early environment are presented. Moreover, new data are introduced regarding mutant mice showing phenotypic changes in aggression, such as the serotonin ($5\text{-}HT_{1B}$) and nitric oxide synthase (NOS) knockouts. The information coming from these new genetic models can be of help in understanding possible causes of human pathologic aggression.

Isolation-Induced Offensive Behavior

A manipulation often used to induce aggression is isolation of male animals, typically mice, for several weeks. Many such isolated animals, on encountering another male, will reliably exhibit attack behavior (7). The effect of isolation on aggressive behavior is strain dependent (8). This isolation-induced aggression paradigm in mice is one of the most frequently used aggression models in behavioral pharmacology (9), and it has engendered an extensive pharmacology mainly described in median effective dose (ED_{50}) values. Because there are many ways to affect aggression in a nonspecific way (sedation, motor disturbances, psychostimulation) an ED_{50} value is not at all helpful in delineating how and why drugs reduce aggression.

Because isolated male mice show a full repertoire of agonistic behaviors (10), ethologic techniques have been used to detect very specific drug effects (11). Although most tests are performed in the home cage of the isolated male mouse, performing the test in a neutral arena is attractive because the situation delivers a mix of offensive-defensive and flight behaviors, which are not seen or are infrequently seen in the home cage confrontation (11).

The latter model is very interesting because it shows properties of drugs that are revealed only partially, or not at all, by common pharmacologic test models (10 ,12 ,13). An extensive literature exists about the effects of γ-aminobutyric acid ($GABA_A$)-benzodiazepine agonists in this paradigm. Interestingly, classic non–subunit-selective benzodiazepine-receptor agonists show inverse U-shaped dose–response curves in this model. At lower doses, increases in aggression are seen, whereas at higher doses, no effects or decreases are observed (14), probably because of nonspecific effects such as muscle relaxation or sedation (11 ,15). A similar pattern of activity can be found after alcohol administration or consumption. Miczek et al. extensively investigated the effects of various doses of alcohol on aggressive behavior of male mice, rats, and monkeys and consistently found that individual animals respond differentially to alcohol (14 ,16 ,17 and 18). Approximately 25% of mice show heightened aggression after receiving low doses of alcohol (AHA mice), whereas the remainder show no increase in aggression (ANA mice). Interestingly, this alcohol-heightened aggression is attenuated by pretreatment of $5\text{-}HT_{1A}$

and 5-HT_{1B} receptor agonists (19 ,20), a finding indicating an essential role the serotonergic system in the modulation of offensive aggressive behavior. Enhanced aggression after benzodiazepines and alcohol treatment in some, but not all, animals is highly similar to the pattern found in humans (21 ,22 and 23) and supports the predictive validity of this kind of animal models for some types of human aggression.

Psychostimulants also disturb the normal agonistic behavior, although the resulting behavior is clearly differentially affected (10 ,11 ,19). D-Amphetamine–treated animals show aberrant "stimulated" behavior, which severely interferes with normal agonistic behavior (11 ,15 ,24). Neuroleptics (chlorpromazine, haloperidol) exert antiaggressive effects, but nonspecific effects, such as motor disturbances (catalepsy) (11 ,15), cause this. Serenics (serotonergic 5-$HT_{1B/1A}$-receptor agonists) have a highly selective antiaggressive profile in this test, reducing aggression specifically without dramatically affecting other behaviors dramatically and certainly not causing any unwanted side effects (25 ,26).

In the 1990s, molecular biological techniques provided us with potentially very exciting ways of studying aggression. Several gene knockout mice were generated, and some have been tested on their aggressive behavior. Several knockouts seem to be more aggressive than their wild types, including, among others, the 5-HT_{1B} receptor (27), the neural form of nitric oxide synthase (nNOS) (28), monoamine oxidase A (MAO A) (29) and calcium-calmodulin kinase II (CAMKII) (30). Interestingly, mice with a deletion in the endothelial form of the nitric oxide synthase (eNOS) (31) exhibit a virtual elimination of aggressive behavior. One has to be careful to consider the hyperaggression obtained after the mutation directly caused by the absence of the gene. Genetic background effects may cloud a clear interpretation, whereas adaptational processes over time may also influence the outcome. Most studies reported do not use extensive description of the behavioral phenotype, and conclusions whether the observed "aggressive" phenotype of the mutant is directly caused by the absence of the gene or results from maladaptation of the mutant to external stimuli have to be investigated before a mutant can be considered as a putative model for a certain kind of aggression. Nonetheless, studies screening knockout mice for alterations in aggressive behavior should prove useful in identifying novel mechanisms involved in aggression and provide useful models for development of novel drug intervention targets.

The 5-HT_{1B}-receptor knockout mouse (27) has been evaluated most extensively on different aspects of its hyperaggressiveness and has been proposed as an animal model of impulsivity (32 ,33). The latter study investigated territorial aggression in 5-HT_{1B} knockout males and corresponding wild types (in a 129SV background) while equipped with telemetric senders to record heart rate and body temperature during the experiment. Ethologic analysis of the behavior showed that the knockouts where more aggressive than the wild types. The significant findings from these studies were that, although these animals displayed higher levels of offensive aggression with a faster onset, other behaviors, including social investigation, defense, and exploration were completely normal (Table 118.1).

	Frequency		Duration	
Behavior	**Wild-Type**	**Knockout**	**Wild-Type**	**Knockout**
Nonsocial activity

[a]Male wild-type and 5-HT_{1B} receptor knockout mice were singly housed (residents) for several months. These mice (n = 12 per genotype) were equipped with telemetric devices to record heart rate and body temperature. Mice were subjected to a 10-min encounter with a group-housed male intruder, and the behavior of the resident was scored, using an ethologic method. Data are given as median (using twenty-fifth to seventy-fifth percentiles) frequencies and duration (seconds) per 10 min. Mann-Whitney U test: the asterisk means significantly different from wild-type mice (p .< 05).

TABLE 118.1. ANIMAL BEHAVIOR ANALYSIS

Telemetric data on heart rate and body temperature showed no obvious abnormalities during the fight, although 5-HT_{1B} knockouts responded faster to all types of sensory stimuli such as opening the cage, handling, and injection (33). This pattern of reactivity was in line with the presumed impulsivity of this mutant and lends support to the use of this animal model in research into the mechanisms underlying impulse and aggression disorders, and it will be of help in screening new potential antiaggressive or antiimpulsive drugs. Much more fundamental work, including pharmacology, has to be done on this mutant, but the appearance of new animal models of human diseases seems a realistic option (34 ,35).

Isolation-induced aggression in mice is an animal model of offensive aggression with excellent predictive validity toward human aggression. Although some face validity is clearly present (offensive impulsive aggression in human aggression), the construct validity is as yet largely unknown.

Resident-Intruder Offensive Behavior

This model, very frequently used in psychopharmacology, uses the resident animal's response to a conspecific intruder (24 ,36 ,37). In the *resident-intruder paradigm*, a male rat is housed with a female, a situation resembling the natural situation in which animals establish and defend territories (38). When resident or territorial males meet an unfamiliar male intruder in their territory, heavy fighting may ensue, considered natural fighting (39 ,40). The attacking male performs a complete agonistic repertoire including both appetitive and consummatory behaviors Aggressive behavior in this situation may consist of searching (patrolling), approach, investigation, threats fighting, chasing, and dominant posturing The nature of such interactions between an attacking resident and an opponent varies with the quality of the intruder, especially age and hormonal status, and the resident's experience. The types of behaviors displayed by the resident toward the intruder are not random but follow certain rules (15), a strong indicator of the neural substrates involved (4).

The resident-intruder model differs both from isolation-induced aggression in mice and intermale aggression in rats, because there is no isolation, which may lead to behavioral abnormalities (8). Moreover, resident-intruder paradigms have a very wide species generality (41), including humans (42). Isolation-induced aggression, in contrast, is far more restricted to certain species (10). This model discriminates effectively the quality and behavioral mechanisms of action

of several drugs with proaggressive and antiaggressive actions (13 ,15 ,43).

Benzodiazepines at low doses enhance aggression (14 ,44), whereas at higher doses they clearly cause ataxia, which interferes with the behavioral performance. Alcohol, as in mice, enhances aggression in some rats, but not in others (14 ,18). Interestingly, this increased aggression in a subpopulation of the resident males was observed both after experimenter-administered ethanol and after self-administered ethanol (18). Understanding the underlying neurochemical mechanisms responsible for the individual differences in behavioral response to ethanol in these two subpopulations of rats or mice should prove valuable for understanding the factors resulting in pathologic aggression in humans.

Neuroleptics, like psychostimulants, alter the display of agonistic behavior (15), although in different ways (25). Serenics display a highly specific antiaggressive profile. This effect is caused by the activation of postsynaptic 5-HT_{1B} receptors because ligands affecting other 5-HT receptors have quite different antiaggressive profiles.

The resident-intruder paradigm has also been used in hamsters to elucidate a novel neurochemical pathway involved in aggression. Hamsters, which are territorial, quickly attack intruders. The neuropeptide vasopressin has been shown to act in the preoptic area and anterior hypothalamus to stimulate both displays of dominance and aggression (45). Vasopressin receptor antagonists injected into this area are potent inhibitors of aggression. Fluoxetine, a selective serotonin uptake inhibitor, decreases offensive aggression in male hamsters and prevents vasopressin-induced aggression. This finding has led to the hypothesis that there is an interaction between vasopressinergic and serotonergic systems in the regulation of offensive aggression. Hamsters subjected to social subjugation as juveniles displayed elevated levels of aggression toward smaller hamsters as adults (46). As adults, these subjugated hamsters had altered levels of both vasopressin and serotonin in the anterior hypothalamus, a finding providing a potential mechanism by which environmental influences may permanently alter the neural circuits regulating aggression. Interestingly, elevated levels of vasopressin in the cerebrospinal fluid has been correlated with indices of aggression in personality-disordered patients (47). This model provides an example in which discovering the neural mechanisms underlying aggression could potentially lead to new targets of intervention for therapy in pathologic aggression.

The resident-intruder paradigm has a very good predictive validity toward human aggression. Both proaggressive (alcohol and benzodiazepines) and antiaggressive effects of

psychoactive drugs are highly similar in rodents and humans. Because of the species generality of this type of aggression, the model also has considerable face validity. Construct validity is as yet less clear, but the brain mechanisms involved, the hormonal sequelae, and the behavior-evoking stimuli support reasonable construct validity. As such, this paradigm seems an excellent choice in screening for potential antiaggressive compounds (serenics), but it also indicates other drug effects such as sedation and sensory and motor impairment (15).

Offensive Behavior after Electrical Brain Stimulation

Behavior largely similar to that of offensive territorial males can be elicited by electrical stimulation in the medial-lateral hypothalamus of male and female rats (48 ,49 and 50). Hypothalamic aggression in male rats is sensitive to manipulations of androgen levels (51), and it can be induced in an area (52) roughly coinciding with the areas where levels of circulating sex hormones are regulated. Moreover, stimulation of this area is accompanied by elevated levels of stress hormones (adrenocorticotropic hormone, corticosterone, and prolactin) resulting from activation of the area itself and not caused by the stress of fighting (53). In female rats, aggression can be elicited in this same area (54 ,55). This behavior is readily reproduced under controlled circumstances, thereby meeting an important requirement for a model to study aggression. The aggressive behavior induced by the stimulation can be explosive. Depending on the stimulus intensity, extreme forms of offensive attack and severe damage to the opponent can be observed (50). The attack behavior is not purely driven by internal stimulation of the hypothalamic substrate. The animal's response is still dependent on external cues such as the age and sex of the opponent. In addition to aggressive behavior, stimulation in this area of the hypothalamus also stimulates other behaviors, including locomotion and teeth chattering (54 ,56), thereby allowing for the determination of the specificity of the drug. In this paradigm, the effects of drugs are measured by the changes in the current thresholds required to evoke the respective behavior (56). Increases in the current thresholds for aggression indicate antiaggressive effects, considered specific if simultaneously the drug does not affect thresholds for locomotion. Several drugs have been analyzed in this model, including benzodiazepines, neuroleptics, psychostimulants, alcohol, 5-HT_{1A}-receptor agonists, serenics (5-$HT_{1A/1B}$-receptor agonists) and selective serotonin reuptake inhibitors (56 ,57 ,58 and 59).

Chlordiazepoxide, in contrast to its effects in the isolation-induced and resident-intruder paradigms, had no effect on aggression and teeth-chattering thresholds at lower doses and enhanced the thresholds for both aggression and locomotion only at high doses, presumably reflecting the muscle relaxant properties at these doses. Alcohol, up to a dose of 2 g/kg, had no effects on any parameter, a finding suggesting that the proaggressive actions of alcohol and also the benzodiazepines seen in the territorial and isolated male paradigms are probably related to variables (anxiety?) other than aggression *per se*.

Haloperidol enhanced aggression thresholds simultaneously with locomotion, again indicative of nonspecific effects on aggression. Because thresholds for teeth chatter, which accompanies normal aggression, were not affected, it was concluded that aggression was not at all influenced by haloperidol, in line with earlier findings that antiaggressive actions of neuroleptics result from their side effects (catalepsy). D-Amphetamine had no effect on aggression and teeth chattering, but it decreased the locomotor threshold, a finding illustrating its stimulatory action without having specific effects on aggression. Scopolamine, a (muscarinic) anticholinergic drug, had effects similar to those of D-amphetamine, again illustrating that activation of substrates for locomotor activity is independent from activation or inhibition of aggression substrates in the brain. Naloxone, an opiate antagonist, did not influence any aspect of the brain stimulation–induced behaviors, in line with its absence on spontaneous aggression (11 ,15). Manipulation of various serotonergic mechanisms showed that activation of the 5-HT_{1B} receptor, by eltoprazine, fluprazine, meta-chlorophenylpiperazine, DL-propranolol and other phenylpiperazines (25 ,26), induces a highly specific effect on aggression. Aggression and teeth-chattering thresholds were enhanced, although aggression still could be evoked, but locomotor activity was not affected or was even somewhat decreased. The profiles of drugs that modulate other serotonergic receptors, including 5-HT_{1A}, 5-HT_3, and the serotonin transporter, demonstrate the specificity of the 5-HT_{1B} receptor in aggression, a finding suggesting that the nonspecific effects of serotonergic drugs are mediated through other 5-HT-receptor mechanisms.

This hypothalamic-induced aggression model is highly relevant for modeling certain kinds of human aggression. By directly stimulating neural substrates in the brain involved in offensive aggression, this model has great potential to predict violent, pathologic aggression in humans. In contrast to the more natural models (isolation-induced, resident-intruder, maternal aggression), this model is not sensitive to certain intervening variables present in the other paradigms (anxiety, fear, sedation, and motor and sensory disturbances) and directly reflects antiaggressive properties of drugs. In addition, this model is not completely artificial or pathologic in the sense that attacking animals do not respond to nonsalient stimuli in preparation of or during the attack. For example, such animals do not attack rats that previously have defeated them or females in estrus. The predictive validity of this model seems to be somewhat less than the other models; nonetheless, the model is useful in determining how drugs bring about the antiaggressive effect.

Maternal Aggression

Although aggression is often considered a male-related phenomenon, females can be quite aggressive under certain conditions, such as in hypothalamically induced aggression in rats (54 ,55), aggression in nonestrus hamsters (58), and maternal aggression in several rodent species (59 ,60). The use of a female aggression paradigm to model human (female?) aggression has been quite uncommon, particularly for psychopharmacologic purposes. The maternal aggression model seems to constitute such a model because it shows very wide species generality, including humans (61), and it has clear neural and hormonal determinants. Maternal aggression is highly purposeful, providing protection to the offspring. The maternal aggression paradigm is based on the finding that a lactating female rat or mouse with pups will exhibit offensive behaviors toward a wide variety of intruders. This behavior is most pronounced during the first part of the lactating period (62 ,63). Because the critical stimulus is clearly the proximity of some threatening object to the female's young, some authors (2) consider this behavior mainly defensive. However, the behavior of the lactating female toward an intruder is clearly self-initiated, proactive, and not necessarily reactive to any threat initiated by the intruder. Although the paradigm is labor intensive and needs extensive planning, several psychoactive drugs have been tested in it and have led to a model with a comparable predictive validity as the male offensive paradigms in rats (resident-intruder) and mice (isolation-induced). The psychopharmacology of maternal aggression has been mainly studied in rats, although some work in mice has been performed (64).

Although the topography of the aggressive behavior of the attacking female is clearly different from male aggression (63), the effects of several classes of drugs were remarkably similar to those found in the male paradigms. Benzodiazepines and alcohol showed, at low doses, proaggressive effects, which faded at higher doses because of nonspecific effects (sedation, ataxia, and muscle relaxation). D-Amphetamine reduced aggression at higher doses, but this was clearly attributable to interfering effects of motor stimulation, whereas haloperidol inhibited aggression by its highly nonspecific side effects. Serenics (eltoprazine and related phenylpiperazines) have a highly selective effect in this paradigm, reducing aggression without affecting other behaviors, including pup care. The critical role of the $5\text{-}HT_{1B}$ receptor in this effect was again demonstrated by additional pharmacology showing that modulating other serotonergic receptors did not have such effects.

MODELS OF DEFENSIVE BEHAVIORS

Part of "118 - Animal Models of Aggression "

Those forms of agonistic behavior in which elements of initiative and approach prevail belong to the offensive repertoire, characterized by initiative, attack, and similar proactive behavior. This sharply contrasts with the defensive repertoire, which is characterized by submission, flight, and similar reactive behaviors. Fighting, when it occurs in a defensive animal, is merely a reaction to attack. Other defensive behaviors, such as flight or submission, are apparently intended to escape from or prevent further agonistic interactions (65 when it occurs in a defensive animal, is merely a reaction to attack. Other defensive behaviors, such as flight or submission, are apparently intended to escape from or prevent further agonistic interactions (65when it occurs in a defensive animal, is merely a reaction to attack. Other defensive behaviors, such as flight or submission, are apparently intended to escape from or prevent further agonistic interactions (65). Some of the drugs known to suppress offensive behaviors have highly undesirable effects on defensive behavior; for example, neuroleptics inhibit all activities including defensive and flight reactions.

Pain- or Shock-Induced Defensive Behavior

Delivering electric shock to the hind paws of a pair of rats or mice evokes so-called *foot shock*– or pain-induced aggression (66). Similar behavioral responses can be found when certain drugs (apomorphine, mescaline) are given to pairs of animals. Whereas either or both animals may attack, the behavior is conceived as defensive (5), in part because the animals mutually exhibit typical upright defensive postures and squealing and the behavior is clearly reactive; without switching on the current, no agonistic interactions will occur. Although this paradigm was extensively used in the past to assess antiaggressive activity of drugs, a confounding factor in the model is that the behavior-releasing factor (pain) can be masked by analgesic properties of drugs. This fact, together with the limited behavioral repertoire exhibited in this paradigm, limits its utility considerably.

A useful application of foot shock–induced defense behavior is to determine the ED_{50} to lower the amount of fighting episodes by 50% and concurrently to determine an ED_{50} for paralysis, the ability of mice, hanging by their forelimbs from a thin bar, to bring their hind limbs on to the bar within a certain time. Specificity of the antidefense effects is calculated as the ratio between these two ED_{50} values. A high ratio indicates good antidefense specificity; low values suggest strong interfering effects.

Neuroleptics show very low ratios (less than 1), tricyclic antidepressants have ratios of approximately 1, whereas benzodiazepines also have ratios less than 1 because of their muscle-relaxing effects (26 ,67). Serenics (eltoprazine, fluprazine, and others) appear highly selective; ratios of more than 20 (fluprazine) or, in the case of eltoprazine, not determinable have been found. Eltoprazine did, up to a very high dose, not inhibit this foot shock–induced behavior, thereby illustrating its highly selective antioffense character.

Defensive Behavior in Rats (Intruder Model)

A more natural model of defensive behavior is the behavior shown by an intruder in the resident-intruder or maternal aggression situation. Defending animals in these paradigms

use special tactics to protect the more vulnerable parts of their bodies. In unconstrained conditions, animals on the defense usually flee from the territory of the residential male or lactating female, but when this is impossible, as in laboratory conditions, they defend themselves by flight, crouching, upright defensive postures, emission of ultrasounds, and submissive postures. Generally, these behaviors aim at protecting the back, the area where most wounds are inflicted by attacking rats (68).

Although this model involves at least two animals, the offender and the defender, it provides an opportunity for various drug manipulations and to study direct and indirect drug effects (69). Drugging the offender and changing its offensive behavior have clear effects on the behavior of the intruder (26 ,70). The quality of the intruder (i.e., age and size) also determines the behavioral outcome, and interactions between drug effects and the intruder quality have been observed for D-amphetamine and chlordiazepoxide (44 ,70). This finding illustrates the construct and face validity of this model because it has high resemblances to the human (psychiatric) situation.

This model has been of limited use in psychopharmacology mainly because of the complexity in interpreting the interaction between drug effect and intruder quality. However, using standardized circumstances in which the intruder is basically not threatening the role of the resident, that is, by using young or inexperienced inexperienced intruders, the direct effects of drugs on the behavior of the intruder can be studied. It appears that influencing the sensory or motor capabilities of the intruder (by neuroleptics, alcohol, benzodiazepines, or psychostimulants) leads to changes in the defense or flight responses of the animals indicating enhanced flight (D-amphetamine) or impaired defense or flight (haloperidol). This may lead to enhanced attacks on the intruder in the case of D-amphetamine or diminished interest in the intruder by the resident in the case of neuroleptics (26). Serenics do not affect the defense or flight capabilities of the intruders (26), an effect in line with their specific antioffense qualities.

The resident-intruder model is a unique animal model for different aspects of social interactions and provides an opportunity to determine not only what drugs are doing directly to an organism, but also the indirect effects on the partner. Human pathologic aggression is often associated with complex interpersonal interactions, and the resident-intruder interaction model may be particularly relevant to predict what drugs may do in humans in particular circumstances.

MISCELLANEOUS MODELS

Part of "118 - Animal Models of Aggression "

Predatory aggression, such as mouse killing (muricide) in rats or locust killing (insecticide) in mice, occurs spontaneously in a proportion of individuals, depending on the strain used (71). There has been a great deal of dispute about the nature of muricide in rats, resulting in various descriptions of the behavior including, interspecies aggression (72), predatory aggression (73), or simply predatory behavior (74). This model is clearly different from those described earlier, and its human equivalent is questionable, although predatory aggression has been described in relation to pathologic aggression in humans. Predatory attack clearly differs from intraspecies attack with regard to neuroanatomic, physiologic, and hormonal mechanisms (75), but the pharmacology is less developed. The model is rarely used anymore because of several ethical constraints, and therefore most data are from before the 1990s (26). Benzodiazepines and alcohol, unless given at extremely high doses, do not inhibit muricide. Neuroleptics and psychostimulants do inhibit muricide but clearly not in a very specific way (cataleptic, motor stimulation). Antidepressants (tricyclics and selective serotonin reuptake inhibitors) inhibit muricide in a quite specific way, and in the 1950s up until the 1970s, the muricide test was in use in the pharmaceutical drug discovery process as an antidepressant screen. 5-HT_{1A}-receptor agonists do not inhibit muricide, whereas 5-HT_{1B}-receptor agonists (serenics) inhibit it, but only at much higher doses than the antioffense effects. Therefore, this model is not believed to have potential qualities to predict certain human pathologic aggression situations.

DISCUSSION

Part of "118 - Animal Models of Aggression "

The present contribution has suggested a limited number of animal models for different forms of aggression, namely, offensive aggression, defensive aggression, and predatory aggression. This is absolutely not an exhaustive coverage of the field and shows a logical way to frame the existing animal tests and paradigms into meaningful categories especially for predicting the effects of psychoactive drugs for human pathologic conditions. This approach led to the development in the 1970s and 1980s of a group of serotonergic agonists, serenics, as potential antiaggressive agents to treat certain types of human pathologic aggression (26 ,76).

Moreover, the animal models outlined appeared to have predictable validity and enable us to predict putative outcomes when applied in humans. Good examples are the benzodiazepines, with which, at low doses, aggression-enhancing effects were often found that corresponded to the so-called “paradoxic” aggression seen after human use (22 ,23). The antiaggressive effects of neuroleptics, often clinically used as first treatment in emergencies, are not specific at all but result from interference with vital functions (cognition, motor, sensory). Antiaggressive effects can be the result of many (side) effects of drugs, and the proposed animal models are capable of detecting and describing these effects. Consequently, they have a high predictable validity

toward their effects in humans, although it is very difficult to predict for which human disorder or symptom (77).

One of the biggest obstacles in the study of the psychopharmacology of aggression and the predictability for the human situation is the lack of consensus on definitions. The only primary aggression disorder in DSM-IV is intermittent explosive disorder, but all other aggression and impulsivity occurring in various disorders are considered as symptoms of different underlying disorders; this situation makes it extremely difficult to compare human with animal aggression directly. From the animal research, the evidence is very strong that there are specific neural substrates in the brain subserving these different functions in agonistic behavior, and it is more than likely that similar mechanisms are available in the human brain (78 ,79). The fundamental research in animals suggests that serotonin, actually only a subset of the system, such as the postsynaptic 5-HT_{1B} receptor (80), is an important neurotransmitter in at least part of this brain circuitry. Genetic modification of this system (5-HT_{1B}-receptor knockout mouse) has added considerable evidence for the importance of this system, although it is clear that the latter is only a small part of a much bigger and very complex circuitry in the brain involved in agonistic behavior.

Preclinical aggression research is under considerable pressure because of ethical and societal constraints on doing “biologically” oriented research in understanding the neurobiology of aggression and possible disturbances of the systems involved in the case of pathologic aggression (81). However, further research, using animal models of aggression, is needed to discover new treatments for pathologic aggression and violence. Analysis of the behavioral profiles of genetically altered mice with targeted gene deletions holds great promise over the next decade for discovering novel neurochemical pathways in the brain involved in the control of aggression. New developments in the molecular biology area, generating inducible, and brain region–specific mutants will engender exciting tools to study the role of genes, environment, and their interaction in the causation of aggression, and important new clues for the study and treatment of pathologic aggression in humans will emerge.

Pathophysiology and Treatment of Aggression

Emil F. Coccaro

Larry J. Siever

Emil F. Coccaro: Department of Psychiatry, University of Chicago, Pritzker School of Medicine, Chicago, Illinois.

Larry J. Siever: Psychiatry Service, Bronx Veterans Affairs Medical Center, Bronx, New York.

Human aggression constitutes a multidetermined act that often results in physical (or verbal) injury to others or self (or objects). It appears in several forms and may be defensive, premeditated (e.g., “predatory”), or impulsive (e.g., “nonpremeditated”). *Defensive aggression* is generally seen within the normal range of human behavior. However, *premeditated and impulsive aggressive behaviors* are commonly viewed as pathologic.

Aggression may be measured as both a dimensional and a categoric variable. However, whereas aggressive behavior (or the tendency to behave aggressively) is truly dimensional, it is difficult to estimate the societal relevance of aggressive behavior using dimensional assessments. As a categoric variable, aggressive subjects (“cases”) may be counted in populations of interest. For example, the current age-adjusted rate for homicide in the United States is 0.01% (1). With respect to physical assault, approximately one-fourth of all men and approximately half as many women report a history of physical fighting after 18 years of age (2). From these figures, it may be estimated that approximately 35 million adults in the United States have engaged in at least one *serious* act of aggression. The rate of individuals demonstrating “recurrent, problematic, aggression” is lower, of course. Using DSM-IV intermittent explosive disorder (IED) as a proxy for “recurrent, problematic, aggression,” Zimmerman et al. reported that nearly 7% of psychiatric outpatients meet criteria for IED at any point in their lives (3). Including borderline and antisocial personality-disordered patients, who are also quite aggressive, increases this number to about 13% of psychiatric outpatients. Regardless, these data suggest that the lifetime prevalence of recurrent, problematic, aggressive behavior may be 1% or higher (at least 2.5 million) in the general community (4).

Research into the etiologic determinants of both premeditated and impulsive human aggression has focused on various genetic, biological, and psychosocial factors and reveals a rich and complex picture of human aggression involving both constitutional and nonconstitutional elements. Twin, adoption, and family studies all suggest a genetic influence underlying aggression (5), with heritability estimates for dimensional measures of aggression ranging from 44% to 72% in adults. A metaanalysis of more than 20 twin studies confirmed a substantial role for a genetic influence underlying aggression (6). Although behavioral genetic studies to date have not attempted to distinguish among aggression subtypes, impulsive aggression appears to be quite distinct from premeditated aggression. Overall, the recurring theme emerging from more than 20 years of empiric research is that “impulsive aggression” demonstrates the most consistent and noteworthy findings with respect to both biological correlates (7 ,8) and psychopharmacologic treatment (9 ,10). Biological factors include a variety of neurotransmitter and neuromodulator systems. Most data involve the central serotonin (5-hydroxytryptamine or 5-HT) system, although limited data is now emerging for a role for other central systems involving catecholamines, steroids, neuropeptides, and cholesterol and fatty acids. This chapter reviews the neuropsychopharmacologic data relevant to these systems and concludes with a discussion of the psychopharmacology of aggression.

NEUROPSYCHOPHARMACOLOGY OF AGGRESSION

Part of "119 - Pathophysiology and Treatment of Aggression "

Serotonin

The hypothesis that 5-HT modulates impulsive aggressive behavior in humans was first advanced in the same year by both Sheard et al. (9) and Asberg et al. (11). The former group demonstrated that treatment with lithium carbonate (an agent with putative 5-HT–enhancing properties), but not placebo, reduced impulsive aggressive behavior in prison inmates; the latter group demonstrated that violent (and

eventually lethal) suicidal behavior was a characteristic of patients with low lumbar cerebrospinal fluid (CSF) concentrations of 5-hydroxyindolacetic acid (5-HIAA). This work led to a large number of subsequent studies, using a variety of 5-HT measures, designed to test the 5-HT hypothesis of aggression further.

5-HT and Aggression: CSF 5-HIAA Studies

Brown et al. first reported a strong inverse correlation between CSF 5-HIAA and a life history of aggression (r = -.78) in male personality-disordered adults (12). This finding was replicated in a follow-up study using another variable reflective of aggression (i.e., "psychopathic deviance," defined as defiance of authority and impulsivity) (13). In both samples, a trivariate relationship between reduced CSF 5-HIAA and aggression and suicidal behavior was demonstrated. Later reports demonstrated that reduced CSF 5-HIAA was specific to impulsive rather than premeditated (i.e., nonimpulsive) aggression (7 ,14). Linnoila et al. first demonstrated that CSF 5-HIAA among violent offenders whose index crime was classified as "impulsive" (i.e., no apparent plan) were significantly lower than those among violent offenders whose index crime was classified as "nonimpulsive" (i.e., knew the victim and planned the crime) (7). The hypothesis that "impulsiveness" is the key behavioral correlate of reduced 5-HT activity was later advanced in a series of studies from Virkkunen et al. (8 ,15 ,16). In these studies, CSF 5-HIAA concentrations of "impulsive" arsonists were reduced to the same degree as in "impulsive violent offenders" and were significantly lower than those observed in healthy volunteers. Because both impulsive arsonists and impulsive violent offenders had (theoretically) "impulsivity" in common, these investigators proposed that the key correlate to reduced CSF 5-HIAA was impulsivity as opposed to aggression. Closer inspection of the data reveals, however, that impulsive "arsonists" and impulsive "violent offenders" also shared a general history of impulsive aggression (e.g., similar rates of IED and suicide attempts), and, accordingly, it may be premature to conclude that the key behavioral correlate of reduced central 5-HT function is impulsivity rather than a combined construct of impulsive aggression. An inverse relationship between CSF 5-HIAA and aggression or impulsivity has also been reported in male patients with alcoholism (17), in behaviorally disruptive male children and adolescents (18), and in rhesus (19) and pigtailed macaques (20).

Despite these data, some studies have not replicated the finding of an inverse relationship between CSF 5-HIAA and aggression (21 ,22 ,23 ,24 and 25). The reason probably is the presence of subjects who are less severe in their aggressive behavior. Because the relationship between CSF 5-HIAA and aggression appears to be direct (rather than inverse) in several of these studies, it is possible that the direction, as well as the magnitude (17), of this relationship is a function of the severity of aggression. A direct relationship between lumbar CSF 5-HIAA concentration and aggression in these subjects suggests that aggressiveness may be associated with increased (rather than decreased) intrasynaptic concentrations of 5-HT. These data could be consistent with a deficiency hypothesis of 5-HT for aggression if postsynaptic 5-HT function is reduced by compensation. If postsynaptic 5-HT function is unchanged (or increased), however, these data would suggest increased "net" 5-HT function in these subjects. Evidence examining these hypotheses is discussed in the following sections.

5-HT and Aggression: Pharmacochallenge Studies

Coccaro et al. first reported a blunted prolactin D,L-fenfluramine (PRL[D,L-FEN]) response in drug-free mood-disordered and personality-disordered patients compared with healthy volunteers (24 ,26 ,27). In addition, patient subjects with a history of a suicide attempt displayed blunted PRL[D,L-FEN] responses compared with those without this history. Personality-disordered, but not mood-disordered, patients also displayed an inverse relationship between various measures of impulsive aggression (but not depression) and PRL[D,L-FEN] responses. Because experimental reduction in norepinephrine (NE) activity has been shown to eliminate the expected aggressive behavior of animals with reduced 5-HT (28), a reduction in NE system function in the mood-disordered (29), but not the personality-disordered (30), subjects could have mitigated the influence reduced 5-HT function could be expected to have on the expression of aggressive behavior. For the depressed patient, reduced NE system function may be associated with a reduction in efficiency to attend to novel (e.g., aversive) stimuli. If so, only the most potent stimuli (e.g., suicidal ideation) would be likely to trigger a behavioral action that could be poorly inhibited by a dysfunctional central 5-HT system. Further study noted that PRL[D,L-FEN] responses were inversely related to CSF 5-HIAA and were directly related to PRL[meta-chlorophenylpiperazine or m-CPP] responses, an index of postsynaptic receptor activation (25). When these 5-HT measures were examined in the same personality-disordered subjects, a relationship between 5-HT and aggression was noted for both PRL[D,L-FEN] and PRL[m-CPP] responses (which were also directly correlated) but not for CSF 5-HIAA, a finding suggesting that the 5-HT–aggression relationship, as detected by PRL[D, L-FEN] response, may be caused by a reduction in the sensitivity of the postsynaptic 5-HT receptor. Available data suggest that PRL responses to FEN reflect the activation of central 5-HT_{2C}, but not 5-HT_{1A} or 5-HT_{3}, receptors (27 ,31 ,32); other 5-HT receptors have not been studied in this regard. 5-HT_{1A} receptors may still play a role in human aggression as evidenced by inverse relationships noted between

aggression and physiologic responses to buspirone (33 ,34) and ipsapirone (35 ,36) challenge.

Support for these pharmacochallenge findings has been reported in patients with personality disorders (37), patients with alcoholism (38 ,39), suicidal patients (40), violent offenders (41), healthy volunteers from the community (42), and macaques (43). Nonreplication studies involve subjects with history of primarily nonalcoholic substance abuse (44 ,45) and children with disruptive behavior disorders (46 ,47), in whom positive correlations between D,L-FEN challenge and aggression variables have been reported in several, although not all, studies (48 ,49 and 50). In substance abusers, it is possible that nonalcoholic drugs of abuse modify the neurobiological substrate of subjects so correlations between 5-HT and measures of impulsive aggression are direct rather than inverse, as are seen in patients with alcoholism (38 ,39). In children, two studies reported a positive correlation between aggression and PRL[D,L-FEN] response (46 ,47), and one reported a negative correlation between aggression and thermal [D,L-FEN] responses (50). In adolescents or older children, two studies reported no correlation between PRL[D,L-FEN] and aggression (48 ,49). It is possible that changes in the 5-HT system occurring over development affect the nature of the 5-HT–aggression relationship in that this relationship is positive in some 5-HT–mediated pathways, such as the PRL[D,L-FEN] response, in prepubertal children, is absent in postpubertal children, and is inverse in adults. The neurobiological mechanisms underlying this hypothesis are unknown, although, in animal models, the overexpression of 5-HT early in development has been shown to lead to the down-regulation of the 5-HT system later in life (52).

5-HT and Aggression: Peripheral Marker Studies

Studies examining 5-HT–aggression relationships using peripheral indices of 5-HT are relatively limited. The platelet 5-HT transporter (or 5-HT uptake activity) has been assessed in regard to aggression in children, adolescents, and adults and is the one peripheral 5-HT measure to demonstrate some consistency across studies. Positive findings in children and adolescents include the studies of Stoff et al. (53) and Birmaher et al. (54), in which platelet ^{3}H-imipramine (B_{max}) binding was lower in aggressive subjects. In adult subjects, three of four studies reported inverse relationships between platelet 5-HT transporter binding and aggression or impulsivity in personality-disordered subjects (55 ,56) and aggressive institutionalized adults (57); the fourth study reported an increase in platelet 5-HT transporter binding in criminal offenders when compared with normal control subjects (58). Two studies examined the function of the platelet 5-HT transporter, with one demonstrating a reduction of platelet 5-HT uptake in aggressive adult subjects and an inverse relationship with impulsivity (59), and a second study demonstrating no differences in platelet 5-HT uptake in boys with and without disruptive behavior disorders in a study in which no difference was found in the number of platelet ^{3}H-imipramine binding sites between these two groups of subjects (60). Studies examining the platelet 5-HT_{2A} receptor in aggression are few, and results are mixed, with one study reporting no relationship (61), another reporting a negative relationship (62), and yet another reporting a positive relationship (63) between this 5-HT receptor and aggression.

Published studies of blood and platelet 5-HT and plasma tryptophan in humans are relatively few and inconsistent in their results. Whole-blood 5-HT concentrations have been reported as elevated in juvenile offenders compared with normal control subjects (64) and as a function of age of onset (65). A positive correlation between platelet 5-HT concentration and measures of aggression in adult depressed patients (66) has also been reported. Negative studies, however, include those performed in mentally retarded adults (67) and in children with attention-deficit/hyperactivity disorder (68). The ratio of plasma tryptophan to other competing neutral amino acids was lowest among patients with alcoholism with a history of depression or aggression and was lowest among those patients with alcoholism with a history of both depression and aggression in two studies (69 ,70). Other studies reported elevated levels of plasma tryptophan (or the tryptophan ratio to neutral amino acids) in violent offenders (71 ,72) or positive correlations with aggression in healthy volunteers (73).

5-HT and Aggression: Behavioral Studies

Behavioral measures of aggression have been available for many years and include paradigms in which subjects are instructed to deliver a noxious stimulus (e.g., electric shock or loud noise; Taylor Aggression Paradigm) (74) to, or to take monetary points away from (Point Subtraction Aggression Paradigm or PSAP) (75), “confederate” subjects under specific social conditions. In these paradigms, the amount of the noxious stimuli delivered to (or points subtracted from) the confederate represents the subject’s tendency to behave aggressively. In a study of 14 male personality-disordered subjects (56), both the PSAP and a life history measure of aggression correlated inversely with PRL[$_{d}$-FEN] responses. Another study reported a similar finding with respect to 5-HT_{1A} receptor function (36). In this study, high PSAP (“high aggressive”) responders had blunted thermal responses to ipsapirone challenge compared with low PSAP (“low aggressive”) responders.

Experimental studies in which 5-HT activity is manipulated and aggressive responding is monitored have been conducted in research volunteers without documented psychopathology. Four studies in which brain 5-HT was putatively manipulated by tryptophan depletion, supplementation, or both (76 ,77 ,78 and 79) reported data consistent with an inverse relationship between 5-HT activity and aggressive responding

in the laboratory, although one suggested that this effect is restricted to a subgroup of aggressive subjects (79). The one negative study in this area did not use a laboratory paradigm in which provoked aggression could be assessed (80). Studies in which 5-HT activity was acutely increased by using either single doses of D,L-FEN or of the 5-$HT_{1A/1B}$ agonist eltoprazine (34 ,81) reported a reduction in aggressive responding on behavioral paradigms. For D,L-FEN, but not eltoprazine, this result was specific to aggressive responding (as opposed to both aggressive and nonaggressive responding in the case of eltoprazine). These data are consistent with clinical trial data using 5-HT enhancing agents, discussed later (82).

Catecholamines

Based on animal studies, increased noradrenergic (NE) and dopaminergic (DA) activity could be hypothesized to facilitate aggressive responding in humans (83 ,84). Brown et al. reported a positive correlation between CSF methoxyhydroxyphenylglycol (MHPG), but not CSF homovanillic acid (HVA), concentrations and life history of aggression (12). Further analysis revealed, however, that CSF 5-HIAA accounted for 80% of the variance in aggression scores. Plasma NE was modestly, but positively, correlated with self-reported impulsivity in male personality-disordered subjects in another study (85). However, significant reductions in CSF MHPG in impulsive violent offenders was reported in one study (15), although not in a later study by the same investigators with a much larger sample (8). NE pharmacologic challenge studies in this area have been limited and include a positive correlation between the growth hormone response to the α_2-NE agonist clonidine and self-reported “irritability” (a correlate of aggression) in a small sample of male personality-disordered and healthy volunteer subjects (30). A role of α_2-NE receptors in aggression has been suggested by animal data in which the intrahypothalamic injection of α_2-NE agents enhances aggressive responding in the cat (86). The authors suggested that one putative mechanism underlying this finding could involve stimulation of α_2-heteroceptors on presynaptic 5-HT neurons thereby inhibiting 5-HT outflow.

Support for a DA hypothesis of human aggression is also limited. Although some studies reported no relationship between CSF HVA and aggression (12 ,15), other studies suggested the presence of an inverse relationship between these variables. A reduction in CSF HVA in antisocial, though not “explosive,” impulsive violent offenders was reported in one study (7). A reduction in CSF HVA has also been reported among recidivist violent offenders in comparison with nonrecidivist violent offender controls (16), a finding suggesting that reduced dopaminergic function plays a role in predicting future aggressive behavior. These findings must be taken with caution, however, because an inverse relationship between CSF 5-HIAA and aggression was also present in each of these studies. Because CSF 5-HIAA may “drive” CSF HVA (87), it is possible that these findings are related to a more primary relationship between CSF 5-HIAA and aggression. Conversely, an imaging study of striatal dopamine transporters in human subjects reported greater heterogeneity in these receptors in impulsive violent offenders compared with control subjects (88), a finding suggesting that a reduction in CSF HVA may not be secondary to alterations in 5-HT function.

Neurosteriods

Testosterone

Testosterone and related androgens generally play a facilitative role in aggressive behaviors (see refs. 89 and 90 for review). Positive correlations between plasma testosterone concentrations and measures of aggression have been reported, although not entirely consistently in nonpsychiatric subjects (see refs. 89 and 91 for review). Correlations have also been reported in volunteers between reports of relatives and spouses of their global aggressive behavior and both testosterone and NE (92), and basal testosterone levels have been reported to be higher in subjects with high-normal than those with low-normal aggressiveness (93).

Plasma testosterone levels have also been reported to be higher in psychiatric and criminal populations characterized by high aggression. For example, male criminals with personality disorders had significantly higher levels of circulating testosterone than criminal patients with schizophrenia (94), and high free testosterone concentrations were associated with increased aggression in Finnish violent offenders with alcoholism (8). Plasma concentrations of testosterone appear to be higher in persons with alcoholism with a history of repeated episodes of domestic violence than in comparison groups (95). In criminal offenders, higher CSF testosterone concentrations were found in antisocial impulsive violent offenders, but they were not found in nonantisocial impulsive or nonimpulsive violent offenders, in comparison with a healthy volunteer control group.

There are some reports from in prospective, blinded studies suggesting that administration of exogenous testosterone may result in aggressive behaviors (96), but the percentage experiencing severe mental disturbances is likely to be small (97 ,98 and 99). Anabolic steroid administration may not be uncommon among prisoners (100), and it may induce abnormal personality traits in body builders (101). Naturalistic studies of testosterone concentrations are limited in their interpretation because of the pulsatile nature of testosterone release, so particularly plasma concentrations may be quite variable, whereas CSF may be more reflective of average values. Studies of exogenous steroid administration are complicated by, in most cases, the uncontrolled nature of this steroid use.

Cortisol

In general, cortisol concentrations are reported to be relatively low in aggressive individuals. This finding is consistent with the negative correlation between cortisol and testosterone concentrations (102) in volunteer subjects under controlled conditions. Correlations have been found among plasma PRL, testosterone, and aggression, but not with cortisol, although cortisol and PRL concentrations were correlated with each other in their day-to-day changes in one study (103). In children, increases in cortisol during the day were correlated with increased aggression (104). A low concentration of salivary cortisol was associated with persistent aggression in boys referred because of disruptive behavior (105). In criminal offender or antisocial populations, reduced urinary-free cortisol and CSF adrenocorticotropic hormone (ACTH) concentrations are found compared with healthy volunteers (8). Plasma cortisol has also been reported to be reduced in persons with alcoholism and a history of repeated domestic violence (95) but increased after cessation of drinking in incarcerated persons with alcoholism (106). However, the data in both animals and man are inconsistent because a positive correlation has been observed between plasma ACTH and aggression in nonhuman primates (19), and cortisol rises during competition for dominance in vervet monkey males (107). The relationship between cortisol and aggression is thus likely to be complex and dependent on social context and stress.

Neuropeptides

Among peptides neurotransmitters and modulators, limited data suggest a positive relationship between aggression and central vasopressin and central opioid activity.

Vasopressin

Whereas Virkkunen et al. reported no difference in CSF vasopressin concentrations among impulsive and nonimpulsive violent offenders (8), Coccaro et al. reported a positive correlation between CSF vasopressin concentration and life history of aggression in 26 personality-disordered persons, particularly men (108). Despite a significant inverse correlation between CSF vasopressin and PRL[$_d$-FEN] response, the positive relationship between aggression and CSF vasopressin remained even after the influence of PRL[$_d$-FEN] response on the aggression score was taken into account. These data are consistent with those from animal studies in which vasopressin antagonists reduced aggression in golden hamsters, whereas 5-HT uptake inhibitors increased central 5-HT activity and reduced central vasopressin concentration and levels of aggressive behavior in the same species (109). Differences between the two human studies may be accounted for by significant differences in the sample population (e.g., criminally versus noncriminally violent subjects). It is possible that agents that dampen central vasopressinergic activity could have antiaggressive efficacy.

Opiates

Although opiate withdrawal may precipitate aggressive behavior, there has been little study of the relationship of aggression with endogenous opiates. In one study, a CSF opioid-binding protein was positively correlated with “assaultiveness” in healthy male volunteers (110). Circulating levels of metenkephalins have been associated with self-injurious behaviors in a limited number of studies (111). Postmortem brain studies of violent suicide victims have also found greater numbers of μ-opioid receptors as well (112). Male undergraduates receiving 45 mg of oral morphine tablets or placebo displayed more aggression in the morphine-induced than the placebo conditions (113), whereas naltrexone, an opiate blocker, attenuated self-injurious behavior (114). These studies suggested that increased opioid activity may increase the likelihood of aggressive behavior.

Cholesterol and Fatty Acids

Some studies, both from persons who attempted suicide and from healthy persons, suggested that reduced serum cholesterol may be associated with aggressive behavior (115 ,116). Male monkeys randomized to a low-fat and low-cholesterol diet displayed more aggressive behavior and less prosocial behaviors than those randomized to a high-cholesterol diet (117 ,118). In humans, pharmacologic reduction of cholesterol may increase the risk of non–illness-related mortality such as death by suicide or trauma related to aggression (119). Naturally occurring reduced cholesterol may also be associated with non–illness-related mortality (116 ,120 ,121 ,122 and 123), largely attributable to suicide (116 ,122). Low serum cholesterol has been reported in psychiatric inpatients associated with suicide attempts (124 ,125 ,126 and 127). Reduced serum cholesterol has also been related to the severity of borderline personality disorder traits (115), as well as to antisocial personality disorder and the violence associated with it (128 ,129). It is also found in male forensic patients (130), aggressive conduct-disordered children and adolescents with attention deficit disorder (131), and suicidal adolescents (132).

MOLECULAR GENETICS

Part of "119 - Pathophysiology and Treatment of Aggression "

An understanding of the molecular genetics of impulsive aggression is currently emerging with the rise of association studies involving various DNA polymorphisms of candidate genes. One of the first notable studies in this area was that of Brunner et al. (133), who reported an association between a point mutation for the monoamine oxidase A (MAO A)

gene in an extended family pedigree and impulsive violence in males of low intelligence. The presence of this mutation was associated with evidence of altered catecholamine metabolism (i.e., reduced brain catecholamine breakdown and increased activity at central catecholamine receptors). Although no other families with this specific MAO A point mutation have been reported, this report highlighted the potential of the candidate gene approach to the molecular genetics of aggression. At about the same time, Nielson et al. reported that the presence of the L allele for the (intronic) biallelic tryptophan hydroxylase (TPH) polymorphism was associated with a reduction of CSF 5-HIAA concentration in impulsive violent offenders (nearly all with DSM-III IED) (134). In the same study, the presence of the L allele was also associated with history of suicide attempts in all violent offenders. Although this finding was not replicated by Abbar et al. (135), using a different TPH polymorphism, Nielson et al. did replicate this finding in a second group of violent offenders (136), specifically in impulsive violent offenders and more specifically for severe suicide attempts. Linkage for this TPH polymorphism was also noted in a sib-pair analysis in this same report. New et al. reported a linear association between the TPH genotypes and dimensional measures of impulsive aggression (137). In this brief report of only 21 personality-disordered subjects, those with the LL genotype had significantly higher aggression scores than subjects with the UU genotype. However, an association with the U allele of the TPH polymorphism in patients with a history of suicide attempts has also been reported (138), as has an association with the U allele and aggression scores in community-recruited healthy volunteers (139). It may be that the TPH polymorphism is in linkage disequilibrium with different genes in different populations. Lappalainen et al. reported an association between “antisocial alcoholism” (i.e., alcoholism with antisocial personality disorder or DSM-III IED) and the C allele biallelic polymorphism for the 5-$HT_{1D\beta}$ receptor (140). A study of a 5-HT_6 receptor allelic variant in patients with schizophrenia and in controls was negative for an association with aggressive behavior (141). Finally, Lachman et al. (142) reported replication of a report by Strous et al. (143) of an association between the “low activity” allele of a biallelic polymorphism for catechol-O-methyltransferase (an enzyme that degrades NE) and violence in patients with schizophrenia.

NEUROPSYCHOLOGY OF AGGRESSION

Part of "119 - Pathophysiology and Treatment of Aggression "

The relationship between aggression and neuropsychology is in part dependent on the syndrome in which aggression is observed. For example, the cognitive impairment of dementia may be associated with aggressive behavior. In adolescents with conduct disorder, verbal processing deficits are associated with greater aggressiveness and antisocial behavior (144). Low executive cognitive function is also related to aggressive antisocial behavior (145 ,146). Low executive function also contributed to failures to inhibit responses to stimuli associated with punishment on a “go/no-go” learning task, and poor “self-awareness” possibly related to right cerebral dysfunction has also been related to increased hostility. Verbal signal decoding and P300 amplitudes in an evoked potential paradigm predicted impulsiveness and anger in prison inmates (147). In terms of regional localization, neuropsychological tasks sensitive to frontal and temporal dysfunction have best characterized aggressive antisocial subjects (148 ,149). Thus, neuropsychological and cognitive studies do suggest that abnormalities of higher integrative functions, consistent with reduced cortical inhibitory influences on aggression, result in more disinhibition of aggressive behaviors. As described earlier, certain laboratory paradigms may discriminate aggressive individuals from comparison groups including the PSAP (150) and a “go/no go” version of the Continuous Performance Task (151). The PSAP has been externally validated in violent and nonviolent male parolees, in that violent parolees emit more aggressive responses than nonviolent parolees; furthermore, the number of aggressive responses correlated with other psychometric measures of aggression (76). However, the heritability of these laboratory measures has not been systematically assessed in studies of families or sibs of impulsive or aggressive probands, a logical prerequisite to an endophenotypic approach to borderline personality disorder.

NEUROIMAGING OF AGGRESSION

Part of "119 - Pathophysiology and Treatment of Aggression "

Neuroanatomy of Aggression

Prefrontal cortex, particularly prefrontal orbital cortex and adjacent ventral medial cortex, appears to play a central role in the regulation of aggressive behavior, but temporal cortex, cingulate cortex, and amygdala may also play important roles in the generation of aggression as well. The critical role of prefrontal orbital cortex is exemplified by the case of Phineas Gage, a solid, upstanding railroad worker, who, after a penetrating injury to his orbital frontal cortex, became irritable, hostile, and displayed poor social judgment. Careful reexamination of his skull led to a reconstruction of the location of the lesion at the anterior and mesial aspects of the orbital cortex as well as anterior cingulate and anterior mesial aspects of frontal cortex superior to orbital cortex, with more marked damage in the left hemisphere (152). Other clinical cases support the central role of orbital prefrontal cortex in regulation of aggression (153 ,154 ,155 ,156 and 157). Irritability and angry outbursts have also been associated with damaged orbital frontal cortex in neurologic patients (158), and frontal and temporal hypoperfusion has been noted in frontotemporal dementias (159). Lesions of prefrontal cortex, particularly orbital frontal cortex, early in childhood can result in antisocial disinhibited, aggressive behavior later in life (160).

Temporal lobe lesions have also been associated with a susceptibility to violent behavior, as suggested by multiple case reports of patients with temporal lobe tumors. In one study of violent patients, many anterior inferior temporal lobe tumors were reported (161 ,162), and aggressive behavior has been associated with temporal lesions (163). Although temporal disease may express itself in a variety of ways, there does appear to be a clear association between temporal pathology and aggressive behavior.

The amygdala is also implicated in the regulation of aggression both in electrical stimulation studies, associated with rage attacks, and studies of patients who have undergone amygdalectomy (164), although destructive behaviors have also been observed in the context of coagulation of the amygdala (165). Patients with bilateral amygdala damage judged unfamiliar persons to be more trustworthy than controls, a finding consonant with the role of the amygdala in social judgments of potential threat (166).

The association of violent behavior with aggressive behavior with localized seizure activity provides a further guide to brain regions implicated in the modulation of aggression. Aggressive behavior has been found to be associated with frontal lobe seizure activity (167 ,168) and temporal lobe seizures (169). However, only a few patients with temporal lobe epilepsy engage in aggressive behaviors in the interictal or periictal periods (170 ,171 and 172). These clinical correlations, although pointing to regions of interest for imaging studies, cannot directly address the circuitry involved in impulsive aggression in the absence of specific neurologic disease. These data do support the importance of prefrontal, temporal, and limbic cortex in the regulation of aggression.

Structural Imaging and Aggression

Reduced prefrontal gray matter has been associated with autonomic deficits in patients with antisocial personality disorders characterized by aggressive behaviors (173). Although these deficits are not visually perceptible, they reach statistical significance and are consistent with the neurologic literature (described earlier) and functional imaging data (described in the next section).

Functional Imaging and Aggression

One technique used to identify brain activity in individuals displaying aggressive behavior is the assessment of *in vivo* cerebral glucose metabolism through positron emission tomography. Studies of this type tend to implicate brain hypometabolism in a variety of regions but particularly frontal and temporal cortex. In psychiatric patients with a history of repetitive violent behavior, decreased blood flow consistently has been found in temporal cortex and, to some extent, in frontal cortex (174 ,175). In a study of homicide offenders, bilateral diminution of glucose metabolism was observed in both medial frontal cortex and at a trend level in orbital frontal cortex (176). These deficits were more pronounced in persons without psychosocial deprivation (177). In a study of patients with personality disorders, an inverse relationship was found between life history of aggressive impulsive behavior and regional glucose metabolism in orbital frontal cortex and right temporal lobe. Patients meeting criteria for borderline personality disorder had decreased metabolism in frontal regions corresponding to Brodmann's areas 46 and 6 and increased metabolism in superior and inferior frontal gyrus (Brodmann's areas 9 and 45) (178). Single photon emission computed tomography studies have also suggested reduced perfusion in prefrontal cortex, as well as focal abnormalities in left temporal lobe and increased activity in anteromedial frontal cortex in limbic system in aggressive persons with reduced prefrontal perfusion in antisocial personality-disordered alcoholism (179), and hypoperfusion in the left frontoparietal region associated with attacks of bizarre, impulsive behaviors (180). Cingulate cortex has also been implicated especially in posterior regions in aggressive borderline patients (178), a finding consistent with the putative role of cingulate cortex in the control of affective evaluation of incoming stimuli (134).

Extensive connections between amygdala and prefrontal cortex have been described, suggesting an inhibitory influence of frontal cortex on the amygdala (181). Amygdalotomy has been associated with reduced aggressive outbursts in patients with intractable aggression (182), but there have been no direct imaging studies to date reporting the relationship of amygdala activity and aggression.

Imaging Neurotransmitter Systems in Aggression

Serotonin

Ascending serotonergic neurons from the raphe nuclei project widely throughout the brain, including projections to dorsolateral prefrontal cortex and medial temporal lobe. Dorsal raphe-median forebrain bundle also directly innervates the amygdala, where dorsal raphe tracts outside the medial forebrain bundle project to parietotemporal cortex. Diffuse tracts extend from dorsal and medial raphe project to frontal lobe. Both 5-HT_{2A} and 5-HT_{1A} receptors are found in high concentrations in human prefrontal cortex, as are 5-HT transporter sites (183), and patients with localized frontotemporal contusions show significantly lower 5-HT metabolites in CSF than patients with diffuse cerebral contusions (184). Greater ß-CIT binding to 5-HT transporters has also been reported in nonhuman primates with a higher ß-CIT binding associated with greater aggressiveness (185). 5-HT_{2A} receptor number has been inversely related to aggressive behavior in posterior orbital frontal cortex and medial frontal cortex in the amygdala, whereas increased 5-HT_{2A} number in orbital frontal cortex, posterior temporal

cortex, and amygdala have been correlated with prosocial behavior in primates (186). Thus, serotonergic modulation of frontal and temporal cortical activity by 5-HT receptors, possibly of the 5-HT_{2A} type, may be particularly important in aggression.

The administration of FEN has been shown to increase cortical metabolism in frontal, temporal, and parietal cortex (187 ,188 and 189). In a study of depressed patients that included patients with a comorbid diagnosis of borderline personality disorder and a history of suicide attempts, activation of cortex including orbital and cingulate cortex was significantly blunted in the depressed patients, particularly in those who attempted suicide, compared with the control subjects. The depressed patients showed no significant changes in their glucose metabolic response to FEN compared with placebo, in contrast to the controls (189). In another study, intravenous administration of m-CPP in patients with alcoholism resulted in blunted glucose metabolic responses in right orbital frontal cortex, left anterolateral prefrontal cortex, posterior cingulate cortex, and thalamus compared with controls (190). In the first study directly comparing glucose metabolism after FEN and placebo in personality-disordered patients with impulsive aggression, neurologically normal subjects showed increased metabolism in orbital frontal and adjacent ventral medial frontal cortex as well as cingulate and inferior parietal cortex after FEN compared with placebo, whereas impulsive-aggressive patients appeared to show significant increases only in the inferior parietal lobe. Between-group comparisons demonstrated blunted responses of glucose metabolism in orbital frontal, ventral medial frontal, and cingulate cortex in the impulsive personality-disordered patients compared with the neurologically normal subjects. This study's results were replicated in a study of patients with borderline personality disorder (191), who displayed reduced regional uptake of fluorodeoxyglucose (relative to placebo) compared with control subjects in right medial and orbital frontal cortex, left middle and superior temporal gyri, left parietal lobe, and left caudate. In more recent pilot data from a study of patients with impulsive-aggressive personality disorders and controls that evaluated glucose metabolism after the administration of the 5-HT_2 agonist m-CPP, reduced metabolic responses were found in the aggressive patients, particularly in orbital frontal cortex, compared with controls (192), a finding inviting more direct assessment of components of serotonergic activity such as 5-HT_{2A} receptor number, transporter site number, and 5-HT_{2A} receptors.

In summary, imaging studies of the 5-HT system in impulsive-aggressive patients suggest reduced activation by ascending serotonergic projections on critical cortical inhibitory regions such as orbital frontal and related medial frontal cortex (137). Reduced serotonergic activation of these inhibitory regions mediated in part through 5-HT_{2A} receptors, but probably by other serotonergic mediators as well, may have a disinhibiting effect on the generation of aggression by amygdala and related structures.

Dopamine

In animal studies, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine–induced unilateral striatal dopamine deficiency in vervet monkeys was associated with increased frequency of aggressive behaviors toward other members of the group in the monkey colony (193). Greater heterogeneity was also found in striatal dopamine transporter density, as assessed by ^{123}I (β-CIT distribution) of impulsive violent offenders than controls (88), a finding possibly consistent with hypotheses that aggressive behavior is associated with increased dopaminergic transmission

PHARMACOLOGIC TREATMENT OF AGGRESSION

Part of "119 - Pathophysiology and Treatment of Aggression "

The rational clinical psychopharmacology of aggressive behavior began in the mid-1970s with the first placebo-controlled, double-blind, study of lithium carbonate in prison inmates (9). In this study, impulsive, but not premeditated (or other antisocial behavior), aggression was reduced to extremely low levels during a 3-month course of treatment with lithium carbonate; levels of aggression remained unchanged in inmates treated with placebo. Notably, all gains were lost within a month after a switch to placebo. An antiaggressive effect of lithium was replicated in subsequent studies including a blinded placebo-controlled trial in hospitalized aggressive children with conduct disorder (194) and a blinded, placebo-controlled trial of 42 mentally disabled patients (195). The mechanism of action for lithium in this regard is unknown, but it likely includes an enhancement of 5-HT function and a dampening of catecholaminergic function.

Other agents that may have antiaggressive efficacy include 5-HT–enhancing agents (i.e., 5-HT selective uptake inhibitors and 5-HT_{1A} agonists), anticonvulsants, typical and atypical neuroleptics, ß-blockers, and antiandrogenic agents, among others.

The rationale to treat impulsive-aggressive patients with 5-HT–enhancing agents is rooted in the consistent findings of an inverse relationship between 5-HT and impulsive aggression, reviewed earlier. Since the early 1990s, numerous open and blinded, placebo-controlled, studies have documented the efficacy of these agents, specifically with respect to the 5-HT selective uptake inhibitors (SSUIs). Among the controlled trials, SSUIs have been shown to reduce verbal and nonassaultive physical aggression in personality-disordered patients selected for a history of recurrent, problematic, impulsive-aggressive behavior (82), to reduce nonassaultive physical aggression in patients with borderline personality disorder who were recruited from the community (196),

to reduce anger attacks in depressed patients undergoing a clinical trial for the treatment of aggression (197), and to reduce impulsive aggression in adults with autistic disorder (198).

Although enhancement of central 5-HT function by the SSUI is presumed to underlie the antiaggressive effect in these subjects, the one study that examined 5-HT function before treatment actually found a positive relationship between pretreatment 5-HT function, assessed by PRL[$_d$-FEN] response, and improvement in aggression scores at end of trial (199). These data suggest that SSUIs may work best in patients whose postsynaptic 5-HT receptors are normal, or only moderately impaired, in function. If so, other agents that do not work primarily on presynaptic neurons may be necessary in patients with severe impairment of postsynaptic neurons. Such agents could include 5-HT receptor agonists or anticonvulsants, for example. Although evidence for the antiaggressive efficacy for 5-HT$_{1A}$ agonists is limited, buspirone, at doses of 20 to 50 mg per day, was shown to reduce aggression in two studies of mentally retarded patients (200 ,201). More data, however, are available to support the antiaggressive efficacy of anticonvulsants.

Carbamazepine has been shown in blinded, placebo-controlled, trials to reduce episodes of behavioral dyscontrol markedly in borderline personality disorder (202) and to reduce agitation and aggression in nursing home patients with dementia (203), although not in children with conduct disorder (204). Phenytoin was also shown to reduce impulsive, but not premeditated, aggressive behavior in a blind, placebo-controlled, study of prison inmates (10). Divalproex sodium, another anticonvulsant, showed promise in open (205 ,206 ,207 and 208) and early blinded, placebo-controlled, trials (50) of personality-disordered patients and conduct-disordered adolescents. Open trials also suggested that this agent may reduce behavioral agitation and mood lability in elderly demented patients (209 ,210) and in patients with aggression and mood lability secondary to brain trauma (211).

The use of typical neuroleptics in the treatment of aggression has largely been aimed at sedating psychotic patients or to reduce the psychotic thinking that may trigger aggressive behavior. In addition, these agents have also been used in nonpsychotic patients to treat aggression and agitation, with mixed results. Thioridazine was reported to diminish impulsive behavior in an open-label study of patients with borderline personality disorder (212), and low-dose haloperidol was reported to reduce hostility and impulsivity compared with amitriptyline and placebo in patients with borderline or schizotypal personality disorder (213). These findings were not reproduced in two other double-blind, placebo-controlled studies of borderline and schizotypal personality-disordered patients treated with thiothixine (214) or trifluoperazine (202). Treatment with the newer, atypical neuroleptics may prove to be more effective than that with the earlier typical antipsychotic agents. Antagonism of 5-HT$_2$ receptors appears to decrease aggression in animal models, and this effect may explain the ability of newer antipsychotic agents (which, unlike the older medications, block 5-HT$_2$ receptors) to produce a reduction in aggression and agitation independent of effects on psychotic symptoms (215 ,216). Studies suggest that the overall frequency of assaults, use of seclusion, mechanical restraint, and chemical restraint in patients with schizophrenia who are treated with clozapine are reduced over traditional neuroleptics (217). In a double-blind study, risperidone had a greater selective effect on hostility than haloperidol or placebo in patients with schizophrenia (218). Finally, an open-label study of olanzapine in 11 patients with borderline personality disorder reported significant reductions in anger (219), a finding suggesting that the potential benefit of atypical neuroleptics in treating aggression may extend to nonpsychotic patients as well.

Given the potential facilitory role of the central noradrenergic system, agents that dampen the function of this system could be expected to have antiaggressive efficacy. Notably, ß-noradrenergic blockers have been found effective in reducing aggressive behavior in patients with organic brain syndromes or chronic psychosis. Propranolol has been shown to reduce aggressive behavior in patients with traumatic brain injuries (220 ,221) or in patients with dementia (222). Both propranolol and nadolol have been shown to be effective in reducing aggressive behavior in chronic psychiatric inpatients, independent of psychotic symptoms (223 ,224). The use of these medications is limited, however, by hypotension and bradycardia, which can be side effects at the higher doses that are often used in these cases.

The use of antiandrogens in the treatment of some types of aggression, specifically sexual aggression, has undergone limited study. Antiandrogens such as medroxyprogesterone acetate and cyproterone acetate appear to lower both deviant and nondeviant sexual drive and activity in men with paraphilias, and this behavioral improvement is associated with decreases in testosterone level (225). However, although no data support the routine use of antiandrogens in nonsexual aggressive behavior, patients with sexual aggression do appear to respond, in some cases, to antiandrogen treatment.

SUMMARY

Part of "119 - Pathophysiology and Treatment of Aggression "

The study of the pathophysiology and pharmacologic treatment of aggression has undergone much progress since the 1980s. Extensive evidence supports an important role for central 5-HT function in the regulation impulsive aggressive behavior. In addition, more is known about potential regulatory roles of other central neurotransmitters and modulators, as well as their possible interaction with 5-HT. This knowledge has led to the development of a more rational approach to the psychopharmacologic treatment of impulsive aggression (e.g., treatment with 5-HT uptake inhibitors). Recent work examining the relationship of DNA polymorphisms

and aggression and work examining the relationship between brain structure and function in aggressive persons could yield critical data that will bring our understanding of the pathophysiology of aggression to a new level.

Pathologic Gambling and Impulse Control Disorders

Mark N. Potenza

Eric Hollander

Mark N. Potenza: Director, Problem Gambling Clinic; Department of Psychiatry, Yale University School of Medicine and Connecticut Mental Health Center, New Haven, Connecticut.

Eric Hollander: Professor of Psychiatry, Seaver Autism Research Center, Department of Psychiatry, Mount Sinai School of Medicine, New York, New York.

Impaired regulation of impulse is a central feature in several psychiatric disorders and behaviors, including drug use disorders, cluster B personality disorders such as borderline personality disorder, bipolar disorders, and suicide attempts. The DSM-IV's "impulse control disorders (ICDs) not specified elsewhere" (1) have historically received less attention than other psychiatric conditions. This heterogeneous group of illnesses includes intermittent explosive disorder, kleptomania, pyromania, pathologic gambling (PG), trichotillomania, and ICDs not otherwise specified. We review the neurobiology and treatment of one of these ICDs, PG, and describe the nature and treatments of several other potentially related conditions that have recently received increased attention: (a) compulsive buying (CB); (b) compulsive sexual behavior (CSB); and (c) compulsive computer use (CCU). These disorders, linked by a failure to resist urges to engage in ultimately self-destructive behaviors, appear to be relatively common, frequently go unrecognized for considerable periods, and may constitute greater threats to personal health than is often appreciated.

PATHOLOGIC GAMBLING

Part of "120 - Pathologic Gambling and Impulse Control Disorders "

Descriptions of gambling and gambling disorders are found in some of the earliest human records (2 ,3). Historically, gambling has been viewed as a sin and later as a vice (2 ,3 ,4 and 5). More recently, disordered gambling has been seen as an illness determined by genetic and environmental factors and individual decision making. The most extreme form of disordered gambling, PG, was first included in the DSM in 1980 (1). Since that time, there has been increasing research into the clinical features and neurobiological causes of PG.

Theoretic Conceptualizations

PG has been described as sharing features with several groups of disorders (Fig. 120.1). Some authors have hypothesized that PG lies along a compulsive-impulsive spectrum (6 ,7), and PG represents an obsessive-compulsive (OC) spectrum disorder (8 ,9 and 10). Consistent with the classification of PG as an OC-spectrum disorder, individuals with PG engage in repetitive (gambling-related) behaviors, often in response to overwhelming thoughts to engage in the behavior (11). Studies of comorbidity between OC disorder (OCD) and PG have yielded mixed results, with some studies finding rates of OCD in individuals with PG higher than in the general population (12 ,13), whereas others have not found elevated rates of comorbidity (14 ,15 ,16 and 17) or elevated rates of positive family histories for PG in patients with OCD (18). A direct investigation into OC characteristics of individuals with PG found that those with PG scored significantly higher than those without on the Padua Inventory (19). The differences clustered within two factors corresponding to obsessive qualities of impaired control over mental activity and worries of losing control over motor behavior, respectively (19). Although the findings support the notion that PG lies toward the impulsive end of a compulsive-impulsive spectrum, the authors cite a central difference between gambling in PG and repetitive behaviors in OCD (19). Namely, gambling and actions in other ICDs are often related as pleasurable or egosyntonic, whereas performance of repetitive activities in OCD is generally described as egodystonic. Although one study reported the possibility of the association of PG and OCD with the Huntington disease mutation in a family with PG, OCD, and Huntington disease (20), the neurobiological similarities and differences between PG and OCD remain to be defined more clearly, to explore their relatedness further.

FIGURE 120.1. Proposed conceptual model for relationships between pathologic gambling (PG) and other psychiatric conditions. ADHD, attention-deficit/hyperactivity disorder.

Researchers and clinicians have also described PG as an addiction and have cited similarities to substance use disorders (21 ,22 and 23). In fact, the diagnostic criteria for PG were modeled after those for substance dependence (1) and include

aspects of tolerance, withdrawal, and failed attempts to control the destructive behavior. High rates of comorbidity are observed between PG and substance use disorders. Individuals with PG have high rates of substance use disorders, with rates of nicotine dependence approaching 70% (24), alcohol abuse or dependence in the range of 45% to 55% (12 ,25), and other drug use problems nearing 40% (26). Conversely, individuals with substance use disorders are four- to tenfold more likely to have PG (27): 9% of opiate addicts in methadone maintenance (28), 17% of alcohol abusers (29), and 15% of cocaine addicts (30) have PG. The high rates of comorbidity have implications with regard not only to potential similarities in the underlying neurobiological bases of PG and substance use disorders, but also to the clinical needs of individuals with PG. Specifically, individuals dually diagnosed with a substance use disorder and PG were found to require more psychiatric admissions and detoxifications than individuals with a substance use disorder without PG (31). A separate study found that individuals with comorbid substance use disorders and PG were at greater risk for contemplated and attempted suicide than individuals with either diagnosis alone (32). These and other findings (33 ,34) indicate that dually diagnosed individuals with PG appear to be more severely ill than those with either illness alone. Taken together with emerging data suggesting neurobiological similarities between substance use disorders and PG (see the later discussions of genetics and neuroimaging), there is mounting evidence supporting the notion of substance use disorders and PG lying along an addiction spectrum.

High rates of other psychiatric disorders, particularly mood, attention-deficit, and antisocial personality disorders, have also been described in individuals with PG (24 ,35 ,36 and 37). Some data suggest that individuals with features of some of these disorders (e.g., cycling mood disorders) could benefit from different treatment interventions (see the later discussion on pharmacotherapy). Further studies are warranted to investigate the precise relationships between these disorders and PG.

Biochemistry

Multiple factors, including behavioral initiation, arousal, reward and reinforcement, and behavioral disinhibition, have been described as contributing to or disordered gambling behavior in PG (38). Unique roles for specific neurotransmitters have been hypothesized as mediating aspects of PG and other ICDs (Table 120.1). Specifically, serotonin (5-HT) has been described as important in behavioral regulation (behavioral initiation and inhibition, including control of aggressive and other impulses) (38 ,39 ,40 and 41). Data support a central role for norepinephrine (NE) in the control of levels of arousal and detection of novel or aversive stimuli (42). Multiple lines of evidence from studies of human and other organisms cite dopamine (DA) function, particularly within the mesocorticolimbic (MCL) pathways, as critical in processing and modulating rewarding and reinforcing stimuli and behaviors (43 ,44 and 45). Abnormalities in these neurotransmitter systems as they relate to PG are explored in the following sections.

Neurotransmitter	Proposed Role
Norepinephrine	Arousal, excitement
Serotonin	Behavioral initiation and cessation
Dopamine	Reward, reinforcment
Opioids	Pleasure, urges

TABLE 120.1. PROPOSED ROLES FOR NEUROTRANSMITTER SYSTEMS IMPLICATED IN THE PATHOPHYSIOLOGY OF PATHOLOGIC GAMBLING

Serotonin

A role for 5-HT system dysfunction in the neurobiology of PG has come from results of pharmacologic challenge studies (38 ,46). The 5-HT and NE reuptake inhibitor clomipramine (CMI) has been used to investigate neurochemical responses in individuals with PG as compared with those without PG (46). Eight men and women with PG and eight age- and gender-matched controls received a relatively low intravenous dose of clomipramine (12.5 mg), one that the authors argued targeted primarily the 5-HT transporter (46). The persons with PG in comparison with controls were found to have at baseline lower prolactin levels and exhibited significantly blunted prolactin increases 60 minutes after clomipramine administration (46). The blunted prolactin response suggests the possibility of diminished 5-HT transporter binding in individuals with PG.

An independent challenge study investigating 5-HT function in individuals with PG was undertaken by DeCaria and colleagues (38). The investigators administered meta-chlorophenylpiperazine (m-CPP) to 10 men with PG and 10 healthy male control subjects. m-CPP, a metabolite of the antidepressant trazodone and a partial 5-HT_1 and 5-HT_2 receptor agonist, binds with high affinity to 5-HT_{1A}, 5-HT_{1D}, 5-HT_{2A}, 5-HT_{2C}, and 5-HT_3 receptors, with particularly high affinity for 5-HT_{2C} receptors (47 ,48 and 49). 5-HT_{2C} receptors, localized to brain regions including the cortex and caudate, have been implicated in mediating aspects of mood, anxiety, appetite, behavior (including sexual activity), and neuroendocrine function (50 ,51). The investigators found that individuals with PG reported a euphoric response or "high" after m-CPP administration, a finding similar to those reported for other disorders such as antisocial personality disorder (52), borderline personality disorder (53), trichotrillomania (54), and alcohol abuse or dependence (55), in which impulsive or compulsive behaviors are prominent. In addition to differences in behavioral reactions, PG subjects demonstrated altered biochemical responses to the m-CPP challenges. Specifically, increases in prolactin levels were observed in persons with PG, with greater prolactin responses correlating with increased gambling severity.

Additional support for 5-HT dysfunction in individuals with PG has been obtained from investigations of cerebrospinal fluid (CSF) (56). Initial studies into the chemical composition of CSF from men with PG found no significant differences in levels of 5-HT or its metabolite 5-hydroxyindolacetic acid (5-HIAA) as compared to levels in healthy men (57 ,58 and 59). Given that multiple factors can complicate evaluation of CSF data (56 ,60 ,61) and the finding that men with PG have significantly longer CSF tapping times than healthy male controls (62), the authors calculated the concentrations of monoamine metabolites per minute of tapping to obtain an estimate of mass flow through the lumbar puncture needle. When taking tapping time into account, levels of 5-HIAA, as well as those of the NE metabolite 4-hydroxy-3-methoxyphenyl glycol (HMPG), were found to be significantly lower in the group of men with PG. These findings, particularly in light of reports of low CSF levels of 5-HIAA in individuals with impulsive characteristics, such as those attempting suicide (39 ,40 and 41), lend further support to a central role for 5-HT in the underlying pathology of PG. Additional data emerging from pharmacotherapy trials, neuroimaging studies, and investigations into monoamine oxidase (MAO) function (see later) are also consistent with 5-HT dysfunction in PG. Further studies are needed to define the nature and extent of 5-HT perturbations in PG more precisely, particularly as they relate to specific aspects of PG (e.g., behavioral initiation or cessation) and subgroups of individuals with PG (e.g., as distinguished by such characteristics as gender or comorbid diagnosis).

Dopamine

Data support positing a role for DA in reinforcing and rewarding aspects of gambling in PG. Multiple lines of evidence from studies investigating the neurochemical bases of drug use disorders have implicated the MCL DA system in the mediation of rewarding and reinforcing behaviors (43 ,44 and 45). Studies in humans with cocaine dependence have found MCL regional brain activations after a cocaine-induced rush (63) or viewing of cocaine-related videotapes (64), and occupancy of the DA transporter has been correlated with cocaine's euphorigenic effects (65). A role for DA in the rewarding and reinforcing aspects of gambling has been proposed (38 ,66). To explore this hypothesis, Bergh et al. analyzed CSF from ten men with PG and seven matched male controls (59). Decreased levels of DA and increased levels of the DA metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) were observed in the PG subjects (59). The authors concluded these findings to be consistent with an increased rate of DA neurotransmission, although more recently the same group did not find decreased HVA levels when correcting for CSF flow rate (56).

A separate study investigated peripheral levels of DA under gaming conditions (67). Plasma levels of DA were measured when subjects played Pachinko machines, described as a popular form of recreation in Japan and one that combines elements of pinball and slot machines. The authors reported that after a winning streak described as a "fever," six men who were regular Pachinko players were found to have elevated levels of DA. The authors suggested the DA changes may be related to the motivational processes underlying repeated Pachinko playing. Alterations in measures of arousal, NE, endogenous opiates, and immune system function were also described. Although the results of the foregoing studies and additional evidence from neuroimaging and molecular genetic studies suggest DA dysfunction in PG (see later), more studies are needed to clarify the involvement of DA pathology in PG.

Norepinephrine

NE has been hypothesized as mediating aspects of arousal, attention, and sensation seeking in individuals with PG (38 ,57 ,58 ,68). To investigate, Roy et al. measured urinary, peripheral, and central levels of NE or the NE metabolites MHPG and vanillylmandelic acid (VMA) and found the PG subjects to have higher CSF levels of MHPG and higher urinary measures of NE (57). In a subsequent report, the investigators found in the same group of 17 men with PG originally studied, scores of extraversion on the Eysenck Personality Questionnaire were found to correlate positively and significantly with CSF and plasma levels of MHPG, urinary measures of VMA, and the sum of urinary levels of NE and NE metabolites (58). More recently, increased CSF

levels of NE and MHPG were found in a second group of men with PG (59), although a subsequent report from the same research team reported findings of decreased MHPG in men with PG when correcting for CSF flow.

As mentioned in the section on DA, a study of male Pachinko players found NE system changes under gaming conditions (67). Specifically, blood levels of NE were found to increase from baseline over time during Pachinko play, with statistically significant changes noted at the onset and end of Pachinko "fever." Levels of NE decreased but remained significantly elevated 30 minutes after the end of "fever." Alterations in heart rate, a physiologic measurement associated with arousal, was also observed, with peak heart rate measured at the start of "fever."

Monoamine Oxidase Activity

The MAOs, subtypes MAO A and MAO B, are enzymes that metabolize NE, 5-HT, and DA (69). Peripheral MAO derived from platelets is of the MAO B subtype and has been suggested to be an indicator of 5-HT function (70 , 71), although MAO B also binds with high affinity to and catabolizes DA (69). Decreased platelet MAO activity has been reported in association with impulsive behaviors (72 ,73), high levels of sensation-seeking (74 ,75 and 76), and ICDs, including eating disorders (77). Individuals with PG have also been reported to exhibit decreased platelet MAO activities (78 ,79). In one study, 15 men with PG were found to have MAO activities 26% lower than those in a group of 25 male controls (78). A separate study involving 27 men with PG found MAO activity levels 41% lower than in matched male controls (79). Each group investigated personality and sensation-seeking characteristics of the PG and control groups and found statistically significant differences. However, no clear picture emerged regarding correlation of the characteristics with MAO levels, with no associations maintained after Bonferroni correction application in one study (79) and a positive correlation between MAO and several measures of sensation-seeking in the other (78).

Stress Response Pathways

Immune system and cortisol changes have been related to gaming behaviors. The foregoing study involving Pachinko players (67) found alterations in T cells (decreased number of T cells and decreased CD3-56 activity) and natural killer cells (increased number of natural killer cells without change in activity). A separate study of male and female Kimberley aborigines found significantly higher cortisol levels on days in which gambling behavior was concentrated (Thursdays and Fridays) as compared with temporally distinct days (Mondays and Tuesdays) (80). Significantly higher epinephrine levels were also found on the gambling-concentrated days, a finding further implicating adrenergic function in gambling behaviors. Although higher on gambling-concentrated days, differences in blood pressure measurements did not reach statistical significance. A separate study found no evidence of abnormal cortisol responsivity on a dexamethasone suppression test in 21 men with PG (81). Independently, CSF levels of corticotropin-releasing hormone and corticotropin were found not to be significantly different between healthy and PG-affected men (57). Additional studies investigating immune and stress hormone function in gambling and PG situations are warranted, in light of the foregoing data and reports of increased rates of physical health problems in individuals with PG (82).

Opioidergic Pathways

Given (a) the role of endogenous opioids in mediating levels of pleasure and (b) the μ-opioid receptor (mOR) in modulating reward and reinforcement DA pathways by disinhibition of γ-aminobutyric acid (GABA) input to DA neurons in the ventral tegmental area (83 ,84), studies exploring ß-endorphin function in gaming behaviors has been explored. In the previously detailed Pachinko study (67), blood levels of ß-endorphins were found to be elevated during Pachinko play, peaking during the start of "fever." These findings, in conjunction with the results from preliminary studies of the mOR antagonist naltrexone in the treatment of PG (see later), suggest further investigation into opioid function in PG are warranted.

Other Neurotransmitter Systems

Studies of the possible dysregulation of other neurotransmitter systems as related to PG have been undertaken. results of most of these studies to date have been negative, with statistically nonsignificant differences observed between PG and healthy male subjects with regard to CSF levels of neuropeptide Y (57 ,85), galanin (86), GABA (87), "diazepam-inhibitor binding" (57 ,88), neurotensin (57), somatostatin (57), or growth hormone–releasing hormone (57). One study did find decreased levels of the inhibitory neurotransmitter taurine in the CSF of men with PG as compared with healthy controls (89).

Neuroimaging Studies

Few neuroimaging studies directly investigating PG have been performed to date. One study investigated the potential role of the MCL DA system in a study in which participants were paid increasing amounts of money depending on the skill level reached while playing a video game (90 , 98). Positron emission tomography (PET) studies using ^{11}C-labeled raclopride, a ligand with high affinity for D2-like DA receptors (D2Rs), found decreased levels of striatal binding in eight male study subjects playing a tank video game as compared with when they viewed a gray screen image (90). The authors concluded that the observed 13%

reduction in [su>11C]raclopride signal during the gaming condition is consistent with at least a twofold increase in levels of extracellular DA. Because the game involved increasing monetary reward associated with each skill level reached during the video game, the paradigm is similar but not identical to actual gambling.

An independent study investigated for specific DA and 5-HT abnormalities in individuals with PG (91). Using PET, the researchers found decreased striatal binding in PG subjects of [^{11}C]*N*-methylspiperone, a ligand with high affinity for D2Rs and 5-HT_{2A} and 5-HT_{2C} receptors (92). The striatal signal, corresponding to D2R-receptor occupancy, could be explained by multiple, non–mutually exclusive possibilities including decreased numbers of available D2Rs, decreased affinity of D2Rs for the tracer, or increased synaptic concentrations of DA. PG subjects were also found to have impaired performance on multiple neurocognitive tests, including the Halstead-Reitan, Wisconsin Card Sort, Shipley, and California Verbal Learning. Regional cerebral blood flow to the frontal cortex and anterior cingulate was found to be significantly lower in PG as compared with healthy subjects during performance of an auditory continuous performance attention task. These findings are consistent with prior studies implicating involvement of the frontal cortex and anterior cingulate in attention (93), among other processes, and suggest a role for these brain regions in mediating attentional deficits in individuals with PG (35).

Multiple neuroimaging studies into the neural bases of drug use disorders have been performed. Studies of drug craving, a central component in relapsing behavior, have repeatedly identified the involvement of anterior cingulate activation (63 ,64 ,94 ,95), among other brain regions. Studies investigating whether similar brain regions may be involved in PG are under way, with preliminary data suggesting the involvement of parallel neural activities (96 ,97).

Decision Making

An instrument called the Iowa Gambling Task has been developed and used in investigations into decision making (98 ,99 ,100 and 101). The tool involves four piles of cards, each associated with predetermined patterns of rewards and punishments. Selection from two of the piles, each associated with lower rewards and lower punishments, will ultimately result in long-term gains, and selection from the other two piles will result in long-term losses. Without prior instruction into the reward and punishment profile of each pile, individuals are instructed to select from the piles and to maximize gains. Interestingly, individuals with stroke lesions in either the ventromedial prefrontal cortex (VM) or amygdala perform worse than healthy subjects on the task (100 ,101). Additionally, those with VM lesions not only do not improve over time with repeat performance, but also fail to exhibit changes in skin conductance associated with the decision-making processes (102). Individuals with substance use disorders also have demonstrated impaired performance on the Iowa Gambling Task (103 ,104 and 105), and poor performance has been shown to correlate with decreased blood flow measurements to the VM in cocaine-dependent subjects (105 ,106). The extent to which dysfunction of the VM, amygdala, or other brain regions involved in regulation of emotion and decision making may be involved in the pathophysiology of PG remains to be explored more completely.

Genetics

Twin studies investigating disordered gambling behaviors have been published (107 ,108). One study observed significantly greater rates of similarities in male monozygotic as compared with male dizygotic twins with regard to participation in past-year high-action forms of gambling (e.g., casino card, lottery, or gambling machine) (108). No differences were observed in the two groups of males with regard to measures of low action forms of gambling or in female monozygotic versus dizygotic groups with regard to past-year participation in either high- or low-action forms gambling. A larger study used the monozygotic (n = 1,869 pairs) and dizygotic (n = 1490 pairs) twins who served in the military in the Vietnam War era on whom questions pertaining to PG from the Diagnostic Interview Schedule Version III-R were available (107). The authors found inherited factors to contribute between 35% and 54% of the liability for each of the five individual PG-related factors. Higher degrees of familial contribution were estimated for the reporting of three (56%) or four (62%) or more of the individual PG-related factors. The results are comparable to findings derived from the same sample for the heritability of drug use disorders, with 34% and 28% of the variance accounted for by genetic and shared environmental factors, respectively (109). The findings reported by Eisen et al. suggest that familial factors explain a substantial portion of the risk for experiencing symptoms or behaviors consistent with PG. The findings are consistent with the notion that genetic influence significantly affects the risk of developing PG.

Molecular genetic investigations into the origin of PG have been performed (110 ,111 ,112 ,113 ,114 and 115). Investigations described to date have been association studies exploring the involvement of genes related to NE, 5-HT, and DA systems. The first of these studies investigated a role for the *D2A1* allele of the D2R, an allele previously reported by the same research group to be implicated in such compulsive-addictive behaviors as drug abuse, cocaine abuse, and compulsive eating and smoking (116 ,117). In a group of 171 whites with PG, 50.9% carried the *D2A1* allele as compared with 25.9% of the control group (odds ratio (OR) = 2.96; *p* .0000001) (110). Additionally, gambling severity was found to correlate with an increased likelihood of carrying the *D2A1* allele,

and the group of individuals without compared with those with a history of a major depressive episode were more likely to carry the *D2A1* allele (110). This latter finding suggests that differences in underlying motivations for gambling and comorbidity may be important factors in relation to the genetics of PG.

Comings and colleagues also investigated associations of PG with polymorphic variants of the D1, D3, and D4 receptors (111 ,112 ,115). The authors found the frequency of the *Dde I* allele of the D1 receptor (D1R) to be significantly higher as compared with controls in each of three groups: pathologic gamblers, tobacco smokers, and Tourette syndrome probands (111). A negative association for heterozygosity at the *Dde I* polymorphism was observed for all three disease groups. Given the findings of this (111) and their prior study (110) and the roles of the D1R and D2R in modulating rewarding and reinforcing behaviors (118), the authors proposed for the genetic variants at the D2R and D1R with regard to PG the possible existence of heterosis. *Heterosis*, with regard to populations, refers to a situation in which the progeny (hybrid) has a significantly greater effect on phenotype than either parental strain (e.g., certain hybrid strains of corn exhibiting increased vigor) (115). More investigations are needed to replicate the findings in other populations of individuals with PG and to determine the functional significance of the findings.

Allelic variants of the D4 receptor (D4R) differing in the number of 48-base pair nucleotide repeats have been implicated in some studies of novelty-seeking behavior (119 ,120), but not others (121 ,122 ,123 and 124). Moreover, the corresponding proteins derived from the allelic variants demonstrate functional differences (125), a finding lending further support to the concept that differences in the genetic composition of the groups at the D4R site may be directly related to differences in D4R function. Two groups have independently investigated a role for the D4R in PG (113 ,115), with each group finding differences in groups of individuals with PG. Perez de Castro and colleagues reported a significant positive association between PG and the longest allele of the D4R (D7), with a stronger association observed in the female group and a nonsignificant relationship seen in the male group (113). Conversely, Comings and colleagues reported no significant association between the D7 allele carriers and PG, although a significant positive association was found with regard to the number of individuals with a high number of 48-base pair repeats (five to eight) and PG (115). The authors also reported an increase in heterozygosity at the D4R allele in association with PG, invoking the notion of heterosis. Discrepancies in the findings of the two groups may be explained by genetic heterogeneity, or the genetic contributions from these loci may be additive or modest. Taken together, the findings support a potential role for the D4R in PG, and further studies are warranted to clarify the relationship. Comings and colleagues also found a decrease in heterozygosity of the *Msc I* allele of the D3 receptor individually in groups with PG or Tourette syndrome (112). The multiple genetic findings implicating dopaminergic genes in PG lend further support for a role for DA in PG.

Molecular studies have been performed with regard to genes involved in modulating 5-HT function (112 ,114). One report did not find a statistically significant association between PG and allelic variants of the tryptophan 2,3-dioxygenase gene, whose gene product regulates 5-HT metabolism (112). A variant of the 5-HT transporter (5-HTT) promoter region (126), associated with altered protein expression (127), was previously implicated in anxiety (127) and depression (128). Specifically, individuals with at least one copy of the short variant, associated with decreased protein levels, were found to have higher measures of anxiety or depression (127 ,128). Ibanez and Perez de Castro and their colleagues reported an increased association between the short (less functional) variant and PG in the group of males but not females studied, with increasing association observed with increasing severity of PG (129). These findings (a) further support a role for 5-HT dysregulation in PG and (b) suggest the direct target of 5-HT reuptake inhibitors (SRIs), drugs with apparent efficacy in the treatment of PG (see later), may be differentially regulated in certain groups with PG. Further studies are warranted to replicate and extend these findings.

Treatment

Multiple interventions, including imaginal desensitization (130) and aversion therapies (131), have been examined for the treatment of PG (132). Many treatments explored to date have often been inadequate. Arguably the most long-standing form of treatment, Gambler's Anonymous (GA), is associated with an 8% 1-year retention rate, with most participants leaving after one or two meetings (133). Preliminary results of investigations into the efficacy of cognitive behavioral therapy appear promising (134 ,135), although additional studies, particularly with regard to and in conjunction with pharmacotherapies, are warranted.

Psychopharmacology

Relatively few investigations have been performed into the tolerability and efficacy of drug treatments for PG (Table 120.2). Although most studies involve case reports or series, larger-scale, placebo-controlled trials are emerging.

Catagery Reference	Drug	Sample	Design		Outcome
Mood stabilizers					
	Moskowitz, 1980 (137)	Lithium	3 males with comorbid cycling mood disorders	Open-label	Improved control of gambling, cycling mood, risk taking, and mania/hypomania
	Haller & Hinterhuber, 1994 (138)	Carbemazepine	1 male	Placebo-controlled, double-blind, crossover	Decreased gambling behavior maintained at 30 wk
Serotonin reuptake inhibitors					
	Hollander, et al., 1992 (140)	Clomipramine	1 female with comorbid social phobia	Placebo-controlled, double-blind, crossover	Gambling behaviors discontinued persisting through 38 wk
	Hollander, et al., 1998 (141)	Fluvoxamine	16 subjects entered, 10 completed (4 female, 6 male)	Placebo-controlled, single-blind, 16-wk trial (8-wk placebo, 8-wk active)	Seven of 10 completers determined to be responders by PG-CGI and PG-YBOCS scores
	Hollander, et al., 2000 (142)	Fluvoxamine	15 subjects enrolled, 10 completed (10 male)	Placebo-controlled, double-blind, crossover (1-wk placebo Lead-in, 8-wk active/ placebo, 8-wk crossover)	Seven of 10 completers determined to be responders by PG-CGI and PG-YBOCS scores; fluvoxamine superior to placebo, particularly at end of 16 wk of treatment
	Blanco-Jerez, et al., 1999 (143)	Fluvoxamine	34 subjects enrolled	Placebo-controlled trial of 6 mo	No statistically significant difference in response rates for placebo as compared with active drug; high rates of discontinuation were seen
	De La Gandera, et al., 1999 (144)	Fluoxetine	20 subjects enrolled (11 receiving drug and psychotherapy, 9 psychotherapy only)	Open-label trial of 6 mo	Fluoxetine plus psychotherapy better than psychotherapy alone at 6 mo as measured by CGI scores and other measures
	Kim, 2000 (145)	Paroxetine	41 subjects (20 receiving paroxetine, 21 placebo)	Placebo-controlled, double-blind, parallel group (1-wk placebo lead-in, 8 wk of active medication of placebo)	Paroxetine group significantly improved as compared with placebo as determined by CGI; no statistically significant difference on other outcome measures
Opioid antagonists	Kim, 1998 (152)	Naltrexone	1 male with comorbid compulsive shopping behavior	Open-label	Gambling and excessive shopping behaviors eliminated at 100 mg/d with gains maintained through 9 mo
	Crockford & El-Guebaly, 1998 (153)	Naltrexone	1 male with comorbid alcohol dependence and depression	Open-label	Cessation in gambling and alcohol cravings observed through 4 wk following addition of naltrexone to fluoxetine

CGI, clinical global impression; PG, pathologic gambling; YBOCS, Yale-Brown Obsessive-Compulsive Scale.

TABLE 120.2. PSYCHOPHARMACOLOGIC TRIALS IN PATHOLOGIC GAMBLING

Mood Stabilizers

Lithium, a salt with mood stabilizing properties believed to modulate 5-HT systems (136), has been examined in the treatment of PG (137). In three men with PG and comorbid cycling mood disorders, lithium, at daily doses reported up to 1,800 mg per day, was found to be at least partially effective in controlling gambling, cycling mood, hypomania

and mania, and risk-taking behaviors. Durations of treatment were not clearly specified, although at least one patient was maintained for up to 1½ years. No adverse effects were described. The author concluded that lithium may target "an affective component with excitability and impulsiveness-explosiveness." Larger controlled studies seem warranted and are currently ongoing to determine the tolerability and efficacy of lithium, particularly in groups of individuals with PG and cycling mood disorders.

A case report involving the use of carbamazepine in the treatment of a 37-year-old man with PG has been described (138). The gambler had a 16-year history of significant gambling, with periods of abstinence lasting only 2 to 3 months apiece despite participation in GA, behavior therapy, and psychoanalysis. A placebo-controlled, double-blind trial of carbamazepine was undertaken, with no improvement noted in gambling behavior over the 12-week placebo phase. Carbamazepine was introduced at 200 mg per day was increased to 600 mg per day, with blood levels of 4.8 to 9.5 µg/mL achieved. Gambling behaviors decreased 2 weeks into treatment, and gains were maintained at 30 months.

Serotonin Reuptake Inhibitors

Given the efficacy of SRIs in targeting OC behaviors in OCD (139) and the data supporting 5-HT dysregulation in PG, trials of SRIs have been performed. The first of these studies involved a 31-year-old woman with PG and comorbid social phobia and OC personality traits who had been gambling persistently despite multiple prior treatments (140). Clomipramine was administered in double-blind, placebo-controlled fashion in a crossover design. Minimal improvement was seen after 10 weeks of placebo treatment. After initiation of active drug at 25 mg per day with an increase up to 175 mg per day, gambling behavior was discontinued at week 3, with absence of gambling remaining at 38 weeks. The adverse effect of increased irritability was effectively treated with a temporary decrease in dose.

More recently, a single-blind crossover study of the selective SRI (SSRI) fluvoxamine was performed (141). Sixteen subjects entered the 16-week trial (8-week placebo lead-in, 8-week active), with seven of ten completers judged to be responders by (a) a score of "much improved" or "very much improved" on the Clinical Global Impression score for gambling severity (PG-CGI) and (b) greater than 25% reduction in scores on the PG modification of the Yale-Brown Obsessive-Compulsive Scale (PG-YBOCS). Of the completers, four were female and six were male. The medication was well-tolerated, and the average dose for completers was 220 mg per day at endpoint, with responders tending to be treated with a slightly lower dose (207 mg per day on average). Noncompleters left the study during the placebo phase (four for noncompliance, two for lack of response). Of the three nonresponders, two were the only completers with histories of cyclothymia, a finding raising the possibility that individuals with a comorbid cycling mood disorder may respond better to an alternate pharmacotherapy. Further studies are warranted to investigate this possibility.

Hollander and colleagues performed a randomized double-blind, placebo-controlled crossover study of fluvoxamine in the treatment of PG (142). The trial lasted 16 weeks after a 1-week placebo lead-in phase, with subjects randomized to receive either active medication or placebo during the first 8-week phase followed by the alternate treatment during the second 8-week phase. Fifteen subjects meeting the criteria for PG but not for active substance use disorders or past or present major axis I disorders were enrolled, and 10 individuals (all male) completed the study. Two of the five noncompleters left during the placebo lead-in phase, one during placebo treatment in phase I, and two during phase I treatment with fluvoxamine (one for noncompliance, one for interaction with an as-needed medication). Study drug dosing was initiated at 50 mg per day, with fixed increases to 100 and 150 mg per day during the second and third weeks, respectively. Thereafter, the dose was adjusted in 50-mg increments each week with a maximum of 250 mg per day and a minimum of 100 mg per day, based on clinical response and drug tolerance. Mean endpoint dose of fluvoxamine was 195±50 mg per day (range, 100 to 250 mg per day). Adverse effects documented during fluvoxamine treatment were of only mild intensity and were consistent with SSRI treatment, and they were not associated with early withdrawal from the study. Outcome measures included scores from the PG-CGI and PG-YBOCS, as earlier. Data from the investigation demonstrated active drug to be superior to placebo in targeting gambling behavior over time. Both the groups receiving active medication and placebo showed improvement in control of gambling behaviors during the first 8 weeks, and the most significant difference in response was observed at the end of the second 8-week block (Fig. 120.2). In other words, during phase II, improvements seen during the course of the 16-week trial in the placebo-fluvoxamine treatment group were more likely to persist over time, whereas initial gains observed in the fluvoxamine-placebo treatment group declined. These findings are consistent with a high initial rate of placebo responders and suggest that acute trials of longer duration may be important in better distinguishing response to placebo and active drug.

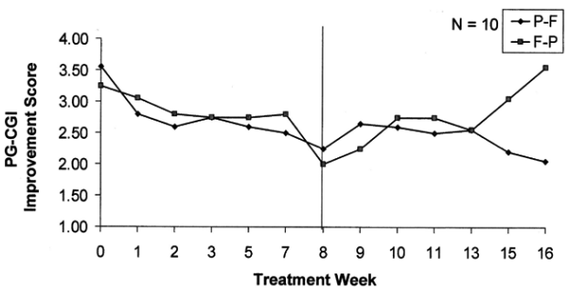

FIGURE 120.2. Clinical Global Impression (CGI) scores are shown for subjects completing a 16-week placebo-controlled, double-blind study of fluvoxamine for the treatment of PG. Measures are shown for individuals receiving placebo in phase I followed by fluvoxamine in phase II *(diamonds)* or fluvoxamine in phase I followed by placebo in phase II *(squares)*. ANOVAR: [F = 14.8 (df = 1,8), p = .005 (drug effect)]; ANOVAR: [F = 6.0 (df = 1,8), p = .040 (phase order × drug interaction)]; *post hoc* ANOVA: phase I: [F = 0.113 (df = 1,7), p = .747]; phase II:[F = 12.45 (df = 1,7), p = .010].

A longer-term placebo-controlled trial of fluvoxamine in the treatment of PG was reported by an independent group (143). In their study, 34 patients were treated for 6 months with placebo or fluvoxamine at 200 mg per day. Outcome was measured by quantification of time and money spent on gambling. The authors found no statistically significant differences in response rates to placebo as compared with active drug for the overall sample. The authors reported observing a statistically significant superiority of fluvoxamine as compared with placebo in the male and younger-aged subgroups of individuals with PG in the study. Strikingly,

a large proportion of individuals did not complete the 6-month study, and this complicated interpretation of the results and suggested that long-term compliance with drug treatment will be a significant consideration for individuals with PG.

A separate longer-term, open-label trial of a different SSRI, fluoxetine, was performed (144). The study compared the results of treatment with fluoxetine at 20 mg per day with support psychotherapy (n = 11) as compared with psychotherapy alone (n = 9). Measures of outcome included scores on the CGI and Ludo-Cage test. The treatment group receiving fluoxetine showed significantly improved outcomes as measured by CGI scores (fluoxetine plus psychotherapy: 1.5±0.8; psychotherapy alone: 3.2±0.7; $p < .001$) and Ludo-Cage mean scores ($p = .004$) at the 6-month assessments. Individuals in the combined fluoxetine and psychotherapy treatment group also demonstrated better adherence to treatment guidelines.

An independent double-blind, placebo-controlled trial of a third SSRI, paroxetine, was performed (145). The study used a parallel group design with each group receiving a 1-week placebo lead-in followed by 8 weeks of either placebo or active medication. Dosing was initiated at 20 mg per day with increases up to 60 mg per day as clinically indicated. Forty-one patients meeting the criteria for PG and no other axis I diagnosis participated in the study (20 paroxetine, 21 placebo). Adverse effects were observed with greater frequency in the paroxetine-treated group (2.3 treatment-emergent symptoms per patient in the paroxetine group as compared with 1.2 in the placebo group). The treatment-emergent symptoms were consistent with SSRI treatment, most frequently involving reports of headaches, fatigue, and dry mouth. Outcome was measured by scores on the patient- and clinician-rated CGI and the Gambling Symptom Assessment Scale (G-SAS). The paroxetine treatment as compared with placebo resulted in statistically significant improvement as determined by the clinician-rated CGI (random regression analysis: $z = -1.99$, $p < .05$), with no statistically significant differences observed between groups on other measures.

Taken together, findings from these initial studies suggest that SSRIs are well-tolerated, efficacious drugs for the treatment of PG. Larger scale (e.g., multicenter), placebo-controlled trials of SRIs are warranted to extend these initial promising results and to define better the short- and long-term efficacies and tolerabilities of specific SRIs in groups of individuals with PG.

Opioid-Receptor Antagonists

The mOR, involved in regulation of DA reward- and reinforcement-related pathways, has been the target for pharmacotherapies in the treatment of addictive disorders. Naltrexone, an mOR antagonist, has been shown to reduce alcohol intake and alcohol cravings in the treatment of alcohol dependence (146 ,147 and 148), as well as to target impulsive, self-injurious behaviors in multiple other patient populations (149 ,150 and 151). Two case reports described a potential role for naltrexone in the treatment of individuals with PG (152 ,153). In an open-label case series of individuals with ICDs, Kim described a 55-year-old man with PG and CB (152). Naltrexone at 50 mg per day was initiated with no clinical change observed at 2 weeks. Several days after an increase to 100 mg per day, a significant decrease in gambling urge intensity was reported by the patient. This decrease was followed by elimination of gambling and excessive buying, with gains maintained for at least 9 months.

An independent case report described the open-label treatment of a 49-year-old man with comorbid PG, depression, and alcohol dependence (153). The patient was initially treated with fluoxetine (dose and duration not specified), with improvements in mood and persistence in urges to drink and gamble. Naltrexone at 50 mg per day was added to the fluoxetine with a cessation in gambling and alcohol cravings observed over a 4-week period. Given the data supporting gambling-induced opioidergic changes (67), the role of opioid function in modulating DA reward

and reinforcement pathways, and the results of the present study, larger-scale, placebo-controlled trials of mOR antagonists seem warranted.

COMPULSIVE BUYING

Part of "120 - Pathologic Gambling and Impulse Control Disorders "

Although recognized by Kraeplin and Bleuler a century ago, CB, then termed oniomania and more recently compulsive shopping or impulsive or addictive buying, has been relatively understudied in psychiatry (154 ,155 and 156). Although not formally listed in the DSM-IV (1), CB has a set of proposed diagnostic criteria (157), which include maladaptive preoccupation with or engagement in buying and the preoccupations or actual buying leading to significant distress or impairment. Additionally, the behavior cannot be better accounted for by a manic episode. Prevalence estimates have been made at 1% to 8% of the general population (157 ,158 and 159). Initial reports describe individuals with CB as generally in their thirties and predominantly female, with a 4:1 or greater female-to-male ratio (156 ,159 ,160). Individuals with CB are reported to have elevated rates of psychiatric comorbidity, particularly anxiety disorders, mood disorders, substance abuse or dependence, eating disorders, ICDs, and personality disorders (157 ,159 ,161).

Pharmacotherapy

Thymoleptic Treatment

Some authors have proposed depression as a significant underlying motivational factor related to engagement in CB (158 ,162 ,163). An early description of pharmacotherapeutic interventions in PG described the use of three antidepressant medications, fluoxetine, bupropion, and nortriptyline, in CB (164). Each of the three patients receiving the medications reported a partial or complete reduction in CB symptoms. In a larger study of 20 individuals with CB, nine of 13 patients who had received thymoleptic pharmacotherapy while they were symptomatic (69%) reported their CB to be in full (n = 5) or partial (n = 4) remission (157). The 20 study participants were predominantly female (n = 16) and often carried active comorbid diagnoses, most frequently mood (n = 18) or anxiety (n = 12) disorders. The effective drugs used varied widely and included bupropion, lithium, valproate, nortriptyline, desipramine, fluoxetine, sertraline, trazodone, clonazepam, diazepam, levothyroxine, and methylphenidate, often used in combination of two or more drugs simultaneously (157). Doses and durations of pharmacotherapy were not clearly defined in the report. The authors described full remissions up to only 7 months and partial remissions up to 13 months and noted that several of the drug trials were terminated after only a short period secondary to intolerable adverse effects (n = 2) or hypomania (n = 1). Although the relationship between pharmacotherapy and CB symptoms cannot be precisely determined from the study, the findings support the need for further systematic investigations into drug treatments for CB.

Selective Serotonin Reuptake Inhibitors

Given the repetitive, ritualistic buying behaviors and the intrusive preoccupations with buying associated with CB, the efficacy of SSRIs in the treatment of OCD, and the initial findings with SSRIs described earlier, an open-label trial of fluvoxamine in CB was undertaken (165). The ten participants in the study met the criteria for CB, as proposed by McElroy et al. (157), and not for an active mood or substance use disorder. Nine participants were female, and the average age of the group was 41.4±9.2 years. The study design included a 1-week placebo lead-in followed by an 8-week period of treatment with fluvoxamine and a subsequent drug taper and discontinuation (over 3 to 4 days) and reassessment off medication at the end of week 13. Responses were measured with the YBOCS modified for CB (YBOCS-SV), the CGI, patient self-rating, and other standardized scales for depression, disability, and OC symptoms. Nine of ten individuals were deemed responders, having a more than 50% reduction in YBOCS-SV scores at week 9 as compared with baseline. Highly significant improvements were observed at week 9 as compared with baseline in scores on both the obsession and compulsion subscales of the YBOCS-SV, the National Institute of Mental Health OC scale, patient self-rating reports, subscales of the Sheehan Disability Scale, and the CGI severity and improvement scales. Symptoms appeared to worsen but often remained improved from baseline during the 4-week discontinuation phase. The adverse effects reported were consistent with fluvoxamine's use in other patient populations, with sedation, headache, dry mouth, and gastrointestinal disturbances reported most frequently. The appearance of adverse effects did not result in discontinuation of the drug for any of the participants. The results from this initial study of fluvoxamine in the treatment of CB suggest it to be efficacious and well-tolerated and support the need for larger scale, placebo-controlled, double-blind studies of SSRIs in CB.

Opioid Antagonists

Given data supporting efficacy of the μ-opioid antagonist naltrexone in urge regulation and the role of μ-opioid function in modulating MCL DA pathways, a trial of naltrexone in the treatment of ICDs (including CB) was reported (152). Two patients with CB treated with naltrexone were described in detail in a series of 15 individuals with ICDs, with an additional three responders with CB mentioned in the report. One of the two responders had comorbid PG and CB, and this response is described earlier (in the PG

section). A second individual, a 46-year-old woman with comorbid CB and bulimia nervosa, was started on naltrexone at 50 mg per day. She initially developed diarrhea, which later resolved without discontinuation of the drug. After not experiencing improvement in target symptoms, her dose was increased to 100 mg per day at week 2. At this dose, she reported a significant decrease in thoughts and behaviors related to excessive shopping and disordered eating. She maintained her gains at 7 months and tolerated the medication with normal liver function tests and without adverse effects. The results from this initial report of open-label, high-dose naltrexone administration suggest that the drug may be effective in targeting symptoms of CB. Larger-scale, placebo-controlled, double-blind studies are warranted to define better the efficacy and tolerability of the drug in the short- and long-term treatment of individuals with CB.

COMPULSIVE SEXUAL BEHAVIOR

Part of "120 - Pathologic Gambling and Impulse Control Disorders "

Traditionally, the majority of attention given to disordered sexual behaviors has arguably been focused on the paraphilias. These disorders involve sexual arousal from inappropriate objects or partners and include fetishism, exhibitionism, voyeurism, sadomasochism, pedophilia, and zoophilia. Nonparaphilic excessive sexual behavior, currently classified as an “ICD not otherwise specified” in the DSM, involves repetitive, interfering sexual behavior without the use of inappropriate objects or partners (166). The term CSB has been used to encompass both paraphilic and nonparaphilic sexual disorders (167). CSB has been estimated to affect 3% to 6% of individuals in the United States (167 ,168 and 169), with most of those with the disorder thought to be male (167 ,170 ,171). Given the relatively high estimated prevalence rates and the clinical or social impairment often experienced with CSB, there exists a need for further well-defined studies into the epidemiology and treatment of CSB.

Pharmacotherapy

Thymoleptics

High rates of mood disorders have been reported in individuals with CSB (167 ,172). Case reports have been described supporting the efficacy of multiple thymoleptics in the treatment of CSB. Specifically, the following have been reported: electroconvulsive therapy (173) and treatments with lithium (174 ,175 and 176), buspirone (177), imipramine (178 ,179), desipramine (180), clomipramine (180), and the SSRIs (172 ,178 ,181 ,182 ,183 ,184 ,185 ,186 and 187), particularly fluoxetine and sertraline. In the following section, we describe one of the larger, systematic investigations performed to date.

Selective Serotonin Reuptake Inhibitors

Initial studies into the efficacy and tolerability of SSRIs in the treatment of paraphilic and nonparaphilic CSBs have been performed (187). In one study, 20 men with CSB were entered into a 12-week open-label trial of fluoxetine (172). Ten of the men had solely nonparaphilic CSBs, and the other ten had both paraphilic and nonparaphilic CSBs. Nineteen met the criteria for comorbid dysthymia and 11 for current major depression. Outcome measures included the Inventory to Diagnose Depression (IDD) and the Sexual Outlet Inventory (SOI). IDD scores were obtained at baseline and weeks 4, 8, and 12. Of the 20 entered participants, four discontinued (three nonparaphilic and one paraphilic, one each for alcohol abuse, no change in CSB, increase in CSB after initial remission, and increased anxiety and CSB). The mean dose of fluoxetine at week 12 was 39.37±14.81 mg per day. Significant reductions in both depressive and CSB symptoms were observed, with improvement in sexual symptoms independent of baseline depression scores. Sexual symptoms showing significant improvement included total sexual outlet and unconventional forms of masturbation, sexual activity, desire intensity, and sexual interests. Conventional sexual symptoms were not adversely effected. The promising results of this open-label study warrant larger, placebo-controlled, double-blind studies of specific subgroups of individuals with CSB to determine further the efficacy and tolerability of fluoxetine and other SSRIs.

Dopamine Augmentation

In individuals who respond incompletely to SSRIs, trials of augmentation with the DA-enhancing drugs methylphenidate or bupropion have been described. The rationale for use of these drugs has been described as related to multiple findings, including the efficacy of similar augmentation strategies in depressive disorders, improvement of SRIinduced adverse effects with these DA “agonists,” and comorbidity and similarities with attention-deficit/hyperactivity disorders (172). One investigator reports having treated more than 30 patients with the combination of an SRI and a DA drug (172). Further studies are needed to both explore possible DA dysfunction in CSB and to determine the efficacies and tolerabilities of DA drugs in CSB.

Hormone System Treatments

Several classes of drugs modulating hormonal systems, including antiandrogens, estrogens, and gonadotropin-releasing hormone (GnRH) analogues, have been investigated in the treatment of CSBs (187 ,188 ,189 ,190 ,191 ,192 and 193). The group of antiandrogens includes medroxyprogesterone acetate (MPA) and cyproterone acetate (CPA). MPA, a potent progestogen lacking antiandrogen effects at the androgen receptor level, has been tested in targeting CSB (reviewed in refs. 187 and 193).

CPA, also a potent progestogen but also with testosterone antagonist activity at the receptor level, has also been studied in the treatment of CSB (190 ,194). The results of placebo-controlled trials of MPA, CPA, or both (190 ,194 ,195), as well as data from a large number of open-label trials and case reports (reviewed in refs. 187 and 193), suggest a role for the drugs in the management of groups of individuals with CSBs, particularly sex offenders and elderly individuals with aggressive sexual behaviors. Although these agents are not effective for all patients (196), accumulating data suggest this family of drugs may be effective in subgroups of individuals with CSB, particularly those with repetitive deviant sexual behaviors (193). The drugs are limited by the emergence of adverse effects, including commonly weight gain, fatigue, hypertension, headaches, hyperglycemia, leg cramps, and diminished spermatogenesis (187). More rarely, feminizing effects may be seen, and thromboembolic phenomena may be seen more frequently with use of the drugs (187). Additional studies are needed to determine the long-term efficacy and tolerability of the antiandrogen drugs MPA and CPA in nonparaphilic and paraphilic CSBs.

Fewer studies have been performed to date to test the efficacy and tolerability in CSB of estrogens such as diethylstilbestrol (DES) (197) or transdermal estrogen (198) and GnRH analogues such as triptorelin (191) and leuprolide (196). Estrogen treatment works in a similar fashion to MPA and CPA in terms of decreasing luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion and thereby decreasing testosterone production. In contrast, GnRH analogues suppress testosterone production by stimulation of LH and FSH secretion leading to increased testosterone and estrogen levels. Continued administration results in insensitivity of the pituitary to GnRH, significantly reducing LH and FSH levels. One of the larger studies includes an open-label trial of triptorelin in the treatment of 30 men with paraphilic CSB. Treatment of 8 to 42 months' duration with injectable triptorelin at 3.75 mg per month resulted in significant decreases in deviant sexual fantasies and behaviors along with significant decreases in serum testosterone levels (191). Adverse effects included erectile failure, hot flashes, and decrease in bone mineral densities. As with antiandrogens, adverse effect profiles of estrogens and GnRH analogues may preclude widespread use of these classes of drugs in the treatment of CSB. However, a role for these drugs may exist in the treatment of specific subgroups of individuals with CSBs.

COMPULSIVE COMPUTER USE

Part of "120 - Pathologic Gambling and Impulse Control Disorders "

With the increasing availability of personal computers and the rapid expansion in use of the Internet, the emergence of disordered computer use has been described (199 ,200 ,201 ,202 and 203). The Internet provides immediate access to a broad range of impulsive behaviors, including gambling (both traditional forms as well as stock trading), shopping, and sexual behaviors, and it may be associated with an increase in the prevalence of related ICDs. Individuals with excessive and interfering computer use have been termed "webaholics" or "cyberholics," and their computer-related behaviors have been termed computer or Internet addiction or dependency, Internet addictive disorder, cyberaddiction, or CCU (204 ,205 and 206). Given the recent emergence of CCU, formal diagnostic criteria have not been developed or endorsed, pharmacologic treatment studies have not been reported, and its relationship with other disorders (e.g., OCD, substance use, mood and ICDs) has not been adequately investigated. Nonetheless, initial investigations into the characteristics of individuals with CCU have been performed.

One study using a 94-item questionnaire described four factors relating to CCU in a sample of college students (205). From 341 completed questionnaires, four factors (two major and two minor) were identified and were found to explain 31% of the variance. Factor 1 focused on problematic use of the Internet and included significant contributions from questions relating to staying on line too long, having a restricted repertoire of interests, and interference with sleep, diet, exercise, and attending meetings. Within this factor, lower levels of correlation but each above 0.35 were noted for computer hacking and gambling and use of the Internet to relieve sadness or loneliness. The second major factor focused on the usefulness and general purpose of computers or the Internet. Positive correlations with extensive use of the Internet and finding information loaded onto this factor. Interestingly, questions related to on-line shopping and downloading of nude images loaded onto factor 2, as compared with on-line gambling, which loaded onto factor 1. Given the estimated high rates of Internet use for sexually related activities (1% of a group of on-line computer users spending more than 11 hours per week) (207), definition of the characteristics of ICD-related online behaviors seems particularly important. A positive correlation with campus and negative correlation with home computer use also was observed within factor 2. Factor 3 focused on questions relating to a combination of shyness and introversion and using the Internet for sexual gratification (high correlation with physical arousal and downloading of nude images), whereas factor 4 focused on the absence of Internet problems and a mild aversion to or lack of interest in the technology. These initial findings suggest that some similar motivations that underlie other ICDs may lead to CCU and provide data that could be helpful in defining diagnostic characteristics for CCU.

A second investigation recruited 21 individuals (16 men, five women) with self-reported excessive computer use that interfered with social or occupational functioning or caused personal distress (206). Participants were mainly between 20 and 50 years of age, with 43% of the total sample falling between the ages of 21 and 29 years, inclusively. Observed were high rates of attempting to cut back on computer usage (62%) and comorbid psychiatric illness, including mood,

substance use, anxiety, and personality disorders. The findings of the studies by Black et al. and Praterelli et al. suggest the need for additional studies into the epidemiology and neurobiology of CCU, as well as pharmacologic and behavioral treatments for individuals with CCU.

CONCLUSIONS AND FUTURE DIRECTIONS

Part of "120 - Pathologic Gambling and Impulse Control Disorders "

Although understudied for a significant period of time by the psychiatric community, PG and other ICDs appear to be receiving an increasing amount of clinical attention. Significantly more research is needed to diminish the gap in our knowledge of ICDs as compared with other psychiatric illnesses and to optimize treatment strategies for the large number of individuals suffering from these disorders.

Daphne Simeon: Mt. Sinai School of Medicine, New York, New York.

Self-injurious behavior (SIB) is seen in a range of different psychiatric disorders, including stereotypic movement disorder, Tourette's disorder, borderline personality disorder, and psychotic disorders. An immediate question is to what extent similar psychobiological mechanisms mediate SIB across so diverse a spectrum of conditions. It has been argued that specific neurobiological mechanisms may be responsible for various symptoms across diagnostic categories; could the same hold true for self-injurious behaviors?

A closer exploration of the phenomenology of SIB suggests that there are a number of distinct types of self-mutilation (1). "Compulsive" self-injurious behavior is arguably exemplified by the stereotypic self-injurious behavior of stereotypic movement disorder (SMD). By definition, such behavior is composed of repetitive, seemingly driven, but nonfunctional motor behavior. Stereotypical SIB is also seen in a range of specific syndromes, including Lesch-Nyhan syndrome, Cornelia de Lange syndrome, and Prader-Willi syndrome. Although SMD is commonly encountered in patients with developmental disabilities, there is also evidence of it in intellectually normal adult samples (2), in the form of behaviors such as skin picking and nail biting.

The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) specifically excludes from the diagnosis of SMD the repetitive self-injurious symptoms of a range of other disorders such as pervasive developmental disorder, Tourette's disorder, and trichotillomania. Some of these behaviors arguably have an "impulsive" component in that they are preceded by increasing tension, and followed by pleasure, gratification, or relief. Similarly, certain self-injurious behaviors, perhaps predominantly in personality-disordered patients, can plausibly be described as "impulsive" in nature. This phenomenologic distinction between "compulsive" and "impulsive" is intended only to be heuristic; clinically, there may be significant overlap, with the impulsive wrist-cutter, for example, going on to develop apparently compulsive repetitive SIB.

This chapter briefly reviews work from animal studies of SIB, including animal stereotypies and veterinary behavioral disorders, before going on to consider the neuropsychopharmacology of a range of clinical disorders characterized by SIB. These include SMD in developmentally disabled patients, specific syndromes characterized by stereotypic SIB, SMD in intellectually normal patients (e.g., skin picking, nail biting, etc.), Tourette's disorder, autistic disorder, trichotillomania, and impulsive SIB in predominantly personality-disordered patients. Throughout the chapter we follow a schema of reviewing phenomenology, neurochemistry, and neuroanatomy in turn.

ANIMAL STEREOTYPIES

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

Phenomenology

Stereotypy may be defined as the excessive production of one type of motor act (3). Stereotypic behavior is species specific, with common behaviors including grooming, gnawing, and pacing. A subset of these stereotypies are self-injurious; these include excessive grooming and self-biting. Animal stereotypies can be induced by confinement (e.g., to a small enclosure) and by deprivation (e.g., being reared alone). Deprivation stereotypies are more likely to result in SIB (4), particularly in higher mammals (3).

Neurochemistry

Animal research on stereotypic self-injurious behavior has highlighted the role of the dopaminergic, serotoninergic,

and opioid systems. These systems also have important interactions with one another. Nevertheless, for the sake of simplicity, we list studies on each system in turn.

Early work with rodents demonstrated that amphetamines act to produce an increase in stereotypic behavior (5), including automutilation (6), and such findings have been replicated with different dopamine agonists in different species. These responses are prevented by 6-hydroxy-dopamine–induced lesions or by dopamine antagonists (7 ,8), perhaps particularly by D1 antagonists (9 ,10). Furthermore, early destruction of dopaminergic neurons may lead to hypersensitivity of D1 receptors, with increased self-biting behavior in response to later administration of dopamine agonists (11).

Traditional serotonin models include the administration of a monoamine oxidase inhibitor with L-tryptophan to induce a hyperactivity syndrome in rats, and the use of 5-hydroxytryptophan to induce the head-twitch syndrome in mice and the wet dog shake in rats. Reviewing this literature, Jacobs and Fornal (12) conclude that serotonin facilitates gross motor output and inhibits sensory information processing. Certainly, isolation may be associated with decreased serotonin turnover (13). Furthermore, in confining or depriving environments, the animal may activate dorsal raphe neurons by performance of stereotypies (12).

In animal work, opioid agonists may induce autoaggression, and opioid antagonists may be particularly effective in reducing self-injurious stereotypies in younger animals (14). Indeed, it has been suggested that excessive opioid activity is responsible for SIB (15). However, an alternative hypothesis emphasizes that pain associated with SIB results in the release of brain endorphins and draws a parallel between such endogenous release of endorphins and addiction to an exogenous substance (16).

From an integrated brain-mind perspective, interactions and overlaps between environmental and pharmacologic inducers of stereotypy would be predicted. Indeed, compared to normally reared rodents, isolation-reared subjects show increased stereotypic responses after administration of amphetamine (17) or tail-pinch (18).

Neuroanatomy

There is evidence that corticostriatal circuits are important in mediating stereotypic behavior (3). First, infusion of the dopamine into the caudate results in stereotyped orofacial behaviors (grooming, gnawing). Conversely, infusion of dopamine blockers into the same areas reduces amphetamine-induced stereotypy. Second, frontal lesions and dopamine agonists produce similar behavioral and cognitive effects, and frontal lesions exacerbate the effects of these agents. Furthermore, striatal lesions may also lead to stereotypic behavior. Reviewing this literature and his own work, Ridley (3) concludes that loss of inhibition induced by frontal lesions results in a release of previously stored response sequences. This view is consistent with a view of striatal function that emphasizes the development, maintenance, and selection of motoric and cognitive procedural strategies. Different terms given to allude to this group of functions have included habit system, response set, and procedural mobilization (19).

VETERINARY BEHAVIORAL DISORDERS

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

Phenomenology

In addition to animal laboratory studies, there is an interesting literature on veterinary behavioral disorders characterized by SIB (20). Acral lick dermatitis, for example, is a condition characterized by excessive paw licking and scratching in dogs. This results in the characteristic dermatitis; in severe cases sequelae include osteomyelitis. The disorder is seen in certain breeds of large dog, and within breeds may be more common in particular families.

Different species may manifest a range of different kinds of SIB (20). Psychogenic alopecia is found in cats, with excessive depilation leading to bare patches. Feather-picking in birds is seen in a range of avian species, and can be complicated by severe hemorrhage. Although stereotypies may appear to arise spontaneously in companion and domestic animals, as in laboratory animals, confinement and deprivation are robust elicitors of stereotypic and self-injurious behavior.

Neurochemistry

The pharmacotherapeutic profile of acral lick dermatitis overlaps remarkably neatly with that of obsessive-compulsive disorder (OCD) (21). Thus, the disorder responds to selective serotonin reuptake inhibitors (SSRIs), but fails to respond to desipramine or fenfluramine. However, the disorder may also respond to opioid agents. Although not well studied pharmacologically, there are a number of reports indicating that psychogenic alopecia responds to treatment with SSRIs. In addition, administration of a dopamine blocker has been noted to lead to a decrease in symptoms. Similarly, feather-picking in birds and SIB in horses may respond to treatment with SSRIs (20).

We noted earlier the cross-sensitization between pharmacologic and environmental inducers of stereotypies (22). Conversely, it can be emphasized that environmentally induced SIB may respond to psychopharmacologic intervention. For example, in a placebo-controlled study of fluoxetine in isolation-reared primates, this SSRI was effective in reducing such symptoms (23).

Neuroanatomy

In the previous section, the possible involvement of frontostriatal circuits in animal stereotypic behavior was noted.

With regard to stereotypic SIB in higher mammals, a particularly interesting finding is that socially isolated primates develop striatal cellular disorganization together with stereotypic and self-injurious behaviors (24). The neuroanatomy of early social isolation and other developmental stressors would seem to be a promising area for further investigation, one that may have direct relevance to some of the clinical disorders considered in the next part of this chapter.

SMD IN DEVELOPMENTAL DISABILITY

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

Phenomenology

SIB in patients with developmental disabilities may fall within the diagnostic category of SMD. This disorder is characterized by repetitive, seemingly driven, but nonfunctional motor behavior. Examples include body rocking, hand waving, head banging, and skin picking. The DSM-IV provides a subtype “with self-injurious behavior,” to be used when bodily damage requires medical treatment. We have reviewed this disorder elsewhere (25 ,26), and draw extensively on those reviews here.

A number of the DSM-IV criteria for SMD address the severity of the behavior. It must “markedly interfere with normal activities” or result in “bodily injury that requires medical treatment.” In patients with developmental disability the behavior must be sufficiently severe to be a focus of treatment, and the behavior must persist for at least 4 weeks. The DSM-IV also states that stereotypic behaviors in SMD should not be better accounted for by the compulsions of obsessive-compulsive disorder, the stereotypies of pervasive developmental disorder, or the tics of Tourette’s disorder.

SIB in patients with developmental disability may not always meet the rather strict DSM-IV criteria for SMD. Nevertheless, there is evidence that stereotyped, self-injurious, and compulsive behaviors appear to be correlated in such patients (27). Certainly, the relatively large body of work on the pathogenesis and treatment of stereotypic behaviors in this population may be useful in understanding and managing SIB.

Reports of the incidence of SIB in patients with developmental disability range from 3% to 46% (27 ,28). Head banging, head and body hitting, eye gouging, biting, and scratching are the most common of these behaviors (29). Behaviors may cause permanent and disabling tissue damage and may sometimes be life threatening. For example, severe head banging or hitting may lead to cuts, bleeding, infection, retinal detachment, and blindness. Incidence of SIB in patients with developmental disability is dependent on a number of factors that vary within this heterogeneous population, including extent of cognitive impairment (29) and institutionalization status (28).

Neurochemistry

It has been argued that there is phenomenologic evidence of similarities between SIB in patients with developmental disability and symptoms in patients with OCD (28). Furthermore, as noted earlier, in patients with developmental disability, there are significant positive associations between the occurrence of self-injury, stereotypy, and compulsions (27). Nevertheless, relatively few studies have directly explored the role of serotonin in mediating SIB in such patients.

There is, however, some evidence of the value of SSRIs in the treatment of SIB in developmental disabled patients. A retrospective review suggested that response of SIB in such patients was higher for SSRIs and was not predicted by comorbid depressive symptoms (30). Indeed, both open and controlled (31) studies have confirmed the efficacy of SSRIs in the treatment of SIB in developmental disabilities. Although this research is consistent with a role for serotonin in the mediation of SIB in mental retardation, questions remain about whether the effects of these agents are not “downstream” of their primary actions and about their specificity. Several methodologies are available for delineating different aspects of serotonin dysfunction in psychiatric patients, and the “pharmacologic dissection” strategy of comparing responses to clomipramine and desipramine has been useful in showing that serotonin plays a specific role in several disorders characterized by unwanted repetitive and/or self-injurious behaviors (32 ,33). A similarly designed study in mental retardation patients with SIB would be of interest.

It may be noted here that other agents with serotoninergic effects have also been studied for the treatment of SIB in developmental disability (28 ,34). 5-Hydroxytryptophan (5-HT) has been shown useful in only a minority of open studies. Buspirone (15 to 45 mg/day), a 5-HT_{1A} agonist, has been somewhat effective in small groups of adults with developmental disability and SIB. Eltoprazine, a selective 5-HT_{1A} and 5-HT_{1B} agonist, has yielded conflicting evidence of efficacy.

A number of agents, such as lithium and beta-blockers, have multiple neurotransmitter effects including serotoninergic effects. Although early studies in this area suffered from methodologic flaws, lithium has long been used with some apparent success in the treatment of SIB and aggressive behaviors in patients with mental retardation (28 ,34). Propranolol (90 to 410 mg/day) was reported to reduce SIB and aggression in a small case series of patients with mental retardation. Also, in a controlled study, pindolol (40 mg/day) was significantly more effective than placebo in 14 patients with developmental disability and SIB (35).

There has been relatively little direct work on the dopamine system in patients with developmental disability and SIB. Dopamine blockers, however, are often successfully used to manage SIB in such patients (28 ,34). Preliminary evidence suggests that the atypical neuroleptics, which have both dopaminergic and serotoninergic effects, may also be useful in SIB and other target symptoms in this patient population (36 ,37). Given their apparently favorable side-effect

profile, controlled trials with such agents are warranted.

Increased plasma enkephalin levels in patients with developmental disability compared with normal controls have been reported (38). Although this may support the excessive opioid hypothesis, it is also possible that decreased endogenous brain opioid levels ultimately lead to compensatory overproduction (39). It has also been argued, however, that opioid effects on self-injury may be primarily mediated via the dopamine or serotonin system (28).

There is some evidence that the opiate antagonists naloxone and naltrexone lead to a reduction in frequency of self-injury in different patient populations, including those with developmental disability (28 ,34). However, the total number of patients in such studies is relatively small, and the study designs have been criticized (39 ,40). Indeed, in a placebo-controlled study of 32 subjects with mental retardation and SIB and/or autism, naltrexone (50 mg/day) failed to have an effect on SIB and increased the incidence of stereotypic behavior (40). Although this finding does not entirely rule out a role for the opioid system, it further emphasizes the need for caution in drawing conclusions from open trials of treatment for SIB.

SIB may vary in women with mental retardation according to the stage of menstrual cycle. In one study, fluctuations in SIB were associated with early and late follicular phases. Although there are currently insufficient data for a specific association between self-injurious behavior and hormonal factors, such an association warrants further attention.

Further attention should perhaps also be paid to the role of the γ-aminobutyric acid (GABA)ergic system in SIB in developmental disability. The use of benzodiazepines in this population has not been well studied. The anticonvulsant valproic acid, however, was effective in reducing SIB and aggression in 12 of 18 patients with mental retardation and affective symptoms in a 2-year open trial (41). Positive response to valproate was associated with a past history of seizure disorder.

SYNDROMES WITH SELF-INJURIOUS BEHAVIOR

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

Phenomenology

Lesch-Nyhan syndrome (LNS) is an X-linked recessive disorder of purine synthesis. Patients present with hyperuricemia and neuropsychiatric symptoms including spasticity, choreoathetosis, dystonia, mental retardation, aggression, and self-injurious behavior. SIB in LNS is dramatic, and most commonly consists of biting of fingers and lips, although head banging, tongue biting, eye/nose poking, and self-scratching also occur (42).

Cornelia de Lange syndrome (CLS) is a rare congenital disorder characterized by a distinctive appearance and mental retardation. Patients with CLS manifest excessive grooming behavior (hand licking and hair stroking) and SIB including head slapping and self-scratching (43).

Prader-Willi syndrome (PWS) is a congenital disorder that affects approximately 1 in 10,000 newborns and is one of the five commonest abnormalities seen in birth defect clinics (53a ,53b). PWS is associated with marked hyperphagia, and the disorder is the most common dysmorphic form of obesity. In addition, PWS is characterized by behavioral disturbances, mental retardation, sleep disturbances, neonatal hypotonia, and hypogonadism. Behavioral disturbances include compulsive self-mutilation, impulsive temper outbursts, and classic obsessive-compulsive behaviors (44 ,45). SIB is common and not necessarily associated with cognitive impairment (45). It includes skin and nose picking, nail biting, lip biting, and hair pulling (45). Patients frequently have chronic skin sores.

Neurochemistry

Both the biochemical abnormality [virtual absence of hypoxanthine-guanine phosphoribosyltransferase (HPRT)] and the underlying genetic defect (a mutation of the HPRT locus located at q26-28 of the X-chromosome) in LNS are well identified. However, the mechanisms underlying neuropsychiatric symptoms are less clear. Nevertheless, the biochemical systems implicated do include the dopaminergic and serotoninergic systems.

Early postmortem findings in three patients with LNS demonstrated dramatically reduced levels of dopamine, homovanillic acid, and dopa decarboxylase in the basal ganglia (46), placing particular emphasis on the dopamine system. Animal studies with HPRT-deficient models and clinical studies of neurotransmitters and metabolite levels in patients with the disorder support the importance of dopaminergic mediation of symptoms (47).

It is interesting to note that although patients with both LNS and Parkinson’s disorder demonstrate decreased dopamine neurons and motoric symptoms, there are important differences. Parkinson’s disorder, for example, is characterized by diminished motor output, whereas LNS is characterized by uncontrolled and exaggerated motor activity. These differences may reflect the importance of the developmental stage at which dopaminergic deficits occur (11). Although dopamine supersensitivity has also been hypothesized to play a role in SIB in LNS (9), and dopamine blockers have been used for their treatment, long-term treatment with these agents is not clearly of benefit in LNS. Further understanding of the developmental neurobiology underlying this syndrome is therefore needed.

Phenomenologic similarities have been noted between excessive grooming in CLS and animal dopamine agonist-induced stereotypies. Nevertheless, there is little direct research to support a dopamine hypothesis of CLS. Indeed, the underlying neurobiology of this interesting syndrome remains relatively poorly understood.

Research has also focused on the serotonin system in LNS. Studies of cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) have been inconsistent in LNS, but there may be slightly increased putamen serotonin and 5-HIAA (46). In addition, early reports suggested 5-HT (1 to 8 mg/kg) was useful in the treatment of self-injurious behaviors in LNS. However, only a minority of subsequent studies have confirmed this finding (28).

In an early study, CLS patients were found to have reduced whole blood serotonin levels (48). Several possible mechanisms underlying this finding were considered, including a dysfunction in serotonin metabolism, failure to bind to platelets, and transporter abnormalities. Again, however, putative serotonin dysfunction may simply reflect dysfunction in other systems.

Serotoninergic mediation of PWS is raised by the role of serotonin and the efficacy of serotoninergic agents in appetite control and eating disorders, compulsive skin picking, impulsive aggression, and obsessive-compulsive–related disorders. A double-blind trial of fenfluramine found that this agent was useful for weight loss and other-directed aggressive behavior in PWS patients, but did not affect SIB (49). However, the SSRI fluoxetine has been described as useful for SIB in a number of cases of PWS. Similarly, a survey of caregivers suggested that SSRIs may be helpful for both impulsive-aggressive and compulsive symptoms in some PWS patients (45).

There is relatively little work on other systems in these disorders. GABAergic systems have been postulated to play a role in LNS, but again this hypothesis has not translated into successful pharmacotherapeutic strategies. Opioid antagonists have been reported to decrease appetite in some PWS patients, but controlled work has not supported their efficacy.

Abnormalities of chromosome 15 have been implicated in the etiology of PWS, and recent research using cytogenetic and molecular techniques suggests that identification of a specific genetic basis is possible in most patients. In about 70% of patients a cytogenetically visible deletion can be detected in the paternally derived chromosome 15 (15q11q13), whereas in about 20% of patients both copies of chromosome 15 are inherited from the mother (maternal uniparental disomy). Genotype-phenotype correlations in 167 patients with PWS found no significant difference in skin picking between patients with or without a chromosomal deletion (50). Nevertheless, the abnormal gene product in PWS may ultimately provide crucial information on the neurochemistry of the SIB characteristic of these patients.

Neuroanatomy

Most recently, volumetric magnetic resonance imaging (MRI) and positron-emission tomography (PET) techniques have documented reduced caudate volume and reduced dopamine transporters in caudate and putamen (51) as well as decreased dopa decarboxylase activity and dopamine storage throughout the dopaminergic system in LNS (52). It is possible that in LNS there is reorganization of the cortical–basal ganglia–thalamic pathways during development (52).

A number of authors have suggested hypothalamic-pituitary dysfunction in PWS. Again, however, further work is needed to extend these preliminary findings and to determine the relationship with behavioral symptoms. Indeed, at present little is ultimately understood about the underlying neurobiology of self-injury and other behavioral symptoms in this fascinating disorder.

SMD IN INTELLECTUALLY NORMAL INDIVIDUALS

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

Phenomenology

Skin picking and scratching appear to be not uncommon symptoms (53). The incidence of so-called neurotic excoriations in dermatology clinics has been estimated to be around 2%. Medical complications of skin picking include infection and scarring. Furthermore, skin picking may be associated with significant distress and dysfunction. At times, patients with these behaviors may meet criteria for OCD. However, in many other patients, this is not the case. Skin picking may also be seen in patients with the putative OCD spectrum disorders trichotillomania and body dysmorphic disorder.

Nail biting (onychophagia) is a common behavior that is not, however, necessarily benign (33). Nail biting may be associated with serious infection, nail bed damage and scarring, craniomandibular dysfunction, and dental disorders. The apparent ubiquity of mild nail biting should not discourage clinical and research attention to patients with more severe forms of the behavior.

A range of other common self-injurious stereotypies may be seen in intellectually normal adults including lip biting and eye rubbing (1). Certain kinds of stereotypies, such as thumb sucking and head banging, appear more common in children, although on occasion these behaviors may also be seen in intellectually normal adults (2). In a college population, the total number of stereotypic behaviors was significantly associated with increased scores of obsessivecompulsive symptoms, of perfectionism, and of impulsive-aggressive traits (54). Importantly, stereotypic behaviors may be associated with significant medical complications, and they may also lead to distressing feelings of shame and lowered self-esteem, as well as to social avoidance and occupational impairment.

Neurochemistry

Case reports suggested that the SSRIs may have a role in the treatment of skin picking. Indeed, in a series of 30

patients with skin picking, an open trial of sertraline demonstrated efficacy (55). Similarly, a retrospective treatment review of body dysmorphic disorder patients with skin picking indicated that SSRIs were often effective, whereas other agents were not (56). Finally, in their controlled study Simeon and colleagues (53) found that fluoxetine was significantly superior to placebo in decreasing compulsive skin picking in intellectually normal patients.

In nail biting, clomipramine appeared more effective than desipramine, although results were not perhaps as robust as those seen in classic OCD (33). The authors emphasized that there was a high dropout rate at every stage of the study, which appeared in sharp contrast to that seen in other psychiatric populations. They did, however, suggest that their data were consistent with the hypothesis that similar biological systems mediate a spectrum of grooming disorders, including OCD and trichotillomania.

Castellanos and colleagues (2) compared clomipramine and desipramine in a crossover trial of SMD patients. Although clomipramine appeared promising in a number of cases, too few patients completed the trial to demonstrate a clear benefit of clomipramine over desipramine. Nevertheless, several case reports suggest that SSRIs may be useful in patients with skin picking, head banging, and other self-injurious stereotypic behaviors (26). Given that dopamine agonists may result in SIB (57), a possible role for dopamine blockers, and the new atypical neuroleptics in particular, also warrants further consideration. Ultimately, controlled and long-term studies are needed to formulate rational approaches to the pharmacotherapy of SMD.

Neuroanatomy

To our knowledge, there have been no studies on the neuroanatomy of stereotypic movement disorder in normal controls. Given the ubiquity of these behaviors, and the presumptive role of cortico-striatal-thalamic-cortical (CSTC) circuits, this seems an area that may be worth investigating in more detail.

AUTISM

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

Phenomenology

Autistic disorder (or classic autism) is a pervasive developmental disorder characterized by impairment in social interactions, communication deficits, and restrictive and stereotyped behaviors. Stereotyped SIBs are common in patients with this disorder and may also be seen in other pervasive developmental disorders that do not meet the narrower criteria for autistic disorder (58). Common forms of SIB in autism include hand/wrist biting, head banging, self-scratching, self-hitting, self-pinching, and hair pulling.

It has been argued that repetitive behaviors in autism cannot simply be subsumed under the banner of OCD. Indeed, compared to patients with OCD, adults with autism were found to have a different range of repetitive symptoms. They were more likely to demonstrate repetitive ordering, hoarding, touching, tapping, or rubbing, and self-injurious behaviors (59). Nevertheless, it may be postulated that there are at least some similarities in the underlying neurobiological mediation of autism and OCD.

Neurochemistry

There does seem to be evidence of serotoninergic dysfunction in autism (60). Several studies have found elevated platelet serotonin levels in autism. Neuroendocrine challenge studies with serotoninergic agents have indicated reduced serotoninergic responsivity in autism. Furthermore, in a tryptophan depletion study, autism resulted in increased SIB, motor stereotypies, and anxiety.

Despite early reports of the efficacy of fenfluramine in open trials in autism, subsequent controlled trials were disappointing. However, both open and placebo-controlled (61) trials with SSRIs have demonstrated efficacy in reducing symptoms such as SIB in autism. Furthermore, the SSRI clomipramine was more effective than the noradrenergic reuptake inhibitor desipramine in autism (62). Nevertheless, not all studies of these agents have been positive (63).

Other neurochemical systems may also play a role in the mediation of self-injurious behaviors in autism. A PET study demonstrated reduced dopaminergic activity in the anterior medial prefrontal cortex (64). Controlled trials have demonstrated that dopamine blockers (like SSRIs) are effective in about 50% of patients with autism for target symptoms including SIBs (65 ,66). Clinical experience indicates that where a medication is ineffective in autism, an agent from a different class of medication may be useful (60). The atypical neuroleptics, with their combined dopaminergic and serotoninergic effects, also warrant further study.

Various authors have suggested a role for the opioid system in autism (40). However, studies of opioid levels in autism have been inconsistent. Furthermore, despite promising open trials, in controlled studies the effect of opioid blockers on target symptoms including SIB in autism has been disappointing.

There is promise for delineating the specific albeit multiple genetic factors underlying autism (60). Interestingly, there is preliminary evidence of a familial link with Tourette’s disorder. Most recently, a possible link to the serotonin-transporter gene has been suggested. Such work may ultimately lead to a clearer understanding of the neurochemistry of autism and self-injury and to specific therapeutic interventions.

Neuroanatomy

The neuroanatomy of autism has also received increasing attention in recent years (67). Preliminary postmortem studies have found abnormalities in the cerebellum and limbic

system, including the hippocampus and amygdala. Neurophysiologic research has demonstrated various abnormalities including aberrant processing in frontal association cortex. Early work with pneumoencephalography suggested left temporal horn dilatation, and an early MRI study found hypoplasia of the posterior cerebellar vermis, but later studies have been inconsistent. Functional brain imaging studies are also so far inconsistent, although perhaps suggestive of dysfunction in association cortex. Clearly, much remains to be done to understand the neuroanatomy of SIB, and indeed to integrate behavioral and biological findings in this disorder.

TOURETTE'S SYNDROME

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

Phenomenology

Compulsive self-injurious behavior is only rarely seen in OCD. In contrast, SIB is seen in 13% to 53% of Tourette's syndrome (TS) patients (68). A wide range of behaviors may be seen, particularly head banging and self-punching or slapping, but also including lip biting and tongue biting, eye poking, skin picking, and self-punching or -slapping. Medical complications have included subdural hematoma and vision impairment.

In a large study, SIB in TS was not correlated with intellectual function, but was significantly associated with severity of motor tics and with scores of hostility and obsessionality (68). Furthermore, SIB has been described as one of the compulsions that are more common in patients with TS than in OCD. Thus, although the neurobiology of SIB per se in TS has not been well studied, it is possible that this overlaps with that underlying tics and compulsions.

Neurochemistry

Several neurochemical systems have been implicated in TS, most notably the dopamine system, but including also the serotoninergic, noradrenergic, opiatergic, hormonal, and immunologic systems (see Chapter 117). However, to our knowledge little of this work has focused specifically on the neurochemistry of SIB in TS.

Neuroanatomy

From a neuroanatomic perspective, there is strong evidence that prefrontal–basal ganglia–thalamic circuits are involved in OCD. There is also increasing evidence that these circuits are among those that mediate TS (see Chapter 117). Of note, increased metabolism in the orbitofrontal cortex and putamen correlated with complex behavioral and cognitive features such as self-injurious behavior (69). As in OCD, further work is needed to determine whether this reflects a primary deficit or functional compensation.

TRICHOTILLOMANIA

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

Phenomenology

The term *trichotillomania* was coined over a century ago to describe patients with hair pulling. Hair pulling most frequently occurs from the scalp, although it can occur from a wide range of body areas, including the eyebrows, eyelashes, beard, axillae, and pubis (70). Plucking may be confined to a single patch, may involve different areas, or may cover the entire scalp. Some patients also report pulling hair from a child, significant other, or pet.

Patients with hair pulling may demonstrate a range of other stereotypic and self-injurious behaviors (70 ,71). Although hair pulling may lead to significant medical complications, including trichobezoar after ingestion of pulled hair, it is perhaps more commonly associated with significant feelings of shame and lowered self-esteem. Indeed, both the personal and the economic costs of this disorder may be significant.

Neurochemistry

Research on the neurobiology of hair pulling was boosted by a seminal trial comparing clomipramine and desipramine in trichotillomania (32). As in OCD, trichotillomania responded selectively to the SSRI. Nevertheless, although the SSRIs have seemed effective for trichotillomania in a number of open trials, these agents have proved disappointing in placebo-controlled trials (72).

Furthermore, although Swedo and colleagues found that trichotillomania response to clomipramine may be sustained over time, there are also reports that initial response to SSRIs in patients with hair pulling may be lost during continued treatment (72). Taken together, this work indicates that it may be premature to overly emphasize the specific role of serotonin in trichotillomania.

Indeed, few studies of trichotillomania patients have directly assessed monoamine concentrations. Ninan and colleagues (73) obtained CSF from a small group of patients with trichotillomania and found that CSF 5-HIAA levels did not differ from normal controls. However, baseline CSF 5-HIAA did correlate significantly with degree of response to SSRIs. This finding is redolent of some work on OCD and suggests that in both disorders response to SSRIs may be accompanied by a fall in CSF 5-HIAA levels.

There are also few studies of serotoninergic pharmacologic challenges in trichotillomania. Stein and colleagues (74) found that the 5-HT agonist m-chlorophenylpiperazine (mCPP), which has exacerbated OCD symptoms in some studies, did not lead to an increase in hair pulling in women with trichotillomania (74). The interpretation of these data is not straightforward; for example, whereas OCD symptoms may be present throughout the day, hair pulling is often triggered only in particular settings. Of interest,

however, trichotillomania subjects described an increase in feeling “high,” a phenomenon previously documented in patients with borderline personality disorder. It might be speculated that hair pulling in trichotillomania and self-injurious stereotyped behaviors in impulsive personality patients have some overlapping characteristics (71).

There is increasing evidence that dopamine plays a role in OCD and related disorders, perhaps particularly in those with a marked motoric component. There is some preliminary data that dopamine also plays a role in hair pulling. One report noted exacerbation of hair pulling by methylphenidate in a series of children (75). A similar phenomenon can be seen in adults with trichotillomania. Furthermore, preliminary open data suggests that augmentation of SSRIs with dopamine blockers may be useful in the treatment of hair pulling (76 ,77). The atypical neuroleptics, which have dopamine and serotonin antagonist effects, may also be effective augmenting agents in OCD and trichotillomania (78).

Christenson and colleagues found no significant differences in either pain detection or pain tolerance thresholds between trichotillomania patients and controls. On the other hand, this group have suggested that the opioid blocker naltrexone may be effective in the treatment of trichotillomania, indicating that further research on the opioid system in hair pulling may be useful (74).

Trichotillomania is predominantly a disorder of women in the clinical setting. It frequently begins around the time of the menarche, and in some women there is premenstrual exacerbation of symptoms (70). Nevertheless, to our knowledge there are no studies that directly explore hormonal mechanisms and hair pulling. Although there is therefore currently insufficient evidence to indicate a specific link between hair pulling and hormonal mechanisms, further work in this area seems warranted.

Genetic studies might shed light on the particular neurochemical mediators of trichotillomania. Nevertheless, there have been few such studies. Christenson et al. (79) reported that 8% of 161 trichotillomania patients had first-degree relatives with hair pulling. Another study failed to show elevated rates of trichotillomania in first-degree relatives of trichotillomania probands, but did find elevated rates of OCD (80). Furthermore, elevated rates of trichotillomania have been found in a cohort of patients with both OCD and TS as compared to those with TS or OCD alone (Miguel et al., unpublished data).

Neuroanatomy

The neuroanatomy of trichotillomania is comparatively poorly researched. There are only occasional reports of hair pulling in association with neurologic disorders, although once again basal ganglia lesions have been implicated (74). Neuropsychological and neurologic soft sign studies have also been partly consistent with involvement of the CSTC system in trichotillomania (74). Furthermore, a few studies of brain imaging in trichotillomania have now been undertaken.

Stein and colleagues (81) employed brain MRI and found no differences in caudate volume in female patients with trichotillomania and normal controls. O’Sullivan and colleagues (82) similarly found no difference in caudate volumes in trichotillomania and controls on MRI, but did find that patients with trichotillomania had reduced left putamen volumes. This finding is of particular interest given work demonstrating reduced left putamen volumes in Tourette’s syndrome.

Swedo et al. (83) found increased right and left cerebellar and right superior parietal glucose metabolic rates in trichotillomania patients compared with normal controls. This finding does not seem to support the hypothesis that orbitofrontal–basal ganglia circuits are key to this disorder, and differs from findings obtained in OCD and Tourette’s. However, patients were scanned at rest, rather than during hair pulling or during the performance of a neuropsychological test that might have activated these structures. Swedo and colleagues also found that anterior cingulate and orbital-frontal metabolism correlated negatively with clomipramine response, a result they had previously found in OCD. They concluded that increased orbital-frontal metabolism may comprise a compensatory response to basal ganglia pathology in both these disorders.

Stein et al. (74) studied single photon emission computed tomography (SPECT) scans in patients with trichotillomania before and after pharmacotherapy with the SSRI citalopram (74). During treatment there was a reduction in activity in left and right inferior-posterior and other frontal areas. In nonresponders there was an increase in baseline left and right superior-lateral frontal areas. These data are again to some extent consistent with work suggesting that trichotillomania, like OCD, is mediated by corticostriatal circuits.

The neuroimmunology of OCD and TS has recently been an important focus of study. Of particular interest to research on trichotillomania, Swedo et al. (84) reported that like OCD symptoms, hair pulling may relapse after streptococcal infections. In addition, a case report of a patient in whom hair-pulling symptoms appeared closely linked with Sydenham’s chorea has been published (85). Both choreiform symptoms and hair pulling remitted in response to penicillin treatment.

Nevertheless, no data have yet been published that establish a causal connection between *Streptococcus* or Sydenham’s chorea and hair pulling. Furthermore, Niehaus et al. (86) recently found that D8/17, a marker of susceptibility to developing sequelae after *Streptococcus* infection, was not more frequent in patients with trichotillomania than in controls. It remains possible, however, that particular subtypes

of trichotillomania have a specific neuroimmunologic etiology. Further research in this area is warranted.

IMPULSIVE SIB

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

Phenomenology

Common behaviors in this category include skin cutting, skin burning, and self-hitting. These behaviors frequently permit those who engage in them to obtain rapid but short-lived relief from a variety of intolerable states, in this sense serving a morbid and pathologic but life-sustaining function. Descriptive and systematic data indicate that SIBs of this type are typically impulsive, and hence their proposed classification in our schema.

Bennum (87), for example, reported that 70% of self-mutilators feel they have no control over the act. Favazza and Conterio (88) found that 78% of individuals in their sample decided to self-mutilate on the spur of the moment, and another 15% made the decision within an hour of the act. The act was then always (30%) or almost always (51%) carried out. Other studies by this group have also emphasized an association between impulsivity and self-mutilation (89). In another sample, less than 15% of self-mutilators reported any inner struggle to resist the behavior (90). Simeon et al. (91) found a significant correlation between the degree of self-mutilation and an independent measure of impulsivity.

An aggressive component has also been descriptively identified in impulsive SIB. Studies of impulsive self-mutilators show that 18% to 45% of individuals report anger toward themselves and 10% to 32% report anger toward others leading up to the acts of self-injury (87 ,90). Bennum (87) found that self-mutilators had greater outwardly directed hostility than nonmutilating depressives, while not differing in inwardly directed hostility. Simeon et al. (91) reported that, compared to nonmutilating controls matched for personality disorder diagnoses, self-mutilators had lifetime histories of greater aggression and sociopathy, and the degree of self-mutilation correlated significantly with chronic anger.

Some individuals engage in these self-injurious behaviors only a limited number of times in their lifetimes, whereas others do so quite frequently and habitually (1). As with other conditions on the compulsive-impulsive spectrum, the distinction between compulsive and impulsive repetitive self-injury may not always be sharp and clear. Impulsive repetitive self-injury can at times become so habitual as to occur on a daily or weekly basis and without clearly identifiable precipitating external events or affective states, as if it were a compulsion. It could be speculated that individuals who have an obsessive-compulsive predisposition may be more prone to become fixated on SIBs that were initially more episodic and impulsive and over time become habitual and dystonic. Interestingly, the few studies that have examined obsessionality in impulsive self-injury may indeed support such a notion. In one study comparing 22 female inpatient nonpsychotic “repetitive self-cutters” with 22 demographically matched inpatient controls, the patients with self-injury were significantly more obsessional than the controls while not differing in depression, anxiety, phobia, or hysteria (90). In another study comparing mutilating and nonmutilating antisocial women confined to a criminal ward, the self-injurers were found to be significantly more obsessional (92). On another note, impulsive and compulsive self-injurious behaviors can be comorbidly encountered in a certain proportion of individuals.

Although epidemiologic studies are lacking, it has been indirectly estimated that the incidence of impulsive self-injury may be at least 1/1,000 people annually (1). It is more common in females, and typically begins in adolescence or early adulthood, although it has been described as early as in the latency or even the preschool years. It is more commonly associated with certain disorders such as borderline personality disorder, antisocial personality disorder, posttraumatic stress disorder, dissociative disorders, and eating disorders. Of all these diagnoses, the one that appears most commonly associated with SIB is borderline personality disorder, but this is neither a necessary nor a sufficient condition, and the assumption of such may lead to premature diagnostic formulation and closure.

The relationship between impulsive self-injurious behaviors and suicide attempts warrants brief mention here. The coexistence of both behaviors in individuals with severe personality disorders may be more the rule than the exception. In a large, thoroughly studied series of chronically hospitalized highly disturbed patients, of 141 borderline females ten had histories of self-injury alone, whereas 20 had histories of both self-injury and suicide attempts (93). However, a 15-year follow-up of these patients suggested that history of self-injury alone was not a predictor of future suicide whereas a history of suicide attempts was; this observation indeed supports the distinct conceptualization of the two behaviors.

Traumatic experiences commonly predate and appear to contribute to the development of impulsive self-injury, and these traumatic experiences are more typically childhood ones. Although speculative, comparisons can arguably be made between the stereotypic and aggressive behavior of isolation reared primates, and symptoms of impulsive aggression and autoaggression in patients with impulsive personality disorders. In one large study of habitual female self-mutilators, childhood abuse was noted in 62% of the subjects. Of these, 29% reported both sexual and physical abuse, 17% reported only sexual abuse, and 16% reported only physical abuse. The onset of the abuse was typically early, reported as early latency, and it often involved family members (88). Indeed, abused and neglected children can begin to exhibit SIB from a disturbingly early age.

One comprehensive study attempting to tease out the contribution of various factors to the genesis and perpetuation of self-destructive behaviors followed 74 personality-disordered individuals over a 4-year period (94). A portion of this group had a history of self-mutilation, and within the self-mutilating group there was an 89% incidence of major disruptions in parental care and a 79% incidence of childhood trauma such as physical abuse, sexual abuse, or witnessing domestic violence. Sexual abuse most strongly predicted self-injury, which was also associated with younger age at the time of the abuse, as well as with childhood chaos, separations, and neglect. Dissociative experiences also correlated with self-mutilation. Interestingly, neglect and separation from caregivers predicted continuation of the self-injury in the face of treatment efforts, leading the authors to postulate that the latter traumas impaired the capacity to form trusting stable bonds with others that could then facilitate treatment change. Another study of borderline personality disorder inpatients compared to personality-disordered controls similarly found that both parental sexual abuse and emotional neglect were significantly related to self-mutilation (95).

Neurochemistry

Research over the last quarter century, has highlighted the role of the serotoninergic system in impulsive aggression. Initially focusing on serotoninergic dysregulation in attempted or completed suicide, studies later demonstrated similar neurochemical derangement in outwardly directed acts of impulsive aggression, as well as in inwardly directed aggression without suicidal intent.

As a background we briefly review the studies establishing a connection between serotoninergic dysregulation and impulsive aggression. An important series of studies by Brown et al. (96 ,97) demonstrated a decrease in CSF 5-HIAA in patients with personality disorder, and found that this decrease correlated with scores on a lifetime aggression scale. A series of subsequent studies have confirmed a relationship between CSF 5-HIAA and impulsive or aggressive behaviors. Linnoila et al.'s work (98) is of particular interest insofar as it specifically divided aggressive behaviors into impulsive and nonimpulsive forms, and CSF 5-HIAA correlated only with impulsive aggression.

A range of other static measures of serotonin function is consistent with serotonin hypofunction in impulsive aggression (99). In addition, neuroendocrine challenge studies, which provide a dynamic measure of serotoninergic function, confirm this relationship. Coccaro et al. (100), for example, administered fenfluramine to personality-disordered patients and found that prolactin response, a measure of net serotonin function, correlated inversely with impulsive aggression. Similarly, abnormal neuroendocrine responses after mCPP challenge have been observed in borderline personality disorder.

The literature on serotonin and suicide brings another dimension to the relationship between serotonin and impulsive aggression. Early postmortem studies found that brainstem levels of serotonin or 5-HIAA are decreased in suicide victims, and subsequent studies confirm that decreased serotonin and/or 5-HIAA in brainstem (raphe nuclei) and/or subcortical nuclei (hypothalamus) have been consistent postmortem changes in suicide completers (101). Recent genetic findings suggest that particular polymorphisms in the serotonin system may account for some of the variance in symptoms in impulsive personality disorders; such work may ultimately prove of significant value in understanding the neurobiology of SIB.

We previously presented descriptive data conceptualizing impulsive SIB as a form of impulsive aggression. Direct neurobiological data in impulsive SIB are very limited, yet consistent with serotoninergic dysregulation, and we summarize them below. Lopez-Ibor et al. (102) found that inpatient depressives with histories of self-injury without suicidal intent had lower CSF 5-HIAA than those without self-injury histories. Coccaro et al. (100) reported a significant correlation between self-damaging acts and a blunted prolactin response to the serotonin agonist fenfluramine in patients with personality disorders. Simeon et al. (91) reported a significant negative correlation between the frequency of self-mutilation and platelet imipramine binding, a peripheral serotoninergic index. In contrast to these studies, Gardner et al. (103) compared CSF 5-HIAA levels in borderline personality-disordered patients with and without self-mutilation, and found no difference. However, it cannot be ruled out that the different incidence of suicide attempt histories in the two groups may have concealed an association between CSF 5-HIAA and self-mutilation. In this regard, Simeon et al. (91) found a 44% reduction in CSF 5-HIAA in a small subsample of self-mutilators compared to nonmutilators who had never made suicide attempts. In a study by Siever and Trestman (104), self-directed aggression in personality-disordered subjects, as measured by a composite score of suicide attempts and SIB, was inversely correlated to the prolactin response to fenfluramine challenge. In a smaller sample of female personality-disordered patients, the relationship did not reach statistical significance (105).

More indirect evidence for underlying serotoninergic dysfunction in self-mutilation comes from open-treatment treatment studies utilizing SSRIs. Fluoxetine has been reported useful in decreasing SIB in a number of studies of borderline personality disorder. For example, in an open study of fluoxetine in 22 borderline and schizotypal patients, a 97% decrease in self-mutilating episodes was found (106). Clomipramine was apparently useful for SIB in OCD patients, many of whom had a history of sexual abuse (107). In an open trial of venlafaxine in subjects with borderline personality disorder (108), five out of seven subjects who engaged in self-injury ceased to do so after 12 weeks of treatment; of note, venlafaxine is both a serotonin and norepinephrine

reuptake inhibitor. Further pharmacologic trials, conducted in a double-blind fashion, and assessing larger numbers of patients, are needed to conclusively determine whether SSRIs are efficacious in treating self-injury, whether the response is selective in comparison to other pharmacologic agents, how the response compares to the change in other target symptoms, as well as to clarify the time course and maintenance of the therapeutic response.

Other neurotransmitter systems may also be involved in the neurobiology of impulsive SIB but have been even less studied. Siever and Trestman (104) have suggested that, in addition to serotoninergic dysfunction, noradrenergic dysregulation may be implicated in the expression of impulsive aggression. Specifically, noradrenergic hyperreactivity may mediate increased arousal and irritability and trigger acts of impulsive aggression, in conjunction with behavioral disinhibition mediated by serotoninergic dysfunction. A relationship between CSF MHPG and impulsive aggression has not been consistently replicated, but there is some evidence that personality-disordered patients may have increased growth hormone responses to clonidine challenge. We are not, however, aware of any studies of the noradrenergic system specifically in self-injuring individuals. A treatment study describing some success with venlafaxine in self-injury was mentioned above.

Another system implicated in impulsive SIB is the opioid system. Indeed, habitual self-mutilators commonly report the relief of depersonalization and other dissociative states as the motivation to injure themselves, and relative analgesia to the self-inflicted injury is often present in the emotional state surrounding such acts. The role of the endogenous opioid system in stress-induced analgesia seems established.

Actual data examining the opioid system in SIB or SIB-prone groups are limited. Russ and colleagues (109) examined the pain response to a cold pressor test in individuals with borderline personality disorder. Compared to subjects who experienced pain during self-injury, those who experienced analgesia reported less pain during the experiment. However, naloxone pretreatment did not increase discomfort induced by the test (110), casting some doubt on an endogenous opioid hypothesis. In one study of the opioid system, Coid et al. (111) found that habitually self-mutilating individuals had higher plasma metenkephalin than normal comparison subjects, but the finding might have been secondary to recent self-injury itself. A recent open study of naltrexone in female patients with SIB accompanied by analgesia and dysphoria reduction, and typically accompanied by a history of abuse, found that SIB symptoms ceased in six of seven subjects (112). However, these results need to be replicated in controlled studies.

Neuroanatomy

There has been little study of the neuroanatomy of SIB per se in borderline personality disorder (BPD). However, it would again seem relevant to this chapter to emphasize the increasingly large literature correlating frontal hypofunction with impulsive aggression. The classic case of Phineas Gage is an excellent example of the marked dysfunction, with increased impulsivity and perseveration, that results from frontal lesions. Subsequent studies of head injury and of frontal lobe surgery have led to multiple descriptions of such dysfunction.

A body of neuropsychological literature, although open to different interpretations, also points to a relationship between frontal dysfunction and impulsive aggression. Some of the strongest evidence of involvement of frontal lobe dysfunction, however, in impulsive aggression emerges from recent brain imaging studies. Preliminary findings include the demonstration of a significant association between decreased metabolic rates in prefrontal cortex and aggression in personality-disordered and aggressive patients. Similarly, there is increasing imaging evidence for neuronal dysfunction in antisocial personality disorder (113). Also, BPD subjects had diminished response to fenfluramine challenge in a number of areas of prefrontal cortex (114).

It is perhaps important to emphasize the way in which neurobiological factors in BPD may intersect with psychosocial ones. An abusive background, for example, may result in neurobiological changes that then further promote risk-seeking behavior in adult life. Research on the neurobiology of posttraumatic stress disorder similarly may provide a useful framework for developing hypotheses about childhood abuse and subsequent changes in personality. Such work may also shed light on the multiple roots of “impulsive” SIB.

CONCLUSION

Part of "121 - Compulsive and Impulsive Aspects of Self-Injurious Behavior "

In the literature on the obsessive-compulsive spectrum, it has been suggested that compulsive and impulsive symptoms and disorders reflect different kinds of psychobiological mechanisms. Compulsive symptoms, for example, may be mediated by serotonin and frontal hyperfunction, whereas impulsive symptoms may be mediated by serotonin and frontal hypofunction. In reality the complex neurobiology of compulsivity and impulsivity cannot be captured by so simplistic a contrast. Nevertheless, such contrasts arguably have some heuristic value.

Does this contrast apply also to compulsive and impulsive SIB? Perhaps patients with SMD have frontal/serotoninergic hyperfunction, whereas patients with BPD have frontal/serotoninergic hypofunction? Currently, there are insufficient data to make so bold a claim. Furthermore, in clinical and biological reality, the situation may be much more complex than this, with patients demonstrating both compulsive and impulsive features, and with disorders such as OCD, SMD, and BPD exhibiting brain areas of both serotonin hyperfunction and serotonin hypofunction.

Indeed, an alternative hypothesis is that stereotypic SIB can be seen after a number of different situations. First, in patients with overactivation of the basal ganglia, there may be excessive release of various motoric sequences, including SIB. Second, in patients with hypofrontal function, there may be an inability to control such programmed sequences. Environmental conditions such as deprivation may also disrupt the balance in corticostriatal circuits (3), in such a way as to produce symptoms.

Fortunately there a now a range of different approaches to understanding the neurobiology of unwanted repetitive symptoms. These include brain imaging, genetics, neuroimmunology, and pharmacological dissection. Although such approaches have shed light on some relationships between the OCD spectrum disorders, much further work is required before it is possible to make phenomenologic distinctions (such as compulsive vs. impulsive SIB) on the basis of differential psychobiological mechanisms.

In tackling this area of research, it may also be possible to integrate neurobiological with psychosocial data; compulsive SIB, for example, may be seen not only in response to a pharmacologic challenge but also after isolation, whereas impulsive behavior that is induced by an environmental stressor may nevertheless be mediated by specific neurobiological mechanisms. Future research should see an expansion in our understanding of the neuropsychopharmacology of compulsive and impulsive SIB, and thus in our ability to intervene effectively with patients who demonstrate these distressing and disabling symptoms.

Section XII
Movement Disorders and Proxysmal Disorders

Carol A. Tamminga

Carol A. Tamminga: University of Maryland School of Medicine; Deputy Director, Maryland Psychiatric Research Center, Baltimore, Maryland.

Movement Disorders and Proxysmal Disorders - Introduction

Diseases of the brain include human motor disorders and epilepsy, which are distinguished from primary behavioral disorders by the nature of their illness manifestations. These diseases have observable symptoms and, in several cases, cerebral pathology associated with genetic determinants. Especially the features of cerebral pathology and genetic association make it easier to model the critical disease elements in the animal and to move more directly to the neural underpinnings of pathology in human brain. Identified cerebral pathology provides an opportunity for targeting the involved central nervous system (CNS) regions and known brain networks for modeling and focused study. These kinds of CNS illnesses not only serve as models for behavioral disorders of a successful experimental approach, but also generate a valuable knowledge base for understanding human brain physiology in other human CNS illnesses. The known pathophysiology of Parkinson's disease (PD), not information on etiology, has allowed investigators in this field to focus on a relevant region of the brain to explain the neural substrate of Parkinsonian symptoms.

The chapter by Zigmond and Burke addresses the clinical features and critical pathophysiology of PD, and illustrates the value of critical genetic information in the understanding of PD, as well as clear descriptions of tissue pathology. The hypotheses of pathophysiologic mechanisms in PD, whether free-radical–mediated injury, programmed cell death, or effects of protein aggregation in tissue (or some combination of these processes) are identified. Moreover, the authors observe that this disease has been know for two centuries, and its critical pathology described for a half century, but it has only been in recent years that neurobiologic understanding of PD is emerging; this presents a gauge for the difficulty of the work and insight involved in understanding the mechanisms of brain diseases.

The chapter by Wichmann and DeLong does a masterful job of presenting the molecular anatomy and physiology of the basal ganglia thalamocortical network as it relates to PD. It is this feature of network pathology, advanced for several decades by these investigators, that continues to inform not only motor disorder research but aspects of cognition and affective research as well. Moreover, identification of the importance of the structures in this network in these brain diseases has allowed many different investigators to contribute data to produce a rich anatomic and electrophysiologic database of broad relevance for neural mechanisms.

Gracies and Olanow's chapter complements the first two chapters, providing an exhaustive and up-to-date review of therapeutic approaches and their pharmacologic mechanisms. They weave together clinical experience and practical clinical findings with the known neuropharmacology of the illness. L-dopa, dopamine agonists, anticholinergics, and other drug treatments are critically reviewed in detail as are the newer surgical and transplantation therapies now widely discussed. The broad knowledge base available for understanding therapeutic approaches in PD is illustrated in the chapter. After encountering the significant advances made in PD, discoveries in other CNS diseases appear more modest.

Ross and Margolis articulate progress in the understanding of Huntington's disease (HD), the known autosomal-dominant disorder where the gene has been identified for nearly a decade. They describe the characteristic motor, cognitive, and psychiatric symptoms and the usual symptomatic treatments. The known genetic etiology of HD uniquely provides a range of diagnostic and research opportunities

not available in other diseases, including the availability of a diagnostic test and a precise animal model. The genetic mechanism in HD has introduced the consideration of polyglutamine mechanisms in diseases of the brain and rational prophylactic therapies.

The chapter by Tamminga and Woerner presents the clinical course, risk factors, and pathophysiologic considerations for the iatrogenic hyperkinetic motor disorder tardive dyskinesia (TD). Since the etiology of this disorder is known, namely, chronic blockade of the dopamine receptor with antipsychotic drugs, it can be modeled in the experimental animal. This body of research has generated information relevant to TD pathophysiology and treatment, and has relied on the well-described experimental data characterizing basal ganglia structure, neurochemistry, and function.

Schwarcz, Scharfman, and Bertram complete this section with a chapter noting the contribution of extrahippocampal brain regions to the mechanisms of temporal lobe epilepsy. Although of considerable etiologic complexity, temporal lobe epilepsy demonstrates several common aspects of clinical presentation, molecular and cellular changes, and pathologic sequelae. These features are broadly developed in this chapter. The discussion of suspected cellular changes, synaptic reorganization, and neurogenesis in the manifestations of epilepsy makes the chapter an extremely timely contribution.

This section contains a diversity of cutting-edge presentations on human brain diseases that advance the boundaries of not only clinical phenomena but also neuroscience research.

122

Neurocircuitry of Parkinson’s Disease

Thomas Wichmann

Mahlon R. Delong

Thomas Wichmann and Mahlon R. Delong: Department of Neurology, Emory University School of Medicine, Atlanta, Georgia.

Recent progress in neuroscience research has led to major insights into the structure and function of the basal ganglia and into the pathophysiologic basis of Parkinson’s disease (PD) and other movement disorders of basal ganglia origin (3 ,4 ,116 ,313 ,314). The availability of suitable animal models, such as primates rendered parkinsonian by treatment with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), has been crucial in this progress (17 ,57 ,173). In addition, the renaissance of stereotactic surgery for PD and other movement disorders has provided valuable neuronal recording and imaging data from human subjects. Newer genetic models, for instance mice that overexpress αsynuclein, should provide further insights into the genetic backdrop upon which PD develops. This chapter summarizes from a systems perspective the pathophysiologic concepts that have arisen from the animal models and from work in patients with PD.

ETIOLOGY AND PATHOLOGY IN PARKINSON'S DISEASE

Part of "122 - Neurocircuitry of Parkinson’s Disease "

Idiopathic PD is a disorder characterized by the cardinal signs of akinesia (impaired movement initiation and poverty of movement), bradykinesia (slowness of movement), muscular rigidity, and tremor at rest. The etiology of the disease is uncertain and likely multifactorial, with both genetic and environmental/toxic factors playing a role (see below; see refs. 279 and 287 for review). Idiopathic PD must be distinguished from a large number of other disorders (“atypical” parkinsonism, or “Parkinson-plus” syndromes) which share some of the features of PD but exhibit additional signs (for instance, signs indicative of upper motor neuron, cerebellar or oculomotor involvement). Among these disorders are, for instance, the multiple systems atrophies, progressive supranuclear palsy, and corticobasal ganglionic degeneration. These “atypical” forms of parkinsonism are associated with different and more widespread pathologic abnormalities than those seen in PD proper, and will not be dealt with further in this chapter.

The salient pathologic feature of idiopathic PD is relatively selective degeneration of dopaminergic neurons in the substantia nigra pars compacta (SNc) that project to the striatum (99 ,137), and, to a lesser extent, to other basal ganglia nuclei such as the external and internal segments of the globus pallidus (GPe, GPi, respectively), the subthalamic nucleus (STN), and the substantia nigra pars reticulata (SNr) (99 ,137). Consistent with the early manifestations of motor dysfunction, in the early stages of PD, dopamine depletion is greatest in the sensorimotor territory of the striatum, the postcommissural portion of the putamen (157).

Although it appears that only a small minority of patients suffer from purely inherited forms of PD, investigations into the genetic mechanism that may underlie these cases are being very actively pursued in hopes of discovering pathogenetic mechanism for parkinsonism in general. Inherited forms of parkinsonism in fact have been known for many years (11 ,24 ,113 ,270 ,272), and it has been shown that specific forms of parkinsonism may be caused by different genetic mechanisms. For instance, in a large kindred with *autosomal-dominant* parkinsonism, the disorder was linked to genetic markers on chromosome 4 (PARK1) (233), and has subsequently been shown to be due to a mutation in the α-synuclein gene (215 ,234). α-Synuclein is one of the major components of Lewy bodies, i.e., eosinophilic inclusions in degenerating neurons in the SNc that have long been accepted as one of the pathologic hallmarks of PD (273). A form of *autosomal-recessive* juvenile parkinsonism is caused by a mutation in a gene on chromosome 6, called parkin (PARK 2) (160 ,192 ,286). Finally, *mutations in the mitochondrial DNA*, particularly those affecting complex I function, may also cause or contribute to PD (81 ,120 ,165 ,203 ,248). An involvement of mitochondrial dysfunction in

the development of some forms of parkinsonism is also suggested by findings indicating that the toxicity of MPTP may be due to its inhibition of the mitochondrial complex I enzyme reduced nicotinamide adenine dinucleotide (NADH) coenzyme Q1 reductase (58 ,120 ,197 ,247), and the recent discovery that systemic administration of the pesticide rotenone, a mitochondrial complex I inhibitor, induces striatal dopamine depletion in rats (33).

Overall, however, a *genetic predisposition* for environmental insults that lead to parkinsonism may be far more common than gene mutations that directly result in the disease (87 ,102 ,171 ,288 ,289). Epidemiologic studies have shown an association with rural living, well-water drinking, pesticide exposure, and wood-preservative use (70 ,163 ,236 ,237 ,253). An interesting inverse relationship has been reported between PD and smoking (112 ,128 ,134 ,153 ,240). Among specific toxins that may contribute to PD are MPTP and other isoqinoline derivatives (172 ,197), organophosphate pesticides (38), and perhaps mitochondrial toxins such as rotenone (33).

ANATOMIC SUBSTRATE FOR CIRCUIT DYSFUNCTION IN PARKINSONISM

Part of "122 - Neurocircuitry of Parkinson's Disease "

To understand how the relatively selective loss of dopamine in the basal ganglia leads to parkinsonism, it is necessary to consider in some detail the circuitry, molecular anatomy, and physiology of the basal ganglia and related structures.

The basal ganglia are a group of functionally related subcortical nuclei that include the neostriatum (composed of the caudate nucleus and the putamen), ventral striatum, GPe, STN, GPi, SNr, and SNc. These structures are anatomically related to large portions of the cerebral cortex, thalamus, and brainstem. The striatum, and, to a lesser extent, the STN, are the main entries for cortical and thalamic inputs into the basal ganglia. From these input nuclei, this information is conveyed to the basal ganglia output nuclei—GPi and SNr. Basal ganglia outflow is directed at a variety of targets, among them frontal areas of the cerebral cortex (via the ventrolateral and intralaminar thalamic nuclei), various brainstem structures (superior colliculus, pedunculopontine nucleus, parvicellular reticular formation), and the lateral habenular nucleus.

Input to the Basal Ganglia

The most abundant inputs to the basal ganglia are the topographically segregated corticostriatal projections (7 ,8 ,225). In primates, projections from the somatosensory, motor, and premotor cortices terminate in the postcommissural putamen, the motor portion of the striatum (97 ,98 ,167 ,168). Similarly, associative cortical areas project to the caudate nucleus and the precommissural putamen (110 ,254 ,320 ,321 and 322) and projections from limbic cortices, amygdala, and hippocampus terminate preferentially in the ventral striatum, which includes the nucleus accumbens and the olfactory tubercle (9 ,121 ,166 ,242).

Cortical inputs also terminate in the STN (1 ,126 ,210). The corticosubthalamic projection is derived from the primary motor, prefrontal, and premotor cortices (1 ,126 ,167 ,210). The segregation of cortical projections found in the striatum is also present in the STN. Thus, afferents from the primary motor cortex reach the dorsolateral part of the STN (126 ,210), whereas afferents from premotor and supplementary motor areas innervate mainly the medial third of the nucleus (126 ,168 ,210 ,212). The prefrontal-limbic cortices project to the ventral portion and the medialmost tip of the STN (1 ,27 ,126 ,193).

A second major group of inputs to striatum and STN arises from the intralaminar thalamic nuclei, the centromedian and parafascicular nucleus (CM/Pf). These nuclei have long been identified as major source of excitatory afferents to the basal ganglia (86 ,92 ,154 ,245 ,281 ,317). The projections to striatum and STN arise largely from different neurons in the parafascicular nucleus of the thalamus in rats (92 , but see ref. 79). In primates, CM projects to the motor portions of putamen and STN, whereas Pf projects largely to the associative and limbic territories (208 ,244 ,245 ,265).

Other thalamostriatal inputs arise from the ventral anterior (VA), ventrolateral nucleus (VL), and possibly even the cerebellar-receiving areas of the thalamus (VPLo) (196 ,265). These thalamostriatal projections are less well documented, and their functional significance is unclear. The available evidence indicates that these projections are much less prominent than the projections from the intralaminar nuclei.

Intrinsic Basal Ganglia Connections

The topographically segregated cortical information is conveyed from the striatum to the output nuclei of the basal ganglia (GPi and SNr). Striatofugal projections maintain the striatal organization into motor, limbic, associative, and oculomotor territories (8). The connections between the striatum and the output nuclei of the basal ganglia are thought to be organized into two distinct pathways, the so-called direct and indirect pathways (3 ,6 ,29). The direct pathway arises from a set of neurons that projects monosynaptically to neurons in GPi and SNr, whereas the indirect arises from a different set of neurons that projects to GPe (see ref. 106 for review). In deviation from this strict scheme, some striatofugal neurons may collateralize more extensively, reaching GPe, GPi, and SNr (226). GPe conveys the information it receives either directly or via the STN to GPi and SNr [and, as was recently shown, back to the striatum (159 , 274)].

Several studies have demonstrated highly ordered and specific relationships between the neurons in GPe, STN, and GPi that constitute the indirect pathway (256 ,262 ,266).

Thus, populations of neurons within sensorimotor, cognitive, and limbic territories in GPe are reciprocally connected with populations of neurons in the same functional territories of STN, and neurons in each of these regions, in turn, innervate the same functional territory of GPi (256 ,262), although additional, more divergent circuits may also exist (149 ,256 ,262 ,266).

The STN also provides a dense feedback projection to the GPe (35 ,52 ,205 ,216 ,256 ,258 ,264) and projections to the striatum (22 ,230 ,265), the SNc (158 ,261 ,264), the pedunculopontine nucleus (124 ,158 ,230), and the spinal cord (285). STN output is highly collateralized in the rat (77 ,297), but is more specific in primates (27 ,122 ,230 ,256 ,297) (but see refs. 228 and 229).

The subpopulation of striatal neurons that gives rise to the direct pathway can be further characterized by the presence of the neuropeptides substance P and dynorphin, by the preferential expression of the dopamine D1 receptors, and by the fact that these neurons (as well as most striatal interneurons) appear to be the targets of thalamic inputs from the centromedian nucleus (231 ,260). The subpopulation that gives rise to the indirect pathway expresses preferentially enkephalin and dopamine D2 receptors (105 ,176 ,283), and may be the principal target of cortical inputs (231 ,260).

Although the segregation of D1 and D2 receptors between the direct and indirect pathways is probably not as strict as initially proposed (2 ,282 ,283), it may still serve to explain the apparent dual action of dopamine, released from the nigrostriatal pathway arising in the substantia nigra pars compacta, on striatal output. Dopamine appears to modulate the activity of the basal ganglia output neurons in GPi and SNr by *facilitation* of transmission over the direct pathway and *inhibition* of transmission over the indirect pathway (104). The net effect of striatal dopamine release appears to be to reduce basal ganglia output to the thalamus and other targets (see below). This implies that a reduction of dopamine release as is seen in PD results in a net increase in basal ganglia output.

Output Projections of the Basal Ganglia

Basal ganglia output arises from both GPi and SNr. The segregation of GPi into a caudoventral “motor” portion and rostromedial associative and limbic areas (225) is maintained in the pallidothalamic projections (259). The motor territory of GPi projects almost exclusively to the posterior part of the ventrolateral nucleus (VLo in macaques), which in turn sends projections toward the supplementary motor area (SMA) (143 ,249 ,280), the primary motor cortex (MI) (135 ,136 ,143 ,148 ,152 ,213 ,241), and premotor (PM) cortical areas (135). The outflow from pallidal motor areas directed at cortical areas MI, PM, and SMA appears to arise from separate populations of pallidothalamic neurons (135), indicating that the motor circuit itself can be subdivided into subcircuits, each centered on specific cortical motor and premotor areas. Associative and limbic areas project preferentially to the parvocellular part of the VA and the dorsal VL nucleus (80 ,155 ,259), and may be transmitted in turn to prefrontal cortical areas (111 ,198), as well as motor and supplementary motor regions (68 ,143).

Other output projections from GPi arise mostly as collaterals from the pallidothalamic projection. Thus, prominent axon collaterals are sent in a segregated manner to the CM/Pf complex, which project to the striatum (see above), constituting one of the many feedback circuits in the basal ganglia–thalamocortical circuitry (259). Additional axon collaterals reach the noncholinergic portion of the pedunculopontine nucleus (PPN) (125 ,227 ,243 ,257 ,277), which gives rise to descending projections to pons, medulla, and spinal cord, and ascending projections to basal ganglia, thalamus, and basal forebrain (see ref. 144 for review).

Although the overlap between motor and nonmotor areas is probably greater in the SNr than in GPi (127), the SNr can be broadly subdivided into a dorsolateral sensorimotor and a ventromedial associative territory (78). By and large, projections from these areas target the same nuclei that also receive GPi output, but tend to terminate in different regions of these nuclei. Projections from the medial SNr to the thalamus terminate mostly in the medial magnocellular division of the ventral anterior nucleus (VAmc) and the mediodorsal nucleus (MDmc), which, in turn, innervate anterior regions of the frontal lobe including the principal sulcus (Walker’s area 46) and the orbital cortex (Walker’s area 11) in monkeys (140). Neurons in the lateral SNr project preferentially to the lateral posterior region of VAmc and to different parts of the MD. These areas of the thalamus are predominately related to posterior regions of the frontal lobe including the frontal eye field and areas of the premotor cortex, respectively (140). As is the case with GPi, SNr also sends projections to the noncholinergic neurons in the medial two-thirds of the PPN (117 ,243 ,271 ,277). Additional projections reach the parvicellular reticular formation, a region whose neurons are directly connected with orofacial motor nuclei (55 ,204 ,304), and the superior colliculus, which may play a critical role in the control of saccades (319). The latter projection is far more prominent in phylogenetically old animal species (amphibians) than in primates (189).

ROLE OF THE BASAL GANGLIA–THALAMOCORTICAL CIRCUITRY IN THE CONTROL OF MOVEMENT

Part of "122 - Neurocircuitry of Parkinson’s Disease "

At the most basic level, voluntary movements appear to be initiated at the cortical level of the motor circuit with output to brainstem and spinal cord, and to multiple subcortical targets, including the thalamus, putamen, and the STN. The exact nature of the information reaching either striatum

or the STN is not clear. Thus, studies of the electrophysiologic properties of corticostriatal projection neurons have shown that these neurons are different from corticospinal projection neurons (20 ,295) and tend to have slower conduction velocities and lower spontaneous rates, and are usually not responding to somatosensory input.

According to the current model of the functions of the basal ganglia–thalamocortical circuitry, activation of an ensemble of striatal neurons that give rise to the direct pathway leads to a reduction of inhibitory basal ganglia output from targeted neurons with subsequent disinhibition of related thalamocortical neurons (142). The net effect is increased activity in appropriate cortical neurons, resulting in a *facilitation* of the movement. In contrast, activation of the striatal neurons that give rise to the indirect pathway will lead to increased basal ganglia output and, presumably, to *suppression* of movement. Because the majority of neurons in GPi increase their firing rate with movement (103 ,202), the presumed increased suppression of unintended competing movements may be a particularly important role of the basal ganglia. Depending on the precise timing and anatomic connectivity, this dual action on movement could result in limiting the spatial or temporal extent of movements.

Clinical and experimental studies suggest that the basal ganglia play a role in specifying the amplitude or velocity of movement (14 ,46 ,59 ,74 ,142 ,296) or in maintaining postural stability during arm movements (142). The combination of information traveling via the direct and the indirect pathways of the motor circuit has been proposed to serve to either scale or focus movements (7 ,200 ,211). *Scaling* would be achieved by a temporal sequence of activity changes in the basal ganglia. Striatal output would first inhibit specific neuronal populations in GPi/SNr via the direct pathway, thus facilitating movement, followed by disinhibition of the *same* GPi/SNr neuron via inputs over the indirect pathway, leading to inhibition (“braking”) of the ongoing movement. In the *focusing* model, by contrast, inhibition of relevant pallidal/nigral neurons via the direct pathway would allow intended movements to proceed, whereas unintended movements would be suppressed by concomitant increased excitatory input via the indirect pathway in *other* GPi/SNr neurons (see discussions in refs. 145 and 309). Overall, the effect exerted by the two pathways in this case would be to further shape or sculpt the movement.

Both models are not entirely compatible with the available data. The focusing model, however, is difficult to reconcile with the fact that basal ganglia neurons become active after changes in cortex and thalamus are manifest (13 ,63 ,73 ,75 ,103 ,202 ,293 ,294 ,309). Both models are at odds with the fact that although STN lesions (thus an interference with the indirect pathway) result in spontaneous dyskinesias, they do not directly disrupt or alter voluntary movements.

The view that the basal ganglia are involved in the direct control of ongoing movements is too simplistic. A multitude of other motor functions of the basal ganglia are strong candidates, such as a role in self-initiated (internally generated) movements, in motor (procedural) learning, and in movement sequencing (115 ,250 ,318). These can only be mentioned in passing here, but will probably gain greater prominence in future models of basal ganglia function.

CHANGES IN BASAL GANGLIA CIRCUIT ACTIVITY IN PARKINSONISM

Part of "122 - Neurocircuitry of Parkinson’s Disease "

Regardless of the precise causation of the disease, all of the proposed proparkinsonian mechanisms have in common interference with the synthesis, and release or action of dopamine in the basal ganglia as well as cortex and thalamus. The study of pathophysiologic changes in the basal ganglia that result from loss of dopaminergic transmission in the basal ganglia has been greatly facilitated by the discovery that primates treated with MPTP develop behavioral and anatomic changes that closely mimic the features of PD in humans (17 ,47 ,100 ,170).

Changes in the activity over striatopallidal pathways were first suggested by studies in MPTP-induced parkinsonism in primates that indicated that the metabolic activity (as measured with the 2-deoxyglucose technique) is increased in both pallidal segments (60 ,201 ,222 ,252). This was interpreted as evidence of increased activity of the striatum-GPe connection and the STN-GPi pathway, or, alternatively, as evidence of increased activity via the projections from the STN to both pallidal segments. It was then shown directly with microelectrode recordings of neuronal activity that MPTP-induced parkinsonism in primates is associated with reduced tonic neuronal discharge in GPe, and increased discharge in the STN and GPi, as compared to normal controls (see example recordings in Fig. 122.1) (31 ,39 ,94 ,95 ,199).

In parkinsonian patients undergoing pallidotomy it has also been shown that the discharge rates in GPe are significantly lower than those in GPi (83 ,182 ,284 ,302), as had previously been shown in the MPTP-primate model. Recently, we have shown that treatment with MPTP results also in changes of neuronal activity in the second output nucleus of the basal ganglia, the SNr (Fig. 122.1). These changes in activity are qualitatively similar to those occurring in GPi (312). In addition, loss of dopamine in the striatum should also lead to reduced activity via the inhibitory direct pathway. To date, this has not been directly demonstrated, however.

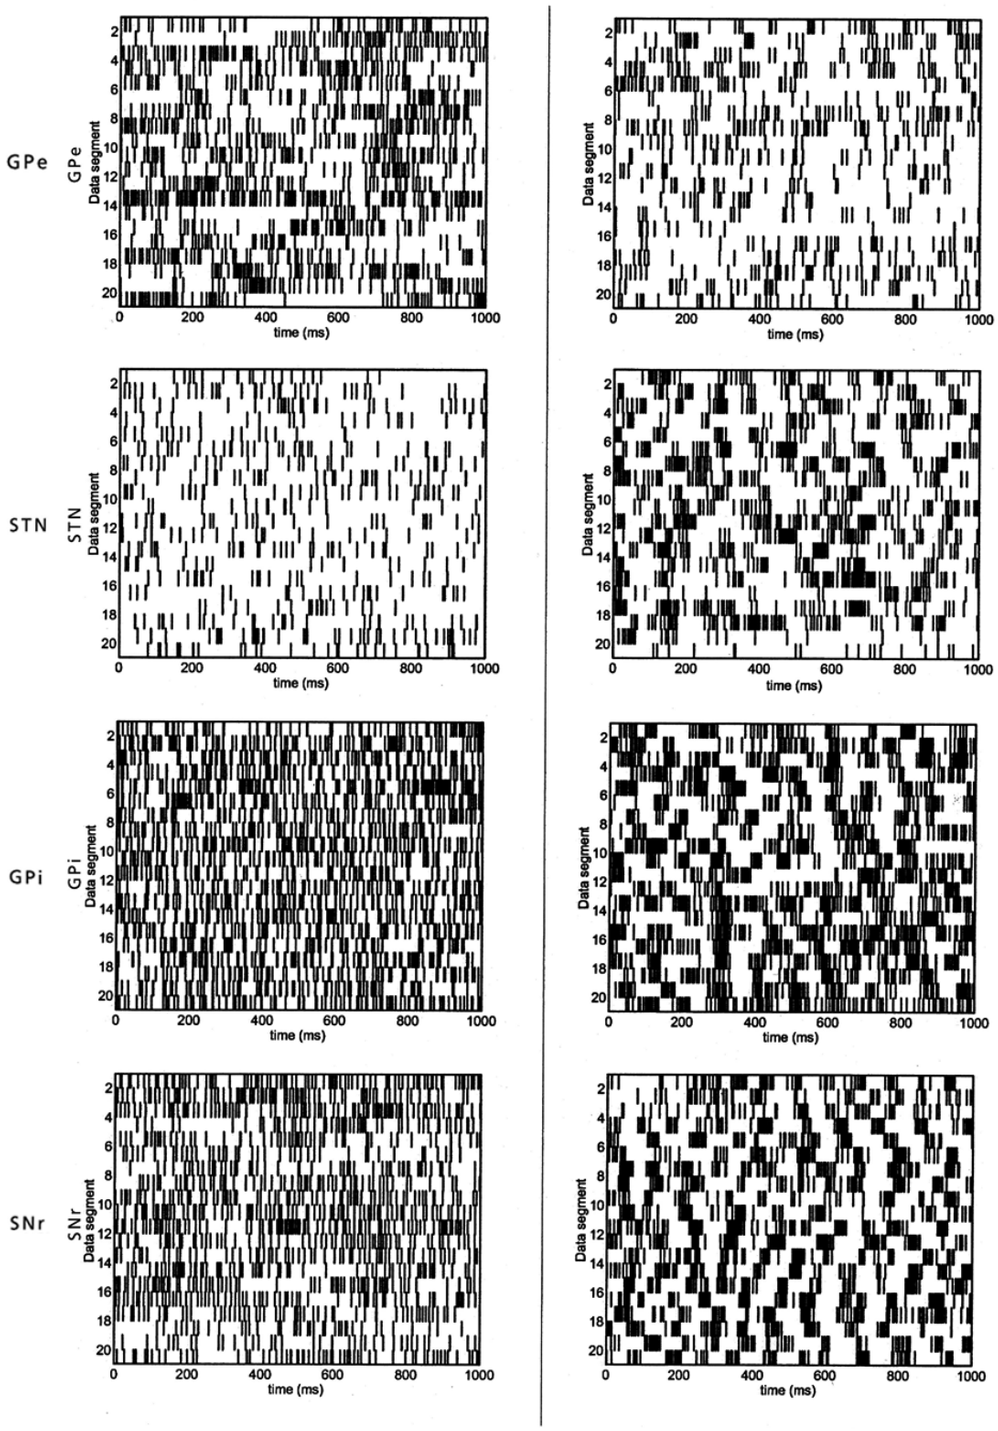

FIGURE 122.1. Raster displays of spontaneous neuronal activity recorded in different basal ganglia structures within the basal ganglia circuitry in normal and parkinsonian primates. Shown are ten consecutive 1000-msec segments of data from the external and internal segments of the globus pallidus (GPe, GPi, respectively), the subthalamic nucleus (STN), and the substantia nigra pars reticulata (SNr). The neuronal activity is reduced in GPe, and increased in STN, GPi, and SNr. In addition to the rate changes, there are also obvious changes in the firing patterns of neurons in all four structures, with a marked prominence of burstiness and oscillatory discharge patterns in the parkinsonian state. For further explanations, see text.

The changes in discharge rates in the subnuclei of the basal ganglia have been interpreted as indicating that striatal dopamine depletion leads to increased activity of striatal neurons of the indirect pathway, resulting in inhibition of GPe, and subsequent disinhibition of STN and GPi/SNr. The proposed pathophysiologic model of changes in the level of activity in the basal ganglia–thalamocortical motor circuit is summarized in Fig. 122.2 .

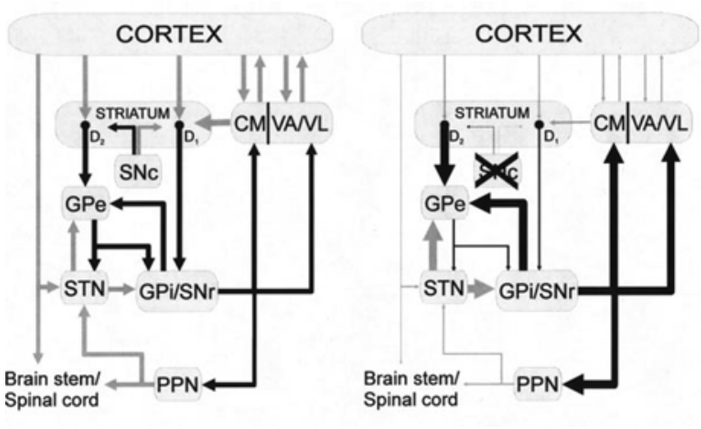

FIGURE 122.2. Model of the proposed rate changes in the basal ganglia–thalamocortical circuitry under normal (**left**) and parkinsonian conditions (**right**). In parkinsonism, dopaminergic neurons in the the substantia nigra pars compacta (SNc) degenerate, which results, via a cascade of changes in the other basal ganglia nuclei, in increased basal ganglia output from GPi and SNr. This, in turn, is thought to lead to inhibition of related thalamic and cortical neurons. In addition to the changes shown here, there are prominent alterations in discharge patterns (see text).

The basal ganglia circuitry incorporates multiple negative and positive feedback loops that may play a prominent role in the development and maintenance of abnormal discharge in the basal ganglia output structures. Some of the primary feedback loops that may directly affect GPi activity involve intrinsic basal ganglia structures such as GPe and STN (the two pathways labeled *3* in Fig. 122.3), or structures outside of the basal ganglia, such as the thalamic nucleus CM (labeled *1* in Fig. 122.3), the PPN (labeled *2* in Fig, 122.3) (101 ,117 ,161 ,263), and the habenula (e.g., GPi → lateral habenula → raphe nuclei → SNc → striatum → direct, indirect pathway → GPi; not shown in Fig. 122.3). Positive feedback loops, such as the one involving PPN and the STN (labeled *2*) and the pathway through CM and the putamen (labeled *1*) will tend to aggravate or enhance the abnormalities of discharge in the basal ganglia output nuclei associated with movement disorders, such as PD, whereas negative feedback circuits, such as a feedback involving CM and STN (not shown) will act to normalize neuronal discharge in the basal ganglia output nuclei. It is worth noting that via the CM nucleus, activity changes in the indirect pathway may influence the activity along the direct pathway. Thus, increased STN output in parkinsonism, by an action via GPi and CM, may result in a reduction of activity along the direct pathway.

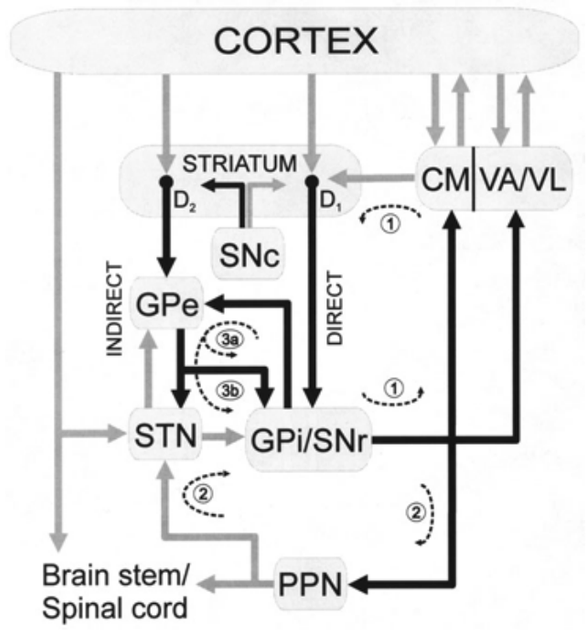

FIGURE 122.3. Simplified schematic diagram of the basal ganglia–thalamocortical circuitry under normal conditions. Inhibitory connections are shown as *filled arrows*, excitatory connections as *open arrows*. The principal input nuclei of the basal ganglia, the striatum, and the STN are connected to the output nuclei—GPi and SNr. Basal ganglia output is directed at several thalamic nuclei [ventral anterior/ventrolateral (VA/VL) and centromedian (CM)] and at brainstem nuclei [pedunculopontine nucleus (PPN) and others]. Some of the many important feedback connections are shown by the *dashed lines*. For further explanation of the model, see text.

The pathophysiology of early parkinsonism may differ from that of late parkinsonism in several aspect. For instance, increased STN output in early parkinsonism may have a compensatory function by increasing glutamatergic drive on SNc neurons. Thus, it has been shown that local injections of glutamate receptor blockers into the SNc significantly worsen motor signs in early stages of MPTP-induced parkinsonism (36 ,37), whereas such worsening is

no longer seen in later stages of the disease, probably reflecting loss of the majority of dopamine neurons in the SNc. At the same time, increased glutamatergic drive onto surviving SNc neurons may also be (excito-) toxic (239).

The reciprocal changes in activity in the indirect and direct pathways following dopamine depletion should both result in increased activity in GPi/SNr, and, subsequently, increased basal ganglia output to the thalamus and increased inhibition of thalamocortical neurons. The 2-deoxyglucose studies mentioned above demonstrated increased (synaptic) activity in the VA and VL nucleus of thalamus (60 ,201 ,252), presumably reflecting increased inhibitory basal ganglia output to these nuclei. Consistent with this are positron emission tomography (PET) studies in parkinsonian patients that have consistently shown reduced activation of motor and premotor areas in such patients (42 ,48 ,54 ,88 ,90), although no changes have been seen in the thalamus. Alterations of cortical activity in motor cortex and supplementary motor areas have also been demonstrated with single-cell recording in hemiparkinsonian primates (306).

The finding that SNr activity is also abnormal in parkinsonism is potentially important, because output from this nucleus reaches different cortical targets than output from GPi. For instance, the movement-related output from the SNr appears to reach predominately premotor areas, and could conceivably play a role in some aspects of akinesia (141). In addition, the SNr carries a substantial portion of the nonmotor circuitry of the basal ganglia. Abnormal SNr discharge may therefore be associated with some of the non-(limb)-motor abnormalities in parkinsonism, including oculomotor disturbances as well as cognitive, behavioral, and emotional disturbances.

Brainstem areas such as the PPN may also be involved in the development of parkinsonian signs. It has been shown that lesions of this nucleus in normal monkeys can lead to hemiakinesia, possibly by reducing stimulation of SNc neurons by input from the PPN, or by a direct influence on descending pathways (51 ,146 ,162 ,206). It remains unclear, however, whether the motor abnormalities seen after PPN inactivation in fact are related to parkinsonism or represent changes in the behavioral state or other disturbances that have no direct relation to PD. It is noteworthy that these animals do not manifest rigidity or tremor, which appear to be critically dependent on thalamic circuitry (see below).

It is important to realize that parkinsonism is a *network* disease. Changes that arise in any portion of the complex basal ganglia–thalamocortical circuitry will have significant consequences in all other areas of the network. This implies that the search for a parkinsonism-inducing “source” of abnormalities in the neuronal activity within the network may be futile, but suggests also that surgical or pharmacologic interventions at a variety of targets within the network could be successful. This can indeed be appreciated when considering the results of lesion studies in parkinsonian primates. One of the most important and dramatic in this regard was the demonstration that lesions of the STN in MPTP-treated primates reverse all of the cardinal signs of parkinsonism, presumably by reducing GPi activity (16 ,30 ,119). Similarly, GPi and SNr inactivation have been shown to be effective against at least some parkinsonian signs in MPTP-treated primates (179 ,181 ,308 ,315).

Over the last decade, these results from animal studies have rekindled interest in functional neurosurgical approaches to the treatment of medically intractable PD. This was first employed in the form of GPi lesions (pallidotomy) (19 ,85 ,169 ,183 ,276 ,301) and, more recently, with STN lesions (108). In addition, high-frequency deep brain stimulation (DBS) of both the STN and GPi have been shown to reverse parkinsonian signs. The mechanism of action of DBS remains controversial. It appears most likely, however, that DBS and lesions act similarly in that both result in an overall reduction of basal ganglia output.

PET studies in pallidotomy patients performing a motor task have shown that frontal motor areas whose metabolic activity was reduced in the parkinsonian state became again active after the procedure (53 ,85), providing support for the concept of excessive pallidal inhibition of thalamocortical systems in PD, which, when eliminated, reverses the major parkinsonian signs. DBS of the STN and GPi have revealed similar changes with PET, further supporting this concept as well as the belief that DBS appears to act functionally like ablation.

The experience with inactivation or deep brain stimulation of the SNr is very limited at this point. There are no studies of the effects of (exclusive) lesioning of the SNr available, and one case report on the effects of (inadvertent) stimulation in the ventral STN/dorsal SNr area reported the appearance of psychiatric depression during episodes of stimulation (23). This clearly needs further study, but it seems that the SNr may not be a feasible target for surgical interventions, because of its prominent involvement in nonmotor functions, and possibly also because of the greater degree of overlap between the different functional territories in this nucleus (123 ,127 ,186).

Controversial Issues

It has long been clear that the aforementioned models of the pathophysiology of parkinsonism are too simplistic, and that they cannot explain many of the clinical and experimental features of the disease. Thus, although the results of lesions in parkinsonism seem at first glance easily explained by the above-mentioned rate-based model of parkinsonism, more detailed studies of the results of lesions in patients with parkinsonism have brought to light several important findings that are not compatible with the models. For instance, in contrast to the prediction of simple rate-based models, lesions of the “basal ganglia–receiving” areas of the thalamus (VA/VL) do not lead to parkinsonism and in fact are beneficial in the treatment of both tremor and

rigidity (45 ,109 ,220 ,290)). Similarly, lesions of GPi in the setting of parkinsonism lead to improvement in all aspects of PD without any obvious detrimental effects. Furthermore, they are, often in the same patient, effective against both parkinsonism and drug-induced dyskinesias (217 ,235). In contrast to the abnormalities seen in parkinsonism, such dyskinesias are thought to arise from pathologic *reduction* in basal ganglia outflow (223 ,313), and thus should not respond positively to further reduction of pallidal outflow (190).

The assumption that parkinsonism may at least in part result from altered processing of proprioceptive input, abnormal timing, patterning, and synchronization of discharge that introduces errors and nonspecific noise into the thalamocortical signal may help to explain these seemingly paradoxical findings. Alterations in discharge patterns and synchronization between neighboring neurons have been extensively documented in parkinsonian monkeys and patients. For instance, neuronal responses to passive limb manipulations in STN, GPi and thalamus (31 ,95 ,199 ,299) have been shown to occur more often, to be more pronounced, and to have widened receptive fields after treatment with MPTP. There is also a marked change in the synchronization of discharge between neurons in the basal ganglia. Cross-correlation studies have revealed that a substantial proportion of neighboring neurons in the globus pallidus and STN discharge in unison in MPTP-treated primates (31). This is in contrast to the virtual absence of synchronized discharge of such neurons in normal monkeys (309). Finally, the proportion of cells in STN, GPi, and SNr that discharge in oscillatory or nonoscillatory bursts is greatly increased in the parkinsonian state (31 ,94 ,199 ,300 ,302 ,311). Oscillatory burst discharge patterns are often seen in conjunction with tremor. The question of whether this is simply a reflection of tremor-related proprioceptive input or of active participation of basal ganglia in the generation of tremor is still unsettled (see below).

Conceivably, altered neuronal activity patterns in the basal ganglia may play an important role in parkinsonism. Thus, increased phasic activity in the basal ganglia may erroneously signal excessive movement or velocity to precentral motor areas, leading to a slowing or premature arrest of ongoing movements and to greater reliance on external clues during movement. Alternatively, phasic alteration of discharge in the basal ganglia may simply introduce noise into thalamic output to the cortex that is detrimental to cortical operations. The polarity and exact nature of the abnormal patterning and overall activity in the basal ganglia–thalamocortical pathways may determine the nature of the resulting movement disorder.

The foregoing discussion indicates that in patients with movement disorders it is not only the loss of basal ganglia contribution to movement that must be compensated for, but also the disruptive influence of the inappropriate basal ganglia output. The therapeutic benefits of GPi and STN lesions suggest that in patients with PD and other movement disorders the absence of basal ganglia input to the still intact portions of the basal ganglia–thalamocortical network is more tolerable than abnormal input. Near-normal motor function is still possible in these disorders once the abnormal basal ganglia–thalamocortical input is removed. It needs to be emphasized, however, that the surgical interventions do not necessarily normalize cortical motor mechanisms in parkinsonian subjects, but rather may allow the intact portions of the thalamocortical and brainstem system to more effectively compensate for the loss of the basal ganglia contribution to movement.

Another recent further challenge to the proposed pathophysiologic model of parkinsonism has arisen from histochemical studies on the amount of messenger RNA (mRNA) for GAD_{67}, one of the enzymes synthesizing γ-aminobutyric acid (GABA) in basal ganglia neurons. In contrast to GAD itself, which is found in neuronal cell bodies or terminals, the mRNA for the enzyme is thought to be contained exclusively in cell bodies. In these studies the GAD mRNA activity in a given nucleus is therefore taken as a parameter for the level of activity of GABAergic neurons in the nucleus under study. Experiments in parkinsonian primates have shown that, as expected from the above-mentioned model, GAD_{67} mRNA activity is increased in GPi neurons (131 ,132 ,269), and is reversed with levodopa administration. GAD_{67} mRNA activity in the GPi of humans with parkinsonism, however, was found to be similar to that in controls, possibly because these patients were chronically treated with levodopa (131 ,132). Some of the findings regarding GAD mRNA in GPe, however, are at odds with the above-mentioned model in which the activity of GABAergic neurons in GPe is decreased. In rats, primates and humans, GAD_{67} mRNA in GPe was either unchanged in the parkinsonian state or even increased (56 ,72 ,131 ,132 ,268). These results have been interpreted as evidence that GPe and GPi function may not be as tightly linked via the indirect pathway as proposed by the model outlined above, and that the observed activity changes in the basal ganglia may primarily be due to altered activity via the corticosubthalamic projection or dopaminergic inputs to STN itself, which, by changing STN activity, may cause the neuronal activity in both nuclei to increase, possibly due to a greater tendency of neurons to discharge in bursts (178). However, the consistent finding of significantly decreased GPe discharge in MPTP-treated animals (93 ,94 ,199) and patients with PD (83 ,182 ,284 ,302) is difficult to reconcile with the lack of change in GAD_{67} mRNA in GPe. Conceivably, GAD_{67}-mRNA levels may reflect something other than neuronal discharge rates (191 ,238), or may be greatly influenced by the emergence of burst discharges. In a recent study it was shown that GABA levels in the STN, which are at least in part reflective of GABA release from terminals of GPe axons, were reduced in MPTP-treated primates, as predicted by the above-mentioned model (267). This finding casts further

doubt on the assumption that GAD_{67}-mRNA levels are a reliable predictor of the activity along the GPe outflow pathways.

PATHOPHYSIOLOGY OF INDIVIDUAL PARKINSONIAN MOTOR SIGNS

Part of "122 - Neurocircuitry of Parkinson's Disease "

Although the cardinal parkinsonian signs of tremor, rigidity, akinesia, and bradykinesia are generally all present in a given patient, they can occur independently of each other. For instance, patients with severe akinesia/bradykinesia do not necessarily exhibit tremor or rigidity, and severely akinetic patients may not experience significant bradykinesia or rigidity. This suggests that the different signs may depend on different pathophysiologic mechanisms, possibly involving different subcircuits of the larger motor circuit. The physiologic basis of the cardinal parkinsonian motor signs will be briefly considered in the following subsections.

Akinesia

Akinesia, the hallmark of PD, is characterized by a global impairment of movement initiation, affecting gross and fine movements as well as gait. In extreme cases, akinesia is experienced as freezing episodes, i.e., periods of complete motor block (107). Although there is some evidence that certain aspects of akinesia may be related to abnormal activity along the brainstem projections of the basal ganglia output nuclei (162), most authors attribute akinesia to changes in cortical processing, due to altered basal ganglia output to the thalamus. Freezing episodes may be the manifestation of temporary near-complete failure of compensatory mechanisms. This happens more often in late than in earlier stages of the disease, suggesting that the compensatory reserve of remaining intact thalamic, cortical, and brainstem circuits becomes smaller as the disease progresses.

As mentioned above, as a first approximation, overall discharge rates in the basal ganglia output nuclei have an impact on movement. GPi/SNr rates are determined by the amount of striatal dopamine, which in turn determines the balance between overall discharge in the direct and indirect pathways. There are many possible ways in which increased basal ganglia output could lead to akinesia. For instance, increased tonic inhibition of thalamocortical neurons by excessive output from GPi/SNr may reduce the responsiveness of cortical mechanisms involved in motor control. Increased tonic inhibition of thalamocortical neurons by increased basal ganglia output in parkinsonism may also render precentral motor areas less responsive to other inputs normally involved in initiating movements or may interfere with "set" functions that have been shown to be highly dependent on the integrity of basal ganglia pathways (6).

Akinesia may be a good example of a parkinsonian sign whose development appears to depend on discharge abnormalities in specific subcircuits of the motor loop. PET studies of cortical activation in akinesia-predominant parkinsonism suggest that the supplementary (SMA) and dorsal premotor areas are hypoactive in such patients (44 ,147). Moreover, pallidotomy results in increased metabolism in these areas in association with improvement in akinesia and bradykinesia (43 ,88 ,91 ,114 ,129 ,246). Further evidence for abnormal activity in these nuclei comes from studies of the Bereitschaftspotential (readiness potential), a slow negative cortical potential that precedes self-paced movements and is thought to reflect the neural activity in SMA (71). The early portion of the Bereitschaftspotential is smaller in parkinsonian patients than in age-matched controls (82 ,218), suggesting a deficit in the normal function of the SMA in the early stages of preparation for self-initiated movements. Akinesia may be thus related to abnormal discharge in a subcircuit whose activity may be to a large degree "preparatory" (5 ,12 ,40 ,61 ,148 ,251), interfering with the planning and early execution stages of movement. A disorganization of preparatory activity in SMA neurons was indeed identified with electrophysiologic methods in hemiparkinsonian primates (306).

One of the inconsistencies with the concept of akinesia as a consequence of increased inhibition of thalamocortical neurons is the finding that thalamic lesions per se do not appear to result in akinesia, as predicted by the model (but see ref. 49), although VA/VL lesions are effective in reducing rigidity and tremor. These findings argue against the view that increased tonic pallidal output and resulting inhibition of the neurons in the VA/VL nuclei is the sole or even the major reason for the development of akinesia. Alternatively, the fact that ventral thalamic lesions do not appear to influence akinesia may indicate that akinesia develops as a consequence of abnormally reduced activity in the intralaminar thalamic nuclei, or in the PPN with its descending brainstem projections. As discussed earlier, CM/Pf involvement may be the reason for the finding of prominent changes in cortical activity associated with akinesia, whereas involvement of the PPN is suggested by the finding that lesions of this structure result in poverty of movement (162 ,206).

Bradykinesia

Although bradykinesia is usually associated with akinesia, as mentioned earlier, these two signs can be strikingly dissociated in some patients. The pathophysiology of bradykinesia may be closely associated with the postulated scaling function of basal ganglia output (see above) (25 ,305) and is probably also dependent on abnormal processing in prefrontal cortical areas that are strongly influenced by increased basal ganglia output. In normal monkeys, neurophysiologic studies and, more recently, PET studies investigating cerebral blood flow have described an influence

of velocity/amplitude on the discharge of neurons in these premotor cortical areas (21 ,62 ,130 ,296).

Conceivably, abnormally increased phasic GPi/SNr output during movement may signal excessive speed and/or amplitude of ongoing movement, leading to a corrective reduction in cortical motor output (as mentioned above). PET studies, measuring cerebral blood flow in human parkinsonian patients investigated before and during deep brain stimulation of GPi, have revealed that stimulation that improved bradykinesia led to an increase in blood flow in the ipsilateral premotor cortical areas (69). A PET study has shown a significant correlation between movement speed and basal ganglia activation (296), and the loss of this in PD (Turner et al., personal communication). Thus there are several independent lines of evidence for the role of the basal ganglia motor circuitry in the scaling of movement and the disruption of this in diseases such as PD.

Rigidity

Parkinsonian rigidity is characterized by a uniform (“plastic”) increase in resistance to passive movements about individual joints. A “cogwheel” feature may result from superimposed, and usually subclinical, tremor (96). The pathophysiology of rigidity is elusive, but it has been suggested that altered basal ganglia output, mediated via the PPN and its output to the pontine nucleus gigantocellularis and the dorsal longitudinal fasciculus of the reticulospinal projection, may lead to increased inhibition of spinal Ib interneurons, which in turn may disinhibit α-motoneurons (50 ,76 ,139 ,175). Abnormalities of long-latency reflexes (LLRs) may also play a role in abnormal α-motoneuron excitability (26 ,174 ,291 ,292 ,316), although the velocityindependence of rigidity suggests that it is not a reflex phenomenon per se. The finding that rigidity can be abolished by interruption of the basal ganglia–thalamocortical circuit at multiple levels (STN, GPi, and thalamus) suggests that pallidal output leads to rigidity via the thalamocortical route rather than via brainstem projections.

Tremor

Parkinsonian tremor is typically a 4- to 5-Hz tremor at rest that is suppressed by voluntary movement. Parkinsonian tremor has been shown to be critically dependent on the integrity of the thalamic nucleus ventralis intermedius (Vim), which contains neurons that exhibit oscillatory discharge at the tremor frequency (177 ,214 ,219), although a tight correlation between oscillatory discharge and tremor is often not observed (28 ,221). Lesions of Vim have also been shown to abolish tremor (207). It has been proposed that thalamic oscillatory discharge may be induced by hyperpolarization of these cells induced by increased inhibitory basal ganglia output (224). This increases the likelihood that these cells will discharge in bursts (156 ,180 ,278). On the other hand, tremor may also arise from oscillatory discharge originating within the basal ganglia, based on the finding of oscillatory discharge patterns in the STN and GPi in parkinsonian patients and animals (31 ,84 ,150 ,284 ,311). These oscillatory discharge patterns may arise from local pacemaker networks, such as a feedback circuit involving GPe and STN (232). It has also been speculated that intrinsic membrane properties of basal ganglia neurons are conducive to the development of oscillatory discharge (15 ,34 ,209) in basal ganglia neurons themselves, or that they may contribute to the generation of oscillatory discharge in the thalamus (303 ,310 ,313), which may then be transmitted to the cortex. Finally, and perhaps most likely, oscillations throughout the entire basal ganglia–thalamocortical network may be tightly related to each other, so that no one oscillator can be identified as their sole source (187 ,188).

Support for the concept that altered basal ganglia discharge either alone or as part of the basal ganglia–thalamocortical network is important in the pathogenesis of tremor comes from lesion studies showing that parkinsonian tremor in MPTP-treated African green monkeys and in patients with parkinsonism is significantly ameliorated by lesions of the STN and GPi (19 ,29 ,284 ,310). It has been suggested that loss of *extrastriatal* dopamine may contribute to the development of tremor, because primates in which MPTP treatment affects the dopamine supply to GPi (African green monkeys) tend to develop tremor, whereas species in which the dopamine supply to GPi is not as severely affected (Rhesus monkeys) rarely develop parkinsonian tremor (28). Furthermore, in a postmortem study it was found that the degree of dopamine loss in the striatum did not correlate with the extent of tremor in parkinsonian patients, whereas the degree of dopamine loss in the pallidum did (32). More direct evidence for a role of extrastriatal dopamine in the development of tremor is lacking, however.

It remains unclear which oscillation frequency within the basal ganglia in fact is related to tremor. Oscillatory discharge in the basal ganglia of MPTP-treated primates has been shown to occur in at least two different frequency bands—the 3- to 5-Hz range, and the 8- to 15-Hz range (28 ,31 ,310). Although, intuitively, discharge in the lower frequency range would be expected to be more directly related to tremor at the typical parkinsonian frequency range, there is some evidence that oscillations in the higher frequency range in fact may be an important determinant of tremor. Thus, in MPTP-treated animals in which tremor had been eliminated with STN lesions, oscillations in the 8- to 10-Hz range in GPi were also greatly reduced, whereas oscillatory discharge in the lower frequency band persisted (310). In addition, basal ganglia neurons in tremulous animals show considerable coherence in the 8- to 15-Hz range, but not in the 3- to 5-Hz range (28). A process by which 10-Hz oscillations could be transformed in the thalamus into 5-Hz oscillatory discharge has been proposed by Pare

et al. (224). However, even primate species that generally do not show tremor after MPTP treatment (i.e., Rhesus monkeys) develop 8- to 13-Hz oscillations in the basal ganglia output nuclei (28 ,31 ,199 ,312). The difference between monkeys with and those without tremor may therefore lie not in the presence or absence of oscillations, but rather in the degree of synchronization between neighboring neurons. For tremor to occur, significant synchrony with little phase difference in large neuronal assemblies may be required. Thus, in one study the phase shift distribution of oscillatory cross-correlograms of neighboring pallidal cells in MPTP-treated vervet monkey were tightly clustered around a 0-degree phase shift, whereas the oscillatory correlograms in the MPTP-treated rhesus monkey were more widely scattered between 0 and 180 degrees (28). It is tempting to implicate the motor subcircuit that is centered on the motor cortex in the pathogenesis of tremor, because tremor-related neurons are focused primarily in the most ventral portions of the sensorimotor GPi (118), a region that in the monkey has been shown to project (via the thalamus) to the motor cortex.

Nonmotor Symptoms of Parkinson's Disease

Besides the cardinal (and early) skeletomotor abnormalities, parkinsonism is also associated with oculomotor abnormalities, such as hypometric and slow saccades (41 ,138 ,184 ,185 ,255 ,298 ,307), autonomic dysfunction, depression, anxiety, sleep disturbances, impaired visuospatial orientation and cognitive abnormalities (18 ,64 ,67 ,194 ,275). It is likely that at least some of these abnormalities rely on abnormal discharge in nonmotor circuits of the basal ganglia, which may be affected by dopamine loss in much the same way as the motor circuit. This is particularly true for oculomotor abnormalities that may directly result from dopamine depletion in the caudate nucleus (151 ,164). Similarly, some (20) of the cognitive and psychiatric disturbances seen in parkinsonian patients are reminiscent of syndromes seen after lesions of the dorsolateral prefrontal cortex (problems with executive functions) or of the anterior cingulate (apathy, personality changes), and may be the result of loss of dopamine in the dorsolateral or ventral caudate nucleus, respectively (65). Besides abnormalities in dopaminergic transmission in the striatum, several studies indicate that concomitant noradrenergic and serotoninergic deficiencies could contribute to the mood alteration in PD. For instance, cerebrospinal fluid levels of the serotonin metabolite 5-hydroxyindolacetic acid are reduced in depressed parkinsonian patients compared with nondepressed parkinsonian patients, and selective serotonin reuptake inhibitors are effective in treating parkinsonian depression (10 ,67 ,195). Finally, disturbance of the normal function of cortical–basal ganglia–thalamocortical circuits has also been implicated in the occurrence of obsessive-compulsive disease, as well as in Tourette's syndrome (66 ,89 ,133).

CONCLUSION

Part of "122 - Neurocircuitry of Parkinson's Disease "

From the considerations above, a complex model of parkinsonism emerges in which relatively selective dopamine depletion in the striatum and other basal ganglia nuclei results in increased and disordered discharge and synchronization in motor areas of the basal ganglia–thalamocortical motor loops. Abnormal activity in one or more of the basal ganglia feedback loops may contribute to the development of parkinsonism. Individual parkinsonian motor signs appear to be caused by distinct abnormalities in basal ganglia discharge, and by involvement of specific subcircuits related to distinct cortical targets. It is probable that progressive loss of dopamine in nonmotor areas of the striatum and other basal ganglia nuclei may underlie the nonmotor abnormalities of PD. By contrast, drug-induced dyskinesias are characterized by decreased pallidal output. Differences in the balance between direct and indirect pathways, and in the degree of synchronization of discharge in the basal ganglia output nuclei must be invoked to explain the striking clinical differences between PD and the drug-induced dyskinesias and dystonia. A critical analysis of the effects of pallidal and thalamic lesions in hypo- and hyperkinetic disorders strongly suggests that the main features accounting for the different signs of movement disorders are the appearance of not only changes in discharge rate, but also altered discharge patterns, changes in the degree of synchronization of discharge, altered proprioceptive feedback, and "noise" in the basal ganglia output signal. It is proposed that both ablation and deep brain stimulation are effective in treating both hypo- and hyperkinetic disorders because they both remove the abnormal signals directed to the thalamus and brainstem, thus allowing these intact systems to compensate more effectively.

The current models of basal ganglia pathophysiology are incomplete and should be taken as a first draft of basal ganglia dysfunction in the different disease states. Most pertinently, changes in phasic discharge patterns, and new anatomic connections need to be better incorporated into any new concept of basal ganglia function and a greater emphasis placed on the manner in which thalamic, brainstem, and cortical neurons utilize basal ganglia output.

Pathophysiology of Parkinson's Disease

Michael J. Zigmond

Robert E. Burke

Michael J. Zigmond: Departments of Neurology and Psychiatry, University of Pittsburgh, Pittsburgh, Pennsylvania.

Robert E. Burke: Department of Neurology, Columbia University, New York, New York.

Parkinson's disease (PD) is thought to affect more than 1 million people in the United States alone, 1 of every 100 individuals above the age of 55. In the two centuries since it was first described by James Parkinson, we have learned a great deal about the disorder. We have, for example, learned where the primary lesion is and what many of the clinical manifestations are. However, it has only been in the past few decades that insights have begun to emerge regarding the cause of the disease, and only now can one begin to see the possibilities of treatments emerging that will provide more than temporary symptomatic relief. Beginning with the Nobel Prize–winning work of Arvid Carlsson, which pointed to the loss of dopamine (DA) as the principal deficit in PD and to levodopa as a mode of pharmacotherapy, we have come to understand what fails in this disorder and, more recently, how we might correct that failure. Moreover, although Parkinson focused entirely on motor symptoms, we have come to realize that the disorder is much more complex and includes a panoply of psychiatric symptoms as well.

The clinical features, course, and treatment of PD are presented in detail in Chapter 122 and Chapter 124 ; thus, for the purposes of this review of etiology and pathogenesis, we only briefly highlight the more important aspects of these topics, including those of a psychiatric nature. We then describe the pathology before turning to several promising leads with regard to the underlying etiology of the disorder.

CLINICAL SIGNS AND SYMPTOMS

Part of "123 - Pathophysiology of Parkinson's Disease "

Motor Manifestations

PD is a chronic, progressive neurologic disease. It presents with four cardinal motor manifestations: tremor at rest, rigidity, bradykinesia (or slowing of movement), and postural instability. Not all patients initially present with all of the classic signs of the disorder; there may be only one or two. Often, the first complaint is one of motor weakness or stiffness, and the cause is commonly misdiagnosed. However, postural deficits and tremor may soon emerge, prompting a reconsideration of the basis of the problem. It is important to note, however, that the clinical diagnosis of PD is made on the basis of a medical history and neurologic examination; there is currently no laboratory test that can definitely establish a diagnosis. Even neuroimaging, which can be used to obtain an estimate of DA loss (15 ,128), is imperfect and in any event is too expensive to be used as a routine diagnostic tool. As a result, it has been estimated that a significant number of individuals diagnosed as having PD fail to show the histopathologic hallmarks of the disease upon autopsy (48 ,70 ,134).

A *tremor* at rest is one of the most characteristic features of the disease, occurring in 70% of patients (68). Whereas it is not required for diagnosis, the prolonged absence of tremor in the course of a patient's illness should lead to the careful consideration of other neurologic conditions that can present with signs of parkinsonism, including the multiple system atrophies, progressive supranuclear palsy, corticobasal ganglionic degeneration, and others (94). *Rigidity* is a motor sign more often appreciated by the examining physician than the patient; it is detected as a resistance to passive movement of the limbs. It is often uniform in directions of flexion and extension (“lead pipe rigidity”), but there may be a superimposed ratcheting (“cogwheel rigidity”). *Bradykinesia* refers to a slowness and paucity of movement; examples include loss of facial expression, which may be misinterpreted as a loss of affect, and associated movements such as arm swinging when walking. Bradykinesia is not due to limb rigidity; it can be observed in the absence of rigidity during treatment. When bradykinesia affects the oropharynx, it can lead to difficulties in swallowing, which in turn may cause aspiration pneumonia, a potentially life-threatening complication. Of the cardinal motor signs, *postural*

instability is the most potentially dangerous, because it can lead to falls with resulting fractures. It is also one of the manifestations that responds less well to levodopa therapy. Tremor may also be less responsive, even early in the course (95).

An additional motor feature of PD is the freezing phenomenon, also referred to as “motor block” (51). In its most typical form, freezing occurs as a sudden inability to step forward while walking. It may occur at the beginning (“start hesitation”), at a turn, or just before reaching the destination. It is transient, lasting seconds or minutes, and suddenly abates. Combined with postural instability, it can be devastating. Freezing does not always improve with levodopa, and, in fact, can be made worse.

Cognitive and Psychiatric Manifestations

It is increasingly clear that there are many parallel circuits within the basal ganglia, each subserving a different function and each modulated by DA (see Chapter 122). Thus, it is reasonable to predict that patients will have a wide variety of dysfunctions extending well beyond the classic motor disabilities associated with the disease. Indeed, patients with Parkinson's disease appear to be at increased risk for a variety of cognitive and psychiatric dysfunctions. Most common is dementia and depression. However, hallucinations, delusions, irritability, apathy, and anxiety also have been reported (1). Here we will comment on the most prevalent of these symptoms.

Dementia is now recognized as one of the cardinal nonmotor manifestations of PD. It is a major cause of disability, and, unlike the motor manifestations, there currently is no effective symptomatic treatment. Aarsland and co-workers (2) identified in dementia in 28% of PD patients. The prevalence depends on age; in a study of PD patients over the age of 85 by Mayeux et al. (108), 65% were demented. PD patients with dementia show a more rapidly progressive course (110), and are more likely to be institutionalized, than nondemented individuals (2).

Years ago, there was debate about whether *depression* is a primary manifestation of PD or a reaction to having a chronic neurologic illness. There is now little question that it is a primary manifestation. Mayeux and colleagues (109a) have found that 47% of PD patients show evidence of depression, and some have found an even higher incidence (147). Moreover, Aarsland and colleagues (2) report that major depression is much more common among PD patients who also have signs of dementia (22%) than those who did not (2%). The depression, however, is not related to the severity of motor signs; indeed, many patients are depressed prior to the onset of frank neurologic dysfunction. Moreover, the depression is often greater than that seen in individuals with comparably debilitating motor dysfunction due to other disorders.

It has long been suggested that patients with PD can have particular premorbid *personality traits* (126 ,129 ,152). For example, some have argued that they tend to follow socially approved paths, are more introverted, and have less addictive personalities (e.g., are less inclined to smoke or drink) (158). Support for this hypothesis comes from a number of studies, including several involving twins that are discordant for Parkinson's disease (65 ,128). Many of these studies suffer from such problems as small sample size and retrospective analysis. Nonetheless, as noted at the outset of this section, the anatomy of basal ganglia circuitry is consistent with a broad range of functions, and some of these could easily affect personality in subtle ways. Might one, posit, for example, a “rigid PD personality” that parallels the rigid PD motor capacity? The issue is an important one, not only for our understanding of PD and of the neurobiology of behavior, but also because of the value of developing diagnostic screens that will permit the detection of PD at the earliest possible stage. Such early detection will become increasingly important as neuroprotective strategies emerge.

Other Manifestations

In addition to these neurologic signs and symptoms, PD patients often have disturbing sensory symptoms and pain in affected limbs. Many PD patients also have signs of autonomic failure, including orthostatic hypertension, constipation, urinary hesitancy, and impotence in men (90 ,107 ,133).

PATHOLOGY

Part of "123 - Pathophysiology of Parkinson's Disease "

Neuron Loss

A hallmark pathologic feature of PD, and essential for its pathologic diagnosis, is loss of DA neurons of the substantia nigra pars compacta (SNpc). At the time of death, even mildly affected PD patients have lost about 60% of their DA neurons, and it is this loss, in addition to possible dysfunction of the remaining neurons, that accounts for the approximately 80% loss of DA in the corpus striatum. We have discussed the basis for the need for extensive loss of DA neurons before the emergence of gross neurologic deficits in the previous edition of this series (5) and elsewhere (164 ,165). Briefly, our conception is as follows: As the terminals of DA neurons degenerate, there is a reduction in high-affinity DA uptake. This, coupled with some inherent redundancy in DA terminals and DA receptors, appears to permit striatal function to continue without disruption or active compensation during early phases of the neurodegenerative process. After somewhat larger lesions, the remaining DA terminals appear to increase the amount of transmitter synthesized and delivered to the extracellular fluid. This seems to be due at least in part to a net increase in the amount of DA released in response to terminal depolarization, a consequence of the transient disruption of the homeostatic regulatory systems that exist within the affected

systems (164). Once released, a portion of the DA appears to diffuse out of the synapse and into the extracellular space, where its actions are prolonged due to the relative absence of high-affinity DA uptake sites. We hypothesize that these events permit the SNpc to continue to exert dopaminergic control over striatal cell function as long as some minimal number of DA terminals remain. However, the increased synthesis and release of DA may increase reactive metabolites formed from DA and thus contribute to the progression of the disease (see below).

Neurologic deficits emerge when the availability of DA falls below the level required for rapid compensation or when the system is subjected to certain pharmacologic, environmental, or physiologic challenges. These can subside if additional, slowly developing compensations, such as the synthesis and insertion of additional DA receptors, the induction of typrosine hydroxylase (TH) synthesis, sprouting, or regeneration, occur at a more rapid rate than does the underlying neurodegeneration. This has been observed to be the case in animal models, wherein recovery often occurs after the abrupt loss of even 90% of striatal DA, as occurs in most animal models. In patients, however, where the degenerative process is typically progressive, such recovery would not be expected to occur spontaneously. However, an important implication of the ability of brain to compensate for partial loss of DA neurons in these ways is that once deficits do occur, the task of medicine need not be to restore the entire nigrostriatal projection but only the far less daunting objective of returning the availability of DA to the level required to attain the preclinical state.

Although there are several groups of dopaminergic neurons in the central nervous system (CNS), it is the loss of DA cells in the SNpc that is believed to account for all of the motor manifestations of PD. This clinicopathologic correlation is supported by observations that the *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is selective for DA neurons of the SNpc in humans and primates, and yet can produce the full spectrum of motor signs seen in PD (96). Moreover, it is not even all of the SNpc DA neurons that appear to be involved in PD. The ventral-lateral tier is more severely affected than the dorsal tier (36), and this accounts for a more severe loss of DA in the putamen, where dorsally the loss can be as much as 95%, as compared to the caudate, where ventrally the loss can be as little as 60% (87). Some central dopaminergic systems, such as the ventral tegmental area and hypothalamic systems, are relatively spared, and descending spinal dopaminergic systems are spared entirely (6).

Although some DA neurons are spared in PD, it is also the case that neuron loss is not restricted to the dopaminergic neurons. Other catecholaminergic cell groups including the locus coeruleus are involved, as are some cells of the sympathoadrenal system and the serotoninergic neurons of the raphe nuclei (6). There is also loss of cholinergic neurons of the nucleus basalis of Meynert, and this may be responsible, at least in part, in some cases, for dementia (159).

Lewy Bodies

Another pathologic hallmark of PD is the Lewy body, an eosinophilic inclusion identified within neurons. On histologic stains, Lewy bodies have an eosinophilic core, and a surrounding pale halo. They are usually rounded, although their shape can be pleiomorphic (50), and they are generally 5 to 25 μm in diameter. They usually are observed within the cell soma, but also can be seen in neurites or free in the extracellular space. Lewy bodies are commonly observed in the brain regions showing the most neuron loss in PD, including SN, locus coeruleus, the dorsal motor nucleus of the vagus, and the nucleus basalis of Meynert, but they are also observed in neocortex, diencephalon, spinal cord, and even peripheral autonomic ganglia (50).

On ultrastructural analyses, Lewy bodies consist of an electron dense granular core and a peripheral halo consisting of radially oriented filaments 7 to 8 nm in width (28). The filaments resemble neurofilaments, and can be immunostained with antisera to neurofilament proteins (53), including the NF-L, -M, and -H forms (67). Immunostaining can be achieved with antibodies that recognize phosphorylated as well as nonphosphorylated epitopes (13 ,40). The cellular kinases responsible for the phosphorylation are not known. However, two candidates, Ca^{2+}/calmodulin–dependent protein kinase II (75) and cyclin-dependent kinase 5 (14 ,98 ,118), have both been immunolocalized to Lewy bodies.

Another major antigenic feature of Lewy bodies is the expression of cellular proteins involved in protein degradation, including ubiquitin (93), and the proteasome (37 ,71). Presence of these antigens has been hypothesized to represent efforts on the part of the cell to degrade the abnormal protein aggregate.

Following the identification of mutations in the α-synuclein gene in a few cases of familial PD (see below), it was discovered that α-synuclein is a component of Lewy bodies (11 ,142 ,143). α-Synuclein in Lewy bodies can be labeled with antibodies to the C- or N-terminal, suggesting that full-length molecules are present (142). α-Synuclein immunostaining is identified in isolated Lewy filaments, and the pattern of staining suggests a polar orientation of the molecules (142). Staining of filaments *in situ* has been confirmed by immunoelectron microscopy (10). Synphilin, a protein known to interact with α-synuclein (33), also has been identified within Lewy bodies in PD (156).

α-Synuclein is identifiable not only in Lewy bodies of PD, but also the Lewy bodies of Hallervorden–Spatz syndrome (8), familial Alzheimer's disease (99), sporadic Alzheimer's (55), Alzheimer's associated with Down syndrome (100), and diffuse Lewy body disease (10 ,11). In Alzheimer's disease, Lewy bodies demonstrated by immunostaining for α-synuclein are most often observed in the amygdala.

The demonstrations of Lewy bodies in Alzheimer patients add to the growing evidence of important pathologic overlaps between Alzheimer's and PD. This evidence is further supported by the demonstration of co-localization of phosphorylated > and α-synuclein in Lewy bodies of PD and diffuse Lewy body disease (9).

In addition to its localization in Lewy bodies in PD, abnormal α-synuclein immunostaining has been identified in axon terminals in the hippocampal dentate, hilar, and CA 2/3 regions in PD (44). Whereas immunostaining for ß-synuclein has not been observed in Lewy bodies, staining was observed in these axon terminals. In addition, although immunostaining for γ-synuclein is not present in Lewy bodies, it is observed within axonal spheroids in the hippocampal dentate molecular layer in PD (44).

ETIOLOGIC FACTORS

Part of "123 - Pathophysiology of Parkinson's Disease "

Aging

The possible role of aging in the pathogenesis of PD is suggested by its usual occurrence in late middle age, and by marked increases in its prevalence at older ages (109). The possible contribution of age to the expression of the disease is further supported by early studies showing a loss with age of striatal DA (18) and DA of cells in the SN (113). However, whereas the gradual loss of striatal dopaminergic markers (88 ,138) and SNpc neurons (36) with age has recently been confirmed, the pattern and timing of these losses differ from what occurs in PD, indicating that aging itself is not likely to play a direct role in the degenerative process. For example, although the number of dopaminergic terminals appears to decrease with age, this takes place with a different temporal and spatial pattern than occurs in PD (138). The loss of SN neurons in aging is linear and predominantly in the dorsal tier of the SNpc, whereas in PD it is exponential and predominantly in the lateral ventral tier (36 ,138). In addition, the SN in PD contains numerous reactive microglia, which are much less frequent in age-matched control brains, indicating an active destructive process that is not present in the normal aged brain (111 ,112). Thus, whereas there is no question that increased age is a risk factor for PD, it remains unclear what precise role aging plays in pathogenesis.

Environmental Factors

Consideration of a role for environmental factors in the cause of PD was given major impetus with the discovery in 1983 that exposure to MPTP is capable of inducing parkinsonism in humans (96). The role of environmental factors was given additional weight by initial results of twin studies, as discussed below, which initially appeared to exclude any important role for genetic factors. The possible role of environmental factors has been addressed by a number of epidemiologic studies that have been well reviewed by others (97 ,148). Many of these studies have shown associations between rural residence, well-water drinking, or herbicide/pesticide exposure and the risk of developing PD (148). However, the precise role played by any specific compounds has remained elusive.

Genetic Factors

For many years, genetic factors were considered unlikely to play an important role in the pathogenesis of PD. This concept was based largely on twin studies conducted in the early 1980s that demonstrated a very low rate of concordance for the disease among identical twins (157) [reviewed by Duvoisin (29)]. Nevertheless, many investigators recognized that PD could occasionally be identified in families (52). The most important advances in PD research in recent years have been the identification of specific disease-causing mutations, making it possible for the first time to begin to explore pathogenesis at the molecular level. For this review, we focus on the best documented and most widely investigated genetic causes—those in α-synuclein and parkin.

Synuclein

After mapping a disease-causing gene locus to the 4q21-q23 region (130) in a large Italian kindred (52), Polymeropoulos and co-workers (131) identified a base pair change from G to A at position 209, which resulted in an Ala to Thr substitution at position 53 in α-synuclein in this family and three small Greek kindreds. Whereas initially there was a question as to whether this may represent a benign polymorphism, that possibility was soon dispelled by the discovery of a second disease-causing mutation, an Ala to Pro substitution at position 30, in an unrelated German kindred (92). The likely role of α-synuclein in the pathogenesis of PD was further supported by the discovery of αsynuclein in Lewy bodies of sporadic PD cases, as outlined above. One of the important aspects of the discovery of these mutations in α-synuclein was that they immediately suggested a possible pathogenetic mechanism, that of protein aggregation, because α-synuclein had been identified in Alzheimer plaques (154), and a central portion of α-synuclein had been shown to have the capacity to self-aggregate (56). The role of α-synuclein in the protein aggregation hypothesis for PD is discussed in the next section.

Little is known about the normal physiologic function of α-synuclein. Scheller's group (104) was the first to discover the compound, identifying it in *Torpedo* as a brain-specific synaptic terminal protein. These investigators subsequently demonstrated that the rat protein homologue is likewise expressed in nerve terminals (105). α-Synuclein messenger RNA (mRNA) is predominantly expressed in forebrain structures, such as hippocampus and cortex, but also in a few specific midbrain-brainstem nuclei, including

the SNpc, locus coeruleus, and dorsal motor nucleus (105), which, interestingly, are typically involved in PD. The human homologue of α-synuclein was independently identified by Ueda et al. (154) and Jakes et al. (78), and demonstrated by Irizarry and colleagues (76) to be expressed in nerve terminals, as is the case for rat. These investigators also showed by fractionation studies that α-synuclein appears to be loosely associated with synaptic vesicles, and this localization has been confirmed in rat brain by ultrastructural analysis (74). Jensen and his colleagues (82) have shown that α-synuclein binds to vesicles via its amino-terminal region, and that it is carried with vesicles by the fast component of axonal transport. Interestingly, the A30P mutation appears to abolish vesicle-binding activity.

What specific physiologic role α-synuclein and its homologues may play as vesicle-binding proteins remains a mystery. George and co-investigators (46) independently identified an avian homologue of α-synuclein, synelfin, as a gene upregulated in the song control circuit during a critical period of song learning, and suggested that it plays a role in neural plasticity (46). We have shown that α-synuclein mRNA and protein are upregulated in the SNpc following early developmental striatal target lesion (85). This lesion results in the induction of apoptotic death in some, but not all, developing dopaminergic neurons (102). However, in this model α-synuclein is not expressed in apoptotic profiles; it is exclusively upregulated in normal-appearing neurons, suggesting that it plays a role either in maintaining their viability, or, alternatively, in plastic change after viability is established. Vila and co-workers (155) reached a similar conclusion in a model of chronic MPTP toxicity. In support of the possibility that α-synuclein may play a role in a plasticity response in these injury models is the observation that α-synuclein mRNA in SN is up-regulated during the first 4 postnatal weeks, a period of maximal differentiation and synaptogenesis among DA neurons (85). What precise role α-synuclein plays in the development of DA neurons remains to be established. Remarkably, homozygous α-synuclein null mice have thus far shown no obvious abnormalities in numbers or morphology of DA neurons; density of striatal dopaminergic terminals; the number, morphology, or patch/matrix distribution of striatal neurons; or the ultrastructural appearance of striatal synaptic terminals (4). These animals, however, do exhibit an increased release of DA in a paired stimulus depression paradigm. In addition, they show diminished behavioral activation following administration of amphetamine (4).

In view of α-synuclein's ability to self-aggregate, there has been a tendency to assume that the mutations cause a toxic gain of function related to aggregation. It is important to keep in mind, however, that its function is unknown, and that a loss of function may relate to disease pathogenesis. In that regard, we have found that α-synuclein mRNA levels are diminished in the SNpc of patients with sporadic PD (120). Markopoulou and colleagues (103) have shown in a large Greek family with the G209A mutation that there is diminished expression of the mutant allele in lymphoblastoid cell lines, and they suggest that the parkinsonian phenotype may arise from haploinsufficiency.

Parkin

Mutations in the parkin gene were first identified in Japanese families with a unique variant of parkinsonism (89). This form is inherited in an autosomal-recessive pattern, and typically begins at an early age; in the series of 17 patients studied by Ishikawa and Tsuji (72), the age ranged from 9 to 43 years, with a mean of 28. Many of the clinical features of patients with autosomal-recessive juvenile parkinsonism (ARJP) closely resemble those of idiopathic PD: tremor at rest, rigidity, bradykinesia, postural instability, gait freezing, and marked improvement with levodopa. However, there are differences between ARJP and idiopathic PD in addition to the age at onset. Patients with ARJP more often present with dystonia, show a marked clinical improvement after sleep, and often show hyperreflexia (72). In general, they do not show cognitive decline or autonomic failure, and the course is slowly progressive. The motor predominance of their clinical signs is in keeping with the pathologic findings, which indicate neuronal loss restricted to neurons of the SNpc and the locus coeruleus (146). Lewy bodies are not observed (146).

ARJP was found to map to the chromosome 6q25.2-27 region, and a marker for this region, D6S305, was found to be deleted in a single Japanese patient (89). Screening of complementary DNA (cDNA) libraries with a probe for a putative exon, which was also deleted in this patient, led to the identification of a sequence encoding an open reading frame for a 465 amino acid protein (89). The deduced amino acid sequence of this protein contains a ubiquitin homology domain at the N-terminal, and a ring-finger motif at the C-terminal. The gene encoding the protein is large [>500 kilobase (kb)], and contains 12 exons. Deletion mutations were identified in four other affected patients in three independent families, confirming the pathogenetic significance. A 4.5-kb mRNA transcript was identified in many human tissues, including brain. In brain, it is expressed in various regions, including the SN (89).

Subsequent molecular genetic analysis of 34 affected individuals from 18 unrelated Japanese families revealed four additional deletional mutations (64), bringing the total to six identified at that time (89). The deletions affected exon 3, exon 4, and exons 3 to 4, and a 1–base pair (bp) deletion in exon 5 resulted in a frameshift and an early stop. Further molecular analysis of non-Japanese families in Europe, revealed that in addition to deletion mutations, a variety of point mutations resulting in either truncation or missense could also cause the phenotype (3). In addition, this study identified patients with a late age of onset, up to 58 years

in one case, and indicated that in some instances the clinical phenotype was indistinguishable from idiopathic PD (3).

There is now growing recognition that mutations in parkin may cause what clinically resembles idiopathic PD. In an investigation of the scope of the molecular and clinical features in Europe, Lucking and co-workers (101) found that among 73 families with early onset (<45 years) of parkinsonism and affected family members, 49% had parkin mutations. Among early-onset patients without affected family members, 18% had mutations. The majority (77%) of these were younger than 20 years of age. Many of the patients with parkin mutations lacked the signs thought to be characteristic of ARJP such as dystonia and hyperreflexia, and were clinically difficult to distinguish from idiopathic PD. In all, 19 different rearrangements of exons mutations were identified, including multiplications as well as deletions, and there were 16 different point mutations (101).

The neurobiology of parkin is only beginning to be explored. By immunohistochemistry, the protein has been localized at the regional level to SN and locus coeruleus, and at the cellular level to the cytoplasm (139). Nuclear staining was not observed. Parkin has been shown to play a role in protein degradation as a ubiquitin-protein ligase (140). These findings suggest that abnormal accumulation of proteins or abnormal regulation of the half-life of normal cellular proteins may play a role in cell death.

PATHOGENETIC MECHANISMS

Part of "123 - Pathophysiology of Parkinson's Disease "

Free Radicals and Deficits in Energy Metabolism

The concept that free radical–mediated injury may underlie the neuronal degeneration that occurs in PD has been, and continues to be, the leading hypothesis for its pathogenesis. The free radical theory has been the subject of many excellent reviews (34 ,122), so it will be outlined here only briefly. This theory is also referred to as the oxidant stress hypothesis or the endogenous toxin hypothesis. In their review, Fahn and Cohen (34) point out that the free radical hypothesis is appealing because four aspects of the neurochemistry of DA neurons and their local environment within the SN make the concept plausible. First, a major degradative pathway for DA is its oxidative deamination by monoamine oxidases A and B. This process results in the enzymatic production of H_2O_2, which, while itself not a free radical, can nevertheless react nonenzymatically with ferrous or cupric ions via Fenton-type reactions to form highly reactive hydroxyl radicals. Second, DA can react nonenzymatically with oxygen to form quinones and semiquinones, with the production of superoxide, hydrogen peroxide, and hydroxyl radicals. Third, the SN, particularly the SN pars reticulata, is rich in iron, which as mentioned above, may in its ferrous state catalyze the formation of hydroxyl radicals from H_2O_2. Fourth, the SN contains neuromelanin formed from the auto-oxidation of DA. This auto-oxidation generates toxic quinones and reactive oxygen species. In addition, the presence of neuromelanin in the cell may alter the ability of metal ions to participate in the production of reactive oxygen species (145).

The possibility that DA neurons may undergo free radical–mediated injury in PD has received support from animal studies using one of two neurotoxins that can be used to selectively destroy DA neurons—6-hydroxydopamine (6-OHDA) and MPTP. 6-OHDA reacts with oxygen to produce superoxide anion radical, H_2O_2, and hydroxyl radical. It is a general cytotoxin but derives its specificity by virtue of its affinity for the high-affinity catecholamine transporters. Thus, when used in sufficiently low concentrations, its actions can be directed toward catecholamine neurons. Moreover, it can be limited to acting on DA neurons by pretreating animals with an inhibitor of high-affinity norepinephrine uptake, such as desipramine (19 ,66 ,166).

Interestingly, like 6-OHDA, DA itself is a selective neurotoxin for DA neurons (38 ,54 ,61 ,62 ,114 ,135). This seems to be in large part due to its ability to oxidize to form reactive oxygen species, including DA quinone, which has a high affinity for the cysteinyl residues on proteins (41 ,42 and 43 ,54 ,63). Thus, it seems possible that DA itself can be a source of oxidative stress, particularly under conditions of increased DA turnover and decreased antioxidant defenses (see below).

MPTP acts via its active product MPP^+, which is selectively taken up into DA neurons via the DA transporter, and inhibits complex I activity in mitochondria. Inhibition of complex I not only interferes with adenosine triphosphate (ATP) synthesis, but also results in augmented production of superoxide anion radical. The possible role of superoxide radical in MPTP toxicity has received direct support by the demonstration by Przedborski and co-workers (132) that transgenic mice with high Cu/Zn superoxide dismutase activity are resistant to MPTP.

The free radical hypothesis of PD has also received support from studies of human postmortem brain. Free radicals can cause injury to cells by damaging DNA, proteins, and lipids of the cell membrane. There is evidence from postmortem studies for free radical–induced modification of each of these classes of molecules. Dexter and co-workers (24) have shown that in PD brain there is a reduction in levels of polyunsaturated fatty acids, which provide an index of the amount of substrate available for lipid peroxidation, and an increase in levels of malondialdehyde, an intermediate in the lipid peroxidation process. The increase in malondialdehyde was regionally specific for the SN. These workers subsequently confirmed evidence for abnormal lipid peroxidation in PD by identifying a tenfold increase in cholesterol lipid hydroperoxide, an early marker in the lipid peroxidation process (25). Free radicals are also capable of directly damaging DNA. Sanchez-Ramos and colleagues (136) have shown that regional concentrations of 8-hydroxy-deoxyguanosine,

an index of oxyradical-mediated DNA damage, are increased in the caudate and SN of PD patients. Relatively less attention has been given to the possibilities of oxygen-mediated damage to proteins, or of advanced glycosylation changes to proteins in PD (141). The possibility that such protein changes may also occur in PD brain is supported by the demonstration that protein adducts of 4-hydroxy-2-nonenal, a cytotoxic product of lipid peroxidation, can be identified by immunohistochemistry in many nigral neurons of PD patients in contrast to age-matched controls (162).

Postmortem studies have also revealed neurochemical features that may predispose the PD brain to oxidative damage. Reduced glutathione is an important endogenous antioxidant, and it has been reported to be reduced in the SN in PD (127). Jenner and colleagues (80) have confirmed low levels of reduced glutathione in the SN of PD patients, and have shown that the alteration is disease-specific. Interestingly, they have also shown that reductions are observed in patients with incidental Lewy body disease, which may be a preclinical form of PD (49). This finding suggests that the reduced levels of glutathione may be a fundamental and primary abnormality in PD, rather than a secondary change.

A number of postmortem studies have also suggested that abnormalities of iron metabolism may underlie the neurodegeneration of PD. Iron metabolism is of particular interest in relation to the free radical hypothesis because, as noted above, it normally is found in high concentrations in SN, and is capable of catalyzing free radical formation. Dexter and colleagues (26) reported increased levels of iron in the SNpc of PD patients. This observation took on potentially greater significance when this group subsequently reported decreased levels of ferritin in PD brains (23), as ferritin normally sequesters iron in an unreactive state. However, it has become apparent that increased iron levels may be observed in many brain regions demonstrating neural degeneration in a variety of diseases of the basal ganglia (22), so the specificity of changes in iron levels in PD is less clear. Nevertheless, the possible relationship of altered iron metabolism to the pathogenesis of PD remains of interest, based on the finding of a higher density of lactoferrin receptors on neurons and microvessels of patients with PD (35). This finding suggests that lactoferrin receptors, which regulate intraneuron iron content, may be overly expressed in vulnerable dopaminergic neurons in PD.

Another postmortem finding in PD patients that is compatible with the free radical hypothesis is that of a deficiency in mitochondrial complex I. Such a defect could either result in the abnormal production of free radicals, or be the result of free radical injury (137). This defect takes on particular interest in light of the observation that MPP^+, the toxic oxidative product of MPTP, inhibits complex I (121). The defect in complex I in PD patients has been demonstrated by Schapira et al. (137) to result in a mean 37% decrease in activity. This decrease appears to be both regionally specific for the SN, and disease specific, among basal ganglia disorders, for PD.

Thus, the free radical hypothesis receives indirect support from a large number of separate lines of evidence, and, as stated above, it remains the foremost and most widely tested hypothesis of neural degeneration in PD. Nevertheless, it remains only a hypothesis, and it has its shortcomings (17). For example, there is no specific aspect of the free radical hypothesis as it is currently posed to account for the relative vulnerability of ventral tier dopaminergic neurons in PD. In addition, it must be remembered that nonaminergic neuronal groups, such as the nucleus basalis, which is cholinergic, also degenerate in PD, and aspects of the free radical hypothesis that are dependent on catecholamine metabolism are not relevant to the degeneration of these structures.

Programmed Cell Death

The concept that a genetically regulated cell death process may underlie the neuron-specific degenerations of later life has gathered great attention in recent years. The programmed cell death hypothesis in fact may be related to the concept of free radical–mediated cell death. Although traditional concepts of free radical injury have centered on the ability of toxic molecules to directly injure cellular constituents without any participation of the host cell's own genetic programs, it is now clear that in both *in vitro* and *in vivo* paradigms of free radical–mediated injury programmed cell death may occur. It is also apparent that in some settings programmed cell death may be carried out by the controlled production of free radicals.

In relation to PD, it is important first to consider the evidence that programmed cell death does in fact occur within dopaminergic neurons. As predicted by classic neurotrophic theory, some natural cell event does occur during development in the SNpc, with typical light microscopic morphology of apoptosis, demonstrated both by Nissl stain and suppressed silver staining (79), and we used a double-labeling technique to identify apoptotic natural cell death in phenotypically defined dopaminergic neurons (123). Natural cell death in these neurons has a bimodal time course. There is an initial, major peak that begins on embryonic day 20, and largely abates by the eighth postnatal day (PND). There is a second, minor peak of natural cell death on PND 14. The presence of a postnatal cell death event is in keeping with the demonstration by Tepper and colleagues (151) that there is a decrement in the number of TH-positive neurons in SN postnatally, particularly in the first postnatal week. Although there is evidence that the magnitude of the natural cell death event in DA neurons is regulated by interactions with the target striatum (see below), as classic neurotrophic theory would predict, it remains unknown which neurotrophic factors are involved. We have shown *in vitro* in postnatal primary cultures of DA neurons that GDNF is uniquely able to support viability by

suppressing spontaneous apoptotic death (16) as well as cell death initiated by 6-OHDA (see below). Whether glial cell line-derived neurotrophic factor (GDNF) plays such a role *in vivo* remains to be determined.

We have shown that natural cell death in SNpc can be regulated during development by striatal target interactions. Excitotoxic injury to the striatum on PND 7 results in an eightfold increase in the number of apoptotic profiles (102). These profiles are morphologically identical to those observed during natural cell death, and meet ultrastructural and 3′ end-labeling criteria for apoptosis. Within SNpc, induction of cell death is identified within phenotypically defined dopaminergic neurons.

Programmed cell death also occurs in DA neurons in animal models of parkinsonism. Intrastriatal injection of 6-OHDA results in an induction of apoptotic death in phenotypically defined DA neurons of the SN (106). This induction is most pronounced in a developmental setting, through PND 14, but it can also be demonstrated, at a lower level, in mature animals. Interestingly, at older ages the morphology of cell death becomes mixed, including apoptotic and nonapoptotic features (106). Although in this model 6-OHDA may lead to apoptotic death simply by the destruction of terminals and the resulting failure of target support, there is evidence that the toxin also directly mediates death. In addition to the fact that 6-OHDA is able to induce death long after it is possible to demonstrate target dependence (84), the morphologic features of activated caspase-3 expression, an important mediator of programmed cell death, differs in 6-OHDA–induced death, as compared to natural and target injury-induced cell death (83).

Other important animal models of parkinsonism, in rodents and primates, are induced by MPTP, or its active oxidized product, MPP^+. A number of investigators have shown in a variety of systems that MPP^+ can induce apoptosis *in vitro*. Dipasquale and colleagues (27) first showed that MPP^+ can induce apoptotic morphology and DNA fragmentation in postnatal cerebellar granule cells in culture. Subsequently, others have shown that MPP^+ appears to induce apoptosis in embryonic mesencephalon culture (116), in PC12 cells, both differentiated (117) and undifferentiated (57), and in a human neuroblastoma cell line (73). Tatton and Kish (149) have shown that when MPTP is administered to mice in low doses over a 5-day course, it induces apoptotic death. In this model, induction of apoptosis is dependent on the dosing regimen; acute administration of multiple doses in a single day results in nonapoptotic death (77). Further support for the role of programmed cell death in the MPTP mouse model derives from the observation that Bax, a mediator of apoptosis, is induced (60). In addition, overexpression of Bcl-2, a protein inhibitor of apoptosis, diminishes MPTP-induced injury (161).

It remains controversial whether apoptosis can be identified in the Parkinson brain. One initial report demonstrated intranuclear chromatin clumps by electron microscopy (7), but they were not clearly characteristic of apoptosis. TUNEL labeling (45) has been demonstrated in PD brains (115). However, the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) technique is not entirely specific for apoptosis since it can also label free 3′-ends that are generated by necrotic death, producing false positives. Thus, it is essential to co-identify not only TUNEL labeling but also the classic chromatin clump morphology of apoptosis. Tompkins and co-workers (153) and Tatton and colleagues (150) have both achieved this more specific demonstration. However, many other investigators have been unable to identify specific TUNEL labeling in PD brains (12 ,86 ,91 ,160). Thus, a consensus has not been achieved, and further investigation will require methods beyond these morphologic techniques, such as the utilization of specific biochemical markers for programmed cell death. Hartmann and colleagues (58) have made such an effort utilizing an antibody that is specific for the activated form of caspase-3. They have shown that activated caspase-3 could be identified in Lewy body–containing neurons of the SN in PD brains (58). However, activated caspase-3 was also identified in control brains, in larger numbers of neurons. They attribute this staining to agonal changes. Thus, the staining was not specific for PD, and more study is needed with additional specific immunoreagents for other components and by-products of programmed cell death pathways.

Protein Aggregation

The possibility that protein aggregation may play a role in PD had long been suggested by the presence of Lewy bodies in disease brains. However, this concept was given powerful support upon discovery of the mutations in α-synuclein. Human α-synuclein was originally identified as a proteolytic fragment derived from Alzheimer senile plaques (154). The isolated fragment, termed the non-Aß component of amyloid (or NAC), corresponded to a 35 amino acid hydrophobic portion of α-synuclein. Soon after its discovery, NAC was predicted to form ß-sheet secondary structure, and shown to self-aggregate to form fibrillar amyloid *in vitro* (56). Thus, with the discovery of α-synuclein, PD was placed firmly among neurodegenerative disorders for which protein aggregation is believed to play an important pathogenetic role, including Alzheimer's, motor neuron disease, the triplet repeat diseases, and the prion diseases.

Subsequent biochemical studies have shown that full-length α-synuclein is capable of binding to Aß 1-38 and forming amyloid (163). This binding requires the hydrophobic NAC region. Other investigators have confirmed α-synuclein binding to Aß, and have shown that α-synuclein is capable of homodimerization (81 ,124). Even in the absence of Aß, full-length recombinant α-synuclein is capable of self-aggregation *in vitro* to form fibrillar amyloid material (59). A number of investigators have confirmed this observation, and have found that one or both mutant forms are more likely to form ß-sheet and aggregate, forming fibrils

that resemble those of Lewy bodies (20 ,32 ,47 ,119). Crowther and co-workers (21) have shown that C-terminally truncated α-synuclein more readily self-assembles into filaments that resemble those isolated from diseased brain.

Further analysis of the NAC fragment has shown that the N-terminal sequence is responsible for aggregation (30). NAC aggregates have been demonstrated to have cellular toxicity. They induce apoptotic death in cultured human neuroblastoma cells (31). Low concentrations of aggregated NAC are toxic to DA neurons in primary culture and neuronally differentiated PC12 cells (39). *In vivo* application of NAC aggregates induced death of SN DA neurons. Based on these demonstrations of the ability of α-synuclein and NAC to aggregate and the possible toxicity of aggregates, an abnormality of protein aggregation has become one of the principal hypotheses for the pathogenesis of PD.

FINAL COMMENT

Part of "123 - Pathophysiology of Parkinson's Disease "

Although Parkinson's disease was first described almost two centuries ago, it is only recently that we have begun to understand the complex nature of the functional deficits that it entails or its neurobiological causes. Yet, the pace of discovery is quickening. With the discovery of the genetic basis of some familiar forms of the disorder, the appreciation of trophic factors that influence DA neurons, and the development of new technologies such as the use of stem cells and viral vectors, there is every reason to believe that within a generation Parkinson's disease will become a chapter in the history of diseases of the past.

Current and Experimental Therapeutics of Parkinson's Disease

Jean-Michel Gracies

C. Warren Olanow

Jean-Michel Gracies and C. Warren Olanow: Department of Neurology, Movement Disorders Program, Mt. Sinai School of Medicine, New York, New York.

Three decades after its introduction, levodopa remains the gold standard for the treatment of Parkinson's disease (PD). Levodopa is the most potent symptomatic antiparkinsonian agent, and it is associated with an increase in quality of life and longevity for patients with PD. Dopamine agonists are increasingly being used, not only as an adjunct to levodopa, but as early therapy aimed at reducing the risk of developing levodopa-induced motor complications. Catechol *O*-methyltransferase (COMT) inhibitors extend the elimination half-life of levodopa. They are useful as adjunctive treatment for patients with motor fluctuations to increase the time in which patients respond to the drug. There is now increasing interest in using these drugs from the start of levodopa therapy to deliver levodopa to the brain in a more continuous fashion and thereby, it is hoped, further reduce the risk of motor complications. In the advanced stages of the illness, surgical therapies are being performed with increasing frequency based on evidence that they can restore function when medications fail. Ablative, stimulation, and transplant procedures are all currently under investigation. Finally, there are a series of investigational drugs designed to provide neuroprotective effects and/or to block levodopa motor complications that are now being evaluated in the laboratory and in some instances in PD patients. Thus, therapies and investigational approaches to PD have been markedly expanded in the past several years and include treatments and treatment strategies aimed at restoring function to PD patients in the advanced stages of the illness, preventing the development of the motor complications that are the major source of disability for a large percentage of PD patients, and modifying the disease process so as to slow or halt disease progression.

Parkinson's disease is a progressive motor disorder caused by accelerated degeneration of selected populations of brain cells, primarily including the melanized neurons of the substantia nigra pars compacta (SNc) in the midbrain. It affects approximately 4% of the population over 65 years of age and there are 60,000 new cases each year in the United States (1). With the increasing numbers of elderly individual in modern society, the prevalence of PD is likely to increase in developed countries in generations to come. The classic clinical syndrome is composed of four cardinal features: bradykinesia (slowness of movement), rigidity (increased resistance to passive limb movement), resting tremor (i.e., tremor that is most prominent at rest and tends to abate during voluntary movement), and impairment of gait and posture. The impairment of movement in PD primarily affects “automatic” movements such as those involved during walking, speech articulation and phonation, handwriting, or swallowing. Postmortem studies indicate that approximately 25% of patients who present with a parkinsonian syndrome do not have pathologic changes of PD, but rather of an atypical parkinsonism such as multiple system atrophy (MSA), progressive supranuclear palsy (PSP), or corticobasal ganglionic degeneration (CBGD) (2 ,3 and 4). The clinical features that best predict parkinsonian pathology are resting tremor, asymmetry of motor findings, and a good response to levodopa (see below) (5).

The pathologic hallmark of PD is the loss of pigmented, dopaminergic neurons of the SNc, coupled with intracellular inclusion bodies known as Lewy bodies (6). Pathologic changes frequently including Lewy bodies can also be detected in the locus coeruleus, the nucleus basalis of Meynert, cerebral cortical regions, autonomic regions of the brainstem, the pedunculopontine nucleus, intermediolateral columns of the spinal cord, and peripheral autonomic nerves innervating the cardiovascular system and gastrointestinal tract (7). Without treatment, PD evolves over 5 to 10 years into an akinetic and rigid state in which patients are unable to care for themselves. Death commonly results from aspiration

pneumonia due to swallowing impairment, or complications of immobility such as pulmonary embolism. The introduction of levodopa over 30 years ago (8) represented a revolution in the treatment of PD as it radically altered its prognosis. Under levodopa treatment, good functional mobility can be maintained for a number of years, and the life expectancy of levodopa-treated patients is markedly increased (9 ,10). However, it soon became apparent that levodopa therapy is associated with a series of motor complications that themselves are a major source of disability to PD patients (11). In recent years there have been dramatic advances in the therapeutics of PD with the development of new medical and surgical treatments that restore function to patients with advanced disease and prevent the development of levodopa-related motor complications. The final challenge involves the development of neuroprotective or disease-modifying therapies that slow or stop disease progression and herald the end of this devastating disorder. Here, too, enormous progress has been made, and several putative neuroprotective drugs and restorative therapies are currently being tested. This chapter reviews the major therapies for PD and describes present advances and future directions in the therapeutics of PD.

MEDICAL THERAPIES FOR PARKINSON'S DISEASE

Part of "124 - Current and Experimental Therapeutics of Parkinson's Disease "

Levodopa

Since its introduction in the late 1960s (8), levodopa (L-3,4-dihydroxyphenylalanine) has remained the single most effective antiparkinsonian agent, providing benefit to virtually all patients with PD. Levodopa use is associated with improved mobility, reduced disability, and prolonged survival (9 ,10 ,12). The involvement of dopaminergic systems in PD was first suspected in the late 1950s, following the observation that patients treated with the then newly available dopamine-blocking agents (antipsychotics) developed clinical signs of parkinsonism. In the same period, an animal study showed that movement slowness in rats, due to the catecholamine depletor reserpine, could be reversed with levodopa (13). The discovery that dopamine is depleted in the striatum of PD patients soon followed (14). This in turn gave rise to the notion that a dopamine replacement strategy might be useful in PD, and the therapeutic role of levodopa in patients with PD was subsequently established in 1967 (8 ,15). Levodopa is itself largely inert, and its therapeutic and adverse effects result from the decarboxylation of the prodrug levodopa into the active product dopamine (16). After oral administration, levodopa absorption occurs in the small bowel by way of the active transport system for large neutral amino acids. Thus, it is possible that other large neutral amino acids such as lysine and phenylalanine that are present in protein-rich foods can compete with and interfere with levodopa absorption. Levodopa is used in the place of dopamine as dopamine itself cannot penetrate the blood–brain barrier and enter the central nervous system (CNS). CNS entry is also an active process mediated by the large neutral amino acid transport system, and again there may be competition for brain access between levodopa and dietary amino acids (16).

Levodopa is normally metabolized in the periphery by two enzymatic systems: amino-acid decarboxylase (AADC) and COMT. This transformation occurs in the intestinal and gastric mucosa as well as in the liver. The peripheral metabolism of levodopa is so effective that the plasma half-life is approximately 60 minutes, and only 1% of an administered oral dose reaches the CNS (16). Further, accumulating concentrations of plasma dopamine secondary to decarboxylase-mediated metabolism of levodopa can activate dopamine receptors in the area postrema that are not protected by a blood–brain barrier and cause nausea and vomiting. Indeed, nausea and vomiting are limiting side effects in as many as 50% of patients when levodopa is administered alone. To defend against this complication, levodopa is now routinely administered in combination with a peripherally acting inhibitor of AADC. In the United States, levodopa is combined with the AADC inhibitor carbidopa and marketed as Sinemet. In other parts of the world, the AADC inhibitor benserazide is also frequently used with levodopa and sold as Madopar. The combination of levodopa with an AADC inhibitor permits the use of lower doses of levodopa (by doubling its bioavailability) and reduces the incidence of peripheral dopaminergic side effects such as nausea, vomiting, and hypotension. In most patients, a daily dose of 75 mg of carbidopa is sufficient to inhibit AADC and prevent these side effects. Interestingly, even in the presence of an AADC inhibitor, 90% of levodopa is still metabolized by COMT (17). This has led to the recent introduction of COMT inhibitors (see section below).

In the CNS, dopamine is synthesized from levodopa in dopaminergic terminals, transported into storage vesicles, and released in a spike-dependent manner in association with depolarization of the presynaptic neuron. The released dopamine acts on postsynaptic dopamine receptors (possibly in a volumetric manner). Its action is terminated primarily by a very rapid presynaptic reuptake system that is antagonized by cocaine. It can be degraded either intracellularly or extracellularly by monoamine oxidase (MAO) and COMT enzymes to yield homovanillic acid (HVA)(9). MAO has two subtypes; A, which is primarily intracellular, and B, which is primarily extracellular (18).

Two classes of dopamine receptors (D1 family and D2 family) and five receptor subtypes (D1–D5) have been molecularly cloned to date (19). The D1 receptor family is characterized by positive coupling with adenylate cyclase formation, whereas D2 receptors have an affinity for neuroleptic agents and activation inhibits adenylate cyclase (20). Dopamine receptors are G-protein–coupled receptors, and activation of the different subtypes likely is associated with

a different signaling pattern and different gene and protein regulation (19). Indeed, it is becoming increasingly clear that activation of different receptors, the same receptor with different agents, and the same receptor with the same agent with a different pattern of stimulation can all lead to a different intracellular signaling cascade that potentially has different functional effects (19). Dopamine receptors are diffusely distributed throughout the CNS: motor striatum (D1, D2), hippocampus (D5), frontal cortex and amygdala (D4), hypothalamus (D3, D5), and mesolimbic system (D3). The precise role of each of these receptors in motor function remains unknown; however, it is likely that this wide distribution accounts for the diverse pattern of functional effects that can be obtained when exogenous levodopa is administered to PD patients. Although most attention has focused on the nigrostriatal dopaminergic system in PD, it is important to appreciate that there is also dopaminergic innervation of the cerebral cortex and numerous other basal ganglia regions including the substantia nigra pars reticularis (SNr), the subthalamic nucleus (STN), the globus pallidus pars interna (GPi), and the globus pallidus pars externa (GPe) (21). Activation of dopaminergic receptors in these regions might also contribute to the beneficial and adverse effects observed with levodopa administration to PD patients. Indeed, although levodopa dramatically improves the motor signs and symptoms of PD, it also has effects on vision, memory, mood, reward-related learning, and addiction (22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 and 30).

Levodopa Benefits and Motor Complications

Levodopa is the most effective antiparkinsonian agent for the management of motor dysfunction in PD. Levodopa benefits can be dramatic, and improvement can be obtained in all of the cardinal signs and symptoms of PD. Levodopa has also been shown to provide a dose-dependent beneficial effect on mood and anxiety in PD patients that increases with the duration of therapy (27). These important nonmotor effects can contribute to the benefits associated with the levodopa response. Indeed, more than 30 years after its introduction, no other medication provides antiparkinsonian benefits that are superior to levodopa (30 ,31).

The acute administration of levodopa, even in the presence of a decarboxylase inhibitor can still be associated with nausea, vomiting, and orthostatic hypotension. These are usually seen during the titration phase and can be minimized by initiating levodopa at a low dose and titrating slowly to the desired clinical effect. Persistent nausea and vomiting can specifically be handled by adding supplemental doses of carbidopa (Lodosyn), or using the peripheral dopamine receptor antagonist domperidone (available in Canada and Europe) in doses of 10 mg 30 minutes before the levodopa dose. Postural hypotension can be managed by advising the patient to lie supine at night with the head of the bed elevated and rising slowly. If postural hypotension persists, pharmacologic agents such as fluorocortisone and midodrine may be helpful. If a parkinsonian patient experiences symptomatic orthostatic hypotension, the possibility that he or she suffers from MSA with autonomic involvement should be considered.

Motor complications that develop in association with chronic levodopa therapy are the most disabling side effect for most patients. In the early stages of PD, the duration of benefit following a single dose of levodopa is long lasting and far exceeds the plasma half-life of the drug (60 to 90 minutes) (32). This has been ascribed to the relatively preserved capacity of presynaptic dopaminergic terminals of nigrostriatal neurons to store dopamine and regulate its release. However, after a few years of levodopa therapy, there is further neuronal degeneration, and the duration of benefit following each dose of levodopa is shortened in duration. Thus, patients begin to fluctuate between periods of good motor function (“on” responses) and periods of poor motor function (“off” responses) (33). Further, the periods of good motor function that characterize “on” periods now becomes complicated by involuntary movements known as dyskinesia. These are usually choreiform in nature and occur in association with the peak plasma concentration of the drug. However, they may be dystonic or myoclonic in nature, and occur at the onset and termination of the “on” response. In this situation they are referred to as diphasic dyskinesia (34). Manipulating the dose and frequency of levodopa administration is the usual therapeutic approach to the onset of motor complications, but this can be difficult because doses high enough to induce a motor benefit may induce involuntary movements, and doses low enough to ameliorate dyskinesia may not be sufficient to provide antiparkinsonian benefit. Eventually, it may become virtually impossible to achieve a dose of levodopa that provides motor benefits without inducing dyskinesia, and patients may cycle between intolerable dyskinesia and intolerable parkinsonism.

In the early stages of motor fluctuation, increasing the half-life of levodopa by coadministration of a COMT inhibitor may be helpful (see COMT Inhibitors , below). Sustained-release formulations of levodopa (Sinemet CR, Madopar HBS) have been developed in the hope that they would better control motor fluctuations; however, the unpredictable intestinal absorption of these preparations makes them difficult to employ in routine practice, especially for patients with complex motor complications. Low-protein diets or redistribution diets with restriction of the protein intake until the later part of the day may provide some short-term benefits by facilitating levodopa absorption and thereby improving motor performance (36). Dyskinesias are difficult to treat medically, other than by lowering the dose of dopaminergic agent, and this in turn can be associated with worsening parkinsonism as described above. Amantadine has been reported to have an antidyskinetic effect (37) (see below). When motor complications are fully developed, medical therapies are for the most part ineffective

and patients may be considered for surgical intervention (see below). Thus, despite the best of existing medical therapy, more than 75% of PD patients eventually experience intolerable disability (35 ,38).

It is currently thought that motor complications in PD are related to both presynaptic and postsynaptic mechanisms. Chase and his colleagues initially postulated that levodopa-related motor fluctuations develop because of the progressive loss of nigrostriatal neurons and a loss of their capacity to store dopamine and buffer fluctuations in plasma levodopa. Indeed, his group demonstrated a progressive shortening of the duration of the motor response following a dose of levodopa in patients with advancing disease, despite the fact that levodopa peripheral pharmacokinetics remain stable in all stages of PD (39 ,40). This “storage hypothesis” presumed that with the loss of dopamine terminals, central buffering capacity is lost, and striatal dopamine levels become dependent on the peripheral availability of levodopa. As a result, the patient's motor state begins to fluctuate in parallel with the fluctuating plasma levodopa levels that accompany intermittent administration of oral levodopa therapy. With increasing disease severity, there is progressive degeneration of dopamine terminals with further loss of their buffering capacity and consequent exposure of striatal dopamine terminals to alternating and pathologically high and low or “pulsatile” levels of dopamine. However, the storage hypothesis cannot account for the fact that apomorphine has similar pharmacokinetic and pharmacodynamic responses with advancing disease severity as does levodopa, even though apomorphine is not stored in dopaminergic terminals (41). This implies that postsynaptic mechanisms must play some role in the pathophysiology of levodopa-related motor complications.

Current evidence indicates that levodopa-induced motor complications are related to a sequence of events that include abnormal pulsatile stimulation of the dopamine receptor by dopaminergic agents with a short plasma half-life, dysregulation of downstream genes and proteins, and altered neuronal firing patterns (see ref. 42 for complete review of this topic; also see below). In support of this concept, it has been shown that motor complications in parkinsonian monkeys are induced by short-acting dopaminergic agents such as levodopa, which induce pulsatile simulation of receptors, but not by long-acting dopamine agonists, which more closely simulate the normal tonic activation of dopamine receptors (43). Indeed, intermittent administration of a short-acting dopamine agonist induces dyskinesia, whereas continuous administration of the same short-acting agonist does not (44). Further, altered expression of genes such as preproenkephalin (PPE) in striatal neurons have been recorded in association with the development of dyskinesia in *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) treated monkeys (45). Finally, levodopa-induced alterations in neuronal firing patterns have been described in dyskinetic monkeys, which include changes in firing bursts and pauses, the degree of neuronal synchrony, and neuronal firing frequency (46).

These observations have led to the development of new therapeutic options and treatment strategies designed to reverse or prevent the development of levodopa-related motor complications. One such approach is based on lesioning the output neurons in the basal ganglia so as to disrupt their abnormal neuronal firing pattern and the communication of misinformation from basal ganglia to motor cortical regions. This concept likely underlies the antidyskinesia effects that have been observed with surgical therapies for PD (47 ,48) (see Surgical Therapies for Parkinson's Disease , below). A second approach has been directed at modulating dysregulated signaling pathways in striatal neurons leading to abnormal phosphorylation of *N*-methyl-D-aspartate (NMDA) receptors (49). This concept has led to studies of NMDA receptor antagonists and other agents that interfere with intracellular signals as a means of treating levodopa-induced motor complications in PD (37 ,49 ,50). Finally, and perhaps most importantly from the standpoint of the clinician, are the use of long-acting dopaminergic agents based on attempts to provide more physiologic continuous dopaminergic stimulation to striatal dopamine receptors and avoid pulsatile stimulation of striatal dopamine receptors (51). Indeed, prospective double-blind clinical trials have now demonstrated that PD patients randomized to initiate therapy with a dopamine agonist have significantly reduced risk of developing motor complications compared to those randomized to start with levodopa (30 ,31).

Levodopa can also be associated with dose-related sedation, and neuropsychiatric problems such as hallucinations and confusion. These are most likely to occur in the elderly and in patients with preexisting cognitive impairment. The initial hallucinatory episodes usually consist of benign visual hallucinations that are often a greater source of concern to the family than the patient, who retains insight into the nature of the problem. However, patients who experience levodopa-induced hallucinations are more likely to go on and develop dementia (52). An Alzheimer-type dementia can occur in as many as one-third of PD patients, particularly if they have onset after the age of 70 years. Managing hallucinations and confusion in a levodopa-treated patient (1) involves (a) ruling out other temporary causes of mental dysfunction, such as infection, electrolyte imbalance, other brain lesions; (b) elimination of nonparkinsonian medications that are not essential and can impair cognition, (c) elimination of antiparkinsonian drugs that are prone to causing delirium such as anticholinergics, amantadine, selegiline, and dopamine agonists; thereafter the levodopa dose should be reduced to the lowest dose that provides satisfactory control of mobility; and (d) finally, low-dose therapy with atypical neuroleptics can be considered. Clozapine is an atypical neuroleptic that has minimal parkinsonian effects and has been found to be useful in the treatment of psychotic symptoms in PD patients (53). Low doses are

frequently all that is required to provide benefit for PD patients. Accordingly, treatment is initiated with a dose of 12.5 to 25 mg at night and slowly and modestly increased to the desired effect. Hallucinations can usually be controlled with doses less than 25 mg daily. Clozapine is associated with a small risk of hematologic side effects and periodic monitoring is required. Respiradone (Respiradol), olanzapine (Xyprexa), and quietapine (Seroquel) are alternative atypical neuroleptics, but they have been less thoroughly studied than clozapine for PD psychosis, and anecdotal reports suggest that they are no more, and possibly less, effective.

Sudden withdrawal of levodopa can be associated with sudden deterioration in parkinsonian features and may precipitate a life-threatening neuroleptic malignant syndrome (54 ,55). Abrupt reduction of dopaminergic therapy is rarely indicated in the modern era and should be performed in a setting where appropriate monitoring can be performed. Diagnosis is based on altered consciousness, fever, increase in rigidity and other extrapyramidal signs, autonomic instability, elevated creatine kinase level, and leukocytosis. Treatment involves supportive measures (hydration and muscle relaxants) and reintroduction of dopaminergic therapy. PD can also be associated with features that do not respond to levodopa and can themselves be a major source of disability to the patient. These include dementia, autonomic dysfunction, sensory complaints, and freezing episodes in which patients experience arrests in mobility lasting seconds to minutes in duration.

Finally, there has been some concern that despite its many benefits, levodopa might accelerate neuronal degeneration through the oxidizing species generated through its oxidative metabolism. In particular, levodopa is oxidized by MAO to form peroxides, which can combine with iron to generate the cytotoxic hydroxyl radical (56). Levodopa has been shown to induce degeneration of cultured dopaminergic neurons (57). It is less clear that levodopa induces toxicity in animal models, where it has been shown to induce SNc damage in some studies (58) but not in others (59) where there is even the suggestion that it might be protective. Levodopa has not been shown to induce damage to dopamine neurons in normal animals or humans, but the situation may be different in PD, where the SNc is in a state of oxidant stress and defense mechanisms are compromised. A recent consensus conference concluded that although the possibility that levodopa might be toxic in PD has not been excluded, there was no reason to withhold the medication for this reason based on present evidence (60).

In the United States, levodopa is most frequently administered as Sinemet, which is available in dosages of 10/100, 25/100 and 25/250 (the first number represents the dose of carbidopa in mg and the second number the dose of levodopa in mg). Madopar is available in doses of 12.5/50 and 25/100. Long-acting formulations of both of these drugs are available: Sinemet CR in doses of 25/100 and 50/200 and Madopar HBS in a dose of 25/100. Liquid formulations of levodopa can be made by adding water and ascorbate to a Sinemet tablet, but these must be made fresh and offer little additional advantage for most PD patients. Rapidly absorbed methyl and ethyl ester formulations of levodopa are currently being assessed experimentally.

In summary, levodopa continues to be an important component of the therapeutic armamentarium for PD, but it is associated with troublesome complications and some parkinsonian features do not respond. Theoretically, levodopa could accelerate neuronal degeneration through oxidizing species generated by its oxidative metabolism, but there is little evidence to suggest that this is a concern in PD, and most physicians do not restrict the use of levodopa for this reason (60). On the other hand, current research suggests that if PD therapy is initiated with a dopamine agonist and levodopa is reserved until satisfactory benefits can no longer be controlled with the agonist alone, patients can enjoy comparable motor benefits and reduced motor complications in comparison to when levodopa is administered on its own (see Dopamine Agonists , below). There is also considerable interest in administering levodopa in conjunction with a COMT inhibitor to enhance its duration of effect and thereby improve motor response and reduce the risk of the drug inducing pulsatile stimulation of the dopamine receptor (see COMT Inhibitors , below).

Dopamine Agonists

Dopamine agonists are a group of drugs that act directly on dopaminergic receptors. Historically, they have been used as adjuncts to levodopa in the treatment of PD since the 1970s (61) and offer several theoretical advantages over levodopa (62): (a) They do not depend on enzymatic conversion for activity, i.e., they do not depend on the integrity of the nigrostriatal neurons, such that they should be active even in advanced stages of PD, at which time presynaptic dopamine neurons and terminals are largely degenerated. (b) They can be designed to stimulate specific subtypes of dopamine receptors, which may lead to selective functional responses. (c) Most marketed dopamine agonists have longer half-lives and longer durations of action than levodopa. This may permit more continuous (less pulsatile) stimulation of dopamine receptors than occurs with levodopa therapy. Therefore, there has been interest in the potential of this class of drug to reduce the risk of developing levodopa-related motor complications (62). (d) They do not undergo oxidative metabolism and do not generate free radicals that might promote degeneration of remaining nigrostriatal neurons. There are data now indicating that dopamine agonists can scavenge free radicals and protect dopamine neurons in *in vitro* and *in vivo* models of PD (63 ,64). Therefore, there has been interest in the potential of dopamine agonists to provide neuroprotective effects in PD (65).

Five dopamine agonists, bromocriptine (Parlodel), pergolide

(Permax), cabergoline (Cabsar, Dostinex), pramipexole (Mirapex) and ropinirole (Requip), are currently available for use in the United States and in many other countries throughout the world; cabergoline is approved for the treatment of PD in Japan and several European countries, but it has been exclusively marketed for suppression of lactation in the United States. Lisuride, piribedil, and apomorphine are other dopamine agonists that are available in some countries but not the United States. All dopamine agonists that are marketed for the treatment of PD stimulate the D2 receptor, which is thought to underlie their antiparkinsonian effects. Dopamine and apomorphine stimulate both D1 and D2 receptors. Pergolide is also a weak agonist and bromocriptine a weak antagonist of the D1 receptor. The role of D1 receptor activation or inhibition in PD is not known, although there is some suggestion that stimulation of both D1 and D2 receptors provides enhanced motor responses. Bromocriptine, pergolide, ropinirole, and pramipexole have plasma half-lives of 6 to 15 hours, whereas cabergoline has a much longer elimination half-life of 63 to 69 hours. This contrasts with the plasma half-life of levodopa, which is 60 to 90 minutes.

Dopamine Agonists in Patients with Advanced PD

Since their introduction in the mid-1970s, dopamine agonists have primarily been used as adjuncts to levodopa in PD patients with relatively advanced disease who have begun to experience motor complications (66). As an adjunct to levodopa, numerous prospective double-blind studies have demonstrated that dopamine agonists can significantly improve PD signs and symptoms, reduce dyskinesia and motor fluctuations, and reduce the need for levodopa therapy in comparison to placebo (67 ,68 ,69 ,70 ,71 ,72 and 73). Benefits have been observed with each of the currently approved dopamine agonists and they are of approximately equal magnitude. Apomorphine stimulates both D1 and D2 receptors. It has a very short latency to onset, but also a short duration of benefit. It has been used to provide a “rescue effect” for patients who turn “off” and do not respond to their next dose of levodopa (74). Some physicians have reported benefits in advanced patients with complex motor complications with the use of continuous apomorphine (75). However, apomorphine must be administered parenterally, is associated with cutaneous ulcerations at sites of entry, and is very difficult to manage for both the physician and the patient. It therefore has relatively little role in routine practice.

Despite the benefits obtained with dopamine agonists in patients with advanced disease, they generally do not provide satisfactory control of motor function or motor complications, and sooner or later alternate therapies must be sought.

Dopamine Agonists in Patients with Early PD

As discussed in the section on levodopa-related motor complications (see above), there is growing evidence suggesting that pulsatile stimulation of dopamine receptors due to the use of short-acting dopaminergic agents contributes to the emergence of motor complications. Studies in MPTP-treated primates demonstrate that bromocriptine and ropinirole are associated with reduced frequency and severity of dyskinesia compared to levodopa, even though all groups provide comparable behavioral effects (76 ,77). These data suggest that starting treatment for PD patients with a long-acting dopamine agonist rather than levodopa might reduce the risk of developing motor complications. However, until recently dopamine agonists have not been well studied in early PD. There are now prospective double-blind controlled studies demonstrating that both pramipexole and ropinirole provide improvement in measures of motor functions and activities of daily living (ADL) in otherwise untreated PD patients that are superior to placebo (78 ,79), and almost as good as levodopa (30 ,31). Further, PD patients can be maintained on dopamine agonist monotherapy without supplemental levodopa for a mean of 3 years (80). More importantly, it has now been established in prospective double-blind long-term studies that PD patients randomized to initiate therapy with a dopamine agonist (ropinirole or pramipexole), supplemented with levodopa if necessary, have significantly fewer motor complications than patients randomized to begin therapy with levodopa alone (30 ,31). Reduced rates of both dyskinesia and motor fluctuations were observed in the agonist-treated patients. Measurements of motor function and ADL on the Unified Parkinson Disease Rating Scale (UPDRS) showed slight, but significant, benefits in favor of levodopa-treated patients in both studies. This is difficult to explain, as patients in both groups could have added open label levodopa to their blinded treatment regimen if either the physician or the patient thought it was necessary. This raises the question as to whether the UPDRS fully captures all factors that contribute to PD disability.

Based on these new studies and the concept of continuous dopaminergic stimulation, many authorities now recommend initiating symptomatic therapy for PD with a dopamine agonist, and reserving levodopa until such time as the agonist can no longer provide satisfactory clinical control (51 ,81 ,82 and 83). Others feel that the issue is still somewhat controversial and that physicians must choose between enhanced efficacy now versus delayed motor complications later. Our personal view is that the difference in motor and ADL scores between the agonist and levodopa groups is negligible, whereas the difference in the rate of developing motor complications is substantial and a much greater source of disability for the patient and frequently necessitates surgical intervention as the only means of providing satisfactory control. Accordingly, we favor initiating therapy

with a dopamine agonist in appropriate patients to diminish the risk that disabling motor complications will ensue. We still favor the use of levodopa as the initial agent in patients with cognitive impairment or who are elderly.

Adverse Effects of Dopamine Agonists

The acute side effects of dopamine agonists are similar to those observed with levodopa and include nausea, vomiting, and postural hypotension (84). These side effects tend to occur when treatment is initiated and abate over days or weeks as tolerance develops. Introducing the agonist at a low dose, and slowly titrating to the desired effect reduces the probability that they will occur. Dopamine agonists can acutely cause or intensify dyskinesias, but in the long term they have the potential to lessen dyskinesias and motor fluctuations because of their long duration of action (see above). Psychiatric complications (hallucinations, confusion) may occur and tend to be more pronounced than bioequivalent doses of levodopa (30 ,31). The ergot-derived dopamine agonists, bromocriptine, pergolide, and cabergoline, may have ergot-related side effects including pleuropulmonary and retroperitoneal fibrosis, erythromyalgia, and digital vasospasm, although these are rare (84). The newer non-ergot dopamine agonists are less likely to induce these problems, although there is anecdotal suggestion that they may still occur. Dose-related sedation may occur with dopamine agonists (69 ,78), as with other dopaminergic agents including levodopa. More recently, sudden episodes of unintended sleep while at the wheel of a motor vehicle have been described in PD patients and attributed to dopamine agonists (85). The episodes were termed “sleep attacks” because they occurred suddenly, although others have argued that there is no evidence to support the concept of a sleep attack even in narcolepsy. They have suggested that it is more likely that these patients have unintended sleep episodes as a manifestation of excess daytime sedation due to nocturnal sleep disturbances that occur in 80% to 90% of PD patients and to the sedative effect of dopaminergic medications (86). It is now apparent that these types of episodes can be associated with all dopaminergic agents including levodopa (87). Physicians should be aware of the potential of dopaminergic agents to induce sleepiness, and that patients themselves may not be aware that they are sleepy. To detect excess sleepiness and to thereby introduce appropriate management strategies, it is necessary to employ sleep questionnaires such as the Epworth sleepiness scale, which inquires into the propensity to fall asleep and does not rely upon subjective estimates of sleepiness (88).

Catechol O-Methyltransferase (COMT) Inhibitors

Orally ingested levodopa is massively transformed in the periphery by two enzymatic systems—AADC and COMT—such that only 1% of a levodopa gains access to the brain. To partially counter this effect, levodopa is routinely prescribed in combination with an inhibitor of AADC that does not cross the blood–brain barrier and blocks the peripheral decarboxylation of levodopa into dopamine. This combination reduces peripheral dopaminergic side effects associated with the administration of levodopa alone, and increases the amount of levodopa that is available to access the brain. However, even in the presence of a decarboxylase inhibitor, the bulk of levodopa is still metabolized by COMT and only 10% of a given dose is transported into the brain (17 ,89). Two new drugs that inhibit COMT, tolcapone (Tasmar) and entacapone (Comtan), have recently been introduced to the market as an adjunct to levodopa therapy. Both drugs inhibit COMT in the periphery, although tolcapone has mild central effects as well. Entacapone and tolcapone increase the elimination half-life of levodopa by approximately 40% without modifying the peak plasma concentration of levodopa (C_{max}) or the time to reach peak plasma concentration (*Tmax*) and effects are seen with both immediate and controlled release formulations (90 ,91 ,92 and 93). COMT inhibitors thus modulate peak and trough plasma levodopa concentrations, leading to a smoother plasma curve with reduced fluctuations in levodopa level (94). These pharmacokinetic effects have been shown to translate into enhanced levodopa entry into the brain on positron emission tomography (PET) (95) and clinical benefits particularly for patients experiencing mild to moderate motor fluctuations. Double-blind placebo-controlled clinical trials in fluctuating PD patients demonstrate that COMT inhibitors increase the duration of beneficial effect following a single levodopa dose (96). They also provide an increase daily “on” time of 15% to 25%, a decrease in “off” time of 25% to 40%, improvement in UPDRS motor scores, and a reduction in levodopa dose requirement of 15% to 30% (97 ,98 ,99 and 100). Benefits with COMT inhibitors have also been observed in nonfluctuating PD patients with a stable response to levodopa. Two placebo-controlled trials showed improved motor scores and reduced levodopa dose requirements in the group receiving the COMT inhibitor (101 ,102).

There has also been interest in using COMT inhibitors from the time levodopa is first initiated in order to reduce the risk of developing motor complications (103). As described in the section on motor complications, laboratory evidence supports the notion that treatment for PD patients should be employed in such a way as to try and avoid pulsatile stimulation of dopamine receptors (51). Indeed, there is now evidence indicating that initiating therapy with a long-acting dopamine agonist reduces the risk of dyskinesia and motor fluctuations (30 ,31). However, these patients eventually require levodopa, and when levodopa is administered the frequency of motor complications increases. It therefore has been postulated that administering levodopa from the time it is first introduced with a COMT inhibitor

to extend its half-life and deliver levodopa to the brain in a more continuous fashion might further reduce the risk of motor complications. Based on a similar hypothesis, studies comparing controlled-release levodopa to regular levodopa failed to demonstrate any difference between the two formulations (104 ,105). However, controlled-release formulations have variable absorption and do not provide stable plasma levels of levodopa. Further, the drug was prescribed twice daily in these studies, and that may not have been frequent enough to prevent fluctuations in plasma levodopa concentrations. Clinical trials to test this hypothesis using entacapone as an adjunct to levodopa are currently being planned.

Side effects associated with COMT inhibitors are primarily dopaminergic and reflect enhanced delivery of levodopa to the brain. Dyskinesia is the most common, but nausea, vomiting, and psychiatric complications may occasionally occur. Both the benefits and dopaminergic adverse effects develop within hours to days after initiating treatment. In general, they are easy to manage by simply reducing the dose of levodopa (by approximately 15% to 30%), not the dose of the COMT inhibitor. Dyskinesia is more likely to be a problem in patients who already experience dyskinesia, and the need for a levodopa dose reduction can be anticipated in these patients. An explosive diarrhea has been seen in 5% to 10% of tolcapone-treated and necessitates discontinuing the drug. This has been much less of a problem with entacapone and rarely requires stopping the drug. Brownish-orange urine discoloration may occur with either drug due to accumulation of a metabolite. This is a benign condition, but patients should be advised that it may occur.

Of greater seriousness is the problem of liver toxicity that has been reported in association with tolcapone (106). No evidence of liver dysfunction was detected in preclinical toxicity studies, but in clinical trials elevated liver transaminase levels were observed in 1% to 3% of patients. For this reason, liver monitoring was required. Following approval of the drug, there have been reports of four cases of severe liver dysfunction leading to the death of three of the individuals (106 ,107). These observations led to the drug being withdrawn from the market in Europe and Canada and to the issuance of a “black box” warning in the United States (108). This requires biweekly monitoring of liver enzymes for the first 12 weeks, monthly monitoring thereafter, and discontinuation of the drug if liver enzymes are elevated above normal on a single occasion. No preclinical toxicity, clinical trial, or postmarket reports of liver dysfunction have been described to date with entacapone, and no laboratory monitoring is required with its use (109).

Entacapone is typically administered in a dose of 200 mg with every scheduled dose of levodopa, whereas tolcapone is administered at a dose of 100 or 200 mg three times daily. No comparative studies between entacapone and tolcapone have been performed, but pharmacokinetic and clinical trial data indicate that tolcapone is the more potent agent. However, because of the greater risk of hepatotoxicity and diarrhea, entacapone has become the more widely employed COMT inhibitor. It should be emphasized that COMT inhibitors provide antiparkinsonian benefit only when used as an adjunct to levodopa. By themselves they have no effect.

In conclusion, COMT inhibitors represent an important advance in the medical treatment of PD and may be useful in all stages of the illness (110). Used in combination with levodopa, they extend the half-life of levodopa, smooth the plasma levodopa concentration curve, and enhance clinical dopaminergic benefits. They have been established to provide benefit in PD patients with motor fluctuations, although particular care must be taken in managing the more advanced patients with severe dyskinesia, and this is usually best left to the Parkinson specialist. There are preliminary data suggesting that they enhance motor function in the milder patient with a stable response to levodopa, and this is being further evaluated. Finally, there is good evidence to suggest that administering levodopa with a COMT inhibitor from the time it is first introduced may prevent pulsatile stimulation of dopamine receptors and minimize the risk of developing motor complications. The drugs are easy to use and require no titration. Dopaminergic side effects tend to occur within days and can be managed by tapering the levodopa dose. Because of the restrictions in the use of tolcapone due to liver toxicity, entacapone is now the COMT inhibitor of choice. It is likely that a single tablet will soon be developed that contains the combination of levodopa, an AADC inhibitor, and a COMT inhibitor.

Other Antiparkinson Agents

Anticholinergics

Anticholinergic drugs were first used as a treatment for PD in the 1860s, using extracts from the alkaloids *Atropa belladonna* and *Hyscyamus niger*, which contain hyosciamine and scopolamine (111 ,112). Synthetic anticholinergic drugs were developed in the 1940s, and they became the mainstay of PD treatment until the emergence of levodopa (113 ,114). These drugs have largely been replaced by the newer antiparkinsonian drugs, but are still used occasionally in the modern era particularly for the treatment of tremor (115). The main anticholinergic agents currently in use are trihexyphenidyl (Artane), benztropine (Cogentin), biperiden (Akineton), orphenadrine (Disipal), and procyclidine (Kemadrin). An interaction between dopaminergic and cholinergic neurons in the basal ganglia has long been recognized, and classic experiments demonstrated the capacity of cholinergic agents to worsen and anticholinergic agents to improve parkinsonian features (116). Cholinergic agents have been shown to block dopamine reuptake into presynaptic dopaminergic terminals (117) and dopamine receptor activation has been shown to regulate acetylcholine release (118).

More recent work has demonstrated that dopamine-regulated neuropeptide (preproenkephalin) expression in striatal neurons is regulated by cholinergic interneurons (119). Despite these observations, the relationship between the cholinergic and dopaminergic systems is poorly understood, as is the basis for the clinical benefits that are seen with anticholinergic agents.

Clinical studies demonstrate that anticholinergic agents provide a 10% to 25% improvement in rest tremor, whereas akinesia and postural impairment are not affected (120). In practice, anticholinergic agents can be used in early PD patients to treat tremor when it is the predominant complaint and to delay the introduction of levodopa, provided that cognitive function is preserved and that the patient does not have narrow angle glaucoma or orthostatic hypotension (see General Adverse Effects of DBS , below). Trihexyphenidyl is the most widely used anticholinergic agent in PD, although head-to-head comparisons have not been performed. The usual trihexyphenidyl doses range from 0.5 to 1 mg b.i.d. initially, with gradual increase to 2 mg t.i.d. Benztropine is also commonly used, with doses ranging from 0.5 to 2 mg b.i.d.

Side effects are a major limiting factor with respect to the use of anticholinergic drugs in PD. The most important of these are central, and consist of memory impairment, confusion, hallucinations, sedation, and dysphoria (115). These tend to be most pronounced in older individuals with some preexisting cognitive impairment, but can affect young patients with seemingly intact mentation as well. Peripheral side effects include dry mouth, dysuria, constipation, dizziness due to orthostatic hypotension, tachycardia, nausea, blurred vision, and decreased sweating. Anticholinergic agents should be avoided in patients with narrow angle glaucoma, and caution is required in using them in patients with prostatic hypertrophy because of the risk of inducing acute urinary retention. Anticholinergic drugs can enhance levodopa-induced choreiform dyskinesias, and orobuccal dyskinesias have been reported with anticholinergic therapy alone (121). If the decision is made to discontinue anticholinergics, this should always be done gradually to avoid withdrawal effects and acute exacerbation of parkinsonism (122).

Peripherally active anticholinergic drugs are also used in PD. Anticholinergic agents that are relatively selective for bladder cholinergic receptors such as tolterodine tartrate (Detrol), and oxybutynin (Ditropan) can be used to treat bladder instability (123). Anticholinergic agents that are relatively selective for salivary gland receptors such as glycopyrrolate (Robinul) can be used to treat sialorrhea.

Because of their adversity profile, and particularly their tendency to induce cognitive impairment, anticholinergic agents are not commonly used in the treatment of PD. They are perhaps most frequently used in younger PD patients with tremor-dominant PD. However, there is evidence suggesting that levodopa and other dopaminergic agents provide antitremor effects that are just as good as or superior to anticholinergic agents (124). Certainly when these agents are employed, side effects should be sought and the drug discontinued when they occur.

Amantadine

The discovery of the antiparkinson properties of the antiviral agent amantadine (Symmetrel) was fortuitous (125). The primary mechanism of action of amantadine in PD is not established with certainty. The drug has been described to increase dopamine release, block dopamine reuptake, and stimulate dopamine receptors. It has also been shown to have anticholinergic effects and weak NMDA receptor antagonist properties (126 ,127 and 128). Improvement in akinesia, rigidity, and tremor, as well as reduction in choice reaction time, have been described in uncontrolled studies, particularly in mildly affected PD patients (125 ,129 ,130 and 131). In comparison to anticholinergic drugs, amantadine was found to have a greater effect on akinesia and rigidity but lesser benefit for tremor (132).

With the recognition that amantadine provides NMDA receptor antagonism (128), there has been interest in the notion that it might have antidyskinetic and even neuroprotective effects. The potential of the drug to interfere with dyskinesia is based on the notion that dyskinesias are related to excessive phosphorylation of NMDA receptors on striatal neurons due to loss of dopamine-mediated modulatory effects (49). Studies in monkeys show that NMDA receptor antagonists can improve dyskinesia (50). Preliminary clinical trials suggest that the same is true in some PD patients (37 ,134), and this has now been confirmed in a double-blind controlled study (135). The potential of amantadine to provide neuroprotective effects is based on evidence suggesting that excitotoxicity contributes to neuronal degeneration in PD (136 ,137). Indeed, one retrospective study did suggest that there was an increase in the survival of PD patients that had been treated with amantadine (138).

The elimination half-life of amantadine is 10 to 30 hours, and the medication is typically administered in dosages of 100 mg two to three times per day. Unfortunately, amantadine is frequently associated with dose-related cognitive problems including confusion, hallucinations, insomnia, and nightmares that limit its usefulness. Amantadine has also been associated with livedo reticularis, ankle edema, and peripheral neuropathy. If amantadine must be withdrawn, it should be done gradually as some patients may experience dramatic worsening of PD on withdrawal.

In conclusion, amantadine can be used in the initial stages of PD to provide some symptomatic benefit and to delay the need for levodopa. It can also be used as an adjunct to levodopa to try to control levodopa-induced dyskinesia. Cognitive side effects limit the usefulness of this drug, and mental status must be closely monitored particularly in patients with advanced disease or preexisting cognitive impairment.

As it is difficult to withdraw in many instances, many physicians do not use this drug as a first-line therapy.

Selegiline

Selegiline (Deprenyl, Eldepryl) is a relatively selective inhibitor of monoamine oxidase-B (MAO-B). It was approved in PD as an adjunct to levodopa that provides a modest increase in “on” time in fluctuating patients with advanced PD (139). However, it is primarily used in the treatment of early PD patients as a putative neuroprotective agent. This was based on two important observations that suggested that an MAO-B inhibitor might alter the natural course of PD. First, the neurotoxin MPTP causes parkinsonism (140) by way of an MAO-B–catalyzed oxidation reaction forming the toxin MPP^+ (141), and second, dopamine is oxidized by MAO-B to generate peroxides and other potentially cytotoxic oxidizing species (56). In the laboratory, selegiline has been shown to protect nigral dopaminergic neurons in cell cultures and in MPTP-treated animals (142 ,143). Prospective double-blind clinical trials in previously untreated PD patients have demonstrated that selegiline delays the emergence of clinical dysfunction as determined by the need for levodopa and the progression of parkinsonian signs and symptoms (144 ,145). However, post hoc analyses have demonstrated that selegiline has symptomatic effects that might account for these benefits. These confound interpretation of these studies (146). In addition, the disease continues to progress, and initial benefits do not appear to persist (147 ,148).

Although there remains equipoise with respect to the possible beneficial effects of selegiline, it is now clear that the drug has clear neuroprotective effects for dopaminergic neurons in both *in vitro* and *in vivo* laboratory models (see ref. 149 for review). Further, it is now clear that neuroprotection with selegiline does not depend on MAO-B inhibition (150 ,151), and is mediated by the drug's metabolite desmethyl selegiline (DMS) (152). Work by Tatton's group (153 ,154 and 155) has now shown that DMS and other propargylamines provide neuroprotective effects by binding to the protein glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and preventing its translocation to the nucleus. GAPDH accumulation in the nucleus inhibits BCL-2 expression and promotes apoptosis (153 ,154). These findings, indicating that selegiline is an antiapoptotic drug, are particularly relevant to PD, where there is evidence that cell death occurs by way of an apoptotic process (155).

Selegiline is administered in a dose of 5 mg b.i.d. and is generally well tolerated. In levodopa-treated patients it has the potential to increase dopaminergic side effects and to possibly induce cardiovascular problems. Its amphetamine metabolite can also cause insomnia, and for this reason the second dose is usually not administered after 12 noon. The adversity profile of selegiline has been somewhat clouded by the findings of a 5-year open label study reporting increased mortality in patients receiving the combination of levodopa-carbidopa/selegiline as opposed to those treated with levodopa-carbidopa alone (156 ,157). However, the statistical methods used in this study were questioned (158), and increased mortality has not been confirmed in a metaanalysis evaluating mortality in all other prospective trials of selegiline (159).

In summary, there is theoretical evidence suggesting that selegiline might provide neuroprotective benefits in PD. Clinical trials are consistent with this notion, but might be explained by the drug's symptomatic effects. The drug is generally well tolerated, and claims of increased mortality have not been substantiated. It remains a matter of judgment and personal philosophy as to whether or not to use selegiline as a putative neuroprotective drug.

SURGICAL THERAPIES FOR PARKINSON'S DISEASE

Part of "124 - Current and Experimental Therapeutics of Parkinson's Disease "

In the past few years, the renaissance of functional neurosurgery has transformed our vision of PD therapy. Functional neurosurgery for movement disorders dates back to the beginning of the 20th century, with the introduction of pyramidal tract lesions or dorsal root sections (160 ,161 and 162). These were unfortunately characterized by their unacceptable morbidity. Lesions of the basal ganglia as a treatment for PD were introduced by Meyers in the early 1940s (163 ,164). These procedures provided some benefits for tremor and rigidity, but adverse events were common and there was an unacceptably high mortality rate ranging from 8% to 41% (162 ,163 ,164 ,165 ,166 ,167 and 168). Surgery therapies for PD became more widely accepted with the introduction of stereotactic techniques (169) and the determination that lesions of the thalamus could provide benefits with fewer adverse events (170). With the introduction of levodopa, surgery for PD was almost abandoned. However, the shortcomings of classic levodopa therapy (as discussed above), the tremendous advances in brain imaging and intraoperative monitoring techniques for target localization, and insights into the pathophysiology of the basal ganglia (171 ,172) have catalyzed a dramatic resurgence of interest in surgical procedures for PD. However, most current information is based on open trials that do not control for placebo effects and physician bias, and may thus have overstated the benefits that can be achieved (173). There is little doubt that surgical techniques offer the potential to provide benefit to PD patients with advanced disease who cannot be controlled with medical therapies, but well-designed placebo-controlled double-blind studies are required in order to determine their true value (174).

Ablative Procedures

Thalamotomy

Current knowledge of basal ganglia physiology in the normal and PD state suggest several targets for ablative procedures,

one of which is the ventral intermediate nucleus (VIM) of the thalamus. Metabolic and physiologic studies consistently indicate that the ventral anterior and ventral lateral thalamic nuclei, the STN and the GPi, are overactive in PD (175 ,176), probably reflecting increased inhibitory output from the GPi. Cooper (170) and Hassler and Riechert (177) noted in the 1950s that thalamic lesions could relieve contralateral tremor. Their experience led to thalamotomy becoming the preferred surgical procedure for the treatment of tremor-predominant forms of PD. Their choice of target was facilitated and supported by electrophysiologic studies demonstrating abnormal tremor synchronous electrical activity in this region (178 ,179 and 180). Ohye and Narabayashi (181 ,182) subsequently used these techniques to conclude that lesions in the VIM nucleus of the thalamus were most effective in reducing contralateral tremor. Studies reported a consistent reduction in contralateral tremor, but it is less certain that there are benefits with regard to rigidity, and there is virtually no benefit for more disabling features such as bradykinesia or postural impairment (183 ,184 ,185 and 186). These studies also suggested that thalamotomy has the potential to reduce or prevent the development of levodopa-induced dyskinesia (183 ,184 ,187 ,188 and 189). In recent studies, persistent morbidity associated with unilateral thalamotomy occurs in less than 10% of patients. Complications includes dysarthria, dysequilibrium, contralateral hemiparesis or hemiataxia, cognitive impairment, and personality changes (185 ,190). Bilateral thalamotomy is associated with a further increase in morbidity including dysarthria, dysphagia, and cognitive impairment, and is usually avoided (185 ,190).

In conclusion, for a select group of PD patients with disabling tremor that cannot be controlled with medications and marked unilateral predominance, thalamotomy can still be considered; however, this technique has now been largely replaced by a different surgical procedure (deep brain stimulation) and alternate targets (STN or GPi) (see below).

Pallidotomy

Despite the early encouraging reports (163 ,164), lesioning the pallidum or its efferent fibers fell out of favor and was replaced by thalamotomy. However, Leksell persisted in developing this surgery and was able to determine that lesions placed in the posteroventral portion of the globus pallidus pars interna (GPi) were the most beneficial in relieving PD signs and symptoms (191). A generation later, his pupil Laitinen performed Leksell's technique using more modern stereotactic techniques, and described benefits with respect to bradykinesia, rigidity, and levodopa-induced dyskinesias (192 ,193). Complications were observed in 14% of patients and included partial homonymous hemianopsia, transient dysphasia, and facial weakness. These results followed shortly after neurophysiologic studies demonstrating that the pallidum was hyperactive in PD (171 ,194). These results prompted a renaissance in pallidotomy as a surgical option for PD. Using the posterolateral pallidum as a target, several surgical groups have now reported benefits in PD patients (195 ,196 and 197). The most dramatic finding is a consistent long-lasting abolition of contralateral dyskinesia; antiparkinsonian benefits are more modest (198 ,199). Complications occur in 3% to 10% of patients and are primarily visual in nature, although cognitive impairment, sensory deficits, and motor weakness may all occur. Bilateral pallidotomy is associated with increased risk of disabling dysphagia, dysarthria, and cognitive impairment (200 ,201), and has largely been abandoned with the availability of stimulation procedures. Current pathophysiologic models of PD explain the improvement in parkinsonism, but do not explain the striking antidyskinetic effect of pallidotomy (202). It has been proposed that the antidyskinetic effect of pallidotomy may be due to elimination of an abnormal firing pattern in pallidal output neurons that are providing misinformation to cortical motor regions that result in the emergence of dyskinesia (42).

In summary, unilateral pallidotomy provides consistent and dramatic improvement in contralateral levodopa-induced dyskinesia. However, improvement in parkinsonian features is modest and the procedure is associated with lesion-related side effects, especially when it is performed bilaterally. Here, too, it is being replaced by stimulation procedures in many centers (173).

Subthalamotomy

Physiologic and metabolic studies demonstrate that the subthalamic nucleus (STN), similar to the GPi, is overactive in parkinsonian syndromes (171 ,175 ,202 ,203). This has led to the notion that lesions of the STN might provide benefits in PD. Indeed, subthalamotomy has been shown to improve parkinsonian features in MPTP-treated monkeys (204 ,205). However, lesions of the STN are associated with hemiballismus, and accordingly physicians have been reluctant to perform this procedure in PD patients. Deep brain stimulation procedures avoid the need to make lesions in target structures (see below), and stimulation of STN is associated with marked improvement in parkinsonian features. Preliminary studies of subthalamotomy have been performed and indicate that it also can provide excellent benefits in PD with minimal adversity (206). Nevertheless, until further experience has been gained with respect to the long-term safety and efficacy of this procedure, it must be considered experimental.

Deep Brain Stimulation Procedures

High-frequency deep brain stimulation (DBS) was introduced by Benabid and his group (207) alternate to ablative procedures. Benabid et al. noted that high-frequency stimulation of selected brain targets simulates the effects of a

lesion without the necessity of making a destructive brain lesion. In this procedure, an electrode is implanted into the desired brain target and connected to a stimulator placed subcutaneously over the chest wall. DBS has several advantages over ablative procedures: (a) It avoids the need to make a destructive brain lesion. Side effects due to stimulation can be reversed by changing the stimulator settings. (b) Bilateral procedures can be performed with relative safety. (c) Stimulator settings can be adjusted as with the doses of a medication to maximize benefit and minimize adversity. The precise mechanism of action of DBS is unknown, but it may involve jamming abnormal firing patterns of nerve cell populations within the stimulated area. Other possible mechanisms include depolarization blockade, release of inhibitory neurotransmitters, and indirect effects due to backfiring with stimulation of distant cell populations through orthodromic or antidromic firing.

Deep Brain Stimulation of the VIM of the Thalamus (DBS-VIM)

The initial trials of DBS were performed in the VIM nucleus of the thalamus. The procedure provided prominent antitremor effects in the vast majority (80% to 90%) of patients with tremor predominant PD and essential tremor (208). Tremor arrest occurrs within seconds following the onset of stimulation, and the effect is lost within seconds of its cessation. These results were confirmed in a double-blind crossover study (209) that led to the approval of unilateral DBS-VIM as a treatment for essential or parkinsonian tremor by the Food and Drug Administration (FDA) in the United States. Interestingly, stimulation slightly posterior and medial to the VIM—close to the centromedian and parafascicular complex of the thalamus—also induced reduction in levodopa-induced dyskinesias (210). Unfortunately, DBS-VIM does not meaningfully improve the more disabling features of PD such as bradykinesia and gait impairment. This shortcoming has led to consideration of other targets for DBS, such as the GPi and the STN (see below). DBS-VIM remains a very valuable procedure for PD patients for whom tremor is the main handicap.

Deep Brain Stimulation of the Subthalamic Nucleus (DBS-STN)

A large body of experimental evidence has pointed toward targeting the STN as a treatment for PD: (a) neurons in the STN are hyperactive in PD (203 ,211); (b) lesions of the STN provide benefit to MPTP-treated primates (204 ,205); (c) improvement in contralateral parkinsonism following a spontaneous hemorrhage into the STN of a PD patient (212); and (d) improvement in MPTP-treated monkeys following stimulation of the STN (213). Based on these findings, DBS-STN was introduced as a treatment for PD patients (214 ,215 and 216). Significant benefits of stimulation have been reported for all of the cardinal features of parkinsonism; these have been confirmed in a double-blind crossover study (217). Improvements in motor function range from 40% to 80%. Highly significant benefits have also been observed in home diary assessments of percent “on” time without dyskinesia, leading to a dramatic reduction in patient disability. This is all the more remarkable when one considers that these benefits have been obtained in a population of patients that could not be further improved with medical therapy. Interestingly, dyskinesias have not been a problem, which may be related to disruption of the abnormal firing pattern in STN neurons. Finally, it has recently been proposed that DBS-STN might provide neuroprotective effects by inhibiting STN-mediated excitotoxic damage in its target structures (137). Indeed, lesions of the STN have been shown to protect SNc neurons in 6-hydroxydopamine lesioned rodents (218). It is currently thought that stimulation of the STN is the most effective surgical procedure, but prospective double-blind placebo-controlled studies directly comparing stimulation of the STN to other target structures such as GPi (see below) remain to be performed (173).

Deep Brain Stimulation of the Globus Pallidus Pars Interna (DBS-Gpi)

The experimental rationale for performing stimulation of the GPi is similar to that for STN. As is the case with the STN, the GPi is also overactive in PD (203 ,211), and lesions of the GPi provide benefits in MPTP monkeys (219). Several studies have now reported that DBS-GPi can improve all of the cardinal features of parkinsonism and reduce the severity of levodopa motor complications (220 ,221 and 222). Benefits do not appear to be as potent as with DBS-STN, but a prospective controlled trial has yet to be performed to objectively compare these two targets.

General Adverse Effects of DBS

Adverse effects of DBS can be related to the surgical procedure, the device, and the stimulation itself. Surgical complications involve hemorrhage and infarction and occur in less than 3% of cases. The electrode itself does not seem to be toxic to local tissues, as in the only postmortem pathologic study available, gliosis around the electrode tip was less than 1 mm in diameter (223). Problems associated with the implanted material (infection, dislodgment, mechanical dysfunction) occur in 1% to 3% of cases and may lead to the need to replace the electrode. Stimulation-related side effects include paresthesiae, motor twitch, dysarthria, and eye movement disorders. They are usually transient and controllable by stimulator adjustment. Finally, the battery has limited longevity, ranging from 6 months to 5 years or more, depending on the electrical consumption of the stimulator

settings chosen. The battery in the chest wall can be easily replaced under local anesthesia in most cases.

Despite the potential side effects of the DBS procedure, the risk of permanent side effects is less than with ablative procedures, particularly when bilateral with procedures (224).

Management of DBS

Optimization of stimulator settings is necessary to achieve maximal benefit with DBS procedures. This is not an easy task because of the large number of stimulation variables. These include electrode configuration, amplitude, pulse width, and frequency. Determination of the optimal stimulation settings may be complicated and time consuming (hours) and may require multiple visits. Validation of a rapid and simple method for determining stimulator adjustment will enhance the utilization of these techniques.

In conclusion, DBS of selected brain targets offers PD patients the potential of experiencing clinical benefit when this cannot otherwise be attained with medical therapy. Further, this can be accomplished without the need to make a destructive brain lesion with its accompanying side effects. Studies to determine the long-term safety and efficacy of DBS and the optimal target site for individual patients remain to be performed. Nevertheless, studies performed to date indicate that this procedure has much to offer patients with advanced PD. Based on existing information, DBS-STN appears to provide the best clinical effects and is presently considered to be the stimulation target of choice. It is possible that other brain targets such as the globus pallidus pars externa and selected cortical motor regions will prove superior in the future.

Transplantation Procedures

Yet another approach to the treatment of patients with advanced PD is transplantation of dopaminergic neurons aimed at replacing host neurons that degenerate during the course of the disorder. Transplantation is a rational strategy for treating PD because (a) PD is due to specific degeneration of dopaminergic nigrostriatal neurons and its symptoms are dramatically relieved by dopaminergic treatment; and (b) the striatum, which is denervated in PD, is a well-defined target for transplantation (225). In animal models, fetal nigral neurons have been shown to survive, reinnervate the striatum, produce dopamine, and improve motor dysfunction in rodent and primate models of PD (226 ,227 ,228 and 229).

The first clinical trials in PD patients involved implantation of adrenal medullary cells into the caudate nucleus, but despite the initial encouraging reports (230), the inconsistent outcomes and the associated adverse events led to this procedure being abandoned (231 ,232). Human fetal nigral grafts provide more potent results in animal models (225), and led to the initiation of clinical trials in PD patients (233 ,234 ,235 ,236 ,237 and 238). Results were somewhat inconsistent among the different groups, but some studies noted consistent and clinically meaningful benefit. In one study using a predetermined transplant protocol, six PD patients who could not be improved with medical management experienced significant improvement over baseline in motor scores when “off” (mean of 31%) and in percent “on” time without dyskinesia (mean of approximately 250%) (238). The variability in clinical response in the different centers may have related to the use of different transplant variables (e.g., donor age, method of tissue storage, target site for transplant, volume of distribution within target site, amount of implanted tissue, use of cyclosporine). In trials documenting clinical benefit, striatal fluorodopa uptake on PET demonstrated a significant and progressive increase in striatal fluorodopa uptake (237 ,238 ,239 and 240). Benefits on PET correlated with improvement in motor scores (238 ,241). Postmortem studies have been performed on some patients who have received transplants and expired for reasons not related to the transplant procedure (242 ,243). These studies demonstrated robust survival of implanted neurons and reinnervation of the striatum in an organotypic fashion (242). In this study, there were strong correlates between the number of surviving cells and UPDRS motor scores and striatal fluorodopa uptake on PET.

Following these open studies, two prospective randomized double-blind placebo-controlled trials have been initiated. The first was a 1-year study involving 40 patients. Two donors per side were implanted into the caudate and putamen bilaterally, without immunosuppression (244). Quality of life was the primary endpoint and was not improved. However, significant improvement in UPDRS motor and ADL scores were observed in patients under 60 years. The second study is a 2-year study that compares bilateral transplantation into the postcommissural putamen with one versus four donors per side (174). Immunosuppression with cyclosporine was employed in this study. The study is still ongoing and will terminate in 2001.

Several hundreds PD patients have now undergone transplant procedures. In general, the procedure has been well tolerated, especially when performed in major university centers. There is one report of a death due to obstructive hydrocephalus caused by graft migration into the 4th ventricle. Postmortem study revealed that the migrated tissue was composed of nonneural tissue containing bone, cartilage, hair, and epithelium (243). This study illustrates the importance of developing experience in transplant biology and appropriate dissection techniques before embarking on this surgical adventure. There has also been a report in abstract form of new-onset disabling dyskinesia that persists even when levodopa is withdrawn for prolonged periods of time (245). The frequency, clinical significance, and basis for this problem remain unknown, but clearly warrant further investigation.

The role of fetal nigral transplantation in PD has not

yet been fully determined, but the only double-blind study completed so far has not shown satisfactory benefits, and there are concerning side effects that remain to be explained. Concomitant use of antioxidants, lazaroids, antiapoptotic agents, and trophic factors, or modifications in the type of donors, the amount of cells transplanted, and the site of transplantation may all enhance transplant benefits. Also, alternate sources of dopaminergic tissues will have to be found to avoid the societal and logistical problems associated with the use of fetal human tissue. Transplantation of fetal porcine nigral cells has been shown to provide some clinical benefit and postmortem cell survival (246), and a prospective double-blind clinical trial is ongoing. Other experimental approaches to repopulating the basal ganglia with dopaminergic cells include the use of stem cells and gene therapies. The concept of restoring dopaminergic innervation to the basal ganglia is appealing, and to some extent it is now clear that this can be accomplished. For the present, however, transplant therapies must still be considered experimental and not a practical option for PD patients outside of research trials.

FUTURE RESEARCH DIRECTIONS

Part of "124 - Current and Experimental Therapeutics of Parkinson's Disease "

Symptomatic Therapies: Nondopaminergic Agents

Despite the advances in the therapeutics of PD, patients continue to experience parkinsonian disability and disabling motor complications. New treatment strategies aimed at providing more continuous dopaminergic stimulation to prevent motor complications and surgical approaches to ameliorate them represent major advances. Nonetheless, many patients continue to experience disability despite these new treatment approaches. This has led to experimentation with other approaches to the symptomatic treatment of PD and its complications. Although most interest has focused on the motor aspects of PD, dementia is the greatest unmet medical need and the major reason for nursing home placement for patients with this condition (247). There are currently no treatments that are established to attenuate the decline in mental function that accompanies PD. Some physicians use central cholinergic medications such as donepezil or rivastigmine on an empiric basis, but there are no studies confirming their value in PD.

There has been increasing interest in developing new antidyskinetic therapies for PD based on activating the numerous nondopaminergic cell-surface receptor targets on basal ganglia neurons that modulate dopaminergic activity or other systems that are affected in PD (248). The development of an agent that blocks dyskinesia would permit levodopa to be used in larger doses and thereby eliminate motor fluctuations. Some possible antidyskinetic agents include drugs that are glutamate antagonists, adenosine A2A antagonists, opioid antagonists, serotoninergic 5-HT_{2C} agonists, canabanoid CB1 agonists, α_2-antagonists, dopamine uptake inhibitors, selective muscarinic antagonists, and nicotinic agonists (249). Glutamate antagonists have already been shown to have antidyskinetic effects in some PD patients (133 ,134 and 135), but they are complicated by mental side effects that limit their utility in PD. However, other agents such as riluzole that inhibit sodium channels and impair glutamate release have also been reported to improve dyskinesia and are better tolerated (250). The adenosine A2A receptor is localized to striatal cholinergic interneurons, and antagonists to the adenosine A2A receptor have been shown to increase motor activity in rodent and primate models of PD, without provoking a dyskinetic response, even when administered to levodopa-primed animals (251 ,252). Clinical trials of this agent are currently under way. Nicotine receptors are present on terminals of nigrostriatal neurons, and their stimulation has been shown to increase dopamine release in the rat nucleus accumbens (253). This may account for why cigarette smoking is addictive, and why there is a seeming reduction in the frequency of PD in smokers (254). In MPTP-treated primates, nicotine has no effect on the basal motor disability or on levodopa-induced dyskinesia, but muscarinic agonists and antagonists did influence levodopa-induced dyskinesia (255 ,256).

Restorative Therapies

The threshold for developing levodopa-induced dyskinesias appears to depend on the degree of denervation of the SNc (42 ,257). This has led to the hypothesis that increasing the number of dopaminergic terminals might better regulate dopamine storage and release and control dyskinesia. Bjorklund et al. (258) have shown that dyskinesia can be prevented in a rodent model following transplantation of dopamine neurons with restoration of greater than 20% of striatal dopamine terminals as detected by staining for dopamine transporter protein. There is considerable interest in the potential of neurotrophic factors, such as brain-derived neurotrophic factor (BDNF) or glial-derived neurotrophic factor (GDNF), to provide restorative effects and increased numbers of dopamine terminals in PD. GDNF has been shown to promote functional and anatomic recovery in MPTP-treated monkeys (259 ,260). GDNF treatment in these animals was associated with improvement in motor behavior, a reduction in levodopa-induced dyskinesia, and increased dopamine production. This approach could provide combined symptomatic and neurorestorative benefits. Clinical trials of intraventricular GDNF administration in PD patients have been stopped, presumably because of lack of efficacy. This may relate to failure of GDNF to cross the blood–brain barrier. Further studies of direct intraparenchymal injections are warranted. Administration of GDNF by gene therapy using a lentivirus vector has been shown

to prevent motor deficits and nigral degeneration in MPTP monkeys (261). This provides another opportunity for introducing GDNF to PD patients, although such trials are not likely to be started until a number of regulatory concerns have been addressed. Stem cells have tropic properties and can migrate to sites of neuronal damage. They also have the potential to be converted to dopaminergic neurons. The question is, Can the two functions be merged? This too is a promising area of research, but clinical trials may be far in the future.

Neuroprotective Therapies

Neuroprotective therapies are designed to slow or stop disease progression by rescuing or protecting vulnerable neurons. To date, no therapy has been established to be neuroprotective in PD. When a neuroprotective treatment becomes available, it will be important to define at-risk subjects or patients with very early PD so that treatment can be initiated at the earliest time possible. An ideal neuroprotective therapy would eliminate the cause of the disease. Unfortunately, it is likely that both genetic and environmental factors contribute to the etiology of PD, and they may be different in different patients (262). The recent twin study indicates that genetic factors do not play a role in the etiology of PD in the majority of patients (263). A small number of familial cases are now known to be due to mutations in the genes that code for the proteins α-synuclein and parkin (264 ,265). Although they represent a small number of individuals, these findings may yield clues for understanding the pathogenesis of PD and permit the development of therapies that are of value for the majority of cases. α-Synuclein is a protein that accumulates even in sporadic PD (266). Parkin is now known to be a ubiquitin-protein ligase that is involved in protein degradation and reduced in activity in the mutant form (267). These observations suggest that protein clearance may be a fundamental problem in the origin of nigral degeneration in PD and a source of new therapeutic opportunities. Pathogenetic factors that have been implicated in PD include oxidative stress, excitotoxicity, mitochondrial dysfunction, and inflammation (268). It is unknown to what degree each of these contributes to the initiation of cell death, but each represents an opportunity for targeting a neuroprotective therapy. There is also a growing amount of evidence supporting the notion that cell death in PD occurs through an apoptotic process (155 ,269). Apoptosis is a gradual form of cell death that is associated with intracellular signaling mechanisms (270). The knowledge of these signals and the ability to manipulate them provide another opportunity for developing neuroprotective strategies.

Thus, there are numerous possible avenues for neuroprotective therapies (82): antioxidants (free radical scavengers, glutathione, ion chelators); glutamate inhibitors (excitatory aminoacids antagonists, glutamate release inhibitors, e.g., riluzole); calcium channel blockers; mitochondrial “energizers” (creatine, coenzyme Q10, nicotinamide, gingko biloba, carnitine); antiinflammatory agents (steroids); estrogens; trophic factors (GDNF, see above); transplant strategies (human, porcine, see above); antiapoptotic agents (desmethylselegiline, TCH 346, caspase inhibitors, cyclosporine); and agents that prevent intracellular protein accumulation. To date, none has been proven to be neuroprotective in PD. Indeed, the challenge is to find sufficient funding so as to be able to evaluate so many promising new therapies (271).

Huntington Disease

Christopher A. Ross

Russell L. Margolis

Christopher A. Ross: Departments of Psychiatry and Neuroscience, Johns Hopkins University School of Medicine, Baltimore, Maryland.

Russell L. Margolis: Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, Maryland.

Huntington disease (HD) is a progressive neurodegenerative disorder with an established genetic origin and symptoms that are referable to specific regions of brain disease. Cellular and molecular techniques are rapidly elucidating the pathogenesis of the disorder and are leading to approaches designed to develop rational treatments. Thus, HD serves as a model for the future study of those psychiatric disorders in which abnormal brain function is thought to arise from predominantly genetic factors.

CLINICAL FEATURES

Part of "125 - Huntington Disease "

HD can be described as a triad of motor, cognitive, and emotional disturbances (1 ,2). Symptoms usually begin between the ages of 35 and 50 years, although the onset may occur at any time from childhood to old age. Death occurs an average of 15 to 20 years after symptoms first appear, with some patients dying earlier from falls or suicide and others surviving for 30 to 40 years (Fig. 125.1).

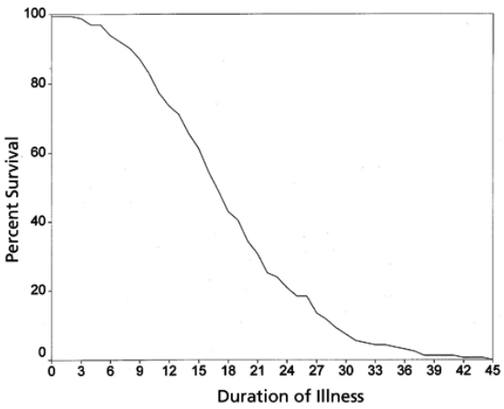

FIGURE 125.1. HD survival curve. The percentage of patients surviving as a function of years since disease onset. The curve is derived from 163 patients enrolled in the Baltimore Huntington's Disease Center with a record of both age at disease onset and age at death. (From Ross CA, Margolis RL, Rosenblatt A, et al. Reviews in molecular medicine: Huntington disease and the related disorder, dentatorubral-pallidoluysian atrophy (DRPLA). *Medicine (Baltimore)* 1997;76:305–338, with permission.)

Movement Disorders

The *movement disorder* of HD consists of two components: *involuntary* movements and abnormal *voluntary* movements. *Chorea*, or choreoathetosis, is the movement abnormality most frequently associated with HD. It consists of continuous and irregular jerky or writhing motions. Disturbances of voluntary movement, however, are more highly correlated with functional disability and disease severity, as measured by the degree of brain disease. The disordered voluntary movements observed in HD include the following: abnormal eye movements, such as slow, hypometric saccades and catchy pursuit; uncoordinated, arrhythmic, and slow fine motor movements; dysphagia and dysarthria; dysdiadochokinesis; rigidity; and gait disturbances.

The nature of the motor symptoms changes over time. The onset is usually insidious. Early complaints include clumsiness, difficulty with balance, and jerky movements or tremor. In addition to limb and truncal movements, patients may have motor tics or chorea involving respiratory, laryngeal, pharyngeal, oral, or nasal musculature. Chorea often plateaus and even wanes in the later stages of the disease, but disturbances in voluntary movement continue to progress (3). In late-stage HD, patients typically become akinetic and largely nonverbal, with severe rigidity and joint contractures. At this point, they may have few involuntary movements except for occasional movements of the entire body, resembling myoclonic jerks, when disturbed. Difficulties with swallowing commonly lead to death in HD, either directly from suffocation or aspiration or indirectly from starvation.

When HD begins in childhood or adolescence (juvenile-onset HD), the presentation is often somewhat different, with prominent bradykinesia, rigidity and dystonia, and minimal chorea. Involuntary movements may take the form of tremors, and patients may develop seizures and myoclonus.

Cognitive Disorders

Cognitive difficulties usually begin about the same time and proceed at the same rate as the abnormal movements (4), although some patients may have considerable motor impairment with very little dementia, or the reverse. Early in the course of HD, aphasia and agnosia are usually much less obvious than in the cortical dementias such as Alzheimer disease, whereas deficits in cognitive speed and flexibility are more common. In contrast to Alzheimer disease, patients with HD seem to have trouble with retrieval rather than storage of memories. They are more apt than patients with Alzheimer disease to recognize words from a previously memorized list or to respond to other cues to help them recall information. This distinction has led to the classification of HD as a *subcortical dementia* (5). Cognitive losses accumulate progressively. Deficits in memory, visuospatial abilities, and judgment develop, and patients with late-stage

HD demonstrate profound global impairment similar to patients with late-stage Alzheimer disease, although their paucity of speech makes assessment difficult.

Psychiatric Disorders

Patients with HD frequently develop *psychiatric symptoms*, most commonly depression, irritability, and apathy (3). The behavioral expression of these symptoms varies considerably, and it may include aggressive outbursts, impulsiveness, social withdrawal, and suicide. This aspect of HD can be devastating to both the patient and his or her family. The suicide rate alone, estimated at up to 12.7%, indicates the magnitude of the problem. Yet of all the complications of HD, the psychiatric manifestations are the most amenable to treatment.

Affective (mood) disorder is extremely common. Epidemiologic and phenomenologic evidence indicates that affective disorder in HD is a function of the brain disease itself, rather than a reaction to changes in life circumstance (2). HD-related major depression resembles the idiopathic form of major depression. Prominent symptoms include feelings of worthlessness or guilt, self-blame, changes in sleep and appetite, anxiety, anhedonia, loss of energy, hopelessness, and diurnal variation of mood with more severe symptoms in the morning. Delusions and hallucinations, when present, tend to be mood congruent: delusions of poverty, illness, or guilt; auditory hallucinations of derogatory or threatening voices. The diagnosis of major depression may be more difficult in patients with advanced disease, but the condition is often signaled by a departure from baseline levels of activity or functional capacity.

Severe irritability is another common symptom, present in one-third of patients in the Maryland HD survey (2). Irritability and aggression may occur in patients without a prior history of a short temper, but these symptoms are more common in patients who have had these traits all their lives. Apathy may become evident at any time in the course of the disease. Once present, it tends to persist or worsen. Irritability can coexist with apathy. Either apathy or irritability may exist independently or as part of an affective syndrome.

Patients with HD occasionally develop classic obsessive-compulsive disorder, with typical symptoms such as fear of contamination or excessive hand washing. More commonly, however, patients may display an obsessive preoccupation with particular ideas or plans (e.g., obtaining cigarettes, getting a refill of coffee) and may become irritable when these requests are not honored. Rarely, patients develop a schizophrenia-like syndrome, with prominent delusions, hallucinations, or thought disorder in the absence of an abnormal mood.

Clinical Course

In summary, adult-onset HD falls roughly into three stages. Early in the disease, manifestations include subtle changes in coordination, perhaps some minor involuntary movements, difficulty thinking through problems, and, often, a depressed or irritable mood. In the middle stage, chorea usually becomes prominent, and difficulty with voluntary motor activities becomes more evident with worsening dysarthria and dysphagia. As cognitive deficits increase, the patient becomes unable to hold a job or carry out most household responsibilities. Patients with late-stage disease may have severe chorea, but they are more often rigid and bradykinetic. They are largely nonverbal and bedridden, with a more global dementia, although they retain a significant degree of comprehension.

SYMPTOMATIC TREATMENT

Part of "125 - Huntington Disease "

There are no currently accepted specific treatments to slow the rate of clinical progression of HD (6). However, symptomatic management of both movement and emotional disturbances is possible (2). A detailed handbook of HD treatment options was prepared by Rosenblatt and colleagues (6).

Treatment of Movement Abnormalities

Chorea may be a disabling symptom, leading to bruises, fractures, or falls and impairing the ability of patients to

feed themselves. Other patients find the chorea of major cosmetic concern. Treatment with high-potency neuroleptics, such as haloperidol and fluphenazine, may be indicated in such cases, but with important caveats. These medicines may exacerbate the disturbance of voluntary movement, which, as noted earlier, correlates best with functional disability. Furthermore, neuroleptics increase morbidity by making patients more rigid, sedated, and apathetic.

If pharmacologic treatment for chorea is initiated, starting doses of neuroleptics should be low, for example, 0.5 to 1 mg of haloperidol or fluphenazine per day. Doses higher than 10 mg per day of haloperidol yield little or no benefit over lower doses. If patients experience unacceptable rigidity, akathisia or dystonic reactions to high-potency neuroleptics, lower-potency agents such as thioridazine may be better tolerated. However, use of lower-potency neuroleptics increases the risk of sedation, anticholinergic side effects, and postural hypotension.

Dopamine-depleting agents such as reserpine and tetrabenazine represent another option in the treatment of chorea. Reserpine is a known cause of drug-induced depression, and the affective state of patients receiving this agent should be monitored carefully. The benzodiazepine clonazepam may also be useful in the treatment of chorea, and it may be of benefit in the later stages of the disease, when neuroleptic medication often has little effect.

Treatment of Cognitive Abnormalities

There is no known effective pharmacologic treatment for the dementia of HD. Cholinergic agents have not been systematically assessed in HD, but the rationale for using these medications is less compelling than in Alzheimer disease, because cholinergic neurons are relatively spared in HD. Patients can be instructed to jot down notes and reminders and to sequence tasks so they can concentrate on one at a time. Complex cognitive tasks should be minimized, and, as the disease progresses, questions should be framed in a choice format with the provision of frequent cues to assist recall.

Treatment of Psychiatric Disorders

Major depression in HD responds to the same treatments used in idiopathic depression. In general, depression in HD is underdiagnosed and undertreated, perhaps because of the propensity of clinicians to see it as an understandable reaction to having the disease. Although no controlled studies exist, our experience is that both tricyclic antidepressants and selective serotonin reuptake inhibitors are effective. As with any neuropsychiatric disorder, patients should be started on low doses that are slowly increased while the patient is closely monitored for adverse effects, particularly delirium. It is important to remain with a medication for a full therapeutic trial at adequate doses and blood levels. Depressed patients should always be questioned about thoughts of suicide. When suicide is a concern, the patient should receive as few pills as possible, especially if they are to be kept in the patient's care.

The addition of antipsychotic (neuroleptic) medication is indicated as an *adjunct* to antidepressant treatment in depressed patients with hallucinations or delusions. Clozapine and other atypical neuroleptics may have the advantage over traditional neuroleptic medications, such as haloperidol, of causing fewer extrapyramidal side effects and therefore not worsening aspects of the voluntary movement disturbance. Electroconvulsive therapy is indicated for depressed patients who are refractory to treatment with medication, for patients with delusions, for those who are not eating or drinking because of their depression, or for those who are at high risk of suicide. For patients with bipolar disorder, carbamazepine, divalproex sodium, or lithium may the initial treatment of choice; again, it is prudent to start with low doses that are gradually increased until symptoms respond, side effects make further dose increases counterproductive, or therapeutic blood levels have been reached.

In treating irritability, it is important to attempt to identify and to minimize precipitants such as hunger, pain, inability to communicate, frustration with failing capabilities, boredom, difficult interpersonal relationships, and minor unexpected changes in routine. Pharmacologic treatment can be very effective. We have had success using selective serotonin reuptake inhibitors (7) and divalproex. Sexual disorders in HD, particularly aggressive hypersexuality, can be treated with antiandrogenic medications. Obsessive-compulsive disorder in HD can be treated with standard antiobsessional agents, such as selective serotonin reuptake inhibitors and clomipramine.

DIFFERENTIAL DIAGNOSIS

Part of "125 - Huntington Disease "

The clinical features of HD are often characteristic, and the diagnosis is not difficult in a patient with a known family history, typical choreiform movements, and cognitive dysfunction. The diagnosis is less clear in patients with uncharacteristic presentations or a lack of family history (1 ,8). For instance, patients may present with very little chorea or with movements that are predominantly athetoid, dystonic, or even ticlike. All the affected members of a pedigree may manifest atypical features of the disorder, such as prominent brainstem involvement, a finding contributing to diagnostic confusion. Occasional patients (particularly with late onset) may have only subtle movement abnormality and relatively little cognitive disorder (1 ,8). Fortunately, with the availability of the HD gene test, it is now possible to establish the diagnosis of HD definitively even in patients with no family history or an atypical presentation. Most patients thought to have HD on clinical examination but who do

not have the triplet repeat expansion appear to have atypical features, more characteristic of spinocerebellar ataxias or other multisystem atrophies.

HD is now recognized as part of a family of related neurodegenerative disorders, all caused by expansions of CAG repeats encoding glutamine (9). The diseases share certain clinical features, especially ataxia and dementia, and can be confused with each other. Among these diseases, Machado–Joseph disease (MIM no. 109150) and dentatorubral pallidoluysian atrophy (MIM no. 125370) are most like HD. Various other diseases may also present with HD-like symptoms, including Wilson disease, Creutzfeldt–Jakob disease, forms of ceroid neuronal lipofuscinoses, chorea with red blood cell acanthocytosis, hereditary nonprogressive chorea, paroxysmal choreoathetosis, mitochondrial disorders, corticobasal degeneration, basal ganglia calcification, forms of hereditary dystonia, Sydenham chorea, vitamin E deficiency, and cerebral vascular disease (10).

GENETIC ETIOLOGY

Part of "125 - Huntington Disease "

Discovery of the HD Mutation

HD was the first disease mapped (to chromosome 4p) using the techniques of linkage analysis with anonymous DNA probes (11). The techniques of linkage analysis were used to demonstrate that HD exhibited almost complete genetic dominance (13) and locus homogeneity (14). Many of the techniques of positional cloning, including marker development, recombination and haplotype analysis, linkage disequilibrium, physical mapping, and exon amplification, were first developed or tested during the search for the HD gene (12).

Using exon amplification and cDNA cloning, the actual gene (IT15 or huntingtin) was identified in 1993 (15). The mutation proved to be an expansion of a CAG repeat, making HD a member of a group of similar triplet repeat disorders (9 , 16 ,17 and 18). The IT15 gene is composed of 67 exons in both mice and humans (19), and in human it is located between markers D4S127 and D4S180 on chromosome 4p16.3. It spans a genomic region of more than 200 kb and is transcribed into two versions of mRNA, varying only in the length of their 3′ untranslated region, The open reading frame encodes a protein of about 350 kd with no significant homology to known proteins (15 ,19).

Genetic Diagnosis

Diagnosis of HD has been greatly simplified by the direct triplet repeat gene test. Previously, genetic diagnosis required cumbersome linkage analysis, impossible if family members were not available or were not heterozygous for the linkage markers. By contrast, the direct gene test, typically a single polymerase chain reaction, enables the length of the repeat in each allele to be measured. The test is highly sensitive and specific, although several variations in the sequence surrounding the repeat can lead to erroneous results (20).

On a population basis, there is a clear distinction between expanded and normal length repeats in huntingtin. Repeats with fewer than 29 triplets are within the normal range. The rare repeats with 29 to 35 triplets are considered of intermediate length, prone to expansion but not in themselves of sufficient length to produce a phenotype. Repeats with 36 or more triplets are considered expansions (21).

Before the discovery of the causative expansion mutation, HD was considered 100% penetrant. However, it is now clear that *penetrance* (currently defined as the presence of signs or symptoms of HD by the age of 65 years) is less than 100% in persons carrying an allele with 36 to 40 triplets. For instance, four of seven persons who were more than 70 years old and who had a 36 triplet allele had no signs or symptoms of HD. One person with a 39 triplet allele died at the age of 95 years with no definite clinical or pathologic evidence of HD (21). Because alleles with 36 to 40 triplets are quite uncommon, the frequency of nonpenetrance is difficult to estimate reliably. However, for repeats of 36 or 37 triplets, it may be on the order of 50%.

The discovery of the HD mutation revolutionized genetic counseling of presymptomatic persons at risk of HD. Between 1983 and 1993, genetic testing was based on linkage analysis, a complex procedure requiring the cooperation of several family members. HD emerged as a model for presymptomatic genetic testing, and most testing has been carried out under careful protocols involving extensive counseling and patient education (22). Most persons, including those testing positive, state that they are relieved to know the results, and this knowledge enables them to face the future with less uncertainty. Not all patients, however, have had unequivocally positive experiences with testing (23). The central difficulty stems from the availability of a presymptomatic test for a disorder with limited therapeutic interventions (at present), a dilemma termed the *Tiresias complex* from Tiresias' words to Oedipus: “It is but sorrow to be wise when wisdom profits not” (23).

Repeat Length Instability and HD Clinical Genetics

Analysis of the triplet repeat has clarified the issue of new mutations in HD. The previous belief, that new HD mutations do not occur, was disproved with the discovery of the HD repeat expansion. The lengths of normal repeats change in fewer than 1% of intergenerational transmissions; when the length does change, it is typically by only one triplet. The frequency of changes in length increases with transmission of longer repeats and becomes appreciable for alleles with repeats of intermediate length (29 to 35 triplets). During paternal transmission, these alleles are more likely to expand then to contract, and the change, unlike in normal repeats, is often of more than one or two triplets. On occasion,

the repeat can expand to a length sufficient to cause clinical HD. Therefore, new HD mutations do occur, arising from alleles in the intermediate range (24 ,25). Factors increasing instability include change of a CAA triplet adjacent to the CAG repeat into a CAG and advanced paternal age.

The nature of the HD mutation now provides a molecular basis for understanding *anticipation,* the phenomenon of increasing disease severity or decreasing age of onset in successive generations (26). Anticipation in HD has long been recognized (Fig. 125.2). In our clinical sample of affected parent-child pairs, there was no significant change in the age of onset in maternal transmission, but a mean advance of 8 years in paternal transmission. In addition, it is now clear that most patients with juvenile-onset HD arise from paternal transmission (19 ,27 ,28). Two features of the molecular genetics of HD explain the phenomenon of anticipation (29 ,30). First, the age of HD onset is inversely correlated with repeat length, a quite striking phenomenon (Fig. 125.3). Second, the length of the expanded triplet repeat is unstable in vertical transmission (Fig. 125.4). Paternal alleles more frequently expand then contract during transmission, whereas maternal alleles have an equal probability of expanding and contracting. Instability increases as repeat length increases (27 ,31). The net result, driven by paternal transmissions, is a skew toward earlier ages of onset in successive generations of a family.

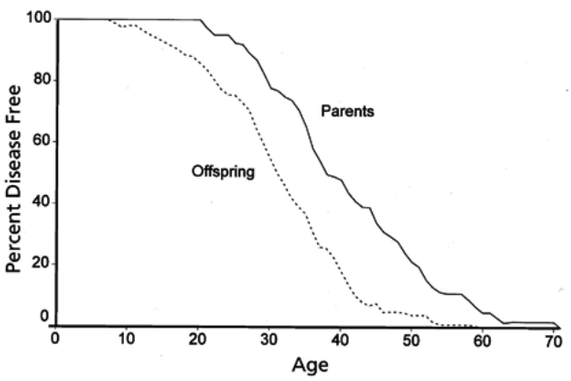

FIGURE 125.2. Anticipation in Huntington disease. The age at which affected parents and their affected children first manifest disease symptoms is depicted as a survival curve. The younger generation is affected at a substantially earlier age. Data from 61 parents and 82 children. (From Margolis RL, McInnis MG, Rosenblatt A, et al. Trinucleotide repeat expansion and neuropsychiatric disease. *Arch Gen Psychiatry* 1999;56:1019–1031, with permission.)

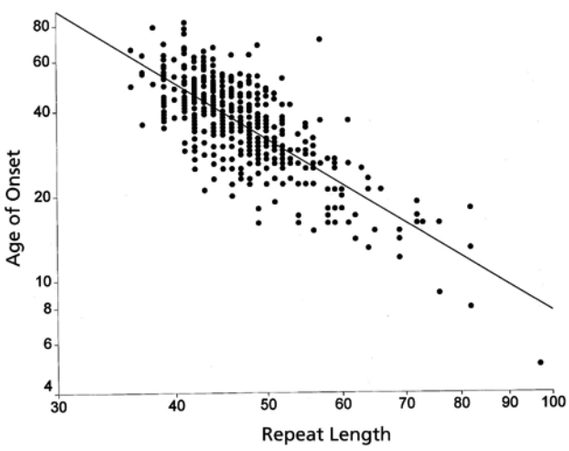

FIGURE 125.3. Correlation of repeat length with age at onset of HD. As repeat length increases, age at onset of disease decreases (n = 480; $r^2 = 0.57$). (From Margolis RL, McInnis MG, Rosenblatt A, et al. Trinucleotide repeat expansion and neuropsychiatric disease. *Arch Gen Psychiatry* 1999;56:1019–1031, with permission.)

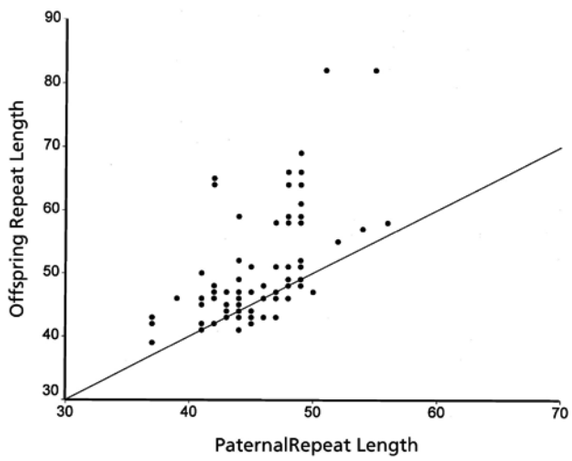

FIGURE 125.4. Increase in repeat length with paternal transmission of the HD disease allele. *Points above the diagonal line* represent cases in which the repeat length increased during transmission from father to child (n = 84 pairs; mean increase of repeat length ±SD = 4.2±0.8 triplets). (From Margolis RL, McInnis MG, Rosenblatt A, et al. Trinucleotide repeat expansion and neuropsychiatric disease. *Arch Gen Psychiatry* 1999;56:1019–1031, with permission.)

The increasing length of the repeat in paternal transmission appears to arise during spermatogenesis (32). In particular, persons with longer expanded repeats (as assayed from DNA obtained from leukocytes) have dramatically variable repeat lengths in individual sperm. The variability in oocytes appears to be less, perhaps because mature spermatocytes have undergone, on average, more cell divisions than mature oocytes. The increased likelihood of transmission of an expanded repeat as paternal age increases is consistent with this observation.

The relationship between the length of the repeat and the *rate* of clinical progression has not been resolved, although this relationship is of considerable importance in determining methods for slowing the course of HD. The rate of disease progression may be more rapid in cases with longer repeats (33), but this is not a universal finding (34). On postmortem examination, pathologic changes in cases with longer triplet repeats were more advanced than in cases with the same duration of illness but shorter repeats, a finding providing support for a correlation between repeat length and rate of progression (35). The related issue whether earlier age of onset correlates with more rapid disease progression has also not been resolved. There is no apparent correlation between repeat length and the presence of psychiatric symptoms.

PATHOLOGY

Part of "125 - Huntington Disease "

The only known pathologic changes of HD are specific to the brain, and they are characterized by striking regional selectivity of atrophy and neuronal loss (18). The most prominent atrophy is found in the caudate nucleus and putamen, which together comprise the corpus striatum within the basal ganglia. Striatal atrophy leads to hydrocephalus *ex vacuo* and marked dilatation of the lateral ventricles. In addition, there is overall atrophy of the brain. Total brain weight is reduced by 25% to 30% in advanced cases, a finding reflecting atrophy of the cerebral cortex and underlying white matter in addition to the basal ganglia.

Within the striatum, there is selective neuronal vulnerability both in the anatomic pattern of regions affected and in the particular neurons lost. Loss of neurons in the caudate and putamen shows a gradient, with early and most severe loss in the dorsal and medial regions and progressive loss of neurons in ventral and lateral regions as the disease progresses (36). There is severe loss of medium spiny projection neurons, especially those synthesizing enkephalin and γ-aminobutyric acid, but relative preservation of large and medium aspiny interneurons (37 ,38). Neuronal loss is accompanied by reactive astrocytosis (gliosis). Other areas of the basal ganglia, especially the globus pallidus and subthalamic nucleus, also become atrophic, although less than the striatum. A 0 to 4 rating scale of gross and microscopic neurodegeneration, based primarily on changes in the caudate and putamen, has been used semiquantitatively to grade the severity of HD (39). Patients with more severe neurodegeneration have greater clinical impairment before they die, and, as more recently observed, they tend to have longer expanded repeats (35 ,40).

Quantitative studies of cell number and morphology have demonstrated shrinkage and loss of neurons in the cerebral cortex (41), consistent with previous evidence from gross pathology and neuroimaging studies. Large cortical neurons appear to be most severely affected, and there is laminar specificity, with greatest loss in layer VI and significant loss in layers III and V. The neurons lost in the greatest numbers appear to project to the thalamus, whereas most neurons that project to the caudate and putamen lie in more superficial regions of layer V. In addition, the extent of cortical degeneration does not closely correlate to the severity of striatal degeneration. This set of observations indicates that the loss of neurons in the cortex does not arise simply from retrograde changes beginning in the striatum.

Whereas the atrophy and neuronal cell loss of HD have been extensively studied, less attention has focused on the morphology of the surviving neurons. Contrary to expectations, application of the Golgi metal impregnation method to study neuronal morphology in the caudate and cortex from HD cases revealed evidence, in the surviving neurons, of “regenerative” or “plastic” changes (42 ,43). Relative to neurons in these regions from normal brains, surviving neurons in HD cases had more dendrites, more long recurved dendrites, greater density and larger size of dendritic spines, and greater somatic area. A complete understanding of the pathogenesis of HD will need to encompass an explanation of these regenerative changes as well as neuronal death and brain atrophy.

Many of the clinical symptoms of HD correlate to pathologic features in the basal ganglia and cerebral cortex. The motor changes are believed to stem from interruption of a set of neuronal circuits interconnecting the cerebral cortex, the basal ganglia, and the thalamus. The involuntary and voluntary movement abnormalities in HD may arise from early degeneration of specific populations of medium spiny neurons. Changes in the basal ganglia also likely underlie the early and relatively mild “subcortical” cognitive changes seen in HD. The more severe global dementia seen late in the illness may relate to the widespread loss of neurons in the cerebral cortex, which does not appear to occur until relatively late in the disease.

Although it is relatively straightforward to correlate clinical symptoms with atrophy or neuronal cell loss, it is more difficult to determine the role of functional changes in neurons in the production of symptoms. In most cases, symptomatic HD is reflected in neuronal loss at autopsy. However, occasional cases arise of patients with clinically diagnosed HD but no discernible cell loss. These have been termed “grade zero” in the Vonsattel severity scale (39 ,44): there is no appreciable gliosis or neuronal loss. Therefore, it is possible that symptoms in these patients arise more from functional changes than from actual neuronal loss.

Degeneration is also observed, although less consistently and less prominently, in other regions of the brain, including the brainstem, the cerebellum, the lateral tuberal nucleus of the hypothalamus, the amygdala, and portions of the thalamus. The relationship between these changes and clinical features is not clear.

Studies of human postmortem HD brain tissue using antibodies directed at the N-terminus of huntingtin have

revealed small intranuclear inclusion bodies present in neurons but not in glia (45 ,46). Although they are present in other brain regions, inclusions are most abundant in the cortex and the caudate, and in those cell types (medium spiny neurons of the striatum) and cell layers (III, V, and VI of the cortex) most severely affected in HD. The density of inclusions is significantly correlated with the length of the CAG repeat in IT15 (47). Inclusions were not present in the brain of one presymptomatic person with the HD mutations.

The inclusions cannot be detected by antibodies directed at internal epitopes of huntingtin, a finding suggesting that huntingtin within the inclusions is abnormal, most likely truncated but possibly misfolded such that internal epitopes are sequestered. The inclusions can, however, be detected with antibodies to ubiquitin, a tag for proteins undergoing proteolytic degradation. This could mean that huntingtin within inclusions has been targeted for degradation but cannot be removed by proteolysis. Ultrastructural analysis of the inclusions indicates that they are composed of a mixture of granules, straight and tortuous filaments, and masses of parallel and randomly oriented fibrils, not enclosed by an intracellular membrane. Similar inclusions have been detected in transgenic mouse models of HD (48).

In addition, huntingtin has been found in aggregates in dystrophic neurites in HD-affected brains (45). These were present predominantly in cortical layers V and VI and appeared to be contained within neurofilament labeled axonal processes. Such dystrophic neurites may reflect dysfunction of retrograde axonal transport.

PATHOGENESIS

Part of "125 - Huntington Disease "

Certain lines of evidence indicate that the major pathogenic mechanisms of HD involve a toxic gain of function by the mutant protein; in other words, the abnormal length of the polyglutamine repeat gives huntingtin a toxic property not found in the wild-type protein. First, HD, like all the other polyglutamine repeat disorders, has a dominant mode of inheritance, which is typically the result of gain-of-function mutations. Second, the age of onset for homozygotes for the HD mutation generally is not markedly less than the age of onset for cases with only one copy of comparable repeat length (13), although this is not necessarily the case in the other glutamine repeat diseases. Third, no cases of HD or related polyglutamine disorders have been identified with deletions or point mutations in any of the causative genes. In contrast, the fragile X phenotype can be caused by a triplet repeat expansion leading to impaired transcription, a deletion, or a point mutation; all three types of mutations result in loss of normal protein function (49). Finally, mice with targeted deletions of the HD gene resulting in expression that is a small fraction of normal demonstrate developmental abnormalities rather than a progressive neurologic disorder (50).

Neurotoxicity Models

Before the discovery of the genetic etiology of HD, animal models of HD had been generated using neurotoxins. Injections of *N*-methyl-D-aspartate–receptor agonists, such as quinolinic acid, into the striatum induce HD-like disease, with loss of medium spiny projection neurons and sparing of cholinergic and reduced nicotinamide-adenine dinucleotide phosphate diaphorase neurons (51). Peripheral injections into rodents or primates of several mitochondrial toxins, including 3-nitropropionic acid, also reproduce aspects of striatal disease found in HD (52). Other metabolic poisons cause preferential toxicity in different regions of the brain, often those regions affected in other glutamine repeat diseases.

These neurotoxin experiments suggest several pathways that could be involved in HD cell death (53). For instance, both excitotoxicity and metabolic poisoning may be mediated, in part, by damage from free radicals (54). In addition, neurotoxic stimuli can give rise to *apoptosis*, a controlled form of cell death under control of cellular machinery that plays an essential role in normal development. The process is triggered by a group of aspartate proteases termed caspases, and glyceraldehyde phosphate dehydrogenase (GAPDH) and other metabolic enzymes may also serve as initiating factors (55 ,56).

Studies of subjects with HD have yielded results consistent with some of these neurotoxicologic mechanisms. For instance, nuclear magnetic resonance spectroscopy suggests the presence of metabolic compromise within neurons (57). Marked biochemical defects of mitochondrial complex II and complex III activity, and moderate defects of complex IV activity, have been detected in mitochondria isolated from the brain tissue of individuals with HD. Evidence of free radical activation is also present in HD postmortem tissue (58 ,59).

Huntingtin Biochemistry

The *huntingtin* protein is widely expressed in both the brain and peripheral tissues (60 ,61). The CAG repeat, even when expanded, is translated into polyglutamine (62). Immunocytochemical and subcellular fractionation studies indicate that huntingtin is present in neuronal perikarya, dendrites, and terminals, with a generally cytoplasmic localization. Huntingtin has not been consistently detected in the nucleus. The protein appears to associate with cytoskeletal elements and intracellular vesicles, with enrichment in endosomal compartments and Golgi complex membranes (63), and it is detected at all stages of embryonic and postnatal brain development. Within the striatum, huntingtin may be enriched in the medium spiny neurons, the neuronal

population most severely affected in HD; expression level may therefore contribute to the selective vulnerability of the medium spiny neurons.

To provide clues about the normal function of huntingtin and about HD pathogenesis, an intensive effort has been devoted to finding proteins that interact with huntingtin. Interactors of particular interest include HIP1, HAP1, GAPDH, and SH3GL3 (64). Some of these proteins are directly or indirectly associated with microtubule motor proteins and intracellular vesicles, findings suggesting a role for huntingtin in cytoskeletal function or vesicular transport. The interaction of huntingtin and other proteins containing glutamine repeats with the metabolic enzyme GAPDH is of potential significance, given the possible role of GAPDH in apoptosis (65). Huntingtin also interacts with the nuclear co-repressor protein, and the strength of the interaction correlates to the length of the huntingtin glutamine repeat (66). This interaction suggests that huntingtin may have some role in transcriptional regulation, although relatively little huntingtin is detected in the nucleus of normal cells under most conditions.

Polyglutamine Biochemistry

Many proteins contain stretches of polyglutamine, and such tracts are more common than repeats of other amino acids (67). However, the normal function of glutamine repeats remains unknown. Proteins containing glutamine repeats often appear to have a role in the regulation of development and neurogenesis, and certain proteins with glutamine repeats are transcription factors (68). Glutamine-rich regions may function as factor interaction domains in transcription factors, but it is unclear whether glutamine repeats serve this or more specialized functions. The lengths of glutamine repeats tend to vary considerably in homologous genes from different species; mouse huntingtin has only seven consecutive glutamines, and the puffer fish homologue has only four.

One hypothesis for the role of glutamine repeats in human disease is based on the “polar zipper” model proposed by Perutz (69). He suggested that two antiparallel ß strands of polyglutamine can be linked together by hydrogen bonds between their main chain and side chain amides, to form ß sheets and potentially to lead to protein aggregation and precipitation. Circular dichroism, electron microscopic and x-ray defraction studies of synthetic peptides, and an engineered protein provide *in vitro* evidence supporting the formation of ß strands and possibly ß sheets by glutamine repeats. Alternatively, it has been suggested that the covalent modification of glutamines by an isopeptide linkage to lysine by the enzyme transglutaminase could also lead to an insoluble precipitate of proteins containing long stretches of glutamine (70).

In support of the polar zipper hypothesis, an *in vitro* filter assay was used to demonstrate that a short truncation (exon 1 only) of the huntingtin protein with an expanded glutamine repeat can aggregate to form amyloid-like fibrils (71 ,72). These fibrils showed green birefringence when they were stained with Congo red and viewed by polarized light microscopy, consistent with the presence of ß sheets. Aggregation did not occur when the polyglutamine repeat was of normal length. In addition, aggregation only occurred when a huntingtin fragment with an expansion of typical length was first cleaved from the carrier protein to which it was fused during synthesis for the assay. The implication, consistent with cell and mouse models described later, is that generation of a proteolytic fragment of HD may be an important step in HD pathogenesis. In fact, consensus cleavage sites for caspase-3 (also termed apopain or CPP32) exist at approximately position 513 and 530 of huntingtin, and huntingtin can be cleaved by purified caspase-3, caspase-6, and caspase-8.

Cell Models

Research into the pathogenesis of HD has been greatly facilitated by the development of cell models. Two approaches have been used. In the first, huntingtin is introduced into cells through transient transfection; in the other, cell lines are engineered that stably express huntingtin (77 ,78 ,79 and 80). In general, short truncations of huntingtin containing the expanded polyglutamine appear to be much more toxic than full-length huntingtin and more liable to aggregation (81 ,82 and 83). However, aggregate formation and cellular toxicity can be disassociated, a finding suggesting that cell toxicity is not related in a simple way to aggregation (79 ,84 ,85). Elimination of caspase cleavages sites may reduce the toxicity of mutant huntingtin (9 ,73 ,74 ,75 and 76). Cell death does not correspond to all characteristics of apoptosis, but it can be decreased or blocked in several models with caspase inhibitors (79 ,84).

A role of nuclear localization for huntingtin toxicity has been suggested, but it is still not proved. Transfection of primary neurons with constructs incorporating a nuclear export signal diminished toxicity, whereas the addition of nuclear localization signals appeared to enhance toxicity (77 ,79) However, other studies suggested that both the nucleus and the cytoplasm can be the site of pathogenesis (86).

Transgenic Mouse Models

Transgenic animal models have provided some of the most striking evidence for the *gain-of-function hypothesis* of HD pathogenesis. The first animal model of HD was constructed using exon 1 of huntingtin with a very long expanded repeat (87). These animals developed progressive neurologic deficits strikingly similar to those of HD, including incoordination, abnormal involuntary movements, seizures, and weight loss (88 ,89). However, unlike patients with HD, neuronal cell loss is not prominent. These mice

also developed intranuclear inclusions containing the truncated huntingtin transgene product, but not the endogenous huntingtin protein (48). The intranuclear inclusions are present at the time, and perhaps before, the animals have neurologic signs or brain or body weight loss. The intranuclear inclusions are clearly distinct from the nucleolus, and no membrane separates them from the rest of the nucleus.

Several other HD mouse models have been constructed. A truncated N-terminal fragment of huntingtin driven by the prion protein promoter resulted in mice with features very similar to the initial model (90): the mice develop progressive hypoactivity, incoordination, and weight loss, and on neuropathologic examination they have both intranuclear inclusions and neuritic aggregates. A transgene consisting of a full-length huntingtin cDNA driven by the CMV promoter resulted in a line of mice with a rather different phenotype, characterized by early weight gain and hyperactivity followed later by hypoactivity. These mice have both intranuclear inclusions and some loss of neurons (91).

Perhaps the most promising mouse model of HD involves the use of YAC constructs, so the transgene consists of the entire human HD gene, including the human HD promotor and all introns, with an expanded repeat. These mice develop neurologic signs, electrophysiologic abnormalities, and a shortened life span (92). A single founder with a long repeat had striking evidence of selective striatal neurodegeneration and nuclear localization of N-terminal epitopes of huntingtin in striatal neurons. If additional lines can be generated, this model may be the closest to the human disease of any model yet generated.

Another model of potential utility was generated by inserting an expansion of polyglutamine into the mouse huntingtin gene, thus avoiding the confounding factor of the presence of the human transgene. So far, these mice have not developed neurologic signs, and no neuronal loss has been detected (93). There is evidence of translocation of huntingtin into the nucleus in striatal neurons. Thus, these mice may model early aspects of HD pathogenesis and could provide a useful model for studying the early features of the disease.

The construction of an inducible mouse model of HD has yielded insight into HD pathogenesis (94). A transgene containing exon 1 of huntingtin with an expanded glutamine repeat under the control of the tet-off system was inserted so that the timing of transgene expression could be externally controlled by the presence or absence of an antibiotic in the animals' food. With the transgene on, mice developed neurologic signs and neuropathologic changes including nuclear inclusions. Remarkably, when the expression of huntingtin was turned off, these abnormalities partially reversed. This surprising result suggests that the brain may have more restorative and plastic ability than previously appreciated, and that if the pathologic changes of HD could be halted, substantial repair would perhaps be possible.

Invertebrate Models

Invertebrate models offer the potential of using powerful genetic techniques to search for genetic factors that enhance or suppress an experimentally induced phenotype. Several *Drosophila* models of polyglutamine-induced neurodegeneration have been generated (95 ,96 and 97), with many of the same features of neuronal degeneration observed in mammalian cell models and mouse models. Genetics screens have been used to demonstrate that molecular chaperones such as HDJ1 and HSP70 can suppress the phenotype (97 ,98). *Caenorhabditis elegans* models may also prove to be of similar value (99 ,100).

A MODEL OF POLYGLUTAMINE PATHOGENESIS

Part of "125 - Huntington Disease "

A model for HD pathogenesis is depicted in Figure 125.5 . Several of the steps are speculative, and, as has been evident in this summary, the data supporting the model are at times conflicting. Here we highlight areas of uncertainty:

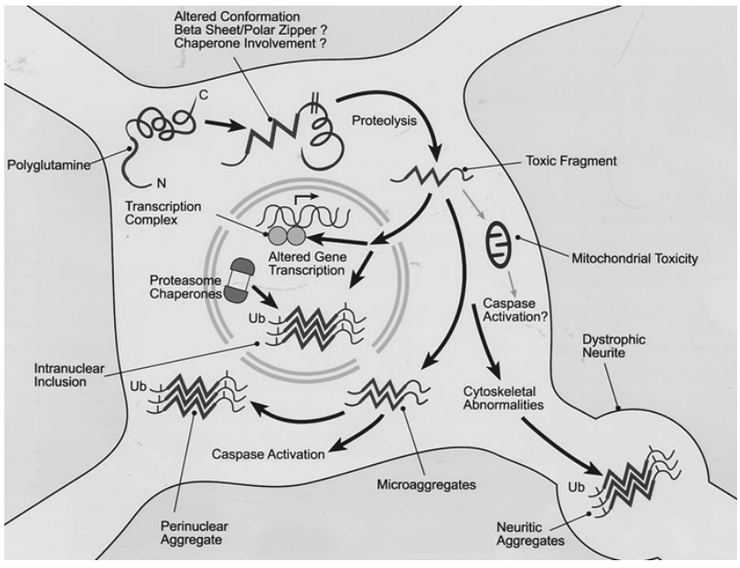

FIGURE 125.5. A model of HD pathogenesis. We propose that HD pathogenesis begins with altered conformation of the protein containing the expanded polyglutamine repeat. Proteolysis generates a fragment that leads to toxicity through several pathways. Nuclear importation may lead to altered gene transcription with a detrimental effect on cell survival. Inclusions also form in the nucleus but may not be a major cause of cell death. Huntingtin fragments may interfere with mitochondrial energy metabolism, either directly, or more likely indirectly, perhaps by altered gene transcription. Microaggregation of the fragment may lead to caspase activation and the consequent initiation of cell death pathways. Fragments may be transported into neurites, interfering with cytoskeletal function. Toxicity may also be mediated by the full-length huntingtin protein with the expanded repeat. As discussed in the text, many of the steps remain speculative.

Evidence for pathogenetically significant proteolytic cleavage of huntingtin remains indirect. The finding that nuclear inclusions can be labeled for N-terminal epitopes, but not for internal or C-terminal epitopes, is consistent with proteolytic cleavage, but it could also result from masking of epitopes. In addition, details of the cleavage, including whether it is processive or endoproteolytic and where in the cell it may occur, are uncertain. The figure shows cleavage taking place in the cytoplasm, but this is speculative.

Another uncertainty is the role of aggregation. It seems likely that the mutant protein adopts an abnormal confirmation and that this is a necessary step in pathogenesis. However, the large inclusion bodies visible by light microscopy may represent a downstream event, an epiphenomenon, or even a protective reaction, and therefore they may not be directly tied to pathogenesis. Our hypothesis is that mutant huntingtin adopts an abnormal confirmation, leading to abnormal interaction with other proteins, including the sequestration of proteins that contain polyglutamine repeats. An example of such protein is CREB binding protein, an important transcriptional regulator; sequestration of this and similar proteins could have marked effects on neuronal function and survival.

The relative importance of nuclear and cytoplasmic events also remains unclear. In our model, the location of huntingtin in the nucleus leads to altered gene transcription. However, huntingtin could act also within the cytoplasm to interfere with proteins that could otherwise be imported into the nucleus. Furthermore, huntingtin may interact with cytoplasmic molecules, including microtubules or microtubule motors, caspase adaptors, and other proteins, to yield toxicity.

THERAPY

Part of "125 - Huntington Disease "

Recent biochemical, cell, and animal studies are beginning to suggest approaches for development of rational therapeutics (Fig. 125.6). As described earlier, current therapeutics for HD are limited to symptomatic treatments, so any intervention that can stop or slow disease progression would be a major advance.

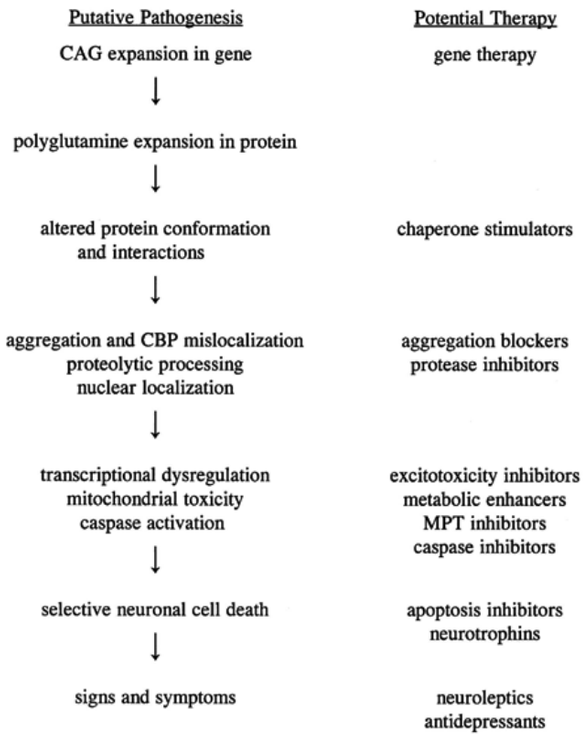

FIGURE 125.6. Approaches to Huntington disease (HD) therapy. The pathogenetic model outlined in Fig. 125.5 suggests certain strategies for slowing, stopping, or even preventing the manifestations of HD.

The first generation of agents designed to slow the progression or delay the onset of HD has emerged from neurotoxicologic models of HD. As of this writing, a major multicenter trial is under way, termed the CARE-HD Study (Coenzyme Q and Remacemide Evaluation in Huntington's Disease). Coenzyme Q is a mitochondrial cofactor, and remacemide is a glutamate-receptor antagonist, and both drugs have efficacy in neurotoxicologic mouse models. The CARE-HD Study is the first multicenter HD drug trial and involves 340 patients treated for 30 months under the sponsorship of the Huntington Study Group. Neurotoxicologic models have also led to smaller trials of other agents, including vitamin E, idebenone, and lamotrigine. None of these agents has demonstrated any clear efficacy (101 ,102 ,103 ,104 and 105).

Another approach to HD therapeutics involves transplantation either of fetal striatal cells or of cells secreting growth factors. These methods have met with at best limited success so far, but they may have promise for the future. Stem cells, if such cells can be differentiated into striatal neurons in a controlled fashion, may have great potential as therapeutic agents.

A screen for therapeutic agents that may alter polyglutamine aggregation is currently in progress using the filter assay developed by Wanker and colleagues. Early results indicate that Congo red and related dyes that intercalate into ß sheets (106) and members of the heat shock protein–chaperone family (16) can reduce aggregation. The effect of these agents in animal or cell models of HD is unknown, and even if effective, it is unclear whether these agents would themselves be good candidates for therapeutic compounds. Nonetheless, these results are very encouraging. New compounds may emerge based on those already shown to be effective *in vitro*, or entirely new classes of effective agents may be discovered with further screening.

Mouse models are also in use to screen for therapeutic compounds. Based on work in cells, the role of caspase inhibitors on disease progression has been investigated. Caspase inhibition led to a modest but significant beneficial effect in the exon 1 HD transgenic mouse model (107). A genetic cross of these transgenic mice with a line of mice overexpressing a caspase 1 dominant negative construct (and hence deficient in caspase-1 activity) also suggested that caspase inhibition can slow disease progress. Creatine, chosen based on its effect in neurotoxicologic models of neuronal cell death, also has a significant effect on disease progression in the exon 1 HD transgenic mouse (108). Minocycline, which has shown some efficacy in ischemic models, also has a beneficial effect on this mouse line (109). The magnitude of the effect on disease progression observed in these studies is significant but modest. A similar effect can be induced by altering the environment in which the mice are raised (110). It is possible that a combination of several of these agents may have enhanced effectiveness. Moreover, most of the agents tested so far have been targeted at relatively downstream points in the presumed pathogenetic pathway; agents that are targeted at earlier steps in the pathogenetic pathway may be more effective. As understanding of the pathogenesis of HD advances, the development of therapeutics should follow soon thereafter.

ACKNOWLEDGMENTS

Clinical Course and Cellular Pathology of Tardive Dyskinesia

Carol A. Tamminga

Margaret G. Woerner

Carol A. Tamminga: Maryland Psychiatric Research Center, University of Maryland School of Medicine, Baltimore, Maryland.

Margaret G. Woerner: Department of Psychiatry Research, Hillside Hospital, Long Island Jewish Health System, Glen Oaks, New York.

Tardive dyskinesia (TD) is an iatrogenic human hyperkinetic movement disorder associated with chronic antipsychotic drug treatment. The cause of the syndrome, namely, chronic dopamine-receptor blockade, is specifically known and is straightforward to model. Thus, disease pathophysiology has been approached with surrogate preparations. Traditionally, factors mediating TD have been sought in striatal dopaminergic transmission. However, several incompatibilities have developed between the characteristics of the dopaminergic model and the presentation of the disorder (10). γ-aminobutyric acid (GABA)–ergic transmission within the basal ganglia has also been targeted as the putative pathophysiologic agent in TD. Here, although biochemical characteristics between the model and the disease have appeared compatible, therapeutic implications have not been fully met, possibly because of inadequate pharmacologic tools (10).

Research has suggested that both these transmitter alterations, dopaminergic and GABAergic, may reflect an action of antipsychotic drugs on neuronal activity within the basal ganglia thalamocortical motor circuit. Clinically, antipsychotic drug action overall tends to normalize mental status in psychosis and produces symptom remission in diverse psychotic illnesses, including schizophrenia, bipolar disease, and dementia (8); parkinsonism characteristically occurs with traditional antipsychotics as a major side effect (42). On a cellular basis, gradual alterations produced by these drugs over time, within selected subcortical brain regions and at selected synapses of this circuit, likely result in TD. The mechanism of all these clinical actions is thought to begin with dopamine-receptor blockade, but thereafter it is critically mediated by altered neuronal activity (including GABAergic) in gray matter regions in the segregated, parallel frontal-subcortical modulatory motor circuits (35).

CLINICAL FEATURES AND COURSE OF TARDIVE DYSKINESIA

Part of "126 - Clinical Course and Cellular Pathology of Tardive Dyskinesia "

The presentation of TD is typical of a dyskinesia, with orofacial, axial, and extremity hyperkinetic movements. The movements worsen with stress and concomitant physical activity and diminish or disappear during sleep. TD onset is defining, in that all dyskinesias with their first onset within 6 months of ongoing antipsychotic treatment are diagnosed as TD (50). Consequently, it is expected that the diagnosis will be confounded by other categories of dyskinesia, including dyskinesias of schizophrenia and of the elderly. TD is distinguished from parkinsonism, the other major category of antipsychotic-induced movements, by being hyperkinetic, with delayed onset and delayed resolution after medication discontinuation, and by its contrasting pharmacology.

Movements in TD are typically suppressed by antipsychotic drugs, and they are suppressed or even show remission with potent GABA agonists; dopamine agonists exacerbate the movements, as can anticholinergic drugs (11). Although TD has a characteristic pharmacology, none of the drugs that suppress movements in probe studies are potent enough to be used as a treatment (36). Treatment approaches for TD are discussed later.

Although TD risk is inevitable with the traditional antipsychotics, the risk appears to have dropped significantly with the second-generation antipsychotic drugs, including clozapine, olanzapine, and risperidone, with which reduced risk has been demonstrated (38 ,63 ,66), and with quetiapine, with which reduced risk is probable. Therefore, even though TD may be diminishing as a significant clinical risk with modern antipsychotic treatment, its study has enabled

identification of cellular and circuit determinants of dyskinesias in mammalian brain.

The clinical course of TD varies by psychiatric diagnosis, age, sex, and concomitant medical or neurologic illness. Data from a prospective study of 971 young adult psychiatric patients followed for up to 20 years indicated a increasing cumulative incidence rate of TD over the 20-year interval (Table 126.1). The cumulative incidence of persistent TD was lower but increased proportionally (40). These data are consistent with a declining rate of TD over time, illustrated by the declining hazard rate (Table 126.1). A similar pattern develops in the hazard rates over 20 years for persistent TD. A decline in hazard rate over time was also reported by Morganstern and Glazer (46), although their data show a sharper decline after the first 5 years.

Neuroleptic Exposure (y)	Tardive Dyskinesia Cumulative Incidence, (95% CI)	Persistent Tardive Dyskinesia, (85% CI) Cumulative Incidence	Tardive Dyskinesia Hazard Rate[a]
1	.05 (.04–.07)	.03 (.02–.04)	—
5	.27 (.23–.31)	.20 (.17–.23)	6.1%
10	.43 (.38–.47)	.34 (.30–.39)	4.7%
15	.52 (.46–.57)	.42 (.36–.47)	3.3%
20	.56 (.50–.63)	.49 (.41–.57)	2.1%

[a]Hazard Rate is the rate of tardive dyskinesia occurrence per year among those remaining at risk. The number represents the average yearly hazard rate over the 5-year block of time.

TABLE 126.1. CUMULATIVE INCIDENCE OF TARDIVE DYSKINESIA

Rates of TD are significantly affected by the age and other characteristics of the several samples studied. An increased vulnerability to TD associated with increasing age is the most consistently reported finding in TD research. A prospective study of 261 geriatric patients with a mean age of 77 years revealed cumulative rates of 25%, 34%, and 53% after, 1, 2, and 3 years of antipsychotic drug treatment (74). Similar findings were reported by Jeste et al. (37) and by Yassa et al. (75). In the younger adult sample (40), the hazard rate for TD was lowest for patients in their twenties and thirties at study entry, increased for those in their forties, and sharply increased for those aged 50 to 60 years.

Other variables associated with a significantly increased TD risk in the prospective study (Table 126.1) included the presence of extrapyramidal symptoms during antipsychotic treatment, diagnosis of unipolar depression, the number of peaks in dosage of antipsychotic drug (more than 1,000 mg in chlorpromazine equivalents), and intermittent antipsychotic treatment. Treatment with lithium is associated with a lower risk of TD development.

In this prospective study of 971 psychiatric patients (Table 126.1), the initial episode of TD was persistent for at least 3 months for half of the cases. Of these persistent cases, 68% remitted within the next 2 years. For the half whose initial episode was transient, there was a high risk (32%) of developing a persistent episode within 1 year of additional antipsychotic exposure. Regardless of the duration of the initial TD episode, if it remitted, there was a high likelihood (61%) of developing a second episode within 1 year.

Preliminary data suggest that prognosis for TD remission is better for patients who are treated for shorter times within the follow-up period after TD diagnosis and for those treated with lower doses of antipsychotic during follow-up (41). These facts about TD encourage future study in animals and humans on TD mechanisms and treatment and facilitate the research by providing a firm baseline and a clear description of course.

FUNCTIONAL HUMAN NEUROANATOMY OF ANTIPSYCHOTIC DRUG ACTION

Part of "126 - Clinical Course and Cellular Pathology of Tardive Dyskinesia "

The human central nervous system (CNS) has been the focus of studies to determine the mechanism of antipsychotic drug action with both acute and chronic antipsychotic drug administration. These antipsychotic data are relevant to TD mechanisms insofar as the localization of the neural pathways subserving antipsychotic drug action can suggest the regions that likely contain the neurochemical disorder underlying TD. The firm association between striatal dopamine-receptor blockade and antipsychotic drug action was established early and has been consistently confirmed in subsequent study (4 ,7 ,53). It has been suggested that antipsychotic drugs deliver their full antipsychotic action by blocking the D2 dopamine receptors in limbic cortex (25 ,54). Alternatively, as argued here, antidopaminergic drugs could deliver their antipsychotic action by altering activity in neuronal populations within the long-loop feedback neurons in the basal ganglia thalamocortical pathways, at least in part, thereby modulating neocortical activity indirectly. The mechanisms responsible for TD may well occur at sites within these modulatory pathways.

Early investigators observed an elevation of neuronal activity in the human caudate and putamen with antipsychotic drug treatment using functional *in vivo* imaging (33 ,69). To refine the localization of the signal, our laboratory

conducted a within-subject crossover study comparing haloperidol (0.3 mg/kg/day for 4 weeks) to placebo (0 mg/kg/day for 4 weeks), with a positron emission tomography scan using [^{18}F]fluorodeoxyglucose carried out at the end of each treatment period (35). Regional cerebral metabolic rates of glucose, calculated using the usual analytic techniques, were used for pixel-by-pixel regional comparisons. Haloperidol significantly activated neuronal activity in the basal ganglia (caudate and putamen) and thalamus, whereas the frontal cortex (especially the middle and inferior regions) and the anterior cingulate cortex demonstrated a reduction in regional cerebral metabolic rates of glucose with haloperidol (Fig. 126.1). Activational differences between the on-drug and off-drug conditions were surprisingly restricted to these areas, despite the systemic manner of drug delivery and steady-state kinetic conditions at testing. The striatal changes had been previously reported (6 ,68). Subsequent evaluation of haloperidol action using regional cerebral blood flow analysis pharmacodynamically verified these regional actions.

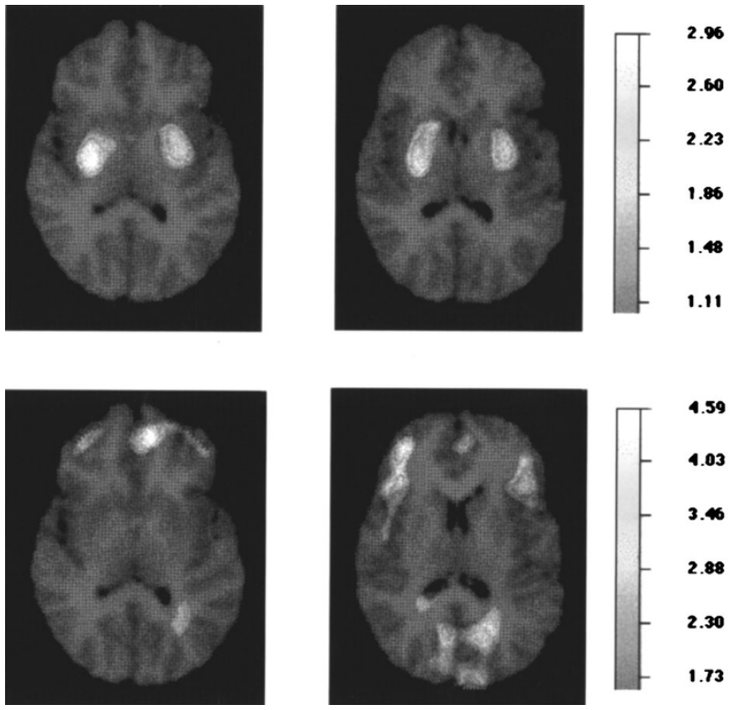

FIGURE 126.1. The regions of color indicate quantitatively the areas of regional cerebral blood flow (rCBF) activation (ON-30 day OFF) or inhibition (30 day OFF-ON) with subchronic haloperidol treatment (0.3 mg/kg/day). In the **top two figures**, at -04 and 00 mm from the anterior commisure/posterior commissure line (ACPC) plane, the basal ganglia show significant rCBF activation with haloperidol. In the **bottom two figures**, at -04 and +04 mm from the ACPC plane, both the anterior cingulate cortex and the middle frontal cortex show significant diminished rCBF with haloperidol. See color version of figure.

The regions identified in the foregoing experiment, whose activity is perturbed by haloperidol, are the same ones already known to be connected within the basal ganglia thalamocortical pathway (15) and involved in modulation of motor and cognitive function (2). In an animal preparation, Abercrombie and DeBoer demonstrated the principle that a pharmacologic perturbation delivered to a restricted region in the basal ganglia (e.g., striatum) can exert distant neurochemical and functional effects (1). The model of antipsychotic drug action we propose suggests that a primary effect of dopamine-receptor blockade occurs in the caudate and putamen with antipsychotic drug treatment, and the transmission of this primary action through the basal ganglia thalamocortical pathway to limbic and neocortex mediates antipsychotic and motor aspect of the drug actions in humans. The full mechanism of antidopaminergic actions therefore could include altered GABAergic transmission in the globus pallidus (GP), which alters activity in the basal ganglia output nuclei; these changes then modify GABAergic transmission from substantia nigra pars reticulata (SNR) to the thalamus, inhibit thalamic nuclei, and reduce the overall excitatory glutamatergic signal to the cortex. These observations suggest the hypothesis that the same basal ganglia thalamocortical circuits that mediate

basal ganglia modulatory influence on prefrontal cortex may also mediate the therapeutic effect of antidopaminergic antipsychotic compounds in schizophrenia. We have reasoned that a drug-induced regional change, occurring over time within this basal ganglia–thalamocortical pathway, associated with a regional increase in the thalamocortical signal could be associated with TD.

ROLE OF THE BASAL GANGLIA THALAMOCORTICAL PATHWAY IN MEDIATING AND TRANSMITTING THE ANTIDOPAMINERGIC ACTION IN STRIATUM TO CORTEX

Part of "126 - Clinical Course and Cellular Pathology of Tardive Dyskinesia "

Basal ganglia and thalamic structures modulate functions of the frontal cortex through parallel segregated circuits, a process that has been most fully studied for motor function. This topic is directly addressed in Chapter 122 . For the CNS motor system, specific areas of primary motor cortex, primary sensory cortex, and supplementary motor cortex project topographically to the putamen. These projections are thought to remain segregated but parallel throughout the full course of the circuit, but they are subject to basal ganglia and thalamic influences within each region. Investigators have proposed a family of these frontal circuits whose pathways originate in specific frontal cortex areas, course through the basal ganglia and thalamus, and return to the same areas of cortex, to modulate regional frontal cortical function (3). For the motor system, these subcortical structures appear to contribute to the planning and execution of body movements; for other frontal systems, these same subcortical structures may contribute to maintenance and switching of behaviors and aspects of cognition (2 ,26).

The thalamus exerts an excitatory effect on frontal cortex pyramidal cell activity, partially delivered within each frontal region by the paired parallel segregated circuit. The basal ganglia output nuclei with their high rates of spontaneous discharge keep their own target nuclei of the thalamus under tonic GABAergic inhibition. These inhibitory output nuclei stimuli are, in turn, regulated by two parallel but opposing pathways from the caudate and putamen, one excitatory and the other inhibitory. The primary cortical signal to basal ganglia is mediated by an excitatory glutamatergic pathway. It would be rational to suspect some role of these parallel segregated motor circuits in antipsychotic drug–induced dyskinesias, as well, especially because the primary action of antipsychotic drugs is D2 dopamine-family–receptor blockade in striatum.

ANIMAL MODELS OF TARDIVE DYSKINESIA

Part of "126 - Clinical Course and Cellular Pathology of Tardive Dyskinesia "

The cause of TD in antipsychotic drug–treated patients is, by definition, long-term drug treatment. Thus, putative models of the condition have been developed in nonhuman primates and in small animals using long-term administration of antipsychotics and applied to the study of TD mechanisms. The structural and functional brain characteristics of nonhuman primates are reasonably similar to those of human primates; hence, primate preparations may make more valid TD models (9). Yet, it is the reality of nonhuman primate models that many treatment years are required for dyskinesia development (2 to 6 years), and monkey care is involved and expensive. Alternatively, putative rat models have also been proposed; rat oral dyskinesias develop faster with chronic treatment (6 to 12 months), yet they retain many phenomenologic and pharmacologic characteristics of human TD (61 ,70). These models often provide a more realistic experimental platform, even if not more valid, than the nonhuman primate for developing hypotheses about human TD.

Animal models of all human diseases have been sought for pursuing pathophysiologic hypotheses and for identifying new therapeutics. Investigators have suggested the characteristics of good animal models for an expressed human illness as similarities in (a) origin, (b) phenomenology, (c) biochemical characteristics, and (d) pharmacology (45 ,73). Similarities of these features provide greater validation of the model. Across all the TD models, both primate and rodent, origin and phenomenology approximate characteristics of human TD. Biochemical determinants are unknown for the TD models as well as for the disease itself. However, extensive similarities exist in pharmacologic response between the human illness (TD) and the model preparations. Because rodent models are more practical to pursue, their pharmacology has been more broadly described than the primate model. It would be obvious to suggest that the use of both rat and monkey models would be ideal, as the efficiency and specificity of the questions dictate.

Nonhuman Primate Models

Antipsychotic treatment in the nonhuman primate has been studied to define the mechanism of acute drug-induced parkinsonism and of chronic drug-induced TD (22 ,31). Gunne et al. (28 ,31) showed not only the partial penetration of the syndrome in the nonhuman primate, but also differences in glutamic acid decarboxylase synthesis, the rate-limiting synthetic enzyme for GABA, and GABA levels in GP and SNR between drug-treated monkeys with and without the dyskinesia. Based on these data, Gunne et al. proposed that the mechanism of TD involved a reduction in GABAergic transmission in these regions of the basal ganglia, GP, and SNR. This idea correlated with the known clinical pharmacology of TD, namely, that GABA agonist treatment can improve drug-induced dyskinesias (65).

Rodent Models

Results from many laboratories suggested that rats treated chronically with traditional antipsychotics (e.g., fluphenazine, haloperidol) exhibit seemingly involuntary, irregular, and purposeless oral chewing movements (CMs) over time, often called *vacuous chewing movements* (13 ,16 ,18 ,23 ,27 ,30 ,56 ,61). The phenomenology of CMs resembles TD, in that movements have a gradual onset (61), partial penetrance (34), and a delayed offset, and they are sensitive to stress (49). However, the movements in rats remain limited to the oral region and rarely extend to other body parts. The pharmacology of CMs resembles that of TD: CMs are suppressed by antipsychotics, but not by anticholinergics (52); they are reduced by GABAmimetics (20), and they are attenuated with benzodiazepines. Rat CMs are associated with molecular and cellular changes in CNS histology, including an increase in perforated synapses in striatum and an alteration in relative synaptic number in striatum (47). Administration of the antipsychotic on an irregular schedule can advance the onset and severity of the rat CMs (24). The similarities across phenomenology and pharmacology are close enough between human TD and rat CMs for investigators to pursue the biochemical basis of CMs as a clue to pathophysiology in TD. Moreover, the pharmacology of the two are similar enough for the use of this model as a screen for new antipsychotic drugs to rule out TD potential.

Early pharmacologic studies in the rodent preparation reported that although all traditional antipsychotics are associated with CMs (70 ,71), clozapine is not (19 ,27). Subsequently, the other “new” antipsychotics have been tested and have generated results consistent with clinical data, demonstrating low TD potential for the second-generation antipsychotics (29 ,39). Neither olanzapine nor sertindole produce the CM syndrome at drug doses that produce human therapeutic plasma levels in the animals (21); risperidone at low doses is not associated with CMs, whereas high doses produce haloperidol-like CMs (Gao, unpublished observations). Data using quetiapine or ziprasidone in this animal model have not been reported.

NEUROCHEMICAL CHANGES WITHIN THE BASAL GANGLIA THALAMOCORTICAL PATHWAYS IN A RODENT MODEL OF TARDIVE DYSKINESIA

Part of "126 - Clinical Course and Cellular Pathology of Tardive Dyskinesia "

We designed and carried out a series of studies in a putative rodent model of TD based on the broadly accepted, functional architecture of the basal ganglia and thalamus already described. These studies were based not only on the existence of these theoretic models, but also on early experimental data in nonhuman primates with chronic antipsychotic treatment implicating GABAergic transmission in TD (30 ,31). The drug- and time-induced changes in GABAergic transmission in nonhuman primate basal ganglia directly affected the output nuclei, and from there, the thalamic and frontal regions associated with the segregated motor circuit.

With chronic (6 months) haloperidol treatment, some but not all laboratory rats acquired hyperkinetic oral CMs over time (61 ,63). In comparison, the newer antipsychotics, including clozapine, olanzapine, sertindole, and low-dose risperidone, failed to induce the rat “syndrome” of CMs (21 ,39). Can these preparations contribute to knowledge of TD pathophysiology? Can they contribute unique information to the mechanism of antipsychotic drug action? Comparison of several different animal treatment groups has been useful in addressing these questions: (a) haloperidol-treated rats, *with* versus *without* rat CMs and (b) haloperidol-treated rats versus newer antipsychotic drug–treated rats.

Chronic haloperidol induces similar D2-receptor up-regulation in striatum in the CM compared with the non-CM rat (Fig. 126.2), a finding discouraging consideration of this feature as a correlate of the CMs. Antipsychotic drugs block the inhibitory D2 receptor and disinhibit the medium spiny neuronal projections to the GP. In these studies, striatal disinhibition is reflected in the glutamic acid decarboxylase mRNA increases in GP, especially in the CM rats (Table 126.2). At the same time, activity in the direct striatonigral pathway appears also to be altered possibly by the haloperidol-induced increase in dopamine release in striatum and its action there on the unblocked D1 receptor (12). In the SNR, a primary basal ganglia output nuclei in the rat, abnormalities

also occur. Here the CM rats show reduced nigral D1-receptor numbers, whereas the non-CM treated rats show no change in D1-receptor density (Fig. 126.3). Moreover, this CM-associated receptor change in SNR is blocked (along with the CMs) by concomitant chronic treatment with the GABA agonist progabide (Fig. 126.3), a finding strengthening the association between altered SNR D1 receptors and CMs (45). The reduction in D1-receptor number in SNR could be associated with an antipsychotic-induced increase in the dendritic release of dopamine (Fig. 126.4). D1 receptors in SNR mediate the release of GABA. Hence, an increase in dopamine release within SNR could mediate the release of GABA at striatonigral terminals and subsequently could inhibit activity in the GABA-mediated efferent pathway to thalamus. A reduction in GABA-mediated transmission from SNR to the target nucleus in the thalamus could produce a compensatory up-regulation of thalamic $GABA_A$ receptors, hence marking altered SNR activity. In the haloperidol-treated animals, a significant elevation of $GABA_A$ receptor occurred, and a significant correlation developed between the elevated receptor number and CMs in the mediodorsal thalamus (Fig. 126.5). This positive correlation implicates a nigral D1 defect along with an overinhibition of the nigrothalamic efferent GABAergic pathway as an important mediator of CMs in rat (56). The idea that a reduction in the activity of the basal ganglia output nuclei disinhibits the thalamus and is associated with drug-induced rat hyperkinetic oral CMs is consistent with the already established functional models of these interactions (2).

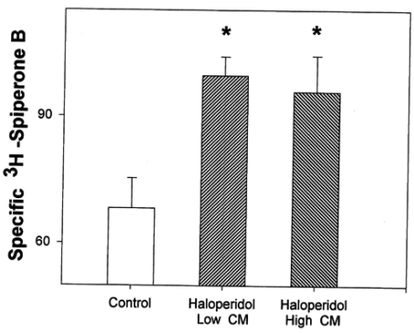

FIGURE 126.2. Specific binding of ^{3}H-spiperone to D2-family dopamine receptors in the nucleus accumbens of control and chronically haloperidol-treated rats. D2 binding data were similar in the caudate and putamen. Significant dopamine-receptor up-regulation was apparent in the haloperidol-treated rats with chewing movements (CMs) and in those without CMs; there was no apparent difference between CM and non-CM rats in the magnitude of increase. *$p < .05$.

arrow, significant change; D_1R, D_1 family dopamine receptor; D_2R, D_2 family dopamine receptor; $GABA_AR$, $GABA_A$ receptor; GAD, glutamic acid decarboxylase mRNA; Tr, trend; VCMS, vacuous chewing movements.

TABLE 126.2.

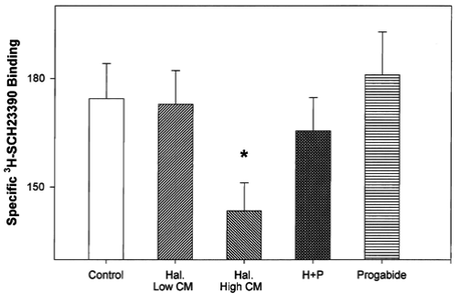

FIGURE 126.3. Specific binding of 3H-SCH23390 to D1-family dopamine receptors in the substantia nigra pars reticulata (SNR). D1 binding was down-regulated by chronic haloperidol (HAL) treatment only in the rats that displayed the vacuous chewing movements (CMs). This reduction was blocked by the GABA agonist progabide (P), as were the CMs themselves. Progabide alone had no effect on the D1 binding. *$p < .05$.

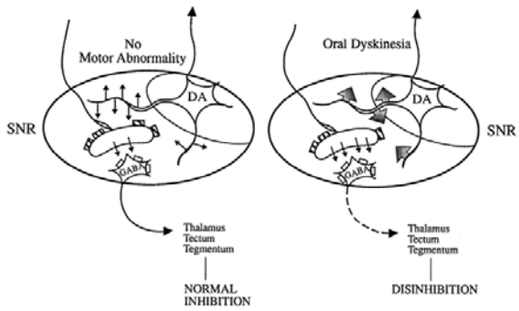

FIGURE 126.4. Hypothetical model for the mechanism of chronic haloperidol-induced chewing movements (CMs) in rat. The data collected can be parsimoniously explained by postulating an increase in dendritic dopamine release associated with the development of dyskinetic movements in the CM rats. An increase in dopamine could stimulate the release of GABA presynaptically from the striatonigral GABAergic neurons and thereby increase the overall GABAergic inhibition on the GABA-containing nigral efferent fibers, including those to the thalamus. This alteration would serve to decrease the level of GABAergic inhibition on critical nuclei of the thalamus. This interpretation of the data, even though parsimonious, is speculative.

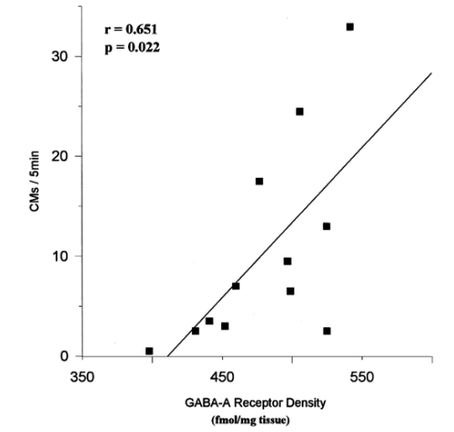

FIGURE 126.5. Correlation of $GABA_A$ receptor density with chewing movements (CMs) in mediodorsal thalamus in rats treated chronically with haloperidol. The significant positive correlation between these two factors suggests their relationship. This correlation supports the hypothesis that CMs are associated with diminished GABAergic transmission from the SNR to significant thalamic nuclei, evidenced by the up-regulation in $GABA_A$-receptor density associated with the putatively reduced GABAergic nigral signal with CMs. However, no other thalamic nuclei show this type of correlation, even the ventral nuclei traditionally associated with motor control in thalamus.

Two second-generation antipsychotics tested in the same animal chronic treatment paradigm differed from haloperidol in their actions. Both olanzapine and sertindole, each at two doses, were compared with haloperidol after 6 months of treatment (56). Neither olanzapine nor sertindole substantially up-regulated striatal D2 binding in the rat, even though we know from human studies that D2 blockade of some strength and duration occurs with each of these drugs (21). Because of the relatively high receptor affinities of these drugs at the D2 receptor, the data suggest that any regional reduction in blockade may occur only at some of the D2 receptors, and the resultant antidopaminergic action is weaker or of a reduced duration than with haloperidol. Nonetheless, olanzapine shows mild, haloperidol-like actions in striatum, and sertindole shows mild, haloperidol-like actions in GP and STN. Still, in SNR, neither new compound is associated with D1-receptor down-regulation or $GABA_A$ up-regulation (Table 126.2), nor are $GABA_A$ receptors altered in mediodorsal thalamus by either new drug in contrast to the haloperidol effect. It is possible

that the mechanism whereby these two effective antipsychotics (each antidopaminergic) fail to induce CMs is different in striatum, but both result in a common sparing of a critical change in SNR. It may be that the common serotonergic influence exerted within the basal ganglia nuclei by both these compounds spares SNR changes.

WORKING HYPOTHESIS OF THE CM-TD MECHANISM

Part of "126 - Clinical Course and Cellular Pathology of Tardive Dyskinesia "

The data summarized here are consistent with many reports in the literature and confirm the central role of the basal ganglia output nuclei and thalamus in mediating hyperkinetic movements in chronic antipsychotic-treated animals. It would be our current notion that traditional antipsychotic drugs alter the dynamic balance of neurotransmitter activity within the indirect and direct striatonigral pathway. This change, perhaps associated with sustained increase in nigral dendritic dopamine release, results in rodent hyperkinetic oral movements through the feedback of this information to motor regions of neocortex through thalamus. This antipsychotic-induced alteration acutely would merely inhibit activity within the indirect pathway and would be associated with parkinsonism. As treatment progresses and CMs begin, the indirect pathway inhibition could be progressively counterbalanced by direct pathway overactivity in the vulnerable animals. We postulate that the changes in SNR in D1-receptor (decrease) and $GABA_A$-receptor (increase) numbers reflect CM-related pathophysiology. These available data so far derive from animal model studies and provide a putative framework for TD pathophysiology. Work now must proceed with the human illness itself, by testing these and other ideas in *in vivo* brain imaging studies and postmortem tissue analysis.

These findings illustrate not only the basal ganglia mechanisms of one type of dyskinesia, but also one outcome of CNS plasticity in response to chronic dopamine-receptor blockade. The difference between those animals who are vulnerable to develop CMs and those who are not remains obscure, as is the vulnerability to TD with antipsychotic treatment in humans.

TREATMENT APPROACHES

Part of "126 - Clinical Course and Cellular Pathology of Tardive Dyskinesia "

There is still no definitive treatment for TD. Nonetheless, therapeutic strategies are often used for patients with TD symptoms. Prevention, reversal, and suppression or (clinical management) all need to be considered (57). Prevention and reversal used to be only theoretic possibilities, but this is no longer the case. The newer generation of antipsychotic drugs, with their low TD incidence, has introduced these various new options.

Prevention

Patients who require antipsychotic treatment for extended times today have the opportunity of treatment with one of the newer antipsychotic drugs and thus are at reduced risk of developing TD, probably at considerably reduced risk. Clozapine (48), olanzapine (50), risperidone (58), and quetiapine (67) all have been reported to have reduced association with TD. Data are not yet available for new antipsychotic treatment of neuroleptic-naive persons, in whom the expectation may be for an even lower association with the syndrome. However, these data will be generated in time.

Whether treatment with very low-dose traditional antipsychotic drugs will result in the same low incidence of TD is a possibility, but it is nowhere nearly as probable as with the use of the newer drugs. Very low-dose traditional drug treatment, such as haloperidol, 2 to 3 mg/day, is being tested in several centers for efficacy in psychosis and for side effects. However, low-dose haloperidol at 4 mg/day has the same incidence of acute parkinsonism and akathisia as a haloperidol dose of 16 mg/day (76), a finding suggesting that low-dose haloperidol still has considerable potency in modifying motor function. Nonetheless, the economic advantage of traditional antipsychotic treatments, when necessity demands it, deserves thorough testing.

The cellular basis for the advantage of the newer antipsychotics with respect to TD risk is being examined and has been inferred from what is known of their pharmacology. Clozapine has a complex pharmacology, and consequently its TD advantage can be theoretically associated with several transmitter mechanisms (14). The possibilities include a D1 antagonist action, a serotonin$_{2A}$ antagonist action, an antimuscarinic action, particularly at the M1 receptor, and even the antihistaminic action that can spare drug-induced TD. Parsimoniously, because this TD advantage appears to be a property of several or all of the newer antipsychotics, one could propose a common mechanism for the TD sparing. Speculations would then center most strongly on the role of the serotonin$_{2A}$-receptor blockade in striatum to attenuate the tardive motor effects of the dopamine-receptor blockade. This could be mediated by a blockade of serotonin action on striatal neurons, and a resultant modulation of dopamine-receptor blockade. Alternatively, the newer drugs may modulate dopamine blockade regionally to attenuate the cellular changes produced by the drugs. The results of the chronic treatment experiments in rat would favor this latter explanation. Additional possibilities exist, including a thalamic or cortical action of the drug at the serotonin 2A receptor.

Reversal

Clinical data with traditional antipsychotic treatment suggests that dyskinesia reversal occurs in persons with TD during ongoing treatment (Table 126.1), however, still conferring future risk. Data suggest that this reversal may happen faster with newer drug treatment than with the continued use of traditional drugs. TD reversal occurs frequently, although not inevitably, with cessation of antipsychotic treatment (43). This reversal appears to be more likely in the young rather than in the older patient, presumably because of greater tissue or system plasticity. The reversal occurs over the course of months to years, not in the range of weeks, so the phenomenon is challenging to document. Based on the simplistic formulation that relieving the brain of the inducing agent will allow the drug-induced tissue changes to reverse, then drugs such as clozapine or other newer antipsychotics, which have clinical efficacy with reduced dopamine-receptor occupancy, may reverse existent TD. Clozapine has been tested in a double-blind protocol comparing dyskinesia scores between two treatment populations during ongoing drug treatment (haloperidol versus clozapine) over the course of 12 months (63). Dyskinesia in the clozapine-treated group tended to be reduced after clozapine compared with haloperidol treatment ($p < .057$). Of some significance is that the rebound dyskinesia with drug withdrawal after a year of haloperidol treatment was significant, whereas after a year of clozapine treatment, the previously sensitive group failed to show any dyskinesia rebound after drug withdrawal, a finding suggesting the lack of system sensitivity (perhaps dopamine-receptor sensitivity) with clozapine. Olanzapine is currently being tested in persons with TD for its ability to relieve dyskinesia symptoms over 12 months compared with haloperidol.

Suppression

The feature that most consistently characterizes the results of suppression trials in TD is the variability within patients

and among clinical centers conducting trials. No drugs have been reliably demonstrated to suppress TD across all patient groups and ages, although some drug classes show more promise and consistency in this regard than other approaches (32).

Benzodiazepines most reliably reduce the dyskinesias of TD, even at doses that do not produce sedation (64). Clonazepine has been widely used and seems to be one of the more effective benzodiazepines (51 ,64 ,72). Even when effective, clonazepam shows tolerance over time and requires continual dose increases to sustain efficacy. Thus, treatment must be occasionally withdrawn to "resensitize" the system to its effects for treatment to sustain action. The mechanism of therapeutic action has always been thought related to the GABA-enhancing drug action. Because the biology of TD has suggested regional GABA reductions, a GABA agonist is rational as a therapeutic choice.

Based on a continuation of this reasoning, other GABAmimetics have been tested in TD (60). It has been challenging to find a therapeutic window for a GABA agonist in TD, in which the GABA agonist action is potent enough to be antidyskinetic but the side effects are not limiting. Valproic acid has not been shown to be an effective therapeutic agent in TD, presumably because of its low potency (44). More potent GABAmimetic, such as γ-vinyl-GABA and tetrahydroisoxazolopyridinol, have shown antidyskinetic efficacy, but in some cases with limiting side effects (62 ,65). The studies that have shown efficacy of GABAmimetics in TD have used younger patients (i.e., less than 50 years old). Studies in older volunteers have not demonstrated efficacy with GABAmimetics (12). Although the question of age effect on TD reversal has not been directly tested, it is generally believed that symptoms are more likely to be suppressed with a GABAergic drug in the young patient than in the older one.

Other drug treatment strategies include vitamin E (17 ,48 ,59), melatonin (55), noradrenergic-receptor antagonists such as propranolol or clonazepan, amantadine (5), and calcium channel blockers, especially nifedipine (58). Whereas each of these approaches provides clinical interest, none has developed into a therapeutic approach.

Treatments for TD will always be needed, even though the incidence of new cases may fall significantly with time. Treatments will always be more effective in younger than in older patients. Opportunities for drug development are likely to be found in the GABAergic or the glutamatergic neurotransmitter systems.

Epilepsy is a chronic condition characterized by spontaneously recurring seizures. Although often viewed and discussed as a single clinical entity, epilepsy is a symptom of several disorders that affect the brain. The variety of causes is quite extensive and includes tumors, congenital malformations, genetic alterations in receptors or channels, and acquired structural abnormalities such as those following trauma or infection. Some of the epilepsies with inborn causes, such as rolandic epilepsy, are self-limited and benign, whereas others are progressive (1). The seizures in some forms of epilepsy may arise from the entire brain at one time, whereas in other forms they start in a particular region or focus. Any region of the brain can serve as a seizure focus, but seizure onset is commonly observed in the temporal lobe. Although there are multiple causes for epilepsy originating in the temporal lobe, the most common form is the *mesial temporal lobe epilepsy syndrome* (MTLE), sometimes also termed *limbic epilepsy* because of the apparent involvement of one or more limbic brain regions (2).

MTLE has been recognized as a distinct entity for many years. The common clinical pattern during the seizure episode includes staring and lack of responsiveness, frequently accompanied by automatisms of hand activity and mastication. There is often (but not always) a history of prolonged febrile convulsions in early childhood and common pathologic features of atrophy and neuronal loss in the hippocampus, a structure located on the medial border of the temporal lobe. Seizure onset is frequently detected in the hippocampus when EEG depth recordings are made directly from this area in patients undergoing evaluation for surgical treatment of uncontrolled seizures. Removal of the hippocampus (together with adjacent structures) often successfully controls seizures in “intractable” patients whose seizures do not respond to medication (2). For these reasons, a general consensus has developed that the hippocampus is the key to understanding and treating limbic epilepsy, and much of the research directed at MTLE has focused on this area of the brain. However, there is increasing evidence that other structures of the limbic system, such as the amygdala, parts of the neocortex, and the entorhinal cortex, which is a phylogenetically older part of the cortex that controls the information flow into and from the hippocampus (3), also play important roles in the initiation and propagation of seizures in MTLE.

Support for the involvement of nonhippocampal limbic sites in MTLE comes from a variety of sources. As reviewed in this chapter, extrahippocampal areas frequently show pathologic structural changes on histologic examination. Intracranial recordings from patients undergoing evaluation for therapeutic epilepsy surgery often present with a pattern of diffuse limbic onset without a regional predilection (4 ,5). Imaging studies have also indicated that there is atrophy or metabolic change in medial temporal structures other than the hippocampus, as well as in subcortical structures with limbic connections (6 ,7 and 8). Surgical results have suggested that it is necessary to remove more than the hippocampus to achieve successful outcome (9 ,10). Finally, there is ample evidence from a variety of animal models of limbic epilepsy that extrahippocampal sites participate in epileptogenesis, demonstrate anatomic and neuropathologic changes, and show alterations in cellular physiology. In many instances, changes in these regions are greater than those seen in the hippocampus.

The advent of new imaging techniques, the development of several useful new animal models of limbic epilepsy that closely parallel the human condition, and improved means

for studying neuronal physiology *in vivo* and *in vitro* have provided new opportunities to explore the role and fate of extrahippocampal brain regions in MTLE. In this chapter, we review current knowledge of the neuropathology, physiology, anatomy, and neurochemistry of MTLE and compare the hippocampus with extrahippocampal limbic regions. In closing, we briefly explore how new research directions resulting from recent data may lead to novel and improved treatments of MTLE.

NEUROPATHOLOGY

Part of "127 - Temporal Lobe Epilepsy: Renewed Emphasis on Extrahippocampal Areas "

Hippocampus

The notion of a central role of the hippocampus in MTLE can be traced to a highly influential review article by Sommer, which was published toward the end of the nineteenth century (11). As a young physician at the “insane asylum” in Allenberg, Germany, Sommer reviewed the anamneses and corresponding neuropathologic features of 90 patients with epilepsy, only five of whom had been patients at his institution. After pointing out that “there can be no question that epileptic symptoms are frequently associated with a disease of the Ammon's horn,” as others had suggested before, he made the ground-breaking observation that patients presented with a preferential degeneration of a band of pyramidal cells termed the CA1 subfield (the *Sommer sector*) of the hippocampus proper (12). With astounding foresight, he concluded that the cell loss was a consequence of prolonged seizure activity and that both head trauma and developmental malformations ought to be considered etiologically important factors in epilepsy. Sommer also noted that neurodegenerative changes in patients with epilepsy are frequently detected in areas surrounding the hippocampus, namely, in the subiculum and in the temporal and occipital cortices. He remarked that “it is not unlikely that a single underlying defect spreading through several anatomically linked brain areas accounts for the various clinical manifestations of the epileptic syndrome.”

During the first half of the twentieth century, Sommer's pioneering insights and predictions were confirmed and refined by many investigators studying brain pathology post mortem. This period was increasingly dominated by the question whether “idiopathic” seizure activity causes neurodegeneration or, conversely, epilepsy occurs only as a sequela of brain damage. The chicken-egg debate, which has not been entirely resolved to this day, was accompanied by uncertainties about the nature of putatively epileptogenic insults, such as respiratory difficulties and asphyxia, infectious diseases leading to encephalitis, and, in particular, vascular abnormalities (13). The advent, in the 1930s, of surgical interventions for the treatment of MTLE revolutionized clinical management of the disease and at the same time provided invaluable information for research purposes (14).

Histologic analysis of excised brain tissue and correlations between the nature of removed temporal lobe structures and surgical outcome unequivocally established the centrality of the hippocampus and associated “limbic” brain regions in MTLE *(psychomotor epilepsy)*. By the 1950s, support had developed among leading epilepsy researchers for the concepts that MTLE (a) was a “network” disorder, caused by abnormal interactions between a limited number of highly interconnected areas within the temporal lobe, and (b) in many cases originated in, and could be treated by removal of, extrahippocampal structures (15). Thus, irrespective of the cellular and molecular events underlying epileptogenesis and the eventual development of spontaneously recurring seizures, which soon were to become the focal points of epilepsy research, brain structures such as the entorhinal and perirhinal cortices and the amygdala were viewed as the critical components of the seizure network.

Studies of the hippocampus of patients with MTLE that used more recent neuroanatomic techniques revealed several signature abnormalities, which, alone or in concert, are suspected to play a critical role in the pathophysiology of the disease. These changes are often seen in conjunction with pronounced neurodegeneration in area CA1 and in the so-called end folium, which includes polymorphic neurons in the hilus of the dentate gyrus and proximal “CA4” pyramidal cells (16) (Fig. 127.1A).

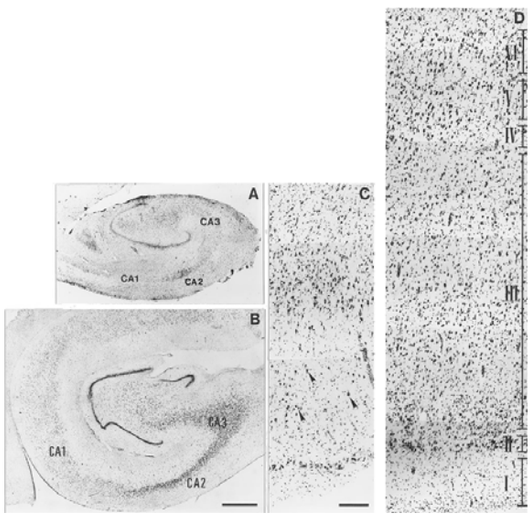

FIGURE 127.1. A and **B:** Nissl-stained coronal sections through the rostral portion of the hippocampus taken from a patient with MTLE **(A)** and a control subject **(B)**. Note the pronounced neuronal loss and gliosis in areas CA1 and CA3 in the patient with epilepsy. Moreover, the epileptic hippocampus is substantially reduced in size compared with the control. **C** and **D:** High magnification of portions of the olfactory field of the entorhinal cortex from a patient with MTLE **(C)** and a control subject **(D)**. Note the substantially reduced width of layers I to III of the entorhinal cortex of the patient with epilepsy. *Arrowheads* in **C** indicate surviving neurons. I to VI, layers of the entorhinal cortex. Scale bars: 1.5 mm in **B** and also in **A;** 200 μm in **C** and also in **D**. (From Du F, Whetsell WO Jr, Abou-Khalil B, et al. Preferential neuronal loss in layer III of the entorhinal cortex in patients with temporal lobe epilepsy. *Epilepsy Res* 1993;16:223–233, with permission.)

Probably the most reliable changes occur in glial cells, which increase in size and number (astrocytes) or change their shape to resemble phagocytotic macrophages (microglia) more closely (17 ,18 and 19). Because of their special biochemical and biophysical properties, these abnormal glial cells are believed to play an active role in the disease process, either by containing or actively enhancing seizure spread (see later).

Of particular interest is the sprouting of mossy fiber axons of surviving excitatory granule cells, which can be visualized by Timm staining or by immunohistochemistry using antibodies against the neuropeptide dynorphin (20). It is often assumed that the new, sprouted fiber network, which has been shown to form recurrent excitatory connections with preexisting neurons (21), may predispose the region to hyperexcitability (22). However, axons also sprout from surviving inhibitory neurons (23), and these novel axons have been proposed to impede chronic hippocampal hyperexcitability (24).

Extrahippocampal Areas

Triggered by new information about the anatomic interconnections in the normal brain and by the results of noninvasive imaging studies of MTLE patients (see later), the 1990s also witnessed a renewed interest in the neuropathology of extrahippocampal temporal lobe lesions in MTLE. As mentioned earlier, lesions in the parahippocampal region or the amygdala, in particular, had been considered among the defining hallmarks of MTLE in earlier days, but they were

less appreciated during a more than 20-year hiatus, ranging essentially from the landmark publication of Margerison and Corsellis (16) to the equally influential monograph of Bruton (25).

In the entorhinal cortex, neuropathologic changes are most readily observed in the superficial layers of the anterior portion of this six-layered parahippocampal structure. Patients frequently present with a characteristic pattern of neuronal loss and associated gliosis, with layer III being preferentially affected and layer II showing pronounced disorganization and some cell loss (26) (Fig. 127.1C). Neuron loss in layer III of the rostral entorhinal cortex can reach dramatic proportions, with only a few, probably γ-aminobutyric acid (GABA)–ergic, cells surviving. This lesion is almost singularly responsible for the substantial tissue shrinkage often described in the epileptic entorhinal cortex (15 ,26). Because pyramidal cells of layer III normally give rise to the monosynaptic "temporoammonic" pathway to area CA1 of the hippocampus (27), their degeneration in MTLE may lead to deafferentation-induced changes in hippocampal excitability, and such changes have indeed been observed in animals (28). Neuropathologic changes in layer

II of the entorhinal cortex, the origin of the major input to the granule cells of the dentate gyrus (the “perforant path”), may also contribute to hippocampal hyperexcitability in MTLE.

Neuronal loss and gliosis in the amygdala are frequently seen in MTLE and often occur in conjunction with lesions in other parts of the limbic system (29 ,30). Although the pattern of cell loss has so far not been analyzed in great detail, degenerative events appear primarily to affect the ventromedial aspects of the lateral amygdaloid nucleus and the parvicellular region of the basal nucleus (31). Based on published studies, this relatively restricted damage not only impedes processing of sensory information in intraamygdaloid circuits, but may also account for the impairment of memory processing in MTLE by interrupting information flow to the hippocampal formation (31 ,32).

It is likely that neuropathologic changes also occur in other areas that are connected to the reverberating seizure network underlying MTLE (33). These structures, which include the thalamus (34), have been shown to be atrophied in patients, but the precise nature and distribution of the degenerative changes, as well as their relation to the pathophysiology of MTLE, have not been elucidated to date.

IN VIVO IMAGING

Part of "127 - Temporal Lobe Epilepsy: Renewed Emphasis on Extrahippocampal Areas "

Structural and functional neuroimaging techniques provide noninvasive means to identify brain abnormalities and have thus become indispensable tools to guide therapeutic interventions in neurologic and psychiatric diseases. These methods have also been, and continue to be, of critical importance for the generation and testing of hypotheses related to pathogenesis and disease progression. In the case of MTLE, techniques such as computed tomography, measurements of regional glucose use and receptor densities by positron emission tomography, single photon emission computed tomography measuring regional cerebral blood flow, and, more recently, volumetric and functional magnetic resonance imaging are now widely used—often in concert—to complement classic EEG and neuropsychological patient evaluation. Imaging test results are increasingly used for diagnostic purposes and, specifically, to provide guidance for neurosurgical procedures.

Improvements in the spatial resolution of most imaging techniques have made it possible to study regional brain abnormalities in MTLE with increasing accuracy. In early studies, hypometabolism and decreases in cerebral blood flow in the temporal lobe were demonstrated even when no structural damage was detectable by computed tomography. These methods were unable to localize the changes and to provide quantitative data adequately (8 ,35), but results obtained by magnetic resonance imaging are remarkably informative on both counts. Thus, using various modifications of the technique, it became feasible to visualize hippocampal atrophy in MTLE (36 ,37) (Fig. 127.2A). In the 1990s, magnetic resonance imaging studies also revealed shrinkage in other areas of the seizure circuit, namely, the amygdala (38 ,39), the entorhinal cortex (40), and the thalamus (6), findings demonstrating that the extrahippocampal changes in tissue volume known to exist in many MTLE patients can be visualized noninvasively (Fig. 127.2B-D). Further methodologic developments are likely to permit the imaging of increasingly smaller lesions and thereby to shed light on the roles of other extrahippocampal brain areas in the pathophysiology of MTLE.

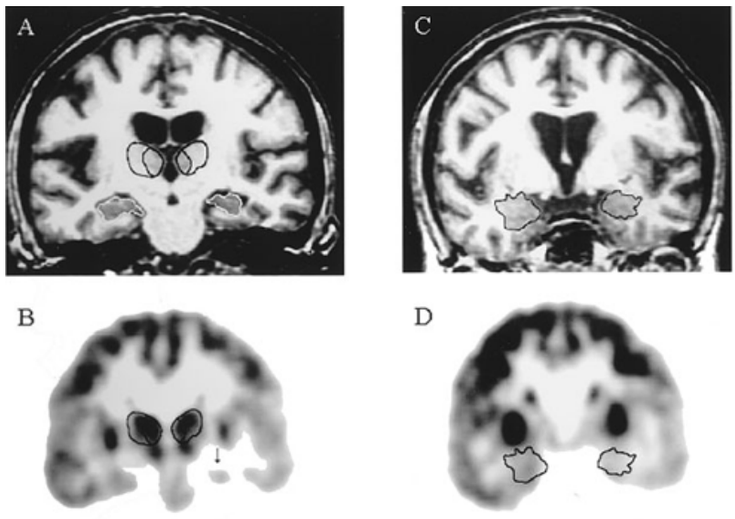

FIGURE 127.2. Imaging studies illustrating changes in extrahippocampal brain regions in MTLE. MRI scans (**A** and **C**) and fluorodeoxyglucose PET scans (**B** and **D**) in a patient with left MTLE. The demarcations on the two sets of scans represent the co-registration of the two techniques so comparable sites are illustrated in the two studies. **A** and **B** show changes in hippocampus (*circled in white* in MRI, indicated with an *arrow* in the PET scan) and thalamus *(outlined in black)* with the medial dorsal nucleus indicated separately in **A**. MRI demonstrates atrophy in the left hippocampus and the left mediodorsal nucleus, and PET shows hypometabolism specific to the temporal lobe and the medial dorsal thalamus. **C** and **D** show atrophy in the left amygdala. The left brain hemisphere corresponds to the right side of the images. (Micrographs courtesy of Drs. C. Juhász and H. Chugani, Wayne State University, Detroit, MI.)

STUDIES IN EXPERIMENTAL ANIMALS

Part of "127 - Temporal Lobe Epilepsy: Renewed Emphasis on Extrahippocampal Areas "

Kindling

Kindling, a phenomenon first described in 1969 (41), has become a major research tool to study seizures involving the limbic system. In this model, a single site in the brain is stimulated electrically with sufficient intensity to induce an electrical after-discharge, but hardly any behavioral changes. With repeated focal stimulations for days or weeks, there is a gradual lengthening of the after-discharge, and behavioral seizures develop. During the seizure, the animal's behavior progresses to the point of a full convulsion. After a number of stimulations, the seizures reach a plateau of

consistent duration and behavioral severity, at which point the animal is considered fully kindled. The number of stimulations required to achieve this plateau depends on several factors, such as the frequency and duration of focal stimulation and the temporal interval between stimuli (42). In addition, however, the site of stimulation is critical for the development of kindling. Studies of several limbic sites, as well as comparisons of neocortical and subcortical regions, demonstrated that some extrahippocampal sites, for example, the amygdala, achieve the fully kindled state much faster than the hippocampus (43). In addition, focal pharmacologic manipulations revealed that both the development and the expression of kindling are significantly influenced by certain subcortical structures, including the midline thalamus and the substantia nigra (44 ,45).

The variable rates of kindling from different stimulation sites suggest that some regions are more *epileptogenic*, that is, more able to generate and support seizure activity than other sites. An alternative explanation is that the areas with more rapid rates of kindling are "closer" to the pathways of secondary generalization. This implies that seizure activity spreads by gradual recruitment of adjacent cortex (similar to the classic *jacksonian march*), exemplified by the proposed role of the perirhinal cortex as the major route from the limbic system to the neocortex (46). However, this idea is confounded by the observation that seizures can appear simultaneously at sites that have few direct interactions (e.g., hippocampus and amygdala) (33). Taken together, these findings therefore suggest the existence of a subcortical "control center," for example, the midline thalamic region, with direct connections to several of the limbic sites involved (Fig. 127.4B).

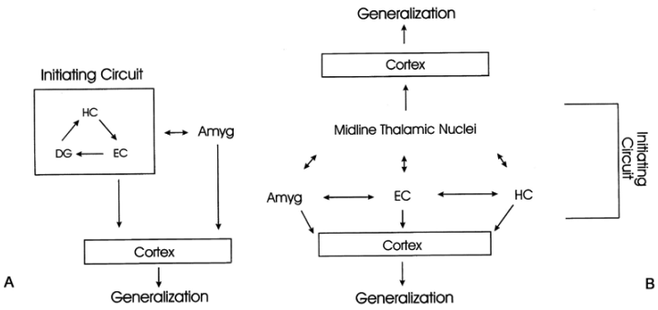

FIGURE 127.4. Schematic representation of the functional anatomy underlying MTLE. **A:** In the conventional model, seizures originate in a reverberating loop consisting of entorhinal cortex, dentate gyrus, and area CA1 of the hippocampus. At some point, seizure activity spreads to the amygdala and other adjacent areas before involving the neocortex and resulting in secondary generalization. **B:** Newer studies suggest an alternative model, in which several limbic sites initially interact with one another independently. Because of their reciprocal connections to all these regions, the midline thalamic nuclei constitute part of the initiating circuit, acting as a subcortical synchronizing site. Generalization can occur through gradual recruitment of adjacent neocortex or through the thalamus, which secondarily recruits the neocortex. Amyg, amygdala; DG, dentate gyrus; EC, entorhinal cortex; HC, hippocampus.

The effect of pharmacologic intervention on the rate of kindling has been of great interest to epilepsy research, because drugs that prolong or abolish kindling acquisition could ameliorate or prevent the development of chronic epilepsy, that is, act as antiepileptogenic agents. Indeed, agents such as phenobarbital, carbamazepine, and several *N*-methyl-D-aspartate (NMDA)–receptor antagonists attenuate the kindling rate, whereas other commonly used antiepileptic compounds, such as phenytoin, do not have such an effect (47). This clinically relevant use of the kindling model will eventually also provide a better definition of the molecular events that underlie the progressive lengthening of seizure activity on repetitive stimulation.

Animal Models of MTLE

The kindling model has been, and continues to be, valuable for our understanding of the role of particular brain regions in the generation and propagation of seizures. However, with a few exceptions, kindled animals do not develop spontaneous seizures. Since the 1980s, the development of animal models with recurrent, spontaneous convulsions has therefore become a major focus of epilepsy research. These models are commonly based on an inciting event of limbic status epilepticus that is precipitated by various methods, including the systemic administration of chemoconvulsants (e.g., pilocarpine or kainate) (48 ,49), focal microinjection of a chemoconvulsant (e.g., kainate) in a limbic brain region (50), or focal, prolonged (up to 90 minutes) electrical stimulation of a limbic structure (hippocampus, perforant path, amygdala) (51 ,52 and 53). In all these models, the animals recover after status epilepticus and, after a latent period of weeks to months, develop spontaneous seizures that continue intermittently throughout the animals' lives.

These rat models parallel the human condition in several noteworthy ways. First, seizures appear spontaneously and, like the seizures of human MTLE, have a clear predilection to occur during daytime hours. This pattern suggests that the seizures are likely to be under subcortical influence. Second, as in the case of human MTLE, there is a latent period during which a previously nonepileptic brain evolves into one that generates recurring seizures. Third, the histopathologic changes in chronically epileptic animals, such as gliosis and neuronal loss in the hippocampus, amygdala, entorhinal cortex, and medial dorsal thalamus, closely resemble those seen in the human condition. Finally, the EEG patterns and the locations of seizure onset are similar in human MTLE and in these animal models, a finding suggesting similarities in the underlying pathophysiology (Fig. 127.3).

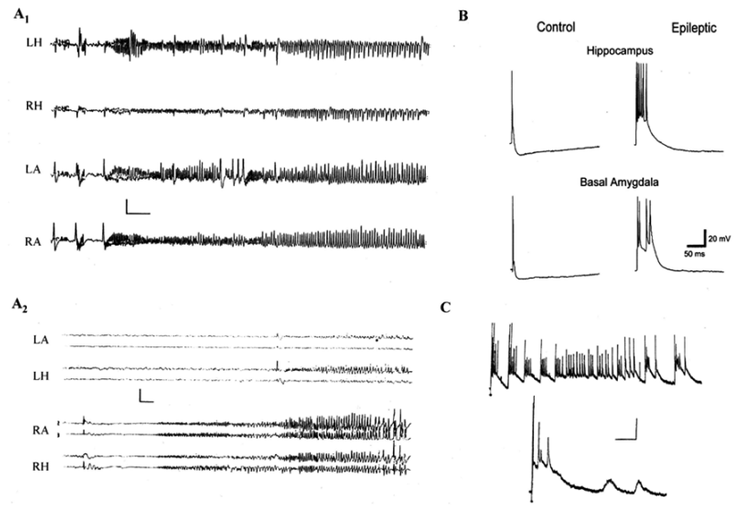

FIGURE 127.3. Seizures in human MTLE and in rat models of MTLE: illustrations of altered neuronal physiology. Chronic epilepsy in animals was induced by prolonged electrical stimulation or chemoconvulsants (see text). **A:** Bilateral recordings from hippocampus (LH, RH) and amygdala (LA, RA) in rat (A1) and human (A2). Both sites are involved at the onset, a finding suggesting a synchronizing pulse from an external site. The human recording shows a later but regionally simultaneous onset on the left hemisphere. This time difference is not seen in rats, probably as a result of stronger interhemispheric connections. **B:** Intracellular recordings from hippocampal and amygdalar neurons in normal and epileptic rats. At both sites, after a brief (0.1-ms) electrical pulse, the neurons from the epileptic animals show prolonged depolarization with multiple superimposed action potentials as compared with normal controls. **C:** Intracellular recordings from the entorhinal cortex of epileptic rats, also illustrating the prolonged depolarizations and multiple superimposed action potentials. Overall, this figure emphasizes the changes throughout the limbic system in nonhippocampal regions.

For these reasons, rat models of MTLE have become increasingly important for the study of limbic epilepsy. The animals offer several important advantages, which largely offset the limitations of the rodent brain, that is, its small size and less developed cortical architecture. Rats are not only relatively inexpensive and easy to manipulate, but allow well-controlled, multidisciplinary studies that can be readily compared across laboratories. The availability of "MTLE-like" animals also makes it possible to study the progression of events that eventually result in a chronic epileptic condition, that is, to assess the silent, latent period between status epilepticus and the first spontaneous limbic seizure. Finally, these animal models provide opportunities to test innovative clinical interventions for the treatment and possible cure of MTLE (54 ,55).

These models of limbic epilepsy have been exploited to test novel concepts related to the pathophysiology of MTLE. For example, hyperexcitable neurons, both projection and interneurons, are often found in many limbic sites associated with MTLE. In some cases, the synaptically mediated responses in these neurons show prolonged excitatory depolarizations with multiple superimposed action potentials (23 ,56 ,57) (Fig. 127.3). Underlying these profound changes are multiple presynaptic and postsynaptic alterations in neurotransmitter receptors and ion channels. Judged by physiologic criteria, there is evidence that changes in both inhibitory and excitatory receptors, namely GABA and glutamate receptors, contribute to the abnormal physiology (58 ,59). These changes are necessarily complex because

they reflect a composite picture of receptors and receptor subunits and their reactive up-regulation or down-regulation (60 ,61 and 62). In addition, the models also involve many other biochemical changes in one or more parts of the limbic seizure network. This ever-increasing list includes ions, enzymes, hormones and their receptors, and a host of other chemical entities. In most instances, however, the possible functional significance of these changes has so far not been elucidated.

Experimental MTLE also provides an opportunity to evaluate the existence and functional significance of synaptic rearrangements, which occur in response to epileptogenic insults or neuronal damage and may be involved in the development of spontaneously recurring seizures (20 ,21 ,22 ,23 and 24 ,63). The prototype for this process, the sprouting of mossy fibers originating from hippocampal granule cells, has garnered substantial attention, in part because of the seeming simplicity of the new circuit and the easily visualized anatomic change (64). Because the animal models of MTLE show extensive neuronal loss in multiple brain areas, it is quite likely that seizure-related synaptic and circuit rearrangements also occur in extrahippocampal regions (65).

CURRENT CONCEPTS OF EPILEPTOGENESIS: MOLECULES AND MECHANISMS

Part of "127 - Temporal Lobe Epilepsy: Renewed Emphasis on Extrahippocampal Areas "

Neurotransmitters

A long-standing theme in epilepsy research has been the role of the major inhibitory neurotransmitter, GABA, in

both epileptogenesis and chronic epilepsy. Defects of the GABA system have been implicated since the 1970s, when a loss of GABA neurons was suspected to underlie seizures (66), but physiologic studies in animal models of epilepsy did not necessarily reveal a reduction in GABAergic inhibition (67). Other studies proposed a specific defect in the excitability of otherwise normal (“dormant”) GABAergic neurons resulting from their deafferentation (68). This hypothesis is still rather controversial, attesting to the complexity of GABAergic neurotransmission (63). However, it seems unlikely that a single deficit in the GABAergic systems of the brain underlies limbic epilepsy.

More recent studies have expanded our understanding of GABAergic transmission. For example, we now have a greatly improved view of GABAergic inhibitory neurons *(interneurons)*. These cells are morphologically heterogeneous, have diverse connections, and contain different colocalized transmitters (69). Thus, many GABAergic neurons also contain the peptides neuropeptide Y and somatostatin or calcium-binding proteins such as parvalbumin or calretinin. Although many anatomic studies have focused exclusively on the hippocampus and the neocortex, some common themes also seem to apply to other sites, such as the entorhinal and the perirhinal cortex. The physiologic characteristics of these different cells and their respective roles in epileptogenesis in both hippocampus and extrahippocampal areas will need to be elaborated in the future. These studies must also be complemented by a detailed molecular and functional analysis of GABA receptors and GABA transporters (70 ,71).

Because MTLE is frequently conceptualized as the result of an imbalance between excitation and inhibition in the brain, the abundant excitatory neurotransmitter glutamate is also likely to play an important role in the pathophysiology of MTLE. Indeed, both ionotropic [NMDA, 2-amino-(3-hydroxy-5-methylisoxazol-4-yl) propanoate (AMPA) and kainate] and metabotropic (i.e., G-protein–coupled) glutamate receptors have been implicated in epileptogenesis and chronic epilepsy (44 ,48 ,50 ,58 ,61 ,62). For example, a decrease in magnesium, an endogenous modulator of the NMDA receptor, greatly reduces the receptor's voltage dependency and allows channel opening at central neurons even at normal, hyperpolarized membrane potentials. The result is spontaneous epileptiform activity (72). NMDA-receptor subunit composition changes in response to seizure activity and may be responsible for the increase in excitability that often follows an initial seizure (61 ,62). Such changes occur in MTLE as well as in relevant animal models and are seen both in the hippocampus, so far the most thoroughly investigated brain region, and in extrahippocampal areas such as the entorhinal cortex (56).

Blockade of AMPA or kainate receptors is one of the most effective means to reduce epileptiform activity. These receptors, which mediate most fast excitatory neurotransmission, are also composed of an array of subunits, which assemble to form distinct receptor subtypes (73). Receptor compositions are abnormal in epileptic brain tissue of both humans and animals (60 ,61), although their role in epileptogenesis is currently unclear. This not only suggests that AMPA and kainate receptors are involved in spontaneously recurrent seizure activity but also offers promising new ideas for antiepileptic drug development (74).

Pharmacologic manipulation of metabotropic glutamate receptors and interference with the function of glutamate transporters, a group of several distinct proteins that control the extracellular concentration of glutamate in the brain, too, have profound consequences on neuronal excitability. These sites are therefore under careful scrutiny both for their potential role in epileptogenesis and as novel therapeutic targets (75 ,76).

A considerable body of evidence suggests that other classic neurotransmitters, such as monoamines and acetylcholine, also play critical roles in MTLE, and that the proconvulsant or anticonvulsant effects of these agents manifest themselves in several regions of the epileptic network. Drugs that selectively influence, for example, noradrenergic or cholinergic neurotransmission are therefore useful experimental tools and of potential benefit in the treatment of MTLE (77 ,78).

Neuromodulators: Neuropeptides, Growth Factors, Cytokines

Neuropeptides have long constituted an enigma to neuroscientists. They are present in many different brain areas, where they are localized in various neuronal types, often in cells expressing GABA as a neurotransmitter (69), yet their physiologic function remains obscure. Some of these agents, such as neuropeptide Y and dynorphin, show increased or reduced brain content after prolonged seizure activity (20 ,79). Physiologic studies have demonstrated that neuropeptide Y has an inhibitory action, suppressing neurotransmission in single hippocampal cells and seizures *in vivo*. It is therefore conceivable that neuropeptide Y, portrayed here as a prototype of a relatively large group of neuroactive peptides, plays an important role as an endogenous modulator of seizure generation and in epilepsy. Its physiologic actions, as well as its chemical and anatomic changes in MTLE, are not confined to the hippocampus but also affect other parts of the seizure network (79).

Several peptides and small proteins with no previously recognized relevance to epilepsy may also turn out to play a role in epileptogenesis. Examples include growth factors and cytokines, which have been shown to be neuroactive in various test systems. Thus, various members of the neurotrophin family, including nerve growth factor, brain-derived growth factor (BDNF), and others, for example, neurotrophin 3 and neurotrophin 4/5, influence neurotransmission, although their effects vary widely in both qualitative and quantitative terms (80). All reports of these neuroactive effects are so far based on exogenously applied neurotrophins; that is, the results could be compromised by the finding

that the concentrations used for experimentation exceeded physiologic levels. Still, it is certainly of interest that the brain concentration of some neurotrophins, such as BDNF, increases dramatically after seizures, whereas others, such as neurotrophin 3, decrease. The high-affinity trk receptors and low-affinity p75 receptors for neurotrophins also appear to change after seizures, setting the stage for potentially important, interactive roles of the various neurotrophins in epileptogenesis and epilepsy (80). Because normal expression and seizure-induced changes of these putative neuromodulators occur throughout the limbic system, critical seizure-related effects may not only take place in the hippocampus, where most studies have been performed to date. For example, potent effects of BDNF in the entorhinal cortex have been described (81).

Cytokines were originally characterized as mediators of inflammatory responses and were discussed as messengers of the immune system. However, some of these compounds, for example, interleukin 1 (IL-1), IL-6, and tumor necrosis factor-α, are expressed in the brain, influence neuronal activity, and therefore have potential links to seizure mechanisms. In particular, the mRNA for IL-1ß and IL-6, as well as IL receptors, is increased by seizures (82). Moreover, IL-1α is elevated in tissue from patients with epilepsy (83). Finally, the finding that cytokines are expressed and released by microglia underscores the role of nonneuronal cells in epilepsy (see later).

Neuron-Glia Interactions

The importance of glia to neuronal function has been appreciated since the early period of neuroscience research. Yet to this day, the interrelationship of glia and neurons continues to unfold. Besides other roles in brain physiology, glial cells may play a significant role in the modulation of seizure phenomena. Thus, both astrocytes and microglial cells, the two major glial cell types in the brain, are rapidly activated by seizure activity in the limbic system (84). It is currently unclear, however, whether this cellular reaction has proconvulsive or anticonvulsive effects. Astrocytes have the ability to buffer extracellular potassium and can avidly accumulate the excitatory amino acid glutamate (76). Moreover, astrocytes increase the production and release of the endogenous neuroinhibitory and anticonvulsant compound kynurenate, possibly as an early defensive response to seizures (85). These and many conceptually related data indicate a protective function of astrocytes in epileptogenesis and, perhaps, in chronic epilepsy. Conversely, both astrocytes and microglia also synthesize endogenous proconvulsive agents such as quinolinate (86) and cytokines (87), which may exacerbate seizure activity during any stage of the epileptic process.

Of possible relevance to their role in epilepsy, glial cells in limbic brain areas are heterogeneous with regard to both structure and function. For example, both the electrophysiologic properties and the histochemical staining pattern of astrocytes in area CA1 of the hippocampus differ from those in area CA3 (88). Similar differences are likely to exist in other brain areas as well, adding another layer of complexity to the study of neuron-glia interactions as they pertain to mechanisms of epileptogenesis and chronic epilepsy.

Seizure-Induced Changes in Gene Expression

Prolonged seizure activity, especially episodes of status epilepticus, often has dramatic effects on gene expression, inducing a bewildering array of new genes in the brain. The expression of a variety of proteins and peptides is increased, whereas that of others is reduced. These changes involve neurotransmitters, neuromodulators and their receptors, growth factors, cytokines, and additional classes of compounds. A popular hypothesis to explain these changes is that seizures induce, or influence the expression of, genes that are normally expressed during development. Sequelae of seizures may therefore mimic or, to use a more teleologic term, *recapitulate* development. Examples include the seizure-induced up-regulation of growth factors and proteins that are involved in synaptogenesis (89). Other investigators have proposed, again arguing teleologically, that seizure-induced changes merely constitute compensatory mechanisms of the adult brain, that is, attempts of the system to counter a potentially dangerous increase in excitability or impending cellular damage. This implies the up-regulation of systems that inhibit neuronal activity. Indeed, seizures lead to changed expression of glutamate decarboxylase, the enzyme responsible for GABA synthesis, and GABA receptors (71 ,90).

Conversely, seizure-induced changes in gene expression may be part of the development of the epileptic state. Thus, a first seizure may induce gene expression of substances that will contribute to further hyperexcitability. One example is the neurotrophin BDNF, which is normally expressed in dentate gyrus granule cells and, to a lesser extent, other areas of the hippocampus and other brain regions (91). After a single seizure, BDNF message, protein, and the high-affinity trkB receptor all increase in granule cells (92 ,93). Because BDNF enhances neuronal activity in the hippocampus, the increase in expression could have functional consequences; that is, it could lead to a reduction in seizure threshold. BDNF also has effects on neuronal structure and could thus contribute to structural changes occurring after seizures that, in turn, increase susceptibility to seizures (81 ,94). Because BDNF, and other neurotrophins and neuromodulators, are expressed in extrahippocampal regions, this hyperexcitability may also occur in these areas.

Synaptic Reorganization

As mentioned above, seizures induce many genes in the brain. These genes express a variety of different proteins,

which often closely resemble or duplicate those that are preferentially expressed during brain development. It is therefore hardly surprising that growth and synaptic reorganization occur as a consequence of seizure activity. In experimental animals, this phenomenon has been studied in great detail in the hippocampus, although it can also be observed in extrahippocampal areas such as the entorhinal cortex (65) and the neocortex (95). In the hippocampus, mossy fiber axons of dentate granule cells grow new collaterals that innervate an abnormal lamina *(mossy fiber sprouting)* (96). It has been suggested that these connections are functional (97 ,98), but opinions are still divided on whether and to what extent they contribute to the precipitation of spontaneously recurring seizures (20 ,21 ,22 ,23 and 24).

Neurogenesis

Confirmation of neurogenesis in the adult mammalian nervous system has galvanized interest in the potential role of newly born cells in the mature brain. This issue may be of particular relevance to the study of epilepsy because neurogenesis is stimulated in adult animals after seizures. This has been documented in some detail in the hippocampus, where an increase in newly born dentate granule cells was detected in response to single seizures (99), kindling (100), or status epilepticus (101). In rats treated with pilocarpine, newly born granule cells develop intrinsic electrophysiologic properties that are identical to normal granule cells. However, the integration of these cells into the host circuitry appears to be different from adult granule cells, because they become synchronized with epileptiform activity in the CA3 cell layer (102). These studies indicate that cells born in response to seizures can become fully functioning neurons and may develop abnormal electrical activity.

More recent studies, although still somewhat controversial, have demonstrated that neurogenesis in the adult brain can also occur in the neocortex (103). Moreover, many newly born cells, possibly neurons, can also be detected in the entorhinal cortex of pilocarpine-treated rats (104). Rather than an isolated, region-specific phenomenon, the birth of new neurons in response to seizures may therefore take place in several parts of the limbic system and possibly elsewhere. Alone or together, these cells may eventually cause enhanced excitability and may decrease seizure threshold. It is tempting to speculate that this may underlie the heightened excitability in patients with cortical dysplasias, which can arise as a result of aberrant migration of newly born cells.

Transgenic Animals

The availability of transgenic mice has provided exciting new research opportunities for the study of MTLE. Thus, targeted genetic manipulation has permitted the detailed examination of the effects of changes in one specific gene product. This selectivity is particularly important in the study of epileptic phenomena, which are associated with many concurrent molecular and cellular changes. Transgenics may be engineered to overexpress or delete a given gene product, and recent techniques have made it possible to modify gene expression conditionally, that is, in a brain region– or age-specific fashion (105).

To name only one of several relevant examples, BDNF transgenics show increased excitability and, in some cases, exhibit spontaneous seizures. BDNF overexpression in these animals is most obvious in mossy fiber axons of dentate gyrus granule cells, and excitability is indeed increased in the postsynaptic targets of mossy fibers. However, BDNF is also overexpressed in other limbic regions such as the entorhinal cortex, and these areas, too, are hyperexcitable (94). These and qualitatively similar results from other genetically manipulated animals illustrate the value of this novel experimental approach for delineating the respective roles of the hippocampus and extrahippocampal areas in epileptogenesis and chronic epilepsy.

MTLE AS A NETWORK DISEASE: IMPLICATIONS FOR FURTHER RESEARCH AND THERAPY

Part of "127 - Temporal Lobe Epilepsy: Renewed Emphasis on Extrahippocampal Areas "

As briefly reviewed here, the available data indicate that both the hippocampus and interconnected extrahippocampal limbic regions play a role in the pathophysiology of MTLE (Fig. 127.4). Methodologic advances, ranging from novel and improved *in vivo* imaging techniques and neurosurgical approaches to increasingly sophisticated assessments of cellular physiology and chemistry, have resulted in a refinement of nineteenth-century concepts without fundamentally altering the major premises of Sommer and his contemporaries. In humans, any of a number of primary insults, such as severe febrile convulsions during childhood, head trauma, infections, tumors, or developmental malformations, have been proposed to be epileptogenic, leading to MTLE after a characteristic latency period. Studies in several new animal models have shown that these pathogenic injuries preferentially affect one or more limbic brain areas, including, but not necessarily limited to, hippocampus, entorhinal cortex, amygdala, thalamus, and neocortical regions. This neuronal injury or degeneration may constitute a major factor in the establishment of epileptogenic circuits within the limbic system and may cause further structural and functional changes. Eventually, after a “silent” interval characterized by functionally significant yet currently still unspecified changes, a hyperexcitable epileptogenic circuit develops, resulting in MTLE.

This concept of epileptogenesis and chronic limbic epilepsy has several ramifications for the treatment of MTLE. First, it is possible that the development of an epileptic circuit will be inhibited if the multiple changes in limbic

circuitry that follow the initial insult are minimized. Second, it raises the possibility that hippocampal or extrahippocampal interventions during the “silent” period may prevent the evolution of spontaneously recurring seizures. Third, it indicates that any of a number of limbic brain areas, or even certain neuronal populations within a given region, could conceivably be targeted for surgical or pharmacologic intervention.

Although the pathophysiologically important role of extrahippocampal brain regions in MTLE is supported by the successful outcome of various surgical interventions in patients with medically intractable epilepsy (5 ,9 ,10 ,14 ,15 and 16), several critical questions need to be resolved before the therapeutic approaches listed earlier can be adequately evaluated in clinical settings. For example, we need to clarify whether neuronal death, gliosis, and synaptic reorganizations promote or attenuate seizure evolution and whether, on the cellular level, pharmacologic or genetic manipulation of receptors and ion channels can influence the development of chronic hyperexcitability. Because circuit disruption is widespread throughout the limbic system, we need to elaborate those subcortical structures that are particularly effective in controlling seizure spread and generalization. Other studies will decipher cell- and region-specific and time-dependent changes in the composition of neurotransmitter receptors and of other proteins that determine the action of endogenous neuroactive agents. These analyses must be complemented by examining shifts in the concentration of endogenous neuromodulators that can alter neuronal excitability. To optimize the development of novel strategies for the treatment of MTLE, these molecular studies should be performed in parallel in extrahippocampal areas and in the hippocampal region whenever possible. This approach should eventually provide significant advances in the therapy of this debilitating disorder.

Section XIII
Chronobiology and Sleep Disorders

David J. Kupfer

David J. Kupfer: Department Of Psychiatry, University Of Pittsburgh Medical Center, Western Psychiatric Institute And Clinic, Pittsburgh, Pennsylvania.

Chronobiology and Sleep Disorders - Introduction

In this section on chronobiology and sleep disorders, the seven chapters describe considerable advances in this field since the *Fourth Generation of Progress* was published. This group of chapters seeks to integrate our basic and clinical knowledge and to convey the high level of current excitement in sleep and biological rhythm research. All these chapters present certain cross-cutting themes providing a basic and clinical integration of both primary sleep disorders and those disorders in which sleep alterations represent important aspects of serious neuropsychiatric disorders.

In Chapter 128, on basic mechanisms, Pace-Schott and Hobson add a wealth of new detail to our knowledge of the brain structures involved in the control of sleep and waking, as well as the cellular level mechanisms that orchestrate the sleep cycle by neuromodulation. This chapter focuses on the brainstem neuromodulatory systems and the more specific organization of those systems in controlling the alternation of wake, non–rapid eye movement (NREM) sleep, and REM sleep. Interactions of diverse neuromodulatory systems operate in widespread subcortical areas to amplify or suppress REM sleep generation, as well as to facilitate onset and offset of the control of behavioral state by the pontine REM-NREM oscillator. This existence of an executive aminergic-cholinergic reciprocal interaction system controlling REM-NREM alternation in the pontine brainstem has been strongly confirmed by recent findings.

In Chapter 129, Lewy discusses circadian phase sleep and mood disorders and covers the following areas: circadian anatomy and physiology; the shifting of circadian phase using bright light; an update on seasonal affective disorders; discussion of other circadian phase disorders such as shift work and jet lag; and, finally, a section on melatonin and circadian phase disorders. In this review, the author discusses phase typing sleep and mood disorders, including both advanced and delayed types, phase shifts with both bright light and melatonin administration, and whets our appetite on the considerable activity on melatonin research. Optimal dosing of melatonin will depend on minimizing its soporific side effect while maximizing its phase-shifting effects. This may entail using a low-dose sustained-release formulation to smooth out any sharp spikes in melatonin levels that appear to cause sleepiness in some people. Another useful product that we may look forward to is a delayed-release sustained-release formulation that can be taken at bedtime to produce increases in melatonin conveniently throughout the night.

Chapter 130, by Kloss, Szuba, and Dinges, covers sleep loss and sleepiness and reviews the four major types of sleep disorder: pathophysiology of difficulty initiating or maintaining sleep; pathophysiology of disorders of excessive somnolence; neurobehavioral and physiologic effects of sleep loss; and treatment for sleep loss and sleepiness. This chapter discusses the causes, consequences, and mechanisms of sleep disruption and concomitant daytime sequelae, namely, sleepiness and neurobehavioral performance decrements. Several advances in the psychopharmacologic and behavioral treatments of the causes and consequences of sleep loss have evolved. Technologies are rapidly developing and show promise for effective evaluation of these highly prevalent problems. The authors also present recent advances in assessment and prevention technology and go well beyond Multiple Sleep Latency Test (MSLT) and pupillometer evaluations. As examples, they also discuss the sleep switch and other operator-centered fatigue monitoring technologies.

Mignot and Nishino's Chapter 131, on the pathophysiologic and pharmacologic aspects of narcolepsy, provides an exciting

set of insights to the advances in this particular area. Narcolepsy is frequently both overdiagnosed and underdiagnosed. However, the condition is not rare and has a population prevalence similar to that of multiple sclerosis. With the availability of validated animal models and as the only known disorder with a complete disorganization of sleep and REM sleep, narcolepsy is also a unique disease model for basic sleep researchers. Our understanding of the pathophysiology of the disorder is rapidly emerging as a result of the discovery that narcolepsy or cataplexy is associated with a deficiency in the hypocretin (orexin) neuropeptide system. The discovery that a deficit in hypocretin neurotransmission, as revealed by cerebrospinal fluid hypocretin studies, frequently causes human narcolepsy opens the door to new diagnostic and therapeutic strategies. Measuring hypocretin levels in the cerebrospinal fluid or other biological fluids may soon be used as a diagnostic test for narcolepsy. The finding that human narcolepsy is HLA associated also suggests a possible autoimmune mediation in many cases.

In Chapter 132, Mendelson discusses certain basic mechanisms on how hypnotics act. Thus, we are beginning to have some insight into an early issue in sleep research: how administration of sedative-hypnotic compounds from such diverse pharmacologic classes can result in sleep induction. It appears that most or all of them produce their pharmacologic effects by altering the function of various moieties of the γ-aminobutyric $acid_A$ ($GABA_A$)-benzodiazepine receptor complex. One possibility that has received little attention has been that classic hypnotics such as benzodiazepines or barbiturates may alter the ascending histaminergic arousal system, which is presumably the mechanism by which antihistamines produce sedating effects. Certainly, one area of interest would be the tuberomamillary nucleus (TMN), which lies adjacent to the mamillary bodies, just above the ventral surface of the hypothalamus. Another focus for dysregulation in insomnia may involve the ventrolateral preoptic area (VLPO) and its interactions with the TMN in the posterior hypothalamus. The GABAergic VLPO has been identified as one of the few “sleep-active” areas of the brain; dysregulation in this nucleus and its efferent projections to histaminergic, cholinergic, and noradrenergic nuclei could conceivably shift the sleep-wake balance in the direction of wakefulness. In principle, benzodiazepine or other hypnotic compounds may act by enhancing GABAergic inhibition of the TMN and thereby decreasing its arousing effects.

In Chapter 133, Buysse and Dorsey provide a superb review on experimental therapeutics of insomnia. Although considerable progress has been made with regard to the epidemiology of insomnia, further work needs to be done regarding its consequences for health and role functioning. Persons with insomnia complain not only of sleep disturbance, but of daytime consequences as well. In addition, investigations into the neurobiology of insomnia are clearly needed. This will help to define the underlying pathophysiology of insomnia in the general sense, but it will also help to define the boundaries of specific insomnia disorders. Several issues also remain with regard to treatment aspects of insomnia. First, the relative benefits and risks of treatment in terms of symptomatic relief, health-related quality of life, and morbidity remain to be defined. These issues are of considerable importance, given the potential for some insomnia treatments to cause significant adverse effects, such as cognitive impairment and injurious falls. The optimal duration of treatment and the conceptualization of potential “maintenance” treatments for insomnia are also areas open for further investigation. With regard to behavioral treatments, one of the major challenges is designing well-manualized and “exportable” treatments that can be applied more readily in a variety of treatment settings, including primary care settings. Data from several studies examining the optimal combination of behavioral and medication treatment approaches suggest better durability of treatment effects with behavioral treatment alone. However, sequential treatments and concurrent treatments need to be investigated. In addition, treatment strategies for nonresponders to either behavioral or pharmacologic interventions must be developed.

The final chapter in this section, Chapter 134, reviews our current understanding of sleep disturbances associated with neuropsychiatric disease. Nofzinger and Keshavan provide a brief review of the advances relating basic research on sleep with clinical sleep findings in major neuropsychiatric diseases such as depression, schizophrenia, Alzheimer disease, and other disorders across the life span. As one of the earlier tools available to psychiatric research for discovering the biological basis of mental disorders, EEG sleep recordings have been used extensively to characterize alterations in brain function across diverse mental disorders. Newer tools available include refinements in electrophysiologic recordings using automated EEG and the concurrent use of electrical recordings of cognitive processes such as evoked responses to characterize changes in information processing during sleep in relation to mental disorders. Advances in functional neuroimaging could provide us with dynamic images of brain function as it makes transitions throughout the sleep-wake cycle. In this manner, the functional neuroanatomic basis of the electrophysiologic abnormalities could be determined, and interventions could be designed targeting not only specific neurotransmitter systems but also systems that are specific to a discrete brain region responsible for the sleep-wake disturbance.

128

Basic Mechanisms of Sleep: New Evidence on the Neuroanatomy and Neuromodulation of the NREM-REM Cycle

Edward F. Pace-Schott

J. Allan Hobson

Edward F. Pace-Schott and J. Allan Hobson: Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School. Boston, Massachusetts.

The 1990s brought a wealth of new detail to our knowledge of the brain structures involved in the control of sleep and waking and in the cellular level mechanisms that orchestrate the sleep cycle through neuromodulation. This chapter presents these new findings in the context of the general history of research on the brainstem neuromodulatory systems and the more specific organization of those systems in the control of the alternation of wake, non–rapid eye movement (NREM), and REM sleep.

Although the main focus of the chapter is on the our own model of reciprocal aminergic-cholinergic interaction, we review new data suggesting the involvement of many more chemically specific neuronal groups than can be accommodated by that model. We also extend our purview to the way in which the brainstem interacts with the forebrain. These considerations inform not only sleep-cycle control *per se*, but also the way that circadian and ultradian rhythms resonate to regulate human behavior including the intensity and form of conscious awareness.

RECIPROCAL INTERACTION AND ITS RECENT MODIFICATIONS

Part of "128 - Basic Mechanisms of Sleep: New Evidence on the Neuroanatomy and Neuromodulation of the NREM-REM Cycle "

Behavioral State–Dependent Variations in Neuromodulation

A paradigm shift in thinking about sleep-cycle control was forced by the discovery of the chemically specific neuromodulatory subsystems of the brainstem (for reviews, see refs. 1 ,2 ,3 and 4) and of their differential activity in waking (noradrenergic, serotonergic, and cholinergic systems on), NREM sleep (noradrenergic, serotonergic, and cholinergic systems damped), and REM sleep (noradrenergic and serotonergic systems off, cholinergic system undamped) (1 ,2 ,3 and 4).

Original Reciprocal Interaction Model: An Aminergic-Cholinergic Interplay

The model of reciprocal interaction (5) provided a theoretic framework for experimental interventions at the cellular and molecular level that has vindicated the notion that waking and REM sleep are at opposite ends of an aminergically dominant to cholinergically dominant neuromodulatory continuum, with NREM sleep holding an intermediate position (Fig. 128.1). The reciprocal interaction hypothesis (5) provided a description of the aminergic-cholinergic interplay at the synaptic level and a mathematic analysis of the dynamics of the neurobiological control system. In this section, we review ongoing recent findings of the essential roles of both acetylcholine (ACh) and the monoamines serotonin (5-HT) and norepinephrine (NE) in the control of the NREM-REM cycle as well as work that has led to the alteration (Fig. 128.2) and elaboration (Fig. 128.3) of the original reciprocal interaction model.

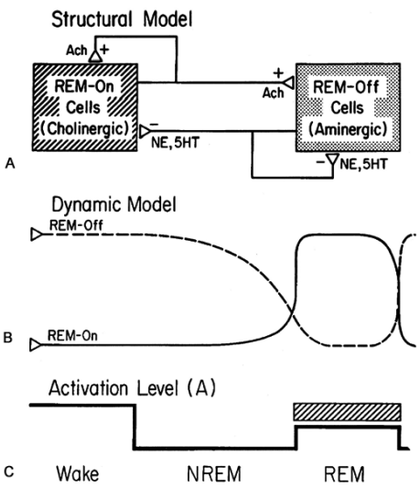

FIGURE 128.1. The original reciprocal interaction model of physiologic mechanisms determining alterations in activation level. **A:** Structural model of reciprocal interaction. REM-on cells of the pontine reticular formation are cholinoceptively excited or cholinergically excitatory (ACH+) at their synaptic endings. Pontine REM-off cells are noradrenergically (NE) or serotonergically (5-HT) inhibitory (-) at their synapses. **B:** Dynamic model. During waking, the pontine aminergic system is tonically activated and inhibits the pontine cholinergic system. During NREM sleep, aminergic inhibition gradually wanes, and cholinergic excitation reciprocally waxes. At REM sleep onset, aminergic inhibition is shut off, and cholinergic excitation reaches its high point. **C:** Activation level. As a consequence of the interplay of the neuronal systems shown in **A** and **B**, the net activation level of the brain **(A)** is at equally high levels in waking and REM sleep and at about half this peak level in NREM sleep. (From Hobson JA, Stickgold R, Pace-Schott EF. The neuropsychology of REM sleep dreaming. *Neuroreport* 1998;9:R1–R14, with permission.)

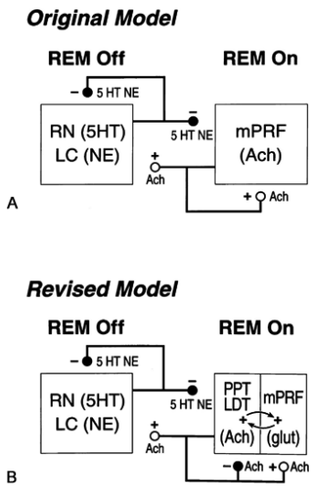

FIGURE 128.2. Synaptic modifications of the original reciprocal interaction model based on recent findings. **A:** The original model proposed by McCarley and Hobson (5). **B:** Synaptic modifications of the original reciprocal interaction model based on recent findings of self-inhibitory cholinergic autoreceptors in mesopontine cholinergic nuclei and excitatory interactions between mesopontine cholinergic and noncholinergic neurons (Fig. 128.3 and 128.4C, for more detail and references). The exponential magnification of cholinergic output predicted by the original model *(A)* can also occur in this model with mutually excitatory cholinergic-noncholinergic interactions taking the place of the previously postulated, mutually excitatory cholinergic-cholinergic interactions. In the revised model, inhibitory cholinergic autoreceptors would contribute to the inhibition of laterodorsal tegmental nucleus (LDT) and pedunculopontine tegmental nucleus (PPT) cholinergic neurons that is also caused by noradrenergic and serotonergic inputs to these nuclei. Therefore, the basic shape of reciprocal interaction's dynamic model (Fig. 128.1B) and its resultant alternation of behavioral state (Fig. 128.1C) could also result from the revised model. *Open circles*, excitatory postsynaptic potentials; *closed circles*, inhibitory postsynaptic potentials; Ach, acetylcholine; glut, glutamate; 5-HT, serotonin; LC, locus ceruleus; mPRF, medial pontine reticular formation; NE, norepinephrine; RN, dorsal raphe nucleus. (From Hobson JA, Stickgold R, Pace-Schott EF. The neuropsychology of REM sleep dreaming. *Neuroreport* 1998;9:R1–R14, with permission.)

Although there is abundant evidence for a cholinergic mechanism of REM-sleep generation centered in the pedunculopontine (PPT) and laterodorsal tegmental (LDT) nuclei of the mesopontine tegmentum (for reviews, see refs. 2 ,3 and 4 and 6 ,7 and 8), not all PPT-LDT neurons are cholinergic (9 ,10 ,11 and 12), and cortical ACh release may be as high during wakefulness as during sleep (13).

Recently, reciprocal interaction (5) and reciprocal inhibition (14) models for control of the REM-NREM sleep cycle by brainstem cholinergic and aminergic neurons have been questioned (10). Specifically, the hypothesized self-stimulatory role of ACh on those mesopontine neurons associated with the characteristic pontogeniculooccipital (PGO) waves

of REM sleep has not been confirmed in *in vitro* slice preparations of the rodent brainstem (10). For example, ACh has been shown to hyperpolarize cell membranes in slice preparations of the rodent parabrachial nucleus (15), LDT (16), and PPT (10). Similarly, those LDT-PPT neurons with burst discharge properties most like those hypothesized to occur in PGO-burst neurons (“type I” neurons) may not be cholinergic (9). Much evidence remains, however, that the reciprocal interaction model accurately describes essential elements of REM-NREM sleep-cycle control even though a few assumptions in its detailed synaptic mechanisms and connectivity are heuristic (see Fig. 128.2 and Fig. 128.3).

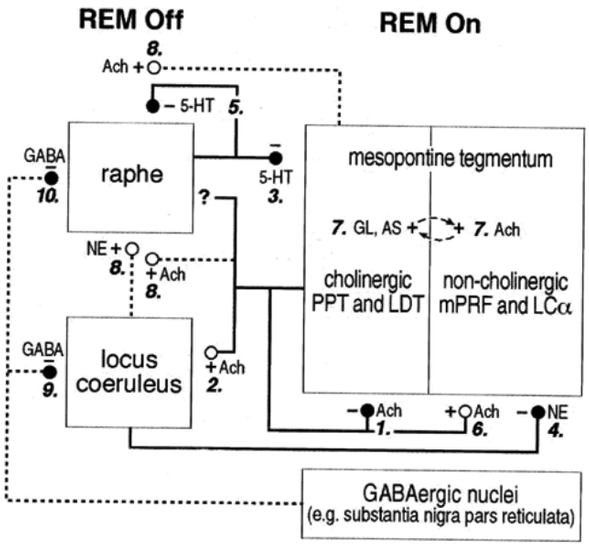

FIGURE 128.3. Additional synaptic details of the revised reciprocal interaction model shown in Fig. 128.2B derived from data reported *(solid lines)* and hypothesized relationships suggested *(dotted lines)* in recent experimental studies (numbered on figure and below). See the text for a discussion of these findings. Additional synaptic details can be superimposed on the revised reciprocal interaction model without altering the basic effects of aminergic and cholinergic influences on the REM sleep cycle. Excitatory cholinergic-noncholinergic interactions using acetylcholine (Ach) and the excitatory amino acid transmitters enhance firing of REM-on cells *(6* and *7)*, whereas inhibitory noradrenergic (4), serotonergic (3), and autoreceptor cholinergic (1) interactions suppress REM-on cells. Cholinergic effects on aminergic neurons are excitatory (2), as hypothesized in the original reciprocal interaction model, and they may also operate through presynaptic influences on noradrenergic-serotonergic as well as serotonergic-serotonergic circuits (8). GABAergic influences *(9* and *10)*, as well as other neurotransmitters such as adenosine and nitric oxide (see text), may contribute to the modulation of these interactions. *Open circles*, excitatory postsynaptic potentials; *closed circles*, inhibitory postsynaptic potentials; AS, aspartate; glut, glutamate; 5-HT, serotonin; LCa, peri-locus ceruleus α; LDT, laterodorsal tegmental nucleus; mPRF, medial pontine reticular formation; NE, norepinephrine; PPT, pedunculopontine tegmental nucleus. (For the specific references corresponding to the interactions numbered *1* to *10*, please refer to ref. 2.)

New Findings Supporting the Cholinergic Enhancement of REM Sleep

Numerous findings confirm the hypothesis that cholinergic mechanisms are essential to the generation of REM sleep and its physiologic signs (for reviews, see refs. 1 ,2 ,3 and 4 , 6 , 7 and 8 , 11 ,12 and 13 , 14 , 17 , and 18).

A selection of the many recent examples follows.

Experimental REM Sleep Induction and Suppression

Microinjection of cholinergic agonist (e.g., carbachol) or cholinesterase inhibitors into many areas of the paramedian pontine reticular formation (PRF) of the cat induces REM sleep (for reviews, see refs. 6 ,7 and 8). The endogenous ACh released into these areas originates in neurons of the mesopontine tegmentum (6). In addition to these short-term REM induction sites, carbachol injection into a more lateral pontine site in the caudal peribrachial area has been shown to induce long-term (more than 7 days) REM enhancement (19) and long-term PGO enhancement but without REM enhancement (20). *In vivo* cholinergic REM enhancement and a specific carbachol-sensitive site in the dorsal locus subceruleus of rats have been described (21).

In addition to the well-known suppression of REM by muscarinic antagonists (1), presynaptic anticholinergic agents have also been shown to block REM (22). Activation of muscarinic M2 receptors (M2AChR) in the pontine reticular formation has been shown to be the primary mechanism for REM induction with carbachol, and such activation has been shown to increase G-protein binding in brainstem nuclei associated with ACh release in the PRF and REM sleep (7, 23).

Cholinergic Neurons and REM Sleep

As reviewed by Semba (6), studies have demonstrated a physiologically meaningful heterogeneity among mesopontine neurons both *in vivo* and *in vitro*. In behaving cats and rats, separate populations of REM-and-wake-on, REM-on, and PGO wave–associated neurons can be identified in the LDT and PPT with strong evidence that a subset of these are cholinergic (6). In rodent brainstem slices, mesopontine neurons can be divided according to their membrane current characteristics into types I, II and III, with types II and III being cholinergic and projecting to the thalamus (6).

Many recent experimental findings associate REM sleep generation with mesopontine cholinergic neurons. For example, although type I bursting neurons are noncholinergic, cholinergic type II and III PPT-LDT neurons have firing properties that make them well suited for the *tonic* maintenance of REM (9). Three supportive experimental studies by Robert McCarley's group at Harvard (reviewed in ref. 2) are as follows: (a) PPT-LDT neurons specifically show immediate-early gene (e.g., *c-fos*) immunoreactivity after carbachol-induced REM sleep; (b) low-amplitude electrical stimulation of the LDT enhances subsequent REM sleep; and (c) electrical stimulation of the cholinergic LDT evokes excitatory postsynaptic potentials in PRF neurons that can be blocked by scopolamine. Finally, the excitatory amino acid, glutamate, when microinjected into the cholinergic PPT, increases REM sleep in a dose-dependent manner (24).

Acetylcholine Release and REM Sleep

Microdialysis studies show enhanced release of endogenous ACh in the medial PRF during natural REM sleep (25). Moreover, stimulation of the PPT causes increased ACh release in the PRF (26). Thalamic ACh concentration of mesopontine origin is higher in both wake and REM than

in NREM (27), and a REM-specific increase of ACh in the lateral geniculate body (LGB) has also been observed (28). Both muscarinic and nicotinic receptors participate in the depolarization of thalamic nuclei by the cholinergic brainstem (29).

Cholinergic Mediation of Specific REM Signs: PGO Waves, Muscle Atonia, Cortical Desynchronization, and Hippocampal Theta

PGO input to the LGB of the thalamus is cholinergic (12), and it can be antidromically traced to pontine PGO-burst neurons (30). In turn, stimulation of mesopontine neurons induces depolarization of cortically projecting thalamic neurons (29). Notably, retrograde tracers injected into the thalamus label 50% or more of cholinergic PPT-LDT neurons (31). Neurotoxic lesions of pontomesencephalic cholinergic neurons reduce the rate of PGO spiking (32), and PGO waves can be blocked by cholinergic antagonists (8). A long history of microinjection studies has shown that, at the level of the pons, cholinergic mechanisms at a variety of sites participate in the suppression of muscle tone accompanying REM (for review, see ref. 33). In addition to brainstem-mediated cholinergic mediation of PGO waves and atonia, cholinergic basal forebrain (BF) nuclei control other distinctive signs of REM including cortical desynchronization and hippocampal theta (see the section on the BF). It may therefore not be an exaggeration to state that the evidence of cholinergic REM sleep generation is now so overwhelming and so well accepted that this tenet of the reciprocal interaction model is an established principle.

New Findings Supporting the Serotonergic and Noradrenergic Suppression of REM Sleep

Aminergic Inhibition of the Cholinergic REM Generator

At the heart of the reciprocal interaction concept is the idea that cholinergic REM sleep generation can only occur when the noradrenergic and serotonergic mediators of waking release their inhibitory constraint of the cholinergic REM generator. The evidence for such inhibitory serotonergic and noradrenergic influences on cholinergic neurons and REM sleep is also now quite strong. (For reviews, see refs. 18 , 34 , and 35 for 5-HT and ref. 36 for NE.)

Serotonin in Natural REM Sleep

Serotonergic neurons from the dorsal raphe (DR) have been shown to synapse on LDT-PPT neurons (37). Extracellular levels of 5-HT are higher in waking than in NREM and higher in NREM than REM in the brainstem and cortex of rats (38) and the DR (39) and medial PRF (40) of cats. Moreover, reduced extracellular 5-HT concentration in REM sleep has been demonstrated in the human amygdala, hippocampus, orbitofrontal cortex, and cingulate cortex (41).

There is also strong evidence that specific physiologic signs of REM sleep are inhibited by endogenous 5-HT (34). For example, in sleeping cats, the firing of DR neurons is inversely correlated with the occurrence of PGO waves (34). Similarly, hippocampal theta activity, another specific sign of REM sleep, is suppressed by serotonergic activity of the median raphe nucleus (42).

Experimental Serotonergic Suppression of Cholinergic Systems and REM Sleep

Numerous experimental findings have shown that 5-HT and its agonists inhibit mesopontine cholinergic cells as well as REM sleep itself. For example, 5-HT has been shown both to hyperpolarize rat cholinergic LDT cells *in vitro* (10) and to reduce REM sleep percentage *in vivo* (43). Experimentally administered 5-HT has also been shown to suppress specific physiologic signs of REM. For example, 5-HT has been shown to counteract the REM-like carbachol-induced atonia of hypoglossal motor neurons (44).

Microinjection of the 5-HT agonist 8-OH-DPAT into the peribrachial region impedes PGO waves and REM sleep initiation in cats (45). Simultaneous unit recording has shown that microinjection of 8-OH-DPAT selectively suppressed the firing of REM-on but not REM-and-wake-on cells of the cholinergic LDT-PPT (46). *In-vivo* microdialysis of 5-HT agonists into the dorsal raphe nucleus (DRN) decreased DRN levels of serotonin (presumably by 5-HT autoreceptors on DRN cells) which, in turn, increased REM sleep percentage (47). Mesopontine injection of a 5-HT agonist depressed ACh release in the lateral genicolate body (28).

Such findings conclusively show brainstem involvement in the serotonergic suppression of REM sleep. However, localization of this effect solely to the brainstem has been challenged in favor of an amygdala-pontine interaction (48).

Suppression of REM by Endogenous Norepinephrine and Its Agonists

Much recent evidence also implicates NE in the inhibitory control of REM sleep. For example, locus ceruleus (LC) neurons have been shown to become quiescent during REM in the monkey (49), as well as in the cat and rat (1). Electrical stimulation of the pons in the vicinity of the (noradrenergic) LC reduced REM sleep in rats (50), and the noradrenergic antagonist idazoxan increases REM when injected into the PRF of cats (51).

Combined Effects of Serotonin and Norepinephrine on REM Sleep

The REM suppressive effects of 5-HT and NE are likely to be additive. This is suggested by the finding that reuptake

inhibitors targeting primarily either 5-HT or NE transporters all suppress REM sleep in humans (52). Unlike the other brainstem monoamines, the REM sleep effects of dopamine (DA) are more complex (see later).

Therefore, like cholinergic enhancement, aminergic suppression of REM sleep is now an established principle. The 5-HT_{1A} receptor may be of the greatest importance in the inhibition of cholinergic firing in the cat PPT (45) and LDT (53), and mesopontine postsynaptic 5-HT_{1A} receptors may be the active site for serotonergic inhibition of REM (35). Although 5-HT_2 receptors may also be involved in modulating the REM-NREM cycle, their roles are unclear because both 5-HT_2 agonists and 5-HT_2 antagonists suppress REM, whereas 5-HT_2 agonists suppress but 5-HT_2 antagonists increase slow-wave sleep (SWS) (35). Both α_1 (54) and α_2 receptors (55) may be sites of adrenergic REM suppression.

Modification of the Original Reciprocal Interaction Hypothesis to Accommodate New Findings

Modifications of simple reciprocal inhibition or interaction models, which are consonant with recent findings, have been proposed for the brainstem control of REM sleep. For example, Leonard and Llinas suggested in regard to the McCarley and Hobson (5) model that "… 'indirect feedback' excitation via cholinergic inhibition of an inhibitory input or cholinergic excitation of an excitatory input or some combination of the two could replace direct feedback excitation in their model" (10). Mutually excitatory or mutually inhibitory interactions between REM-on cholinergic and REM-on noncholinergic mesopontine neurons have also been proposed in the cat (11). Similarly, Semba suggested that naturally occurring REM sleep is instigated when cholinergic LDT-PPT neurons increase their cholinergic stimulation of PRF networks known to be associated with carbachol-induced REM (6). In turn, Semba suggested that PRF neurons may provide a glutamatergic, excitatory feedback to cholinergic neurons in the LDT-PPT thereby maintaining REM sleep (6). Representative hypothetical cholinergic-noncholinergic mechanisms are illustrated in Fig. 128.2B , Fig. 128.3 , and Fig. 128.4C-a . [**Please note** that, with regard to Fig. 128.4A–C , neuronal interactions will be identified in the subsequent main body of the text with *lower-case letters* (e.g., 128.4C-a) that also designate the corresponding excitatory or inhibitory synaptic interaction in the figure itself as well as designating this same interaction in the corresponding figure legend. The illustration of a particular synaptic interaction in a schematic of a particular behavioral state (i.e., Fig. 128.4A -wake, Fig. 128.4B -NREM sleep, and Fig. 128.4C -REM sleep), is not meant to imply that this interaction only occurs in this behavioral state. For example, many of the subcortical excitatory interactions associated with ascending forebrain arousal are shared by both waking and REM sleep (6).]

FIGURE 128.4. Critical neuromodulatory systems for the initiation and maintenance of the behavioral states of wake **(A)**, NREM sleep **(B)**, and REM sleep **(C)**. Illustrated circuits are those hypothesized to play executive roles in state initiation or maintenance or to mediate cardinal physiologic signs of that state (e.g., REM atonia). The major defining neuromodulatory features of each state are described, and the most important of these are depicted with the *heaviest lines* in diagrams. The exclusion of particular circuits in individual state diagrams does not imply that circuit's inactivity during that state, and illustration of a particular synaptic interaction in a particular behavioral state is not meant to imply that this interaction only occurs in this behavioral state. For example, much of the sleep-associated GABAergic neuronal inhibition illustrated in NREM **(B)** is probably maintained in REM **(C)**. Similarly, many of the subcortical excitatory interactions associated with ascending forebrain arousal are shared by both waking and REM sleep (6). Potentially influential peptidergic neuromodulation (e.g., VIP), and behavioral state–related changes in basal ganglia activity (see text) are left out for the sake of clarity. Finally, neuromodulatory changes occurring with the alternations of substages within NREM sleep are not illustrated. Details of neuronal interactions are provided in the text and are cross-referenced using lower-case letters appearing adjacent to the excitatory or inhibitory synaptic interaction illustrated in **A–C**. These neuronal interactions are also summarized at the end of each sublegend with a representative citation.

A: Wake: diverse ascending activation. During the wake state, the full complement of ascending arousal systems classified by Saper et al. (76) actively modulates the forebrain with the chemical products of their respective brainstem and diencephalic nuclei *(heavy lines in diagram)*, including: *serotonin* (5-HT) from the dorsal raphe (DRN) nucleus of the pons innervating the entire forebrain; *norepinephrine* (NE) from the locus ceruleus (LC) of the pons innervating the entire forebrain; dopamine (DA) from the ventral tegmental area (VTA) and substantia nigra pars compacta (SNpc) of the midbrain innervating the entire forebrain; *acetylcholine* (ACh) from the mesopontine laterodorsal tegmental and pedunculopontine nuclei (LDT-PPT), which chiefly modulates the diencephalon; and ACh from the magnocellular cholinergic cells of the basal forebrain that innervate limbic forebrain (e.g., medial septal area or MS to hippocampus) and the cortex (nucleus basalis of Meynert or NBM); *histamine* from the posterior hypothalamus, especially the tuberomamillary nucleus (TMN), which both promotes arousal of the entire forebrain and facilitates other ascending arousal systems in the brainstem; and *orexin* from the lateral hypothalamus that promotes arousal of the forebrain and brainstem arousal systems in a manner similar to histamine. *Selected neuronal interactions: a*, GABAergic inhibition promoting wakefulness versus REM (77); *b*, histaminergic and orexinergic activation of forebrain and brainstem (83,86); *c*, cholinergic activation of diencephalon (see also e) by mesopontine nuclei (6); *d*, cholinergic activation of limbic forebrain and cortex by basal forebrain nuclei (69); *e*, cholinergic innervation of hypothalamic structures by mesopontine nuclei (6); *f*, reciprocal inhibition by wake-promoting posterior hypothalamus of sleep-promoting anterior hypothalamic and basal forebrain nuclei (83); *g*, serotonergic, noradrenergic, and dopaminergic arousal of diencephalon, limbic forebrain, and neocortex by aminergic brainstem nuclei by both inhibitory and excitatory synapses; and *h*, GABAergic inhibition of sleep-promoting anterior hypothalamic ventrolateral preoptic area (VLPO) cells by basal forebrain and other anterior hypothalamic cells (83).

B: NREM sleep: widespread GABAergic inhibition. The attenuation of wake-associated arousal of the brainstem, diencephalon, limbic forebrain, and neocortex by ascending and descending cholinergic, noradrenergic, serotonergic, histaminergic, and orexinergic systems allows inhibitory GABAergic systems (heavy lines) to become prominent at various levels of the neuraxis. Maintained dopaminergic activation of the forebrain (61,62) is insufficient to maintain arousal sufficient to support wakefulness or REM sleep. At the thalamocortical level, such inhibition allows emergence of intrinsic oscillatory rhythms characterized in the EEG by sleep spindles, delta waves, and very slow (less than 1 Hz) oscillations (108). *Selected neuronal interactions: a*, GABAergic and galaninergic inhibition by the anterior hypothalamus (e.g., VLPO) of brainstem aminergic and cholinergic ascending arousal systems (195); *b*, GABAergic and galaninergic inhibition by the anterior hypothalamus (e.g., VLPO) of diencephalic aminergic (especially the histaminergic TMN) and cholinergic ascending arousal systems (83); *c*, high levels of extracellular adenosine accumulated during waking trigger sleep onset by inhibiting specific GABAergic basal forebrain cells that have, in turn, been inhibiting sleep-associated VLPO neurons during waking (83); *d*, extracellular adenosine accumulated during waking inhibits mesopontine cholinergic ascending activating systems (18); *e*, glycinergic midbrain and medullary cells exert tonic inhibition over pontine aminergic ascending activating systems (56); *f*, GABAergic inhibition of limbic and neocortical forebrain (56); *g*, extracellular adenosine accumulated during waking inhibits basal forebrain cholinergic ascending activating systems (18); and *h*, aminergic demodulation and GABAergic inhibition allows emergence of intrinsic thalamocortical oscillations (108).

C: REM sleep: selective cholinergic activation: During REM sleep, cholinergic activation of the forebrain from the brainstem (mesopontine) and basal forebrain ascend ing cholinergic systems is reinstated *(heavy lines)* in the absence of the aminergic (5-HT, NE, histamine) and orexinergic activation present during waking. Such selective cholinergic activation favors the distinctive forebrain-brainstem interactions of REM sleep in which internally generated ascending pseudosensory signals (e.g., pontogeniculooccipital or PGO waves) impinge on thalamocortical relay circuits and descending cortical and subcortical motor commands are blocked (3). Specific brainstem and basal forebrain circuits promoting the distinctive physiological features of REM sleep (cholinergic forebrain activation, PGO waves, skeletal muscle atonia, and rapid eye movements) are detailed in the text and are summarized here. *Selected neuronal interactions: a*, exponentially increasing activity of mesopontine PPT-LDT cholinergic neurons results in part from positive feedback *(heavy lines)* involving cholinergic excitation of pontine reticular formation (PRF) cells by the PPT-LDT and reciprocal glutamatergic excitation of the PPT-LDT by the PRF (6); *b*, GABAergic inhibition of pontine aminergic nuclei withdraws their inhibitory influence on PPT-LDT cholinergic cells (56) (see also *e*); *c*, cholinergic stimulation from the PPT-LDT enhances activity of midbrain dopaminergic cells (31), which, in turn, enhance cortical release of ACh (68); *d*, cholinergic activation of the limbic and neocortical forebrain by the basal forebrain occurs (69); *e*, additional inhibition of pontine aminergic (REM-off) nuclei by midbrain and medullary GABAergic neurons occurs (56); *f*, inhibition of spinal motor neurons by medullary glycinergic neurons is primary source of REM atonia (33); *g*, medullary glycinergic neurons are, in turn, activated by pontine glutamatergic and corticotropin-releasing factor (CRF)–ergic neurons (33); *h*, nitric oxide (NO) co-released from cholinergic cells facilitates self-activation of LDT-PPT (80); *i*, cholinergic activation of the thalamus by the LDT-PPT is facilitated by co-released NO (81); *j*, extracellular adenosine accumulated during waking provides additional inhibition of pontine aminergic (REM-off) nuclei (18); *k*, descending signals from the limbic forebrain may contribute to the initiation of REM by neuropeptidergic efferent projections to the mesopontine tegmentum from central nucleus (CN) of the amygdala (104); *l*, the LDT-PPT cholinergically stimulates basal forebrain glutamatergic cells, which, in turn, excite cholinergic basal forebrain neurons projecting to the limbic and neocortical forebrain (6); *m*, PRF glutamatergic neurons excite basal forebrain glutamatergic cells, which, in turn, excite cholinergic basal forebrain neurons projecting to the limbic and neocortical forebrain (6); and *n*, intrinsic basal forebrain glutamatergic cells excite cholinergic basal forebrain neurons projecting to the limbic and neocortical forebrain (69). SNpr, substantia nigra pars reticulata.

Other suggested modifications have invoked the contribution of inhibitory neuromodulators such as γ-aminobutyric acid (GABA) in the control of the REM-NREM cycle (for review, see ref. 56). For example, from *in vivo* microdialysis studies of GABA in the cat, Nitz and Siegel (57) suggested that GABA suppresses noradrenergic LC neurons during REM (Fig. 128.3 and Fig. 128.4C-b). Similarly, other investigators have suggested that GABAergic inhibition is responsible for the quiescence of serotonergic DR neurons during REM (34). The role of GABA in the suppression of aminergic neurons during REM sleep is strengthened by findings that natural concentrations of 5-HT in the DR during REM are decreased, thereby arguing against serotonergic DR self-inhibition by 5-HT_{1A} somatodendritic autoreceptors (35).

Still other modifications have caused investigators to postulate a role for presynaptic autoreceptors and heteroreceptors. For example, *in vitro* studies in the rat suggested the following modification of reciprocal interaction (58) (Fig. 128.3). During waking, presynaptic nicotinic facilitation of excitatory LC noradrenergic inputs to the DR enhances serotonergic firing. During REM, when the LC is silent, this same presynaptic nicotinic input may facilitate serotonergic self-inhibition by raphe neurons themselves. Notably, all such modifications retain one or both of the major tenets of the reciprocal interaction model: cholinergic facilitation and adrenergic inhibition of REM.

Many of the studies questioning reciprocal interaction or reciprocal inhibition (9 ,10 ,15 ,16) have been carried out on *in vitro* rodent models, and the relation of these findings to findings on the *in vivo* generation of REM sleep signs in the cat is only in its early stages (11). Moreover, the hyperpolarization by ACh of cholinergic cells (9 ,10 and 11 ,16 ,28 ,59) (Fig. 128.3) may result from recently identified ACh M2 autoreceptors that contribute to the homeostatic control of cholinergic activity (7 ,59).

In contrast to the hyperpolarization of some mesopontine cholinergic neurons by cholinergic agonists, many medial PRF neurons are depolarized by carbachol (6). This finding suggests that the exponential self-stimulatory activation that can be triggered by cholinergic stimulation in diverse mesopontine and medial pontine sites (1 ,2 ,3 and 4) may involve noncholinergic excitatory intermediary neurons. Such cholinergic self-regulation, combined with cholinergic-noncholinergic mutual excitation, is illustrated in Fig. 128.2B , Fig. 128.3 , and Fig. 128.4C-a .

Conclusions Regarding the Current Status of Reciprocal Interaction

We conclude that the two central ideas of the reciprocal interaction model are strongly supported by subsequent research: (a) noradrenergic and serotonergic influences enhance waking and impede REM by anticholinergic mechanisms; and (b) cholinergic mechanisms are essential to REM sleep and come into full play only when the serotonergic and

nbnoradrenergic systems are inhibited. Because many different synaptic mechanisms could mediate these effects, we now turn our attention to some intriguing possibilities.

OTHER NEUROTRANSMITTER SYSTEMS

Beyond the originally proposed cholinergic and aminergic neuronal populations, many additional neurotransmitter systems may participate in the neuromodulation of REM and NREM sleep. Since 1975, significant progress has been made in the identification of other chemically specific neuromodulatory systems showing differential activation with particular behavioral states or with specific physiologic signs within a behavioral state. These other neuromodulatory systems may interact with aminergic and cholinergic systems in the generation of REM sleep and its signs. We now discuss these new findings and the ways that they modify and extend the reciprocal interaction model, first in terms of the chemically specific systems and then in terms of the neuroanatomic networks subserving this physiology. In the following sections, we also address current findings on the diencephalic neuromodulation of NREM sleep and the wake-sleep transition.

Dopaminergic Systems

Given the key role of the other monoamines in the control of behavioral state and the powerful alerting effects of dopaminergic drugs, the potential role of DA in the control of the sleep-wake and the REM-NREM cycle has also been examined (see ref. 60 for review). DA release does not vary dramatically in phase with the natural sleep cycle as do 5-HT, NE, and ACh (61 ,62). However, REM sleep deprivation appears to enhance DA levels and DA receptor sensitivities (63).

Experimental manipulation of dopaminergic systems also gives varying results. For example, a DA agonist reduced REM sleep at low doses but enhanced it at higher ones (64), whereas a DA reuptake inhibitor had the opposite effect (65). In addition, although many human studies report REM suppression by DA reuptake inhibitors and indirect agonists (52 ,66), a DA-enhancing agent, bupropion, has been shown to human enhance REM sleep (67). Moreover, studies on the administration of dopaminergic drugs have suggested that DA may play a role in the induction or intensification of nightmares (60). Therefore, the effects of DA on sleep appear to be variable and are in much need of further study.

As is the case with many other neuromodulators, the sleep effects of DA may be mediated by dopaminergic effects on the aminergic and cholinergic systems involved in the executive control of the REM-NREM cycle. For example, DA has been shown to enhance cortical ACh release (68), whereas cholinergic mesopontine neurons have been shown to enhance mesolimbic DA release (31) (Fig. 128.4C-c). Such mutual facilitation between cholinergic and dopaminergic systems may serve to maintain or intensify REM sleep, especially given DA neurons' continued activity during REM (61 ,62) (Fig. 128.4C-c).

GABAergic Systems

Numerous findings have implicated GABA, the most ubiquitous central nervous system inhibitory neurotransmitter,

in the control of the sleep-wake and the REM-NREM cycle (8 ,17 ,56 ,57 ,69 ,70) (for reviews, see refs. 56 and 71). GABAergic inhibition has been hypothesized to play both REM-facilitory and REM-inhibitory roles in its mediation of executive circuits controlling the REM-NREM cycle. In addition, during NREM sleep, GABA has been hypothesized to play key roles in the deactivation of wake-related arousal systems and in the generation of intrinsic thalamocortical oscillations such as the slow oscillations of NREM sleep (see the later section on the thalamus).

REM-facilitory roles of GABA include inhibition of those aminergic neurons, which, in turn, exert tonic suppression of pontine cholinergic REM-generation networks. For example, during REM, GABA may suppresses noradrenergic LC (57) and serotonergic DR neurons (34 ,72) (Fig. 128.4C-b). In addition, iontophoretic injection of GABA antagonists into the LC induced increased LC neuronal activity in all behavioral states, with an especially dramatic rise seen during REM (56). GABA may regulate specific elements of REM activation such as PGO wave activity. For example, in the initial stages of PGO wave generation, GABAergic and glycinergic cells may inhibit aminergic cells and thus may release the cholinergic PGO-triggering or transmitting cells (8 ,17 ,56 ,57 ,71 ,72) (Fig. 128.4C-b).

The REM-inhibitory roles of GABA may include direct inhibition of these same pontine cholinergic REM-generation networks. More specifically, GABAergic afferents to the PPT and LDT originating in the substantia nigra pars reticulata or in GABAergic neurons of the mesopontine tegmentum itself may exert direct inhibitory influences on PGO-related cells of these nuclei (3 ,8 ,17) (Fig. 128.4B-a). For example, the spike-bursting pattern in pontine PGO-burst cells may be the result of excitatory signals impinging on cells that are tonically inhibited by GABA (70). Such excitatory signals may include corollary discharge from ocular premotor neurons commanding REMs (70).

GABAergic inhibition is also important in sleep-promoting dysfacilitation of the brainstem and diencephalic arousal networks that maintain wakefulness and prevent NREM sleep. For example, GABAergic cells of the BF may inhibit hypothalamic and brainstem arousal systems (73) (Fig. 128.4B-b), whereas GABAergic input from a variety of brainstem nuclei may be responsible for decreased activity of the LC and DR during SWS (56) (Fig. 128.4B-a). Similarly, sleep-active GABAergic cells of the VLPO of anterior hypothalamus may maintain or initiate sleep by inhibiting histaminergic arousal networks in the posterior hypothalamus (74 ,75 and 76) (Fig. 128.4B-b) as well as in the LC and DR (56) (Fig. 128.4B-a). Luppi et al. (56) proposed that although VLPO GABAergic neurons inhibit the LC and DR during SWS, a second population of GABAergic cells in midbrain and medulla are recruited to accomplish more complete LC-DR inhibition of REM (Fig. 128.4C-e).

In contrast to the foregoing sleep-promoting effects of GABAergic transmission in the diencephalon, it has been reported that a specific GABAergic mechanism in the nucleus pontis oralis of the cat PRF promotes wakefulness versus REM sleep (77) (Fig. 128.4A-a). Such opposing sleep effects highlight the regional heterogeneity of roles for GABAergic inhibition in modulating behavioral states.

Glycinergic Systems

Glycine, another inhibitory neurotransmitter, has also been shown to influence the neural mechanisms underlying the sleep-wake and REM-NREM cycles (8 ,56 ,78). As in the case of GABA, glycine may provide tonic inhibition of LC and DR neurons during all behavioral states; however, increased GABAergic inhibition of the LC may be more important in progressive deactivation during NREM (56). Like GABA, glycine may regulate specific physiologic manifestations of REM. For example, medullary glycinergic cells are responsible for the postsynaptic inhibition of somatic motor neurons during REM atonia (33 ,79) (Fig. 128.4C-f), and glycinergic inhibition may play a regulatory role in the premotor functions of the pons (79).

Glutamatergic Systems

Glutamate, the most ubiquitous central nervous system excitatory neurotransmitter, has also been shown to influence the sleep-wake and the REM-NREM cycles (3 ,11 ,24 ,33). Semba (6) summarized evidence for excitatory glutamatergic input to the mesopontine tegmentum from the medial prefrontal cortex, from co-release by mesopontine cholinergic neurons themselves, from the PRF, and from the subthalamic nucleus (Fig. 128.4C-a). As described earlier in the section on modification of the original reciprocal interaction hypothesis, such glutamatergic excitation (Fig. 128.2B , Fig. 128.3 , and Fig. 128.4C-a) may widely interact with cholinergic and cholinoceptive neurons to generate the exponential increase of mesopontine and pontine reticular activity associated with REM sleep activation (2 ,6 ,11). Pontine glutamatergic cells may transmit REM sleep atonia-related signals to medullary sites (Fig. 128.4C-g), where they may then activate inhibitory glycinergic as well as GABAergic cells, which, in turn, suppress somatic motor neurons (3 ,33 ,79).

Nitroxergic Systems

The diffusible gaseous transmitter nitric oxide (NO) has been widely implicated in sleep-cycle modulation (for review, see ref. 80). NO is hypothesized to function primarily as an intercellular messenger capable of diffusing into and producing a wide variety of physiologic effects on neighboring cells including enhanced synaptic transmission through enhanced release of neurotransmitter (80). One such neurotransmitter

is ACh (80). NO is co-produced by all cholinergic neurons of the LDT and PPT (80), and inhibition of the NO synthesizing enzyme in the PRF both decreased ACh release and attenuated both natural and ACh-agonist–induced REM sleep (80). Leonard and Lydic (80) suggested that pontine NO thereby serves an important role in maintaining the cholinergically mediated REM sleep state (Fig. 128.4C-h).

Both natural and experimentally increased activity of mesopontine cholinergic neurons results in increased NO release in the thalamus (81) (Fig. 128.4C-i). NO has been shown to enhance capillary vasodilation (80), and, given its co-release with ACh, this has important implications for cholinergically mediated changes in regional blood flow during REM (see later).

Histaminergic Systems

The histaminergic arousal system, originating in neurons of the posterior hypothalamus, is fully discussed in terms of its role in the hypothalamic mediation of the sleep-wake cycle in the following neuroanatomic section. In brief, projections of this system innervate the entire forebrain (Fig. 128.4A-b) and have reciprocal projections to brainstem regions known to be involved in behavioral state control such as the mesopontine tegmentum (82). Histamine is a wake-promoting substance, and experimental lesions of histaminergic nuclei in the posterior hypothalamus such as the tuberomamilary nucleus (TMN) result in hypersomnolence (83). Moreover, microinjection of histamine or histamine agonist into the mesopontine tegmentum results in an increase in waking (82). In turn, there exists strong evidence that, during sleep, wake-active posterior hypothalamic histaminergic neurons are themselves tonically inhibited by GABAergic and galaninergic projections from the anterior hypothalamus and adjacent BF (75 ,76 ,83) (for reviews on histaminergic influences in sleep, see refs. 76 and 83) (Fig. 128.4A-b).

Adenosinergic Systems

Adenosine has received much experimental attention as a probable physiologically important endogenous somnogen (84). Adenosine has been shown to exert multiple effects on behavioral state (18 ,84). For example, adenosine may exert tonic inhibition over the glutamatergic excitatory inputs to the cholinergic cells of the LDT and PPT (18 ,85) (Fig. 128.4B-d), and it may contribute to the REM-related suppression of serotonergic raphe neurons (18) (Fig. 128.4C-j). In addition, adenosine may exert tonic inhibition over BF cholinergic neurons (18). Finally, as noted, extracellular buildup of adenosine may constitute the sleep-promoting factor associated with prolonged wakefulness (18 ,84) (Fig. 128.4B-c).

Neuropeptidergic Systems

Many different neuropeptides have been implicated in regulation of the sleep-wake and REM-NREM cycles. These include galanin (75 ,76) (Fig. 128.4B-b), orexin (86 ,87) (Fig. 128.4A-b), vasoactive intestinal polypeptide (VIP), and numerous hormones (33 ,48 ,88) (Fig. 128.4C-g) (for reviews, see ref. 89 for the cytokines, ref. 90 for hormonal influences, and ref. 88 for VIP).

Many such neuropeptides have, like adenosine, been proposed to be endogenous sleep substances whose accumulation over prolonged waking promotes sleep onset (for review, see ref. 89). As noted by Kreuger and Fang (89), there is especially strong evidence for specific promotion of NREM by tumor necrosis factor, interleukin 1, growth hormone–releasing hormone, and prostaglandin D_2 as well as for promotion of REM by VIP and prolactin. Other neuropeptides such as atriopeptin, bombesin, corticotropinreleasing factor, and substance P are released from mesopontine cholinergic terminals, and these may, in turn, modify the sleep regulatory effects of co-released ACh (reviewed in ref. 6).

Three findings highlight the importance of neuropeptides in the regulation of sleep. The first is that inhibitory neurons in the VLPO of the hypothalamus, a specifically sleep-active area (74), use galanin as well as GABA to inhibit ascending arousal systems such as the LC (75 ,76) (Fig. 128.4B-a). As noted by Shiromani et al. (83), the association of galanin with NREM is particularly significant because this neuropeptide also stimulates release of growth hormone from the pituitary and may therefore play an important role in the pulsatile release of growth hormone specifically associated with NREM SWS. The second is the demonstration that corticotropin-releasing factor participates in the pontomedullary control of REM atonia (33) (Fig. 128.4C-g). The third finding has come from studies on the genetic basis of narcolepsy using animal models. The neuropeptide orexin (or hypocretin), produced only by neurons in the lateral hypothalamus, may play a key role in sleep regulation by its modulation of ascending cholinergic and monoaminergic arousal systems (86 ,87) (Fig. 128.4A-b).

Second Messengers and Intranuclear Events

As in much of neuroscience, research on behavioral state control is now beginning to extend its inquiry beyond the neurotransmitter and its receptors to the roles of intracellular second messengers (7), as well as intranuclear events (91). Results of the molecular genetic approach to sleep research include the discovery of the role of orexin in sleep regulation (see earlier) and the discovery that choline acetyltransferase mRNA levels show behavioral state dependency in the rat (92). As noted by Shiromani et al. (83), the experimental observation of behavioral state dependent immediate early

gene expression in hypothalamic cells indicates that intranuclear events must participate in the control of sleep-wake cycles.

NEUROANATOMY OF REM-NREM CONTROL SYSTEMS

Part of "128 - Basic Mechanisms of Sleep: New Evidence on the Neuroanatomy and Neuromodulation of the NREM-REM Cycle "

At the same time that sleep studies have probed more and more deeply, to the cell membrane and beyond, efforts to understand the mechanisms of state control at a more global and regional level have continued. The picture that we are attempting to sketch is designed to provide an integrating framework for the analytic studies just reviewed. A major breakthrough in the regional brain research effort has been provided by the explosive growth of imaging studies of the human brain. This work provides still another bridge for integration: Now for the first time, we can begin to relate the cellular and molecular-level data from animals to the regional data in humans. This comparison is of particular relevance to dream theory and psychopathology.

Brainstem Executive Control of the REM-NREM Cycle

In the pons, cholinergic, serotonergic, noradrenergic, glutamatergic, and GABAergic neurotransmission among the LDT and PPT (containing cholinergic cells), the DRN (mainly serotonergic), and the LC (mainly noradrenergic) forms the core circuits for the executive control of the REM-NREM cycle (for reviews, see refs. 1 ,2 ,3 and 4 , 6 , 8 , and 17) (Fig. 128.4B and C).

In the EEG-aroused states of REM and waking, the LDT and PPT provide a large proportion of the excitatory cholinergic input to both the thalamus and the BF (Fig. 128.4A-c), which then activate limbic structures and the cortex (6) (Fig. 128.4A-d). Expression of the physiologic signs of REM is, however, modifiable at diverse sites both rostral and caudal to these executive networks, as detailed later. For example, in addition to inputs from the DRN and LC, the LDT-PPT also receives projections from limbic forebrain structures (6) and the basal ganglia (93) (Fig. 128.4C-k). Moreover, in the control of sleep onset, the physiologic features of NREM sleep, and circadian control of the sleep-wake cycle, diencephalic structures come to be of primary importance (Fig. 128.4A and B).

Other Brainstem Structures

Many different brainstem structures in addition to LDT-PPT cholinergic cells and the LC and raphe nuclei are crucially involved in the modulation of REM sleep and its distinctive physiologic signs. These include noncholinergic areas within the PPT-LDT as well as peribrachial areas caudal to the LDT and PPT in the cat (8), diverse cholinoceptive areas in the medial pontine reticular system such as the nucleus pontis oralis of the rat (33), and the gigantocellular tegmental field and LC α of the cat (7 ,14). Adding to the functional complexity of mesopontine cholinergic areas are its important roles in functions other than behavioral state control such as motor control (106).

Structures rostral and caudal to the pons such as the ventrolateral periaqueductal gray (56 ,94) and the medulla (33 ,79) also play key roles in the transmission and modulation of the physiologic signs of REM sleep. For example, sleep-associated inhibition of LC and DR by glycinergic input originates in the periaqueductal gray, the midbrain reticular formation, and various medullary sites (e.g., raphe magnus, gigantocellular α, paragigantocellular nuclei) (Fig. 128.4B-e), whereas GABAergic inhibition originates in an even more diverse set of brainstem and diencephalic regions (56) (Fig. 128.4B-a). Similarly, REM-associated postural atonia involves brainstem networks extending rostrally from midbrain areas such as the periaqueductal gray, through the mesopontine PPT, through the pontine inhibitory area and peri-LC areas to the medullary nucleus magnocellularis, and thence to spinal motor neurons caudally (33) (Fig. 128.4C-f,g). Brainstem structures rostral to the pons could facilitate brainstem-limbic interactions in REM sleep (see later) such as those also hypothesized to contribute to REM-related atonia (33).

Figure 128.4A to C schematizes major neuromodulatory systems involved in the generation and maintenance of the three cardinal behavioral states at different levels of the central nervous system. (For reviews on the functional neuroanatomy of brainstem control of sleep cycles, see refs. 1 ,2 ,3 and 4 , 6 , 8 , 14 , 17 , 56 , and 79 .)

Forebrain Structures

Other important contemporary research now extends the study of sleep-wake and REM sleep control mechanisms rostrally from the pontine brainstem to diencephalic structures in a manner consistent with connectivity studies (48). In addition to the well-described brainstem-thalamus-cortex axis, subcortical sleep control mechanisms intercommunicate with each other and with the cortex through an interconnected network of structures extending rostrally from the brainstem RAS to the hypothalamus, BF, and limbic system.

Saper et al. (76) classified three ascending arousal systems: the brainstem cortical projection system (including DR serotonergic, LC noradrenergic, and LDT-PPT cholinergic elements), the cholinergic BF projection system, and the histaminergic hypothalamic cortical projection system. The BF system projects to topographically specific cortical areas, whereas the other systems project diffusely to widespread areas of the forebrain.

We now briefly summarize recent findings on this extended

subcortical system that are pertinent to sleep-wake and REM sleep control. We focus here on findings in the hypothalamus, BF nuclei, amygdala, thalamus, and basal ganglia.

Hypothalamus

Histaminergic neurons originating in the posterior hypothalamus innervate virtually the entire brain including brainstem structures such as the mesopontine tegmentum (82) (Fig. 128.4A-b). These brainstem regions, in turn, innervate both anterior and posterior hypothalamus (82 ,83) (Fig. 128.4A-e).

Anterior portions of the hypothalamus (preoptic area and adjacent BF) are known to be essential to promoting sleep (73 ,76 ,82 ,83). In contrast, tonic firing of histaminergic neurons in the posterior hypothalamus play an important role in cortical arousal and the maintenance of wakefulness (for reviews, see refs. 76 and 83) (Fig. 128.4A-b). The TMN plays a particularly important role in this posterior hypothalamic histaminergic arousal system, and these neurons have been shown to decrease their firing during sleep (74 ,76 ,83).

Sherin et al. (74) proposed that a monosynaptic pathway in the hypothalamus may constitute a “switch” for the alternation of sleep and wakefulness. Using immediate early gene (*c-fos*) techniques, these workers identified a group of GABAergic and galaninergic neurons in the VLPO, which are specifically activated by sleep (74) and have since been shown to be selectively sleep active using electrophysiology (83). These GABAergic and galaninergic VLPO neurons constitute the main source of innervation to the histaminergic neurons of the TMN (Fig. 128.4B-b) and may therefore specifically inhibit histaminergic neurons of the TMN to preserve sleep (74 ,75 and 76).

One study demonstrated extensive histaminergic innervation of the mesopontine tegmentum including the LDT (82) (Fig. 128.4A-b). Suppression of slow-wave activity and an increase in waking followed microinjection of histamine and histamine agonist into these areas (82). Histaminergic projections from the TMN to areas of the BF involved in sleep-wake control (Fig. 128.4A-b) were also demonstrated in the cat (95). VLPO neurons were also shown to innervate other components of ascending arousal systems such as the monoaminergic nuclei of the brainstem (Fig. 128.4B-b), and there they may also exert a sleep-promoting inhibitory influence (75 ,95). An important finding is that the orexinergic cells of the lateral hypothalamus also innervate most of the brainstem and diencephalic ascending arousal systems (Fig. 128.4A-b), and, therefore, these may also play a modulatory role in the sleep-wake cycle (86 ,87).

Combining the foregoing findings with evidence of the somnogenic effects of adenosine, Shiromani et al. (83) proposed the following model for the control of the wake-NREM transition and its link to the ultradian REM-NREM cycle, detailed here and illustrated in Fig. 128.5 :

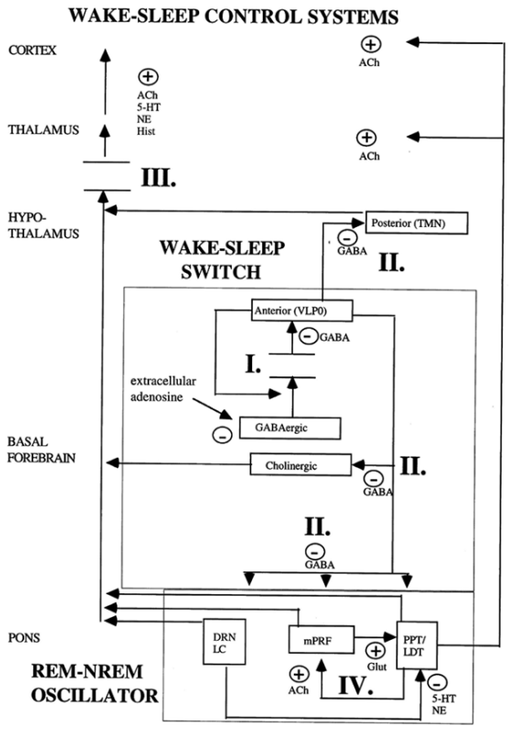

FIGURE 128.5. Integrated model of sleep onset and REM-NREM oscillation proposed by Shiromani et al. (83). *I*, During prolonged wakefulness, accumulating adenosine inhibits specific GABAergic anterior hypothalamic and basal forebrain neurons that have been inhibiting the sleep-active ventrolateral preoptic area (VLPO) neurons during waking. *II*, Disinhibited sleep-active GABAergic neurons of the VLPO and adjacent structures then inhibit the wake-active histaminergic neurons of the tuberomamillary nucleus (TMN), as well as those of the pontine aminergic (DRN and LC) and cholinergic (LDT-PPT) ascending arousal systems thereby initiating NREM sleep. *III*, Forebrain activation by ascending aminergic and orexinergic arousal systems is dysfacilitated. *IV*, Once NREM sleep is thus established, the executive networks of the pons initiate and maintain the ultradian REM-NREM cycle. ACh, acetylcholine; DRN, dorsal raphe nucleus; 5-HT, serotonin; LC, locus ceruleus; LDT, laterodorsal tegmental nucleus; NE, norepinephrine; PRF, pontine reticular formation.

Figure 128.5I : During prolonged wakefulness, accumulating adenosine inhibits specific GABAergic anterior hypothalamic and BF neurons that have been inhibiting the sleep-active VLPO neurons during waking (Fig. 128.4A-h). During waking, TMN neurons may also reciprocally inhibit sleep-active neurons of the anterior hypothalamus and BF (Fig. 128.4A-f).

Figure 128.5II : The thus disinhibited sleep-active GABAergic neurons of the VLPO and adjacent structures then inhibit the wake-active histaminergic neurons of the TMN as well as those of the pontine aminergic (DR and LC) and cholinergic (LDT-PPT) ascending arousal systems, thereby initiating NREM sleep.

Figure 128.5III : Forebrain activation by these ascending arousal systems (Fig. 128.4A-b,c,g) is thus dysfacilitated.

Figure 128.5IV : Once NREM sleep is thus established, the executive networks of the pons initiate and maintain the ultradian REM-NREM cycle described by reciprocal interaction.

Tying the hypothalamus to the pons in this dynamic manner may provide a critical link between the circadian clock in the suprachiasmatic nucleus and the NREM-REM sleep cycle oscillator (83). The circadian control of sleep by the suprachiasmatic nucleus is beyond the scope of this review but constitutes a key influence not only on the sleep wake alternation but also on shorter-period oscillations such as the ultradian REM-NREM alternation (96). (For a comprehensive review of circadian rhythms and the suprachiasmatic nucleus in sleep-wake regulation, see ref. 97 .)

Basal Forebrain

BF nuclei have anatomic connections with the LC, raphe, and pontine nuclei (69 ,73) and, in turn, project to more rostral structures such as the cortex, thalamus, and limbic systems (69 ,98). In addition to its brainstem and cortical connectivity, the BF also has anatomic connections with the anterior and posterior hypothalamus, the amygdala, and the thalamus (73). (For reviews of BF connectivity see refs. 69 and 73 .)

Neurochemically, ACh plays a major role in BF control of behavioral state chiefly by its activating effects on the cortex and other forebrain structures (69). Magnocellular cholinergic cells of the BF nuclei promote the activation of those cortical and limbic structures to which they project (69 ,73 ,98) (Fig. 128.4A-d). For example, cholinergic cells of the nucleus basalis of Meynert activate topographically distinct areas of the cortex (69 ,73 ,98), and cholinergic activity of the medium septum and vertical limb of the diagonal band of Broca mediates hippocampal theta rhythm (42).

There are extensive functional interactions between the brainstem structures (LC, raphe nuclei, LDT-PPT) and the

BF in sleep-wake control (6 ,69 ,73). The PPT-LDT provides a major source of excitatory input to the BF (6) (Fig. 128.4C-l). For example, Shiromani et al. (83) showed that PPT stimulation induces *c-fos* expression in a variety of BF nuclei. Similarly, PPT-LDT neurons were shown to release ACh into the BF of rats (99).

Glutamatergic activation is an important transmitter of reciprocal activation between the brainstem and the BF (Fig. 128.4C-m). For example, BF structures that activate the cortex can be activated by brainstem glutamatergic cells (100), the cortical EEG activation produced by cholinergic mesopontine stimulation of the BF is transmitted within the BF by glutamatergic (versus cholinergic) mechanisms (6) (Fig. 128.4C-n), and glutamatergic systems of the BF can, in turn, affect brainstem behavioral state modulation through projections to the mesopontine tegmentum (101).

In concert with closely related anterior hypothalamic cells such as those of the VLPO, specifically sleep-active BF cells (anatomically and neurochemically distinct from the wake-REM active cholinergic magnocellular neurons) function as NREM sleep-promoting elements (73 ,83). This may occur by GABAergic inhibition of posterior hypothalamic (Fig. 128.4B-b) and brainstem (Fig. 128.4B-a) arousal systems (73 ,74 and 75) as well as of more rostral structures (69) (Fig. 128.4B-f).

In addition to their role in cortical activation and desynchronization (Fig. 128.4A-d and Fig. 128.4C-d), BF neurons have been associated with the specific physiologic features of NREM sleep. For example, although BF lesions can cause the emergence of slow waves (102), magnocellular cholinergic neurons may also participate in the generation of cortical slow waves (103).

As in the brainstem, neuromodulatory systems interact within the BF itself (e.g., the foregoing BF cholinergic-glutamatergic interactions). For example, BF cholinergic neurons may be under tonic inhibition by adenosine (18) (Fig. 128.4B-g). The BF nuclei therefore both directly participate in behavioral state-related functions and modify the activity of other areas involved in sleep such as the pontine REM generator.

Amygdala

Of particular interest in view of recent findings from human neuroimaging studies (see ref. 3 for review), the amygdala has reciprocal connections with pontine regions involved in the control of REM sleep (for reviews, see refs. 48 and 104).

Physiologic signs of REM have been shown to occur spontaneously in the amygdala and in other limbic structures (104). For example, in the cat, PGO-like EEG activity has been detected in the basolateral amygdala, and single-unit activity in the central nucleus (CN) of the amygdala increases during NREM sleep immediately preceding REM (variously termed the “transitional stage,” “SP,” or “SPHOL”) and then increases further during actual REM (104). In addition, amygdalar lesions in the cat have been shown to decrease PGO frequency (104).

Physiologic signs of REM are also modifiable from the amygdala. For example, electrical stimulation of the cat amygdala significantly increased PGO number, spike density, and burst density (104). In addition, cholinergic stimulation of the cat CN enhanced REM sleep for several days by an increased number of REM episodes, an effect akin to the long-term REM enhancement by cholinergic stimulation of the peribrachial pons (104). Moreover, cholinergic stimulation of the CN concomitantly increased PGO density (104). Amygdalar stimulation also increased the amplitude and rate of acoustically elicited pontine PGO waves in the waking rat and burst firing of pontine cells in the rabbit (48).

Aminergic stimulation of the amygdala has also been shown to modify sleep in the direction predicted by reciprocal interaction for pontine sites. For example, serotonergic stimulation of the amygdala in the cat caused short latency changes of state from either NREM or REM (48). Similarly, noradrenergic stimulation of the amygdala suppressed sleep relative to wakefulness (48).

It has therefore been proposed, by Morrison et al. (48) and by Calvo and Simon-Arceo (104), that the amygdala (and, in particular, the CN) stimulates lateral pontine areas involved in REM sleep initiation (Fig. 128.4C-k) that, in turn, initiate REM sleep. However, the continuation of REM-NREM cycling in the pontine cat (2) obviates an obligatory role for amygdalar stimulation of the pons in the initiation of REM, at least in the cat.

Thalamic Structures and Intrinsic Thalamocortical Oscillatory Rhythms

Dysfacilitation of thalamocortical relay neurons after sleep onset allows the emergence of underlying thalamocortical oscillatory rhythms (for reviews, see refs. 127 and 128) (Fig. 128.4B-h). GABAergic neurons of the thalamic reticular nucleus hyperpolarize and dysfacilitate thalamic relay neurons as NREM deepens (127,128). In this hyperpolarized condition, thalamic neurons become constrained to burst-firing patterns first in spindle (12 to 14 Hz) and later in delta (1 to 4 Hz) frequencies as NREM deepens from stage 2 to delta sleep (127,128). The cortex may further constrain these spindle and delta wave–generating thalamocortical bursts within a newly described slow (less than 1 Hz) oscillation seen in cats (127,128) and humans (106).

Mesopontine cholinergic neurons provide a major excitatory input to the thalamus during the EEG activated states of wakefulness and NREM sleep and, during REM, cholinergic excitation alone may prevent the emergence of intrinsic thalamocortical oscillations (6). Findings that ascending cholinergic input from the mesopontine tegmentum influences thalamic blood flow (109) and thalamic NO release (81) (Fig. 128.4C-i) are of particular interest in light of positron emission tomography neuroimaging studies showing a REM-associated increased thalamic blood flow (reviewed in ref. 3). Other thalamic structures such as centralis lateralis nucleus possibly participate directly in the modulation of REM sleep (110).

Basal Ganglia

Although receiving less focus in past experimental studies of sleep in animals, the extensive activation of basal ganglia and related structures in positron emission tomography neuroimaging studies of human REM sleep suggests their involvement in the neural networks subserving this behavioral state (reviewed in ref. 3). There are extensive reciprocal projections between the basal ganglia and the PPT region (3 ,193). This connectivity has been postulated to subserve several specific roles. For example, Allan Braun and colleagues at the National Institutes of Health in Bethesda, Maryland suggested that the basal ganglia may play a role in the rostral transmission of PGO waves (reviewed in ref. 2), whereas Rye (3) suggested that striatal projections to the pedunculopontine region may serve to modulate movement to accord with behavioral state. Additional possibilities are suggested by the extensive activation of the ventral striatum and surrounding BF in REM (reviewed in ref. 2). For example,

Eric Nofzinger and colleagues at the University of Pittsburgh suggested that an important function of REM sleep is the integration of neocortical function with BF and hypothalamic motivational and reward mechanisms (reviewed in ref. 2).

CONCLUSIONS

Part of "128 - Basic Mechanisms of Sleep: New Evidence on the Neuroanatomy and Neuromodulation of the NREM-REM Cycle "

Interactions of diverse neuromodulatory systems operate in widespread subcortical areas to amplify or suppress REM sleep generation as well as to facilitate onset and offset of the control of behavioral state by the pontine REM-NREM oscillator. An ascending medial brainstem and diencephalic system of multiple nuclei with extensive reciprocal interconnections and system-wide sensitivity to neuromodulation controls the regular alternation and integration of the sleep-wake and REM-NREM cycles. The existence an executive aminergic-cholinergic reciprocal interaction system controlling REM-NREM alternation in the pontine brainstem has been strongly confirmed by recent findings. The interaction of pontine structures with other brain structures can now begin to be studied in ways that will enrich our understanding of how the distinctive features of each conscious state are mediated and how their stereotyped sequencing is controlled.

CIRCADIAN ANATOMY AND PHYSIOLOGY

Part of "129 - Circadian Phase Sleep and Mood Disorders "

Anatomy

The Suprachiasmatic Nucleus: Locus of the Biological Clock

Much is known about the neuroanatomic connections of the circadian system. In vertebrates, the locus of the biological clock (the endogenous circadian pacemaker, or ECP) that drives all circadian rhythms is in the hypothalamus, specifically, the suprachiasmatic nucleus (SCN) (1 ,2). This paired structure derives its name because it lies just above the optic chiasm. It contains about 10,000 neurons. The molecular mechanisms of the SCN are an active area of research. There is also a great deal of interest in clock genes and clock components of cells in general, not just in the SCN. The journal *Science* designated clock genes as the second most important breakthrough for the recent year; the year before it was also on the runner-up list. Although clock genes may endow most, if not all, cells with the capacity for circadian time keeping, only the SCN is an endogenous pacemaker. That is, only the SCN receives environmental time cues. In turn, the SCN passes on temporal information to the cells of the rest of the organism.

The Retinohypothalamic Tract: Pathway for Photic Effects

The SCN is sensitive to environmental time cues in the form of photic impulses that are conveyed from the retina via a specific neural pathway, the retinohypothalamic tract (RHT). The RHT is a separate pathway from that which mediates vision (3); however, bilateral enucleation causes circadian blindness, just as it causes visual blindness.

SCN Efferent Pathways

Not much is known about how the SCN entrains overt circadian rhythms. We know that the SCN is the master pacemaker, but regarding its regulation of the rest/activity cycle, core body temperature rhythm and cortisol rhythm, among others, it is not clear if there is a humoral factor or neural connection that transmits the SCN's efferent signal; however, a great deal is known about the efferent neural pathway between the SCN and pineal gland.

The Pineal Gland

In mammals, the pineal gland is located in the center of the brain; however, it lies outside the blood–brain barrier. Postganglionic sympathetic nerves (called the nervi conarii) from the superior cervical ganglion innervate the pineal (4). The preganglionic neurons originate in the spinal cord, specifically in the thoracic intermediolateral column. The pathway between the SCN and the spinal cord synapses in the paraventricular nucleus (PVN) and traverses through the medial forebrain bundle.

Light has two effects on melatonin production. In common with all other circadian rhythms controlled by the SCN, the 24-hour cycle of ambient light and darkness synchronizes (entrains) the melatonin rhythm to a period of precisely 24 hours. The circadian rhythm of melatonin production is the only one in which basal levels are confined to the day alternating with increased levels at night; that is, melatonin production occurs within the margins of the scotoperiod (dark period).

Melatonin is unique in another way: Light acutely stops melatonin production (5). This effect can occur only between dusk and dawn, because melatonin levels remain low during the day given that the SCN turns off melatonin production for about 12 hours each day. That is, darkness during the day cannot increase melatonin production. These two effects of light combine to restrict the duration of melatonin production to about 12 hours or less during the night. In many animals, the changing duration of the scotoperiod across the year results in a corresponding change

in the duration of melatonin production, which is used as a seasonal time cue for regulating hibernation, migration, and estrous (6).

Sympathetic stimulation of the pineal results in the synthesis and secretion of melatonin into the venous circulation, as well as into the cerebrospinal fluid. A major target of melatonin is the SCN. Melatonin is synthesized from serotonin in two steps, one of which (*N*-acetylation) is rate-limiting (7). After conversion of serotonin to *N*-acetylserotonin, hydroxyindole-O-methyltransferase synthesizes melatonin (8). Although this enzyme is not rate-limiting, it may ultimately control the maximum amount of melatonin that can be produced each night.

Pharmacology and Physiology

Pineal Adrenergic Receptors

Norepinephrine (NE) is the neurotransmitter released by postganglionic sympathetic neurons. NE stimulates ß-1-adrenergic receptors on the pinealocytes, resulting in activation of *N*-acetyltransferase (NAT) (9). NAT activation is potentiated by stimulation of α1-adrenergic stimulation of the pinealocytes (10). There are also α2-adrenergic autoreceptors on the postganglionic sympathetic neurons, which decrease melatonin production when stimulated by NE (11). Perhaps unique in the autonomic nervous system, there is no dual parasympathetic innervation opposing sympathetic control of pineal melatonin production; however, melatonin levels do not increase with general "fight or flight" sympathetic stimulation. Regulation of melatonin is tightly controlled by the SCN, which appears to be active during the day (12), thereby exerting inhibition of an otherwise always "on" signal in the PVN for increasing melatonin production (13). Nevertheless, melatonin production is a reliable measure of sympathetic and noradrenergic activity in the pineal gland. Consistent with the catecholamine hypothesis of affective disorders, melatonin production is greater in manic than in depressive states in bipolar patients (14 ,15), although the jury is out as to whether or not melatonin production is decreased in unipolar depression (16).

Pineal Pharmacology

Drugs that affect NE and its receptors can change melatonin levels. ß-Blockers reduce melatonin production (17). In humans, changes in circulating levels in NE must be extreme if melatonin levels are to be increased, such as resulting from high-altitude marathon races; however, tricyclic antidepressants reliably increase melatonin production. Drugs that stimulate and block α2-adrenergic receptors also have the predictable effects on melatonin production. For example, clonidine decreases melatonin production in humans (11), whereas yohimbine increases it (18). Benzodiazepines are also reported to decrease melatonin production. Changes in melatonin duration probably are not as important in humans, who lack seasonal rhythms. Drugs that affect melatonin production generally lower or raise the entire nighttime profile symmetrically; therefore, a circadian phase shift is less likely to result. This concept is best understood after reviewing how melatonin feeds back onto the SCN in order to shift circadian phase (see the following).

SHIFTING CIRCADIAN PHASE USING BRIGHT LIGHT

Part of "129 - Circadian Phase Sleep and Mood Disorders "

Intensity of Light

Acute Suppression of Nighttime Melatonin Production

One of the most remarkable effects of light is suppression of nighttime melatonin production (19). However, scientists in the late 1970s had concluded that humans lacked this and other chronobiologic responses to light. This erroneous thinking was based on temporal isolation studies that showed that social cues were more effective than light in entraining human circadian rhythms (20) and on studies in which light failed to suppress melatonin production in humans (17 ,21 ,22). In both types of cases, ordinary-intensity room light was used. These negative findings caused some scientists to speculate that humans lacked the neural pathways for mediating chronobiologic effects of light.

However, in 1980 we reported that bright light could suppress melatonin production in humans (the brighter the light, the greater the effect) (23) (Fig. 129.1). One implication of this finding was that humans might have biological rhythms that were cued to sunlight and were relatively unperturbed by ordinary-intensity indoor light. A second implication was that bright artificial light might be substituted for sunlight, in order to experimentally, and perhaps therapeutically manipulate biological rhythms in humans.

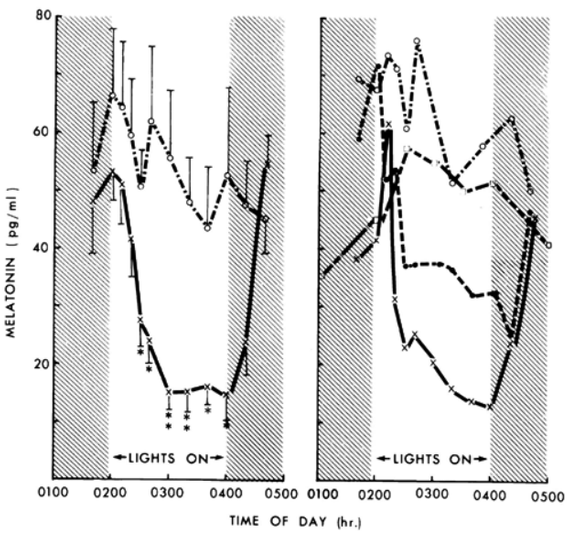

FIGURE 129.1. Left: Effect of light on melatonin secretion. Each point represents the mean concentration of melatonin (±standard error) for six subjects. A paired *t*-test, comparing exposure to 500 lux with exposure to 2,500 lux, was performed for each data point. A two-way analysis of variance with repeated measures and the Newman-Keuls statistic for the comparison of means showed significant differences between 0230 and 0400 (*, $P < .05$; **, $P < .01$). **Right:** Effect of different light intensities on melatonin secretion. The averaged values for two subjects are shown. Symbols: (o) 500 lux; (**x**) 2,500 lux; (●) 1,500 lux; and (□) asleep in the dark. From Lewy AJ, Wehr TA, Goodwin FK, et al. Light suppresses melatonin secretion in humans. *Science* 1980;210:1267–1269, with permission.

Winter Depression

Following our discovery of bright light suppression of melatonin production in humans (23), researchers began to treat depressed patients with bright light (24). We have been concentrating on treating winter depression, or seasonal affective disorder (SAD). We were unaware of the existence of SAD until Herb Kern contacted us, because of a history of an annual rhythm in mood changes: During the winter he became depressed, which he was able to document using a diary he had kept over for over 13 years (25). Since 2,000-light was effective in suppressing melatonin production, we assumed that this intensity would have other chronobiologic effects as well. Mr. Kern responded to a regimen of 2,000-lux light given between 6 and 9 AM and 4 and 7 PM (26).

We exposed him to bright light at these times, because animals tell time of year by the interval between the twilight transitions (6): Our thinking was that we could increase the length of his biological day by scheduling bright light as soon as he awakened, followed by another exposure ending 13 hours later. (Mr. Kern's depression would usually spontaneously remit in the spring.) These two studies (23 ,26) were critical in starting the field of bright light treatment, not only for SAD but for using bright light in other chronobiologic disorders as well (discussed in the following).

Wavelength of Light

With George Brainard (27), we have shown that the peak wavelength for suppressing melatonin production is 509 nm (blue-green light). Most white light sources have this wavelength, which is in the middle of the scotopic spectral distribution. Generally, we prefer to use regular fluorescent light. Rods, not cones, are most sensitive at this wavelength; however, the precise retinal photoreceptors that mediate chronobiologic effects of light have not yet been identified.

Timing of Light

The Light Phase Response Curve

The next step in the course of our work was to address the circadian phase-shifting effects of light. As mentioned in the preceding, Mr. Kern (and most of the other early SAD patients) was treated with bright light based on the idea of lengthening their winter photoperiod to one more typical of spring, the time of year when they spontaneously remitted (26 ,28). It occurred to us that we should have the same phase response curve (PRC) to light commonly found in other animals, except that humans would need bright light to most reliably demonstrate these effects (29). Hence, we postulated the human light PRC, which can be described as follows. A phase advance (shift to an earlier time) results from light exposure between the middle of the night and morning. A phase delay (shift to a later time) results from light exposure between the evening and middle of the night. These phase shifts are greatest in the middle of the night. During the day there are decreased responses to light. Rutger Wever, who previously was the driving force behind the importance of social cues, published a study in 1983, demonstrating that continuous bright light during the day had a more potent effect on the human circadian system than did ordinary-intensity light (30).

Phase-Typing Circadian Rhythm Disorders

Our much less elegant anecdotal report the same year indicated that bright light could be used to treat circadian phase disorders in humans (29); however, we specified that bright light should be confined either to the morning or evening. We proposed that there were two types of circadian disorders, the phase-delayed and phase-advanced types (Table 129.1). We also showed how bright light scheduled in the morning could be used to treat delayed sleep phase syndrome (DSPS) in order to provide a corrective phase advance and that evening bright light could be used to treat at least the early morning awakening of nonseasonal depressives in order to provide a corrective phase delay. However, the first person to treat this latter group of patients was Dan Kripke (24), who used a different approach, giving them bright light in the morning, not to cause a phase shift but

rather to illuminate a “critical interval.” Suffice it to say that no one in those early days, except Wever and our group, was thinking about the circadian phase-shifting effects of light. The following year we showed that—holding the sleep/wake cycle constant—we could shift the melatonin rhythm (a biological marker that we had proposed would be ideal for assessing circadian phase position in humans) by shifting the light/dark cycle (31 ,32).

Phase-Advanced Type	Phase-Delayed Type
ASPS	DSPS
East to west jet lag	West to east jet lag
Adjusting to night work	Readjusting to off-work
	Winter depression

TABLE 129.1. PHASE TYPING SLEEP AND MOOD DISORDERS

The Phase Shift Hypothesis for Winter Depression

When we proposed “phase typing” circadian disorders (29), we hypothesized that most people with SAD were of the phase-delayed type (33). It was our thinking that circadian rhythms drift later with the later dawn of winter and that this is the cue for some people to get depressed at this time of year. Accordingly, we hypothesized that the optimum time for bright light exposure was in the morning, which would provide a corrective phase advance. We further hypothesized that morning light would advance the circadian rhythms that were tightly coupled to the ECP, such as the melatonin rhythm, with respect to the sleep/wake cycle and its evoked rhythms, and therefore that any shift to an earlier sleep time should be held to a minimum. We also expressed concern about the possibility that too much morning light could overly phase advance these rhythms (34). Finally, we pointed out that there might be a small group of SAD patients who cued to dusk rather than dawn, and for whom evening bright light would be most antidepressant, producing a corrective phase delay (34). We also proposed an elaboration of the phase shift hypothesis (PSH): Typical patients are phase delayed, but not necessarily compared to normal controls, in that the phase delay could be ipsative (35); that is, we expected typical patients to be delayed when depressed in the winter compared to when they were euthymic. According to the nomenclature, if SAD patients are thought to have relatively long intrinsic circadian periods, they should have a relatively late dim light melatonin onset (DLMO) given either as clock time or as zeitgeber time (ZT) (that is, delayed relative to wake time). Indeed, as mentioned, it is thought that the DLMO of most SAD patients is delayed relative to the sleep/wake cycle (and therefore the ambient light/dark cycle).

Although some investigators were quick to embrace the PSH (such as David Avery, who underscored the significance of morning hypersomnia as a predictor of response to morning light) (36), many distinguished experts in the field advanced other ways of conceptualizing SAD. For example, the NIMH group published a paper in 1985 recommending 5 to 6 hours of 2,000 to 2,500 lux light in the evening (37). According to their “photon counting” hypothesis, light at any time of day should be antidepressant, as long as light of sufficient duration and intensity was used (38). Because people with SAD do not like to get up any earlier than they have to in the morning, evening was proposed to be the most convenient time for light treatment.

Both hypotheses received help from a review by the Terman group (39). Morning light was shown to be more antidepressant than evening light; however, evening bright light was shown to be more effective than evening dim light. It should be noted, though, that there was no control for the dim evening light condition; therefore, evening dim light could have been eliciting purely a placebo response. Significantly, the Terman group made the important suggestion that 10,000 lux could be used for a shorter duration than the 2,000- to 2,500-lux light that had been the previous standard.

Morning Versus Evening Light

Support for the PSH depends on the superiority of morning light for most patients. Some studies have shown that morning light is more effective than evening light (40 ,41); whereas other studies showed that they are equally effective (42). The former studies used a crossover design, whereas the latter studies used parallel groups. Critics of the PSH pointed out the advantages of the latter type of study design, whereas advocates of the PSH pointed out the advantages of the former compared to the latter. Some critics of the PSH also proposed that exposure to morning light prevented an antidepressant response to subsequent treatment with evening light (43). The Terman group also proposed a corollary to the PSH that could be construed as quite different from the original hypothesis: Light at any time of day should be antidepressant for SAD, as long as it does not produce a phase delay (44).

With the publication of three large studies by independent groups in 1998 (45 ,46 and 47), there is now general agreement that morning light is more antidepressant than evening light in the treatment of SAD. An “order” effect (43) does not seem to confound these studies, and morning light has been shown to be more effective than evening light in both parallel (45 ,46 and 47) and crossover comparisons (40 ,41 ,46). Morning light does not seem to prevent an antidepressant response to evening light (47). Moreover, evening light does not seem to be more antidepressant than a credible placebo control (45).

However, the superiority of morning light does not prove the PSH, because people could simply have a greater overall sensitivity to light at that time of day. This seemed to us to be an unlikely explanation, given that patients become more depressed when switched from morning to evening light, even after they have responded. Recently, however, the Terman group (48) as well as our group (49) found that the antidepressant response to morning light correlates with the amount of phase advance. We had previously shown this relationship with patients exposed to 30 minutes versus 120 minutes of morning light (50), which has the obvious disadvantage that patients would expect light of a

greater duration to be more antidepressant. The PSH continues to remain the most viable hypothesis for explaining why patients with SAD become depressed in the winter and for explaining how light is antidepressant in these patients.

It should be mentioned that even if the PSH is ultimately shown to be correct, it might explain only part of the response to light. As Charmane Eastman has shown, the placebo response is a major component to light treatment (51). Whether or not a specific mechanism for this can be found (e.g., an energizing effect) (52) remains to be determined.

Other Chronobiologic Hypotheses

Finally, four other chronobiologic hypotheses for SAD should be mentioned, none of which are mutually exclusive with the PSH. Martin Teicher has proposed that SAD patients are not stably entrained to the light/dark cycle (53), which in many respects is similar to the PSH. Domien Beersma has proposed that people with SAD are supersensitive to light (54). Accordingly, these people might delay in the winter in response to ordinary-intensity room light in the evening that would not be sufficiently bright to phase delay normal controls. The jury remains out on this hypothesis, which, in any event, is not inconsistent with the PSH. Also, Thomas Wehr has found that the melatonin duration (the time interval between the melatonin onset and the melatonin synthesis offset, or SynOff) expands in the winter in SAD patients but not normal controls (55); however, he also finds an overall delay in the melatonin rhythm in SAD patients in the winter compared to the summer, particularly in the SynOff. A third hypothesis, suggested by Charles Czeisler, is that SAD patients have diminished circadian amplitude when depressed in the winter (56). Czeisler has not done much testing of his hypothesis, and other investigators have not found much support for it (57 ,58).

The DLMO as a Marker for Circadian Phase Position

History

In the early 1980s, we thought that plasma melatonin sampled every 30 to 60 minutes might be able to show differences in circadian phase position between individuals and to monitor the phase-shifting effects of bright light (31 ,32). We further proposed that only one night of sampling is needed, indeed, only during the evening, so as to determine the time when melatonin levels begin to increase. We recommended that subjects be studied under dim light, so as not to suppress the rise in melatonin levels. The DLMO continues to be a useful marker for circadian phase position (59 ,60 and 61). We have also recommended that the time when melatonin levels begin to fall, the synthesis offset, or SynOff, is another useful marker for the ECP (Fig. 129.2) (61); however, the SynOff requires sample collection during sleep.

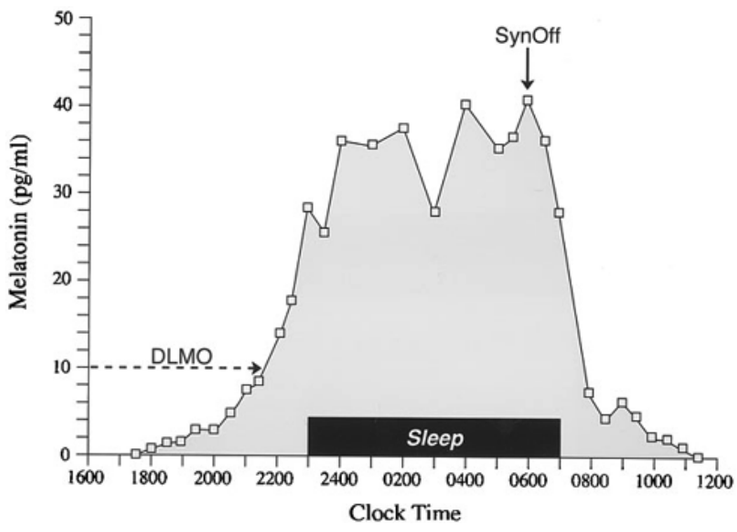

FIGURE 129.2. Representative overnight endogenous melatonin profile, showing the dim light melatonin onset (DLMO), the threshold when melatonin levels cross 10 pg/mL and continues to rise, and the melatonin synthesis offset (SynOff), indicating the beginning of the end of melatonin production.

Current Recommendations

Currently, we are suggesting that the light be so dim that subjects are not able to read without the aid of small book lamps. We further suggest that dim light begin 1 hour before blood sampling (61). The same recommendations apply to salivary collections. It is important not to put the subject in absolute darkness too early in the day, because this might cause a significant phase advance in the ECP (62).

The DLMO is now being employed extensively in research labs, and the salivary DLMO is beginning to be used in clinical settings as well (63 ,64). The DLMO has several advantages. It appears to be relatively free of noise and is easily obtained compared to other techniques for assessing circadian phase position. Outpatient determination of the DLMO usually does not interfere very much with sleep. Saliva can be collected at home.

Low Melatonin Producers

There are a couple of caveats to keep in mind. Very low or very high producers of melatonin may have an artifactually late or early DLMO, respectively (61). When there is a large range in melatonin amplitude between individuals, the DLMO can be adjusted algorithmically, or a lower threshold than the usual 10 pg/mL can be used (the 2 pg/mL DLMO is minimally affected by amplitude). Thomas Wehr has recently shown that the melatonin duration does not change across the year in normal subjects (55); however, in

SAD patients he has reported a greater delay in the SynOff than in the melatonin onset in the winter compared to the summer. Thus, we may be underestimating the amount of delay in SAD patients when just using the DLMO; therefore, for studies of circadian phase, measuring the DLMO may miss a finding that can be demonstrated using the rest of the melatonin profile. However, in most situations, measurement of the DLMO should suffice.

Circadian Amplitude

It is not clear if the overnight melatonin profile is a good marker for the amplitude of its endogenous circadian pacemaker. Furthermore, it is not clear if circadian amplitude is as important as circadian phase, in that an amplitude disturbance has yet to be shown. Moreover, no technique has been shown to enhance circadian amplitude or to reliably diminish it. The jury is out over whether or not suppressing amplitude is important for bright light to cause phase shifts (65 ,66).

The Melatonin Phase Response Curve

Blindness and Constant Dark Conditions

In 1983, Redmond, Armstrong, and Ng showed that a free-running mammal (in this case, rats) could be entrained to a daily dose of melatonin (67). We had been interested in the possibility of using melatonin to entrain the free-running rhythms of totally blind people. There appear to be at least three types of blind people: normally entrained, entrained at an abnormal phase, and free-running [blind free-runners (BFRs)] (68 ,69). BRFs are usually without any light perception, subjective or objective. Of the million or so legally blind in the United States, about 200,000 are totally blind. At least half of them are probably BFRs (70). BFRs generally have a recurrent sleep disorder that occurs when their sleep propensity rhythm drifts 12 hours out of phase with their preferred sleep time. On these days, they have insomnia and have to fight hard to resist urge to sleep during the day.

The technique we use to determine the free-running period of BFRs is to determine the melatonin onset on multiple occasions. We call this the multiple melatonin onset test (MMOT). In a typical BFR, the melatonin onset will be several minutes later each day and several hours later over a few weeks.

Although we were the first group to give melatonin to the blind (71), other investigators preceded us in giving melatonin to sighted people. Jo Arendt was the first to use melatonin in the treatment of jet lag (72); she also was the first to study its phase-shifting effects on the endogenous melatonin rhythm (73). Bruno Claustrat's group (74) also did some early work this area.

Another reason why we started with blind people is that we were concerned that the light/dark cycle would prevent melatonin's phase-shifting effects. The data on sighted subjects were intriguing, but were neither robust nor consistent (75). However, in the blind we were able to demonstrate quite reliable phase shifts using a dose of 5 mg of melatonin (71 ,76 ,77); thus encouraged, we were then ready to study sighted people, even though we had not yet achieved our goal of reliably entraining blind people to a daily dose of melatonin.

Sighted People

In sighted people, we reduced the dose to .5 mg, which produces melatonin levels of the same order of magnitude that occur physiologically. As opposed to previous studies of melatonin (which used higher doses and gave melatonin in the late afternoon or evening), we administered melatonin at different times. In each trial we gave melatonin on four consecutive days, and the results were the first unequivocal demonstration of both phase delays and phase advances, as well as the first description of the melatonin phase response curve (PRC) in humans (78 ,79 ,80 ,81 and 82). The melatonin PRC has now been replicated, by us (83) and two other groups (84 ,85); the earlier melatonin is given in the advance zone, the greater is the phase advance (however, less is known about the delay zone).

The melatonin PRC appears to have an advance zone of about 12 hours' duration, a delay zone of about 12 hours' duration, and it appears to be about 12 hours out of phase with the light PRC. That melatonin causes phase shifts opposite to those of light should not be surprising, because melatonin appears to be a chemical signal for darkness.

Circadian Time

Internal body clock time can be assessed using a variety of marker rhythms. We prefer the DLMO. On average, the DLMO occurs 14 hours after wake time. Because "lights on" is, by tradition, designated circadian time (CT) 0, we use the DLMO as CT 14. That is, no matter what clock time the DLMO occurs, its circadian time is CT 14.

On average the crossover times of the melatonin PRC appear to be at about 1 PM and about 1 AM. In circadian time, these are CT 6 and CT 18, respectively (83). That is, advance responses are obtained when melatonin is given between CT 6 and CT 18, and delay responses are obtained when melatonin is given between CT 18 and CT 6. When comparing the phase of the melatonin PRC to the light PRC, we use the beginning of the stimulus. Accordingly, the Czeisler PRC (which uses 5 hours of bright light) places the crossover times in the middle of the day at CT 6 and in the middle of the night at CT 18, according to these same conventions recommended by the PRC Atlas (86 ,87). This can be confusing, because the light PRC's crossover time in the middle of the night is also thought to occur at

the temperature minimum (86 ,88 ,89 ,90 and 91), which is usually just a few hours before wake time (CT 0).

Phase Relationship between the Light and Melatonin PRCs

In any event, light exposure during the interval between CT 6 and CT 18 causes phase delays, and during the interval between CT 18 and CT 6 causes phase advances; therefore, the light and melatonin PRCs are 12 hours out of phase with each other (Fig. 129.3 and Fig. 129.4). If the midpoint of the stimulus is used as the phase reference instead, the melatonin and light PRCs are still about 12 hours out of phase with each other. The times are given both as average clock times and as CTs. CT is more accurate if it can be calculated using an internal phase marker, such as the DLMO, which is designated CT 14. CT can be more easily but more roughly estimated using sleep onset as CT 16, or preferably, sleep offset as CT 0. The clock times in the figures below are averages, based on the presumption of a habitual wake time of 7 AM. The crossover times could be a few hours later or earlier, depending on how much the habitual wake time (not the wake time on a particular day) differs from 7 AM. For example, a person who habitually awakens at 6 AM will likely have crossover times at noon and midnight, instead of 1 PM and 1 AM.

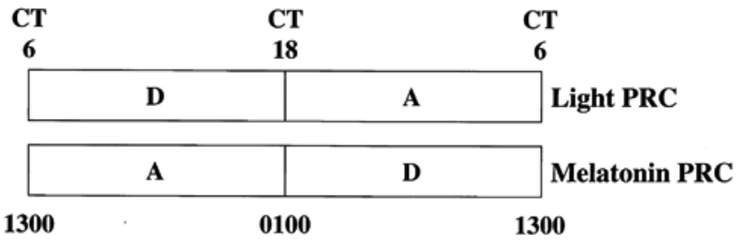

FIGURE 129.3. Schematic diagram of the light and melatonin phase response curves (PRCs). The melatonin PRC appears to be about 12 hours out of phase with the light PRC. The crossover times separating the advance (A) and delay (D) zones appear to be at about CT 6 and CT 18, on average about 1 PM and 1 AM, respectively, for people who awaken at 7 AM. The endogenous melatonin profile usually extends from about CT 14 to about CT 1. Adapted with permission from Lewy AJ, Bauer VK, Ahmed S, et al. The human phase response curve (PRC) to melatonin is about 12 hours out of phase with the PRC to light. *Chronobiol Int* 1998;15:71–83.

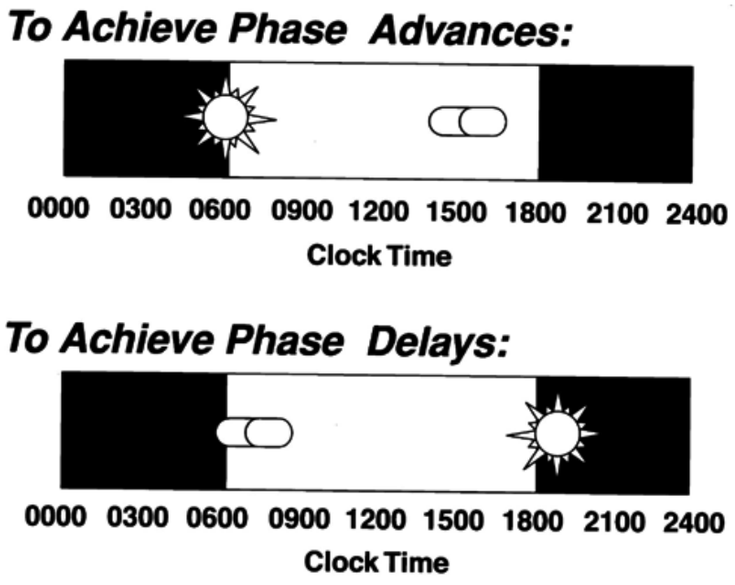

FIGURE 129.4. Phase-shifting effects of light and exogenous melatonin, assuming a normal circadian phase. To cause a phase advance, light should be administered in the morning and melatonin in the afternoon/evening. To cause a phase delay, light should be given in the evening and melatonin should be taken in the morning. The timing of light and melatonin administration is best done with reference to circadian time rather than clock time. Adapted with permission from Lewy A, Sack R. The role of melatonin and light in the human circadian system. In: Buijs R, Kalsbeek A, Romijn H, et al, eds. *Progress in brain research, vol. 111. Hypothalamic integration of circadian rhythms*. Amsterdam: Elsevier, 1996:205–216.

Circadian Time and Zeitgeber Time

A somewhat confusing issue is how to use the DLMO as a marker for internal body clock time. When scheduling bright light and melatonin using the light and melatonin PRCs, we use the CT, which as mentioned in the preceding, is designated CT 14. Therefore, the advance zone of the melatonin PRC begins 8 hours before the DLMO and ends 4 hours after the DLMO. Also mentioned, the DLMO occurs on average 14 hours after wake time. However, if a person has a relatively short intrinsic circadian period, he or she will be entrained by the light/dark cycle in a relatively advanced phase position, and if a person has a relatively long intrinsic circadian period, he or she will be entrained by the light/dark cycle in a relatively delayed phase position. When using the DLMO to provide information about the intrinsic period of the ECP, we speak of the zeitgeber time (ZT) of the DLMO. For example, if a person has a DLMO that is 13 hours after wake time (or the time of first light exposure, the main entraining agent of the ECP), the phase angle of entrainment, or zeitgeber time of the DLMO, is ZT 13. A person with a DLMO of ZT 13 probably has a relatively short intrinsic period. However, the CT of the DLMO (when operationally defined as the crossing of the 10 pg/mL plasma melatonin threshold) is always designated CT 14. In other words, the same DLMO clock time may be ZT 13 and CT 14. This is discussed further in the section on advanced and delayed sleep phase syndromes .

SAD UPDATE

Part of "129 - Circadian Phase Sleep and Mood Disorders "

Confirmation of the PSH for SAD?

The use of melatonin has allowed us to conduct a further test of the PSH for winter depression in order to answer

the following question: Does the correlation between the antidepressant response and the phase-advancing effect of morning light indicate a causal relationship? First, we did a pilot study. Five patients were given placebo in the afternoon and five were given melatonin, which was administered in two divided doses of .125 mg at CT 8 and CT 12. After 2 weeks, there was a significant improvement in the melatonin group compared to the placebo group (92).

These findings led to the study of 81 patients, divided into three groups. One group received low doses of melatonin in the afternoon and evening for 3 weeks. A second group received the same dosing regimen in the morning. There is also a placebo group. Interestingly, the antidepressant response appears to be related to the amount of phase advance (49). Therefore, the phase advance in the ECP appears to be the best-defined mechanism of action for the antidepressant effect of morning light in winter depression.

Clinical Implications of the PSH

We have cautioned (34) that it is possible to overly phase advance the body clock. A phase advance of about 1.5 hours relative to the sleep/wake cycle seems to be the optimal amount (48). Although the duration can be reduced after the patient has responded in 1 or 2 weeks, some patients will not comply with the 1 to 2 hours of bright light exposure immediately on awakening, because they do not want to get up too early. Furthermore, any advance in sleep time should be minimized, since this will retard the antidepressant response to advancing the ECP, because—according to the PSH—the ECP needs to be advanced with respect to the timing of the sleep bout (93 ,94).

Administration of melatonin (.5 mg) in the afternoon will cause a phase advance (82). This can be achieved while minimizing its soporific side effect, by using very low doses (.75 to 1.25 mg) given three or four times every 2 to 3 hours beginning 7 to 8 hours after habitual wake time. The addition of melatonin will reduce the need for an inconveniently long duration of morning bright light exposure by providing some additional phase advance. Those patients who do not get sleepy on melatonin may be able to take a sufficient dose of melatonin so that they do not require any morning bright light. Many patients with SAD seem to be unusually sensitive to the soporific effect of melatonin and will require bright light in combination with melatonin to achieve a therapeutic phase advance.

It takes less of a phase-resetting agent to maintain a certain circadian phase position than to initiate it. Hence, once a patient has responded, the duration of bright light and/or the dose of melatonin can be reduced. Patients will need to be treated until the photoperiod lengthens in the spring. When the patient's habitual wake time is occurring about 30 minutes past dawn, obtaining 15 to 30 minutes of outdoor light immediately on awakening is sufficiently therapeutic. At this time of the year, he or she is probably beginning to spontaneously remit. By the way, another way to cause a phase advance with respect to sleep time is to use a dawn simulator set to start slowly increasing light intensity a few hours before awakening (95 ,96). According to the light PRC, even relatively low intensity of light (diminished further because of closed eyelids) can cause a phase advance if given in the middle of the night.

In order to compare the phase-shifting effects of light and melatonin, ideally each treatment should be optimized. Absent this, we compared 2 weeks of 2,500 lux light at 6 AM to 8 AM or 7 PM to 9 PM in our largest light treatment of winter depression study (46). Phase shifts owing to light were of the same order of magnitude as phase shifts after 3 weeks of a divided dose of .225 to .3 mg of melatonin (which produces high but physiologic levels) used in our ongoing melatonin-treatment study described in the preceding (Table 129.2).

	Phase Advances (Hours ±)	Phase Delays (Hours ±)
Bright light	1.40 (± 0.21)	1.12 (± 0.16)
Melatonin	1.03 (± 0.14)	0.20 (± 0.12)

TABLE 129.2. PHASE SHIFTS WITH BRIGHT LIGHT AND MELATONIN ADMINISTRATION

We think it unlikely that a third week of treatment substantially increases the phase shift. This table indicates the phase-shifting effects of light and melatonin are of the same order of magnitude, although each treatment should be optimized for the most useful comparison.

OTHER CIRCADIAN PHASE DISORDERS

Part of "129 - Circadian Phase Sleep and Mood Disorders "

Shift Workers

The magnitude of the phase shifts in the melatonin PRC are smaller than those of the light PRC. However, subjects in the light PRCs studies had their sleep/wake cycles either shifted 12 hours before bright light exposure was scheduled or free to shift at will (86,88,89 and 90). In the melatonin PRC study, the sleep/wake cycle was held constant, and hence the ambient light/dark cycle also was held constant (82,83).

When we gave .5 mg of melatonin just before bedtime to night workers whose sleep/wake cycles were shifted about 12 hours, we found phase shifts of the same order of magnitude as those obtained with bright light (97). Apparently, holding the light/dark cycle constant diminishes the phase-shifting effects of melatonin (as it does light). Nevertheless, bright light seems to be a somewhat more robust phase-resetting agent than melatonin, although melatonin is of course much more convenient. In all likelihood, greater

phase shifts can be achieved in sighted people when melatonin and bright light are combined.

Jet Lag

The first use of melatonin in humans was to treat jet lag (98). There are surprisingly few studies in this area, however. Sunlight exposure at destination can be scheduled according to the nomogram we published in 1984 (99) (Fig. 129.5). This applies to obtaining (and in some cases avoiding) bright light for the day of arrival. The schedule for subsequent days can be arrived at by assuming a 2- to 3-hour phase shift per day and looking up the instructions for a crossing of the number of time zones. For example, if you have flown to Israel from Portland, OR, follow the directions for 10 time zones on the first day in Israel. For the second day in Israel, follow the directions for crossing eight time zones. Melatonin can also be helpful in the treatment of jet lag. We are currently developing guidelines for the optimal use of melatonin in the treatment of jet lag.

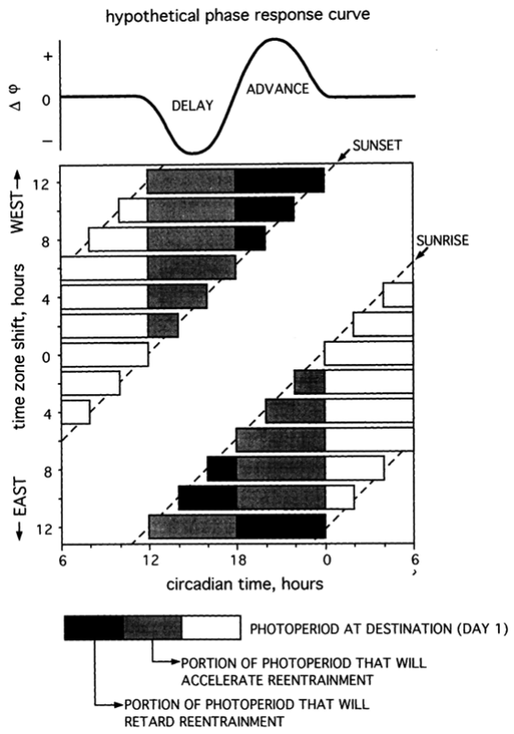

FIGURE 129.5. Proposed times for when bright light exposure should occur and when bright light exposure should be avoided the first few days after transmeridional flight. For example, after a 2-hour west-to-east trip, bright light exposure should begin at dawn and should be (optimally) 2 hours in duration. In another example, after a 10-hour west-to-east trip, however, bright light exposure should be *avoided* until 4 hours after sunrise and should occur (optimally) for 6 hours. From Daan S, Lewy AJ. Scheduled exposure to daylight: a potential strategy to reduce “jet lag” following transmeridian flight. *Psychopharmacol Bull* 1984;20:566–568, with permission.

Entrainment of BFRs

Following the first demonstration of phase shifting the ECP of a BFR (71), others and our group have found cases of varying degrees of certainty in which a daily dose of melatonin appeared to cause entrainment (100,101 and 102). In some instances, only the sleep/wake cycle appeared to be entrained (103,104 and 105).

We estimate that there are at least 100,000 totally blind people in the United States who have periodic insomnia. We have recently discovered a way to entrain most of these people (101,106). A dose of 10 mg given within an hour of preferred bedtime should in all likelihood eventually entrain most of them. Entrainment occurs in just a few days or a few weeks by initiating treatment when the MO is occurring around bedtime. Once the free-running clock of the blind person has been “captured,” the maintenance dose can be decreased to as low as .5 mg. Ongoing work in our laboratory is investigating the possibility of moving the melatonin dose earlier, to 7 to 13 hours after habitual wake time, so as to provide a typical phase angle of entrainment. In three BFRs who had pretreatment circadian periods less than 24.4 hours, we were able to capture their circadian rhythms with a *de novo* bedtime dose of .5 mg. Therefore, it may be possible to entrain people initially with .5 mg, particularly if their free-running periods are not much greater than 24 hours. Indeed, the only person who failed to entrain to the 10-mg dose had the longest free-running period of our group (24.9 hours).

BFRs are perhaps ideally suited for phenotyping people according to their intrinsic circadian period for clock gene studies, particularly bilaterally enucleated people in whom there is no chance for ocularly mediated effects of light on the circadian system. Of course, this presupposes minimal, if any influence of behaviorally related zeitgebers (BRZs) (107,108) or nonocular light (109). If these other possible modes of entrainment are shown to be negligible, then entrained BFRs with one or two eyes are probably still sensitive to the ocularly mediated light zeitgeber, even though they have no conscious light perception or any objective sign of light response, such as the melatonin suppression test, which we developed in sighted people (23,110,111,112,113 and 114) and has also been recommended for blind people (107). However, until we have ruled out entrainment by ocularly mediated light in what are thought to be totally blind people, we do not recommend the use of the melatonin suppression test, which we recently have come to think may risk desensitizing the few remaining photoreceptors that may have been sufficiently

sensitive to mediate entrainment. Furthermore, the melatonin suppression test does not seem to be very useful clinically, because it does not discriminate BFRs from entrained blind people very well. These issues cannot be resolved until the entrainment effects of BRZs (107,108,115) or nonocular light (109) are established or ruled out.

Are Nonseasonal Affective Disorders Chronobiologic?

Daniel Kripke has done more work in this area than anyone else (24). We do not think that bright light has the same robust antidepressant effect in nonseasonal depression as it has in SAD, and the jury is out as to whether it works better than placebo. However, if a patient has a circadian rhythm component to his or her affective disorder, such as early morning awakening or morning hypersomnia, then melatonin and/or bright light can be used to shift sleep to a more desirable time. Whether or not correcting the phase disturbance improves the remaining symptoms is not known at the present time.

Melatonin in Young and Elderly People

There are anecdotal and testimonial reports that melatonin improves the sleep of children with ADHD and adults with Alzheimer disease. A study has been done in elderly people indicating that benzodiazepines can be reduced or eliminated with concomitant melatonin administration (116). Although we might want to use lower doses of melatonin in young and elderly people, melatonin appears to be reasonably safe in these populations as long as a physician is monitoring them. Indeed, to date I know of no reports published in the scientific literature of serious irreversible side effects as the result of taking melatonin, and certainly millions of people have been doing so for the past several years. Nevertheless, there is a continued need for physician monitoring of melatonin usage, particularly when taken every day. However, we do not expect this to be a very common effect of melatonin, given the fact that melatonin can have either progondal or antigonadal effects, depending on whether the species is a fall or spring breeder (6,117) and the fact that there is only a very slight seasonal rhythm in human fertility (118,119).

Advanced and Delayed Sleep Phase Syndromes

Appropriately timed bright light exposure and melatonin administration can be used to treat other circadian phase disorders. These include advanced sleep phase syndrome (ASPS) and delayed sleep phase syndrome (DSPS). Light treatment of these disorders has already been summarized (120), and we are currently developing recommendations for melatonin treatment. A remarkable report was published recently concerning a family with advanced sleep phase syndrome (121). The clock time of the DLMO was quite early, even with respect to sleep; that is, the ZT of the DLMO (the number of hours after wake time) can be calculated as 13.3. The intrinsic period of one of these subjects was studied in temporal isolation and was found to be 23.3 hours, one of the shortest, if not the shortest, ever recorded. Therefore, if the wake time and DLMO time are known, their interval should predict intrinsic period, and perhaps obviate the need for an arduous study under temporal isolation conditions. This should be of interest to those interested in phenotyping sighted people for clock gene studies.

MELATONIN AND CIRCADIAN PHASE DISORDERS: PAST, PRESENT, AND FUTURE

Part of "129 - Circadian Phase Sleep and Mood Disorders "

Past Skepticism about Melatonin

The melatonin fad of a few years ago has stimulated a number of scientists to make skeptical comments. Many of these concerns are well taken. There is no clinical evidence that melatonin is useful for anything other than phase shifting and sleep; however, some investigators have expressed skepticism even for these well-documented uses.

Charles Czeisler has perhaps most comprehensively articulated these criticisms (122). Czeisler contends that our melatonin PRC was not conducted under sufficiently controlled conditions, namely, that subjects were studied at home and under a variety of light intensities. However, we view this as a strength of the methodology: because the subjects lived mainly at home, the findings can be more directly applied to real-life situations. Furthermore, despite “noise” owing to uncontrolled light intensities, the data clearly describe a well-defined PRC, perhaps because of the large number of data points. Moreover, it is difficult to imagine a systematic confound in the study owing to melatonin’s soporific side effect (particularly because naps in the middle of the day do not cause phase shifts) (123); waking up at night to take a placebo capsule causes phase shifts, if any, opposite to those of melatonin (Lewy, in preparation).

Czeisler is also concerned that the Claustrat replication PRC is slightly different from ours. Claustrat used a 3-hour intravenous infusion of melatonin, whereas our .5-mg oral dose kept blood levels elevated for several hours (84). We have speculated that melatonin’s phase-shifting effects are optimal if the exogenous dose overlaps with the endogenous melatonin profile (75). This might explain why the intravenous dose given in the evening produced more of a phase advance than the one given in the afternoon, in that the afternoon dose did not overlap with the endogenous melatonin profile. Our PRC shows that melatonin’s phase-advancing effects increase as it is given earlier in the afternoon: even at this time, the .5-mg oral dose raises blood levels through the time of the melatonin onset.

However, Czeisler's main problem with melatonin as a useful phase-resetting agent has been the difficulty demonstrating its ability to entrain BFRs. This issue is now moot, given the definitive findings of two independent groups (102 ,106).

We agree with Czeisler that light is the most powerful phase-resetting agent. However, Czeisler thinks that light is an order of magnitude more powerful than light, whereas as indicated in the preceding (Table 129.2) we think that there is not that much difference between the two zeitgebers. In any event, melatonin is much more convenient than using light as a phase-resetting agent. Although our group has concentrated on melatonin as a secondary zeitgeber in humans, Czeisler and his co-workers have continued to pursue a longstanding interest in the activity/rest cycle, first as a primary (124 ,125), and then as a secondary (107 ,108), zeitgeber. The jury is out as to the strength of the activity/rest zeitgeber in humans.

The Function of Endogenous Melatonin Production

In many animals, the duration of nighttime melatonin production appears to be critically involved in the regulation of seasonal rhythms. However, this does not appear to be the case in SAD, although Tom Wehr has some intriguing data on this point (55). Although seasonal rhythms are not very robust in humans (118 ,119), we have most of the circadian rhythms found in other animals, and melatonin may play a role, however humble, in helping the light/dark cycle entrain the ECP. This function for melatonin is critically dependent on suppression of melatonin by bright light.

Light entrains the ECP (located in the SCN), which regulates all overt circadian rhythms, including the nightly increase in pineal melatonin production. As mentioned in the beginning of this chapter, melatonin feeds back onto the SCN and stimulates receptors causing phase shifts opposite to those of light (126 ,127 and 128). Sufficiently bright light at the twilight transitions suppresses melatonin production, causing the endogenous melatonin onset to occur later and the endogenous melatonin offset to occur earlier. Thus, melatonin is prevented from stimulating parts of the melatonin PRC that might counteract the phase shift resulting from light (Fig. 129.6). In this way, the phase-shifting effect of light is augmented by an indirect effect of light acting on suppressing melatonin production. For example, if a person who normally gets up at 7 AM goes outdoors at 5 AM during the summer, earlier sunlight exposure will stimulate more of the advance zone of the light PRC, so as to cause a phase advance. Simultaneously, the melatonin offset will occur 2 hours earlier, reducing stimulation of the delay zone of the melatonin PRC. The same thinking can be applied to changes in bright exposure in the evening.

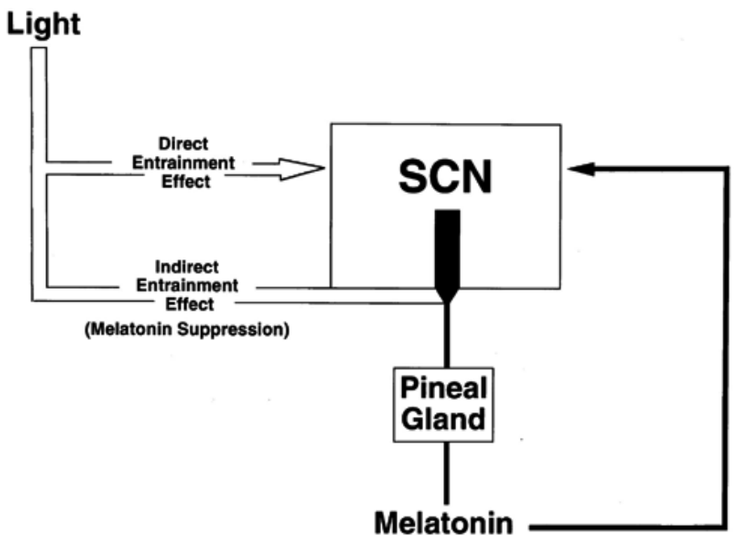

FIGURE 129.6. Schematic diagram of some of the relationships between nighttime melatonin production by the pineal gland, the light/dark cycle and the endogenous circadian pacemaker thought to be located in the hypothalamic suprachiasmatic nuclei (SCN). Acting on the SCN as described by the melatonin phase response curve (PRC) at any given time of the day or night, melatonin causes phase shifts opposite to those that light would cause *(opposing arrows)*. However, the suppressant effect of light pares the margins of the nighttime melatonin profile *(tapered vertical arrow)* and reduces endogenous melatonin's stimulation of the melatonin PRC at the day–night transitions. This second pathway for entrainment by light is particularly significant during shifts of the light/dark cycle. From Lewy AJ, Ahmed S, Jackson JML et al. Melatonin shifts circadian rhythms according to a phase-response curve. *Chronobiol Int* 1992;9:380–392, with permission.

Clearly, light is the major zeitgeber for entraining circadian rhythms. In most mammals, melatonin is used for conveying the time of the year (primarily for seasonal breeding and other photoperiodic effects) and not necessarily the time of day (6). The acute suppressant effect of light (23) is important in truncating the endogenous melatonin profile, and humans have retained the suppressant effect of light but are not really seasonal breeders. It may be that melatonin is primarily used for either circadian or seasonal time keeping, and that this difference might distinguish humans from nonhuman primates. In other words, perhaps primates use melatonin either for telling the time of the year or the time of the day, but not both. For example, in a species of primates that has a seasonal breeding cycle, melatonin has not been shown to have circadian phase-shifting effects (129). Interestingly, activity is an effective zeitgeber in at least one species of primates, which has a seasonal breeding cycle (130). A corollary of this hypothesis is that a species that does not use melatonin for telling time of the day uses activity as the secondary circadian zeitgeber. Humans, who do not appear to use activity as the secondary zeitgeber, use melatonin as one. In other words, light is the primary zeitgeber, and either melatonin or activity is the secondary zeitgeber, depending on whether or not melatonin is used for cueing seasonal rhythms.

Once again, there is no question that light is the primary zeitgeber. Light regulates the melatonin circadian rhythm

in two ways: Light entrains the SCN and acutely suppresses melatonin production. However, in humans melatonin appears to feed back onto the SCN to act as a secondary zeitgeber.

FUTURE DIRECTIONS

Part of "129 - Circadian Phase Sleep and Mood Disorders "

Optimal dosing of melatonin will depend on minimizing its soporific side effect, while maximizing its phase-shifting effects. This may entail using a low-dose sustained-release formulation to smooth out any sharp spikes in melatonin levels that appear to cause sleepiness in some people. The sustained-release formulation also has the advantage of providing continuity between exogenous levels from a low dose and the endogenous melatonin profile.

Another useful product that we might look forward to is a delayed-release sustained-release formulation that can be taken at bedtime to conveniently produce increases in melatonin throughout the night, beginning shortly after CT 18, so as to selectively stimulate the delay zone of the melatonin PRC. It may also be desirable to continue a low level of melatonin until the early afternoon in order to enhance a phase delay.

Clearly, shifting the sleep/wake (and consequently the ambient light/dark) cycle enhances the phase-shifting effects of melatonin. We have also speculated that placing a person in darkness when exogenous melatonin levels are increased may also enhance melatonin's phase-shifting effects. This needs to be more extensively tested.

Finally, we need more field studies of melatonin, not just in jet lag but with shift workers as well. One attempt at this was star-crossed (131). Our advice was not taken in its entirety, and the study design had several serious flaws in experimental design, for example, a failure to induce much jet lag in the placebo group after the first night's sleep at destination (most subjects expected to be an active treatment) and an absence of a circadian phase marker.

In some people, melatonin may be used as a mild sleep-promoting agent. The prospects for using melatonin and bright light to treat circadian phase disorders are even better. Most circadian phase disorders are relatively straightforward, and their treatment is based on the light and melatonin PRCs.

SAD is more complicated, although it is far and away the disorder most often treated with portable bright light fixtures. There appear to be two types of SAD patients (31): The typical patient with SAD is phase delayed (and complains of morning hypersomnia); the atypical patient is phase advanced (these people often report a history of getting up early year round, even on the week-ends, and often wanting to go to bed much earlier in the winter than summer). The phase disturbance in SAD is with respect to sleep as well as with respect to clock time. Therefore, there is an internal phase-angle disturbance in SAD. Sleep time should be held constant in these patients while their other circadian rhythms are shifted into the correct relative phase position with sleep. Even a confirmed PSH, however, raises new questions:

1. Which circadian rhythms tightly coupled to the ECP must be out of phase with which processes tied to sleep in order to trigger a depression each winter?
2. Does light have a specific antidepressant effect other than phase shifting?
3. How can we apply what we have learned about SAD to other affective disorders?

ACKNOWLEDGMENTS

The effects of sleep loss and sleepiness encompass a variety of neurobehavioral and physiologic alterations. This chapter reviews the causes, consequences, and mechanisms of sleep disruption and concomitant daytime sequelae, namely sleepiness and neurobehavioral performance decrements. Given the personal distress, quality of life issues, public health concerns, and economic costs of sleep loss and sleepiness, it is imperative that researchers and practitioners strive to obtain a solid understanding of these consequences and mechanisms. Several advances in the psychopharmacologic and behavioral treatments of the causes and consequences of sleep loss have recently evolved. Technologies are rapidly developing and showing promise for effective evaluation of these highly prevalent problems.

Advances and online monitoring and mathematical modeling of sleepiness and associated neurobehavioral forms are rapidly evolving novel behavioral and psychopharmacologic treatments effective for the causes and consequences of sleep loss.

PATHOPHYSIOLOGY OF DIFFICULTY INITIATING OR MAINTAINING SLEEP

Part of "130 - Sleep Loss and Sleepiness: Physiological and Neurobehavioral Effects "

Insomnia is characterized by difficulty initiating or maintaining sleep that results in psychological distress and impaired social or occupational functioning (1). Individuals with insomnia report a myriad of interpersonal, cognitive, affective, behavioral, and physical symptoms. Not only are there consequences for the individual, but also are there substantial costs to society; the direct economic costs owing to insomnia are estimated at $13.9 billion (2). The etiology of these symptoms has not been clearly delineated, however. The causal explanation that sleep deprivation accounts for the impairment of daytime functioning in insomniacs has been challenged and needs re-evaluation. This section provides a review of the daytime sequelae of the insomnia and a discussion of alternative mechanisms that may account for the daytime symptoms experienced.

Consequences

Persons with insomnia report various somatic complaints and demonstrate increased health-seeking behaviors. The primary complaints among insomniacs include drowsiness and tiredness on awakening, as well as sleepiness throughout the day (3 ,4). Insomniacs complain of physical ailments such as headache, diarrhea, stomach discomfort, heart palpitations, pain, tiredness, and weakness more frequently than do controls (5). Health-seeking behaviors such as hospital and physician visits are more frequent among a clinical sample of insomniacs compared to controls (5). Cardiovascular disease (6) and decreased immune functioning (7) may also be exacerbated in chronic insomnia.

The quality of life among insomniacs also appears to be diminished (8). Absenteeism, and work and social limitations are significantly more prevalent among insomniacs compared to normal sleepers (5 ,8). Insomniacs report restricted physical activities, poorer health, less vitality, and a decreased amount of time spent reading and engaging in recreational activities (8). Insomniacs report more time watching television, relaxing, and shopping than do noninsomniacs, whereas non-insomniacs work more, study more, and socialize more than do insomniacs. Insomnia is also associated with dissatisfaction in interpersonal relationships (4). These data suggest that insomniacs avoid or are unable

to participate in activities that require higher levels of concentration or social engagement.

Insomnia and mood disturbances often coexist. Sleep disruption is the single most common complaint of patients in a major depressive episode (9). Likewise, 30% of patients who complain of insomnia have a concurrent depressive disorder. Some have speculated that chronic insomnia may contribute to the development of major depressions (10 ,11); however, prospective controlled studies are needed to test these speculations. Kales and associates (5) found that insomniacs also exhibited symptoms mood changes, such as dysphoric mood, worry, tension, anxiety, and irritability. Even in nonclinical samples, insomniacs reported decreased mood (4), increased anxiety and depression, and less optimism (8). In contrast, Marchini and associates (12) reported that insomniacs were not particularly ruminative, tense, or physiologically aroused, but rather passive and calm. Marchini and colleagues' (12) unexpected finding led them to hypothesize that there may be different types of insomniacs: (a) hypoactive, as described; and (b) hyperactive, who are more anxious. They also suggested that insomniacs might be hypoactive during the day and hyperactive at night.

The causal direction of the relationship between insomnia and mood disorders is not clearly established. We cannot readily assume that psychiatric symptoms are merely sequelae of insomnia, nor can we definitively assume that insomnia is always a consequence of psychopathology. Clearly, we need to attend to the relationship between mood and insomnia. Even if criteria for a diagnostic disorder are not met, the interplay between moods and insomnia need to be examined in order to increase our knowledge of the etiology and guide treatment efforts.

Insomniacs' primary cognitive symptoms are impaired concentration and memory difficulties (4). Compared to noninsomniacs, insomniacs also rate their attention, memory, reasoning, problem-solving, and reaction time more poorly. Although there is some evidence that insomniacs have difficulty with semantic memory (13), reaction time, and digit span (14), objective verification of performance deficits have not consistently corroborated these subjective performance complaints. Interestingly, Sugerman and associates (15) showed that subjective insomniacs (no PSG corroboration), in contrast to objective insomniacs (PSG corroboration), displayed cognitive deficits. Thus, there may be factors other than sleep loss that account for these reported decrements. First, these data lead one to question whether or not insomniacs are indeed sleep deprived; and second, to hypothesize what could account for these reported symptoms if not sleep deprivation.

Are Insomniacs Sleep Deprived?

Daytime symptoms may not solely be attributable to sleep loss. First, for the majority of insomniacs it is questionable whether they suffer significant sleep loss compared to "good sleepers." Insomniacs have a tendency to overestimate their sleep latency, that is, the time from lights out to the onset of electrophysiologically defined sleep, and underestimate total sleep time (16). Although some insomniacs, particularly those with corroborating PSGs, demonstrate compromised sleep efficiencies and intermittent waking time (13), it is not clear that sleep is significantly disparate from that of noncomplaining sleepers in the majority of insomniacs.

Second, studies consistently find that insomniacs do not demonstrate daytime sleepiness, as measured by the Multiple Sleep Latency Test (MSLT) which measures sleep onset time when an individual is given an opportunity to sleep during the day (17 ,18). In fact, Stepanski and associates (18) found that insomniacs were less sleepy than good sleepers, based on the results of the MSLT. These results must be interpreted with strong caution, however. The MSLT measures sleepiness and ability to fall asleep. Inability to initiate sleep may be a characteristic of insomniacs both during the day and night. Thus, an insomniac may feel sleepy, but not be able to sleep during an MSLT; the results would then artificially underestimate the level of sleepiness. This measure is of dubious utility in the evaluation of sleepiness in those who cannot initiate sleep.

To circumvent this measurement difficulty, Lichstein and colleagues have used an index of sleepiness that does not depend on sleep ability, but rather diameter of the pupil as a measure of sleepiness. Although there is some evidence to suggest that insomniacs differ from noninsomniacs on sleepiness as measured by pupillometry (19 ,20), the effects were marginal. The technique may be promising, but the results are inconclusive.

Third, neither the quality nor quantity of nighttime sleep predicts the next day's functioning. One would expect that a worsening of nighttime sleep would exacerbate daytime impairment. Measures of sleep efficiency (17), total sleep time (TST), and polysomnographic (PSG) recordings (13 ,15 ,20) do not always directly relate to measures of daytime functioning. In fact, TST was correlated with increased tendency for drowsiness (17) and better nighttime sleep was correlated with increased sleep tendency during the day, for both insomniacs and noninsomniacs. Bonnet and Arand (21) also demonstrated that a worsening in sleep was not related to worsened daytime functioning. What, then, could account for the decrements in daytime functioning?

Hypothesized Mechanisms

Several studies support the notion that insomniacs are not necessarily sleep deprived; rather, they are hyperaroused and thus unable to fall asleep (17 ,18 ,21 ,22). This chronic activation may account for the inability to fall asleep at night and during the day, as measured by the MSLT (18). Bonnet and Arand (22) "yoked" the sleep of controls to that of insomniacs. Despite sleeping similar amounts, normal

sleepers exhibited a pattern resembling a sleep-deprived state (decreased tension and vigor, body temperature, and MSLT latencies). Insomniacs demonstrated a pattern of hyperarousal inconsistent with sleep deprivation (increased metabolic rate, body temperature, tension, and decreased vigor); therefore, daytime symptoms may be the result of hyperarousal, not sleep deprivation.

As alluded to in the preceding, perhaps psychopathology, either at the clinical or subclinical level, may account for both insomnia and daytime symptoms. For example, anxiety could account for sleep onset difficulties at night and symptoms of fatigue during the day (23). Likewise, Coyle (24) found that insomniacs with negative affect perceived impaired daytime cognitive functioning and motivation, whereas insomniacs with positive affect perceived better cognitive and motivational functioning.

How an insomniac reacts to his or her sleep disruption may also predict his or her experience of daytime functioning. Several hypotheses related to this notion are offered. Insomniacs may also be “short sleepers,” believe that their sleep is insufficient, and consequently become distressed about it during the day (20 ,25). Insomniacs simply may need more sleep than they are getting or be hypersensitive to small amounts of sleep loss (17). Consistent with these hypotheses, Dorsey and Bootzin (26) examined subgroups of insomniacs classified as objective insomniacs (OI) and subjective insomniacs (SI), with or without corroborating objective sleep disturbances, respectively. Like other studies, differences in performance, alertness, and night sleep parameters were not evidenced. SIs inaccurately estimated sleep/wake state in comparison to objective measures on the MSLT. OIs were more introverted, more withdrawn, and more able to accurately describe the amount of sleep that they had, but were perhaps too internally focused; SIs seemed to be more neurotic and unaware of their internal conscious state. These data suggest that the complaints of insomniacs may be differentiated and better understood by way of personality subtypes.

Studies of physiologic changes accompanying insomnia have produced inconsistent and generally unreplicable findings. The inconsistency may well derive from the heterogeneous samples form the different studies. In fact, the heterogeneity of all those diagnosed with “insomnia” confounds most studies in this field (27).

PATHOPHYSIOLOGY OF DISORDERS OF EXCESSIVE SOMNOLENCE

Part of "130 - Sleep Loss and Sleepiness: Physiological and Neurobehavioral Effects "

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) afflicts up to 4% of middle-aged adults and is characterized by respiratory pauses owing to upper airway closure during sleep, which result in acute hypoxemic events and transient arousals from sleep. Individuals with OSA primarily complain of daytime somnolence, yet are often completely unaware of their loud snoring, apneic and hypopneic events, and sleep fragmentation. Daytime performance is markedly impaired. Studies demonstrate impaired vigilance, reduced reaction times, daytime microsleeps, memory impairment, and depressive symptoms (28 ,29 and 30). Findley and associates (31) found that persons with apnea had poorer performance on “Steer Clear”—a 30-minute computer-generated visual vigilance driving simulation task that measures sustained attention and simple reaction times—than did age-matched control participants. The outcomes of these problems include impairment in work efficiency, increased automobile accident rates, and decrements in quality of life. In the case of truck drivers, pilots, and other operators of heavy machinery, these consequences of sleep-disordered breathing can be catastrophic.

Maintenance of respiration during sleep is dependent on intact central nervous system centers controlling respiration, respiratory reflexes, respiratory musculature, and innervation of the diaphragm and intercostal muscles, as well as a patent upper airway (32). The emphasis of clinical and research approaches to sleep-disordered breathing has focused on this last point—loss of airway patency. Two classes make up most of the obstructive sleep apnea patients. The majority of patients with OSA are obese and have short, thick necks with reduced upper airway diameters owing to excess tissue. A smaller proportion of patients are of normal weight, but are also prone to closure of the upper respiratory tract. These latter individuals typically have oral or maxillofacial structural changes resulting in congenitally small airways. Sleep produces a loss of postural tone of upper airway structures (32) that contributes to the onset of apneic events. Arousals from sleep, owing to combined hypoxemia and hypercapnia, are initiated to restore airway patency (33). Depression of arousal from acute or chronic sleep loss, alcohol, or other sedating drugs increases the propensity for apneic events. Thus, as apneics undergo chronic sleep loss from the repeated arousals, the daytime sequelae progress over time. It remains unclear which elements of OSA are responsible for the hypersomnolence and impaired neurobehavioral performance—repeated arousals from sleep or sleep hypoxemia (34).

Narcolepsy

Narcolepsy, with an estimated prevalence of about 50/100,000 (35), is a disabling disorder that may result in more daytime somnolence than any other major sleep disorder. In addition to the daytime somnolence, it is characterized by cataplexy, rapid switches from waking to sleeping states, sleep paralysis, and hypnagogic hallucinations (36). Not only do patients feel drowsy, but also they rapidly switch from waking to sleeping or cataplectic states—the sudden loss of all skeletal muscle control. This combination of severe excessive daytime somnolence coupled with sleep attacks

makes them particularly prone to impaired daytime neurobehavioral performance. Decrements in performance, including vigilance, and attentional and complex cognitive functioning problems, may be direct consequences of sleepiness (37). In the Findley and associates study, persons with narcolepsy demonstrated marked impairments as the duration of the task increased, with shorter latencies on the MSLT predicting greater performance errors. In addition, 20% to 30% of narcoleptics have comorbid major depressive episodes (38 ,39), although the reasons for this relationship remain largely unexplored.

Until recently, altered cholinergic and monoaminergic systems have been implicated in the pathophysiology of this disorder (40); however, new work from canine strains with narcolepsy, and a strain of Orexin knockout mice (manifesting a phenotype highly similar to narcolepsy) reveals that a genetic defect, disruption of a hypocretin (Orexin) gene may be the primary cause of narcolepsy (41 ,42). Orexins are a class of hypothalamically derived peptides with known effects on appetite and feeding behavior; however, until recently they were not recognized as sleep-modulating neurotransmitters.

Restless Legs Syndrome and Periodic Limb Movements in Sleep

Restless legs syndrome (RLS), a sleep-related disorder with an estimated prevalence of 1% to 5%, is characterized by unpleasant sensations experienced predominantly in the legs, which occur only at rest and become more pronounced in the evening or at night. Patients suffer from an urge to move their legs, often counteracted by walking, which leads to partial, temporary relief of the sensations. Most patients with RLS have periodic limb movements during sleep (PLMS) characterized by repetitive abrupt, involuntary flexion of the extremities that results in brief arousals and repeated complete awakenings. PMLS can occur as an isolated phenomenon, but often occurs with other sleep disorders, including RLS, narcolepsy, sleep apnea syndrome, or REM sleep behavior disorder.

The etiology of RLS and PLMS is unknown. It is hypothesized that PLMS results from a disinhibition of descending inhibitory pathways. Disturbances in dopaminergic, adrenergic, and opiate systems may contribute to RLS/PLMS (43); however, the evidence that these systems are responsible for the pathophysiology is inferentially derived from the fact that pharmacologic agents modulating these systems confer some clinical benefit. Daytime performance impairments that appear secondary to the sleep disruption have been poorly studied.

NEUROBEHAVIORAL AND PHYSIOLOGIC EFFECTS OF SLEEP LOSS

Part of "130 - Sleep Loss and Sleepiness: Physiological and Neurobehavioral Effects "

The evaluation of sleepiness is critical not only to minimize impairment in social or occupational settings, but also to ensure safety. Consequences of sleepiness and fatigue can lead to a myriad of neurobehavioral performance decrements and potentially dangerous situations, such as traffic and work accidents. The following section outlines the primary public health concerns and the populations that are most vulnerable to the consequences of sleepiness and fatigue, such as travelers, truck drivers, and shift workers. In addition, neurobehavioral consequences of experimentally induced sleep loss are reviewed.

Traffic Accidents

According to the National Highway Traffic Safety Administration, 56,000 automobile accidents per year are caused by drivers falling asleep at the wheel (44). Accidents involving truck drivers result in approximately 4,800 fatalities per year (45) and fatigue is the most common cause (46). Sleep-related automobile accidents are associated with fatalities (1.4%) comparable to those of alcohol-related crashes (2.1%) (47). Drowsiness can lead to rapid and frequent uncontrolled sleep or microsleeps, frequent prolonged eyelid closures, and inattention in the form of behavioral lapses that involve a failure to detect a monitored stimulus or a failure to respond in a normal timely manner (48).

Several factors are predictive of fatigue-related traffic accidents. Having an untreated sleep disorder such as insomnia, narcolepsy, or sleep apnea significantly increases the risk of having a motor vehicle accident (MVA) (49 ,50). The amount of sleep truck drivers obtain during the sleep episode prior to the accident inversely predicts the likelihood of an MVA (46). The homeostatic need for sleep and the circadian pacemaker interact in predicting performance in a dynamic, nonlinear fashion (51). Consistent with our knowledge of sleepiness and circadian neurobiology, midafternoon (approximately 3 PM) and nighttime hours (12 AM to 7 AM) are times when both sleepiness is increased and accidents are most likely to occur. Young drivers (under 45 years) are more likely to be involved in an accident during the night, individuals aged 45 to 65 are more likely to be involved in an accident around 7 AM; elderly drivers' peak accident time is at 3 PM.

Shift Workers

As many as 25% of employed individuals engage in shift work—employment outside the typical 7 AM to 7 PM workday—that can have severe personal and public health consequences. Sleepiness is reported by 70% of shift workers (52). Although it is difficult to discern the exact effects of sleepiness on daytime functioning, problem sleepiness among shift workers is associated with decreased quality of life (53), decreased productivity (54), and gastrointestinal and cardiovascular disease (55). Shift workers have a higher incidence of traffic accidents as a result of sleepiness while commuting, compared to non-shift working individuals (56). Shift

workers are also at an increased risk for injury and accidents (51). Three Mile Island, Exxon Valdez, and the Space Shuttle Challenger represent disasters where fatigue among nighttime workers has been implicated.

Both intrinsic biological and environmental factors contribute to the problem sleepiness of shift workers. Compared to individuals engaged in regular hour employment, shift workers sleep approximately 2 hours less per 24-hour sleep cycle as measured by EEG studies (57). Shift workers exist in states of chronic sleep debt because of insufficient sleep during each 24-hour period. Human entrainment to the natural 24-hour light/dark cycle establishes a fixed neurobiologic propensity to be active, alert, and performing during the daylight hours, and to sleep during the nocturne (58). Shift work requires maximum psychomotor and cognitive performance at night, that time when virtually all zeitgebers are cueing the endogenous circadian pacemaker to reduce arousal, activity, and sleep. Thus, not only must shift workers compensate for societal disruptions to their sleep, such as noise and pressures to socialize and perform domestic chores, but they must also overcome daylight and darkness time cues to work and sleep, respectively (53).

Jet Lag

Jet lag is a condition following transmeridian travel that involves a myriad of problems. Symptoms include daytime sleepiness and fatigue, impaired daytime cognitive performance, poor psychomotor coordination, dysphoric mood, and difficulty falling asleep according to the new schedule. The time needed to resynchronize to the new local light/dark cycle increases with the number of time zones crossed.

Like those of shift work, the adverse consequences of jet lag are mediated by disruptions of the sleep and circadian systems. Both the homeostatic mechanism for sleep (sleep drive that increases as duration of wakefulness increases) and circadian neurobiology interact to determine neurobehavioral alertness and performance (59). Jet lag-induced neurobehavioral performance decrements are primarily accounted for by the phase discrepancy between the organism's endogenous circadian rhythms and the new, local 24-hour light/dark cycle, although sleep loss incurred by travel can also serve to exacerbate the condition. The endogenous circadian pacemaker does not immediately adapt to the new light/dark cues, but rather requires a period for resynchronization or re-entrainment occurs during which individuals are likely to experience fatigue and performance deficits. An individual traveling eastward to a destination with a 9-hour time difference may feel compelled to sleep at 9 PM (home time) because of circadian propensity and increased homeostatic sleep drive. However, zeitgebers in the new destination (6 AM) associated with wakefulness, such as sunlight, are discrepant with the individual's endogenous pacemaker and the homeostatic sleep drive associated with sleepiness.

Sleep Deprivation: Experimentally Induced

Sleep loss results in compromised neurobehavioral performance and neurophysiologic functioning (60). Various performance assessments probe the functional capability of the CNS and offer meaning to the physiologic changes that occur as a result of sleep loss (61). Numerous studies show that as sleeplessness increases, so do subjective and objective measures of sleepiness and neurobehavioral problems. Psychomotor vigilance and probed memory impairment as well as somatic complaints appear to increase during acute total and repeated partial sleep deprivation (62 ,63 ,64 and 65). Some studies have been unable to show cognitive impairment during sleep deprivation (66), leading to speculation that chronic partial sleep deprivation does not result in cumulative decreases in performance (67 ,68). A number of factors may have contributed to the disparate outcomes among studies of waking performance after chronic sleep restriction. Many of the negative studies were limited by the fact that the primary outcome measures were performance assessments with robust practice effects (62). Learning curves confound cumulative performance deficit measurements; therefore, they compromise the validity of conclusions concerning the lack of such effects. In other words, repeated testing on a measure with a learning curve will lead to improved performance scores. Thus, if cumulative sleep loss does impair performance on this measure, the decrement will be masked by the learning-derived improvement.

Demonstration of cumulative performance deficits requires utilizing measures that are both sensitive to the effects of sleep loss and have no learning curve. Performance vigilance tasks, cognitive throughput tasks, and tasks requiring rapid response shifts incorporate both of these criteria. Studies utilizing such measures show increased lapses and heightened variability of performance during sustained vigilance tasks (62), all of which show deterioration after acute, total sleep deprivation, and after chronic partial sleep deprivation. During sleep loss, increased rates of slowing in response time result in accelerated decline in average performance with increasing task duration, independent of lapsing. Reduction in speed of response, although not a function of lapses or failure to respond, appear attributable to a decline in the ability to continuously allocate attention to the task and to respond motorically as rapidly as possible. The increase in false response rates or errors of commission, increase during chronic partial sleep deprivation, demonstrating that increased compensatory effort and a loss of motivation cannot account for these neurobehavioral performance decrements.

The magnitude of sleepiness on performance is a result of the dynamic influences of duration awake and underlying circadian rhythms. Motivation and incentive can contribute to, or override, the sleep-induced impairments, but only for a limited time. Sleepiness, fatigue, stress, and impaired

vigilance during sustained sleep restriction accumulate over time (62). Studies suggest that performance degrades in a dose–response manner (69). Kuo found that during chronic partial sleep deprivation, subjective sleepiness increased during the first week, but decreased during the second week (70), suggesting that subjects believed they were adapting to the effects of sleep loss, whereas performance measures indicated that they were not. Subjects were unaware of their neurocognitive dysfunction, because they “felt fine.”

Neurophysiologic functioning is altered during total sleep deprivation of 24 to 48 hours (TSD). (See ref. 60 for review.) Cumulative sleep loss produces decreased latency from wake to sleep onset, microsleep intrusions into wakeful periods, and involuntary sleep onsets. Constricted pupil size, difficulty with balance and coordination, and undulating slow eye movements are also observed as result of TSD. Prolonged sleep loss produces a modest dopaminergic and adrenergic activation, elevated levels of TSH, T3, and T4, hyperactivity of some immune parameters, and hypothermia. Remarkably, the hypothalamic-pituitary-adrenal axis (the “stress” axis) remains largely unaffected by sleep loss. Although recovery from TSD is marked by increased sleep intensity, sleep loss does not produce irreparable harm; changes can be reversed with recovery sleep.

Sleep deprivation in healthy individuals tends to produce little, if any, worsening of mood, anxiety, or anger, but does produce worsening self-reports of fatigue, vigor, and confusion. In contrast, depressed patients demonstrate increased locomotor activity, increased self-ratings of vigor, reduced fatigue, and improved mood after approximately 30 hours of sleep deprivation (71 ,72). This seemingly paradoxic effect in depressed individuals may reflect an underlying heightened sensitivity to the sleep deprivation-induced increases in dopamine, hypothalamic-pituitary-thyroid axis activity (73). Studies aimed at understanding these opposite effects in depressed and healthy persons to elucidate mechanisms are needed.

TREATMENT FOR SLEEP LOSS AND SLEEPINESS

Part of "130 - Sleep Loss and Sleepiness: Physiological and Neurobehavioral Effects "

Insomnia

Results from recent metaanalyses indicate that nonpharmacologic treatments for chronic insomnia are effective for the majority (70% to 80%) of patients (74) in reducing latency to sleep onset and wake after sleep onset by approximately 50% (e.g., to approximately 30 minutes). Effective treatments for insomnia include stimulus control (75), progressive muscle relaxation (76), paradoxic intention, sleep restriction (77), biofeedback (78), and cognitive therapy (79). (See ref. 27 for a further description of nonpharmacologic treatments.) Although the benefits of using combined pharmacologic and nonpharmacologic treatments has not been investigated extensively, some data suggest that behavior therapy alone, pharmacotherapy alone, and the two in combination provide comparable efficacy in the short term, but behavioral approaches may excel in the long term. (See ref. 74 for a review.)

Although patients have reported sleep quality improvement by using these strategies, the degree to which daytime sequelae, such as self-reported cognitive impairment, mood disturbance, and quality of life, remit has not yet clearly been determined. This is particularly relevant given the hypothesis that it may not be sleep loss per se that accounts for daytime impairment, but rather concomitants such as hyperarousal, cognitive distortions, and distressed mood that account for daytime performance and functioning. Strategies such as cognitive-behavioral therapy and progressive relaxation hold promise for managing these noted daytime sequelae.

The classic benzodiazepines and the newer, more selective benzodiazepine agonists zaleplon and zolpidem are extremely effective at inducing and sustaining sleep. The role of these compounds in treating insomnia is described in greater detail elsewhere in this text. Many of them unfortunately also produce residual daytime somnolence and impaired neurobehavioral performance. Typically, the longer-acting agents are more likely associated with these adverse effects. The newer agents, zaleplon and zolpidem, appear to produce less daytime problems than the older agents (80), however, whether any of these compounds reverse the daytime impairments to which insomniacs are prone remains to be seen.

Additional research is needed to assess the effects of pharmacologic and nonpharmacologic treatments not only for sleep quality (total sleep time, wake after sleep onset, sleep efficiency), but also for daytime performance, function, and distress.

Excessive Somnolence

Daytime napping is a behavioral strategy commonly used to alleviate excessive somnolence and enhance alertness in everyday life. The efficacy of napping, however, is contingent on the causes of the sleepiness and performance deficits. For whom and under what conditions is napping effective at alleviating sleep and enhancing alertness? The propensity for adults to nap in the midafternoon is relatively consistent across all cultures and appears tied to the endogenous circadian system. Some cultures, such as those in Mexico, China, or Greece, endorse taking afternoon siestas, consistent with the chronobiologic tendency. Perhaps owing to industrialization or occupational demands, other countries (e.g., the United States and Japan) do not endorse this practice, despite the endogenous drive for sleep in the midafternoon. Thus, napping is a behavior that is consistent with the circadian rhythm dip in the midafternoon and can be used to enhance functioning, even for individuals who do not exhibit sleep disorders (81).

For individuals with sleep disorders, however, the usefulness of napping in alleviating symptoms depends on the nature of the dysfunction (i.e., the underlying mechanism that contributes to the symptoms) (81). One might assume that napping is a healthy way of managing excessive somnolence regardless of the underlying mechanism. Many persons with narcolepsy find brief daytime napping to be helpful, whereas persons with untreated sleep apnea derive no benefit from napping (81). Napping improves reaction time performance in individuals with narcolepsy-cataplexy (82). Likewise, the strategy of “prophylactic napping” in advance to prevent anticipated sleepiness is quite helpful for individuals (e.g., truck drivers or shift workers) who need to work for prolonged hours (83). Appropriately timed napping can be beneficial for treatment of jet lag in some circumstances (84).

Two caveats are described regarding the use of napping for managing excessive somnolence. First, side effects of napping can include sleep inertia, which is characterized by sleepiness, diminished alertness, and reduced performance that occurs immediately on waking from sleep but that dissipates within 1 to 4 hours of awakening (85 ,86 and 87). Sleep inertia can be especially problematic for those who need to perform immediately on awakening. Second, if a nap is too long, it can interfere with nighttime sleep. Hence, napping is not recommended for individuals whose primary presenting problems directly involve difficulty initiating or maintaining nocturnal sleep.

Wake-Promoting Compounds

Caffeine is the most widely used wake-promoting compound in the world, most often consumed in high, intermittent dosages (150 to 300 mg) and usually in the hours just after awakening. Caffeine is most often used to counter the effects of morning sleep inertia. However, some also use it throughout the day to maintain wakefulness. This may be a natural countermeasure to daytime sleepiness caused by insufficient sleep the prior night. Research is needed in this area. Caffeine is a safe and simple wake-promoter that has been “staring us in the face,” but little research has focused on how to use caffeine as a practical and safe wake-promoter in the context of daytime sleepiness.

The mechanisms by which caffeine is able to promote wakefulness have not been fully elucidated (88). Most studies indicate that, at the levels reached during normal consumption, caffeine exerts its action through antagonism of central adenosine receptors (89 ,90). It reduces physiologic sleepiness (91—93) and enhances vigilance and cognitive performance (94 ,95). These beneficial effects have also been reported for caffeine taken during sleep deprivation (91 ,93 ,94).

Classical psychomotor stimulants such as methamphetamine and methylphenidate are potent centrally active compounds with central and peripheral sympathomimetic activity. In contrast to caffeine, methamphetamine and methylphenidate produce neurobehavioral activation and promote wakefulness by increasing dopaminergic and noradrenergic neurotransmission. These compounds have a number of potentially undesirable side effects, including anxiety, appetite suppression, tolerance, dependence, and abuse potential (96).

Modafinil is the first of a new class of wake promoting therapeutics (97 ,98). The mechanism(s) by which it improves alertness and vigilance and reduces sleepiness remains obscure. Some work suggests that modafinil may promote activity at α1- and ß-adrenergic receptors (99) and 5-HT2 receptors (100). Its ability to stimulate dopaminergic activity remains controversial. New work has demonstrated that it actually stimulates Orexin-containing neurons in the hypothalamus of mice (42). Unlike amphetamines, modafinil does not appear to produce dependence or have addictive potential (98 ,101). The novel wake-promoting compounds hold potential for enhancing understanding of the mechanisms of pathologic somnolence and for the treatment of the disorders of excessive sleepiness.

Obstructive Sleep Apnea

Treatments for OSA are directed at maintaining airway patency and thereby preventing the apneic events. The most effective methods developed to date include continuous positive airway pressure (CPAP), weight loss, dental appliances that reposition the jaw and/or tongue, and surgical procedures. These treatments have been demonstrated to improve the daytime somnolence, impaired vigilance, depression, and overall quality of life (28 ,29 and 30). Few randomized, well-controlled trials have been published that evaluate pharmacologic agents in the treatment of obstructive sleep apnea. Respiratory stimulants (theophylline), psychostimulants, adrenergic agonists, opioid antagonists, and nicotinic agents, have been studied with mixed results. Non-OSA sleep-related breathing disorders such as hypercapnic obesity-hypoventilation, myxedema, central apnea, and periodic breathing in congestive heart failure respond to specific pharmacologic measures. Future research including the use of the newer wake-promoting compounds, such as modafinil, is warranted.

Narcolepsy

Until recently, standard treatments for narcolepsy often included a combination of amphetamine-like stimulants for sleepiness and antidepressant therapy for abnormal rapid eye movement sleep events (cataplexy, sleep paralysis, and hypnagogic hallucinations). These treatments are purely symptomatically directed and involve activation of central dopaminergic and adrenergic systems (36). Modafinil is the first specific treatment approved in the United States for treatment of narcolepsy. With the discovery of the genetic

markers for narcolepsy, even more novel approaches appear conceivable. Gene therapy or compounds affecting Orexin, systems one of which is modafinil, are likely directions for future research.

RLS/PLMS

Treatment of RLS/PLMS is targeted toward dopaminergic, adrenergic, GABA, and opiate systems. L-Dopa, dopamine agonists, benzodiazepines, opioids, clonidine, and carbamazepine appear effective. With no obvious cause, treatment has been aimed at symptom control to date (43).

Shift Work and Jet Lag

The disturbances in circadian neurobiology associated with shift work and jet lag appear to be responsive to interventions that alter the underlying circadian system. Bright light therapy and exogenously administered melatonin are potent zeitgebers capable of inducing phase shifts in humans. Regulation of exposure to sunlight and artificial light (102 ,103), napping (104), caffeine to promote alertness at night and hypnotics to help daytime sleep (105), and melatonin to adjust circadian rhythms (106 ,107) are all helpful in limited studies. This evidence is in need of replication and application to other real-world situations.

RECENT ADVANCES IN ASSESSMENT AND PREVENTION TECHNOLOGIES

Part of "130 - Sleep Loss and Sleepiness: Physiological and Neurobehavioral Effects "

As discussed, the MSLT and pupillometry aid in the assessment of sleepiness. Wrist-worn actigraphic devices that monitor locomotion have demonstrated utility in monitoring sleep-wake patterns and sleep quality as well as assessing sleep disorders. (See refs. 108 and 109 for review.) A newly introduced technology, the sleep switch, is a handheld instrument that effectively detects latency to sleep onset (110). The patient presses and holds a button. When the patient lapses into sleep, voluntary motor tone is lost, the button is released, and an event marker notes the time. Unlike actigraphy, it cannot measure total sleep time; however, it has the distinct advantage as an objective estimate of sleep onset latencies for measuring insomnia, compared to actigraphs and compared to the subjective estimates of sleep logs that have traditionally been used (110).

The development and validation of technologies to detect and monitor fatigue is essential (111). As discussed, fatigue-related motor vehicle crashes and performance errors owing to sleep loss are pervasive and individuals are unreliable predictors of their own level of impairment (70 ,112). Moreover, current standards of proscriptive hours are not sufficient at preventing crashes, even when compliance is 100%. Thus, technology offers advantages of both objective verification of sleepiness levels and a viable alternative to enhance and improve safety while facilitating occupational and economic goals.

Four major categories comprise operator-centered fatigue monitoring technologies. First, readiness-to-perform and fitness-for-duty technologies for drowsiness—aim to measure the functional capacity for work to be performed. Some measure fatigue by physiologic fitness (pupil or ocular scanning), whereas others measure performance via a battery of simple performance tests (113). Second, mathematical models of alertness are combined with ambulatory technologies to predict fatigue (114 ,115 and 116). These typically involve a device, such an actigraph, which measures fatigue in combination with a formula (mathematical model) that predicts performance capacity for a given period of time when sleepiness is likely to occur. Third, vehicle based performance technologies focus on the vehicle, in contrast to the driver (117 ,118 ,119 and 120). They are designed to monitor the vehicle hardware systems that are subject to the alterations of the driver's performance, such as steering or speed variability or lane swaying. Fourth, in-vehicle, on-line, operator status monitoring technologies aim to monitor biobehavioral features of the operator (e.g., eyes, face, head, heart, brain electrical activity) on-line. Example of devices include: (a) video of the face, which monitors the eyelid position, blinks, movements, head nodding, direction of gaze; (b) eye trackers; (c) wearable eyelid monitors; (d) head movement detectors; (e) EEG algorithms; and (f) ECG algorithms (111). All these systems have relative merits and drawbacks. Clearly the status of these technologies is promising.

Pathophysiological and Pharmacologic Aspects of the Sleep Disorder Narcolepsy

Emmanuel Mignot

Seiji Nishino

Emmanuel Mignot and Seiji Nishino: Center for Narcolepsy, Department of Psychiatry and Behavioral Sciences, Stanford University Medical Center, Stanford, California.

Narcolepsy is frequently both over- and under-diagnosed. The condition is not rare and has population prevalence similar to that of multiple sclerosis (57 ,78 ,141). Studies have demonstrated a large psychosocial impact of the disease (22 ,23). Narcolepsy is also a unique disease model for basic sleep researchers with the availability of validated animal models and as the only known disorder with a complete disorganization of sleep and REM sleep. Our understanding of the pathophysiology of the disorder is rapidly emerging, thanks to the discovery that narcolepsy-cataplexy is associated with a deficiency in the hypocretin (Orexin) neuropeptide system (30 ,68 ,106). The fact that human narcolepsy is HLA-associated (59 ,82) also suggests a possible autoimmune mediation in many cases. In this chapter, we briefly outline how narcolepsy is diagnosed and treated, as well as discuss future directions for this rapidly evolving area.

CLINICAL AND EPIDEMIOLOGIC ASPECTS OF HUMAN NARCOLEPSY

Part of "131 - Pathophysiological and Pharmacologic Aspects of the Sleep Disorder Narcolepsy "

Cataplexy: A Pathognomonic Symptom of the Narcolepsy Syndrome

Patients with narcolepsy experience brief episodes of muscle weakness when laughing, angry, or elated, a symptom referred to as cataplexy (3 ,7 ,46 ,55 ,114). These episodes most often affect the legs or the face, leading to knee buckling, sagging of the jaw, slurring of speech, and/or dropping of the head (7 ,46 ,55). Episodes are brief (a few seconds to several minutes at most), bilateral, and rarely lead to body collapse and/or long-lasting episodes of complete paralysis. Consciousness is preserved during cataplexy (7 ,46 ,55).

The importance of carefully defining cataplexy should be emphasized. Epidemiologic studies have shown that up to 30% of the general population experiences “muscle weakness episodes in reaction to emotions” (4 ,7 ,57). Clearly, this definition is not sufficient to establish cataplexy. Genuine cataplectic episodes in narcolepsy are triggered by very specific emotions. Joking, laughing, and anger are the most reliable triggering events (7). Rare episodes of muscle weakness occurring exclusively in the context of unusual emotional triggers, for example while tense or stressed, or during sexual or athletic activities, should not be considered as cataplexy (7).

The presence of cataplexy being critical to the diagnosis, it is clinically useful to differentiate definite/clear-cut cataplexy from doubtful, possible cataplexy (very rare events, long duration, and unusual triggers). For many clinicians, the presence of clear-cut cataplexy is sufficient to diagnose narcolepsy and narcolepsy-cataplexy is etiologically homogenous. In favor of this hypothesis, almost all (85% to 100%) patients with definite cataplexy share a specific genetic marker, HLA-DQB1*0602, across various ethnic groups (81). This high association contrasts with DQB1*0602 control frequencies ranging from 12% in Japanese, to 20% to 25% in most white populations, and 38% in African Americans (69 ,81).

Other Narcolepsy Symptoms

Although cataplexy is the most specific symptom of narcolepsy, it is frequently mild and rarely the most significant problem clinically for narcoleptic patients. Rather, persistent daytime sleepiness is the most disabling symptom in most patients. Patients with narcolepsy experience a permanent background of daytime sleepiness culminating in overwhelming sleep attacks (3 ,55 ,104 ,114). Narcoleptic subjects may continue their activity during these sleep attacks in a semiautomatic manner, without any memory of the event (automatic behavior). Daytime napping usually relieves daytime sleepiness temporarily (55). Other symptoms

frequently reported include sleep paralysis, an inability to move occurring at sleep/wake transitions, and hypnagogic hallucinations, dreamlike experiences at sleep onset (3 ,55 ,104 ,114). These symptoms are also not specific to narcolepsy and are frequently observed in the general population and patients with other sleep disorders (4 ,7 ,109 ,110). Patients with narcolepsy also have frequently disturbed nocturnal sleep (3 ,55 ,104 ,114). Nightmares, REM behavior disorder, and periodic leg movements during sleep are commonly observed (56 ,104 ,135). Typically, patients with narcolepsy fall asleep easily and wake up after a few hours, unable to fall asleep again at night (3 ,55 ,104 ,114).

Diagnosis of Narcolepsy

The diagnosis of narcolepsy is primarily clinical but polysomnographic studies are useful to document a sleep abnormality and to exclude confounding and/or associated sleep disorders. These tests are also useful to justify future treatment using amphetamine-like stimulants. Most commonly, nocturnal polysomnography with monitoring of breathing and oxygen saturation is carried out to exclude sleep apnea syndrome or other problems potentially disrupting nocturnal sleep. This is followed by a four- to five-nap multiple sleep latency test (MSLT) (4 ,29). These tests must be carried out without any psychotropic treatment and after adequate washout periods (at least 2 weeks for antidepressants, because of their strong REM sleep effects). Sleep logs are used to document adequate nocturnal sleep amount prior to testing. Nocturnal polysomnography in patients with narcolepsy usually reveals a short REM latency in less than 20 minutes (50% of the cases), low sleep efficiency (associated insomnia), and frequently associated periodic leg movements (56). MSLT data indicates short mean sleep latency (SL ≤ 8 minutes) and REM episodes (2 or more sleep onset REM periods, or SOREMPs), a result generally considered diagnostic of narcolepsy (4) (Table 131.1).

Diagnostic Criteria: Narcolepsy

A. A complaint of excessive sleepiness or sudden muscle weakness
B. Recurrent daytime naps or lapses into sleep that occur almost daily for at least 3 months
C. Sudden bilateral loss of postural muscle tone in association with intense emotion (cataplexy)
D. Associated features include:
   1. Sleep paralysis
   2. Hypnagogic hallucinations
   3. Automatic behaviors
   4. Disrupted major sleep episode
E. Polysomnography demonstrates one or more of the following:
   1. Sleep latency less than 10 minutes
   2. REM sleep latency less than 20 minutes and
   3. An MSLT that demonstrates a mean sleep latency of less than 5 minutes
   4. Two or more sleep onset REM periods
F. HLA typing demonstrates DR2 positively
G. Absence of any medical or psychiatric disorder that could account for the symptoms
H. Other sleep disorders may be present but are not the primary cause of the symptoms (e.g., periodic limb movement disorder or central sleep apnea syndrome)

Minimal Criteria: B + C, or A + D + E + G

From American Sleep Disorders Association. ICSD-International Classification of Sleep Disorders diagnostic and coding manual. Rochestv, MN. American Sleep Disorders Association, 1991.

TABLE 131.1. INTERNATIONAL CLASSIFICATION OF SLEEP DISORDERS (ICSD) DIAGNOSTIC CRITERIA FOR NARCOLEPSY

Epidemiologic Studies of Narcolepsy-Cataplexy

Epidemiologic studies have only been performed for narcolepsy-cataplexy. Hublin and associates performed the best-designed study in Finland (57). Using a twin registry and systematic evaluation of 10,000 twin individuals, this study led to a prevalence of .023%. Other studies have led to very similar prevalence values (.02% to .05%) in North American and various other Western European countries (78). Population-based studies suggest a higher prevalence for narcolepsy-cataplexy in Japan (.16% to .17%), but diagnostic criteria did not require polysomnography to verify the diagnosis (54 ,150). Studies comparing sleep disorder populations in a sleep disorder center in Israel suggest a low prevalence (.002%) for the syndrome in this population (65).

Narcolepsy without Cataplexy and Disease Spectrum

In current patient populations, only 50% to 80% of narcoleptic patients have cataplexy. The presence of cataplexy is not necessary to diagnose narcolepsy based on current international diagnostic criteria. Rather, narcolepsy is either diagnosed: (a) in the presence of cataplexy with or without results from associated sleep tests; or (b) without cataplexy but with abnormal MSLT results, associated sleep paralysis or hypnagogic hallucinations and after excluding other sleep disorders (e.g., abnormal breathing during sleep) (4). The rationale for a broader definition of narcolepsy stems from the observation that sleep paralysis, hypnagogic hallucinations, and SOREMPs are all pathologic manifestations of abnormal REM sleep in narcolepsy (52 ,123).

Whereas the prevalence of narcolepsy-cataplexy is well established, the population prevalence of narcolepsy without cataplexy is unknown and could be as high as several percent of the population. Genetic studies indicate a higher HLA association in narcolepsy-cataplexy (85% to 100% DQB1*0602 positive) versus narcolepsy without cataplexy (40% DQB1*0602 positive) (80), suggesting increased etiologic heterogeneity in narcolepsy without cataplexy.

GENETIC PREDISPOSITION IN HUMAN NARCOLEPSY

The genetic aspects of human narcolepsy are complex. Since 1983–1984, human narcolepsy has been known to be associated with HLA-DR2 (59); more recent results suggest a primary association with HLA-DQ (76 ,82 ,96 ,117), with HLA DQB1*0602 playing a primary role in disease predisposition and other HLA alleles having secondary effects (88). The importance of environmental factors is indicated by the low degree of concordance of monozygotic twins (25% to 31%) (78). Genuine multiplex families are rare; most narcoleptic patients do not have a family history. Only 1% to 2% of first-degree relatives of narcolepsy patients ever develop narcolepsy-cataplexy (20 ,44 ,78). One to two percent affected in first-degree relatives indicates a 20- to 40-fold increased risk that cannot be explained by HLA-associated genetic factors alone (78). Further, multiplex families are more frequently HLA-DQB1*0602 negative than sporadic cases, suggesting the importance of non-HLA genetic factors (83).

The HLA association observed in narcolepsy suggests a primary involvement of the immune system in the pathophysiology of the disorder, yet all studies aiming at demonstrating an autoimmune mediation have failed (28 ,77 ,86). The recent discovery that narcolepsy is associated with undetectable CSF hypocretin-1 levels (106) suggests that this hypothesis should be revisited now that a potential target cell population has been identified.

ANIMALS MODELS OF NARCOLEPSY AND HYPOCRETIN (OREXIN)

Part of "131 - Pathophysiological and Pharmacologic Aspects of the Sleep Disorder Narcolepsy "

In 1973 and 1974, narcolepsy was first reported in a dachshund and a poodle (60 ,91). Autosomal recessive occurrence of narcolepsy in doberman pinschers and Labrador retrievers was subsequently discovered, and a colony of genetically narcoleptic Dobermans and Labradors was established at Stanford University (13). As with human patients, narcoleptic animals exhibit muscle weakness (cataplexy) when emotionally stimulated. Polygraphic studies in narcoleptic dogs have also demonstrated that narcoleptic canines have a shorter latency to drowsiness, light sleep, and REM sleep than do control animals (104). Sleep paralysis and hypnagogic hallucinations may also exist in narcoleptic dogs, but are impossible to document owing to their subjective nature.

In narcoleptic Dobermans and Labradors, the major susceptibility gene, canarc-1, is unlinked to dog leukocyte antigen (DLA) (87). Linkage analysis with various genetic markers, including minisatellite probes and functional candidate gene probes, revealed that the canine narcolepsy gene cosegregated with a polymorphic band cross-reacting with the switch region of the human immunoglobulin μ heavy-chain gene (87). After 10 years of chromosome walking in dogs, the canine narcolepsy gene was finally identified as the hypocretin receptor 2 gene (*Hcrtr2*) (68). Three mutations causing loss of function of Hcrtr 2 and impaired postsynaptic hypocretin neurotransmission were identified in Labradors, dachshunds, and Dobermans, respectively (68). The discovery of *canarc-1* (*Hcrtr-2*) was followed by the report that preprohypocretin (prepro-Orexin) knockout mice also exhibit a narcolepsy-like phenotype, shorter REM sleep onset, and episodes of behavioral arrest similar to cataplexy in canine narcolepsy (30). Deficits of either the hypocretin ligand or its receptor-2–mediated transmission thus generate narcolepsy in animal models.

Following up on this discovery, hypocretin 1-peptide (Orexin A) levels were measured in the cerebrospinal fluid (CSF) of narcoleptic humans. Strikingly, Hcrt 1 was below detectable levels in seven out of nine patients, in contrast to eight control subjects who all had normal Hcrt 1 levels (106). These results suggest that a deficit in hypocretin transmission is also involved in cases of human narcolepsy, although disease heterogeneity may exist (106). (See more details in monoaminergic cholinergic imbalance and deficit in hypocretin neurotransmission sections.)

TREATMENT OF HUMAN NARCOLEPSY

Part of "131 - Pathophysiological and Pharmacologic Aspects of the Sleep Disorder Narcolepsy "

Pharmacologic Treatment of Daytime Sleepiness with Amphetamine-like Compounds

Nonpharmacologic treatments (i.e., behavioral modification such as regular napping and work accommodations) are often helpful (128 ,129), but are rarely sufficient to control the symptoms. Referral to patient support groups (e.g., narcolepsy network) and giving directives regarding driving and other potentially dangerous activities is critical until a better understanding and control of the disorder by the patient is achieved. In a recent survey by a patient group organization (8), 94% of all patients reported using pharmacologic therapies, mostly stimulant medications. Sleepiness is usually treated using amphetamine-like CNS stimulants or modafinil, a novel wake-promoting compound unrelated to the amphetamines (Table 131.2). The most commonly used amphetamine-like compounds are methamphetamine, *d*-amphetamine, methylphenidate, pemoline, and mazindol (Table 131.2). The most important pharmacologic property of amphetamine-like stimulants is to release catecholamines, mostly dopamine and norepinephrine (62 ,147). Monoamine reuptake blockade and MAO inhibition also occur at high doses and the importance of these secondary pharmacologic effects varies from one amphetamine derivative to another (73). Pharmacologic studies using the canine narcolepsy model strongly suggest that presynaptic enhancements of dopamine transmission contribute to the EEG arousal effects of amphetamine-like CNS stimulants and modafinil (103). (See also the Canine Narcolepsy section.)

Of importance is the report that in animals, amphetamine-like stimulants are neurotoxic at high doses for catecholaminergic (e.g., dopaminergic) neurons (127).

Stimulant Compound	Usual Daily Doses[a]	Half-Life (Hours)	Side Effects/Notes
Sympathomimetic stimulants			
D-Amphetamine sulfate[b]	5–60 mg (15–100 mg)	10–12	Irritability, mood changes, (urinary pH-dependent) headaches, palpitations, tremors, excessive sweating, insomnia
Methamphetamine HCl[b]	5–60 mg (15–80 mg)	4–5	Same as *d*-amphetamine (urinary pH-dependent) may have a greater central over peripheral effect[c]
Methylphenidate HCl[b]	10–60 mg (30–100 mg)	3–4	Same as amphetamines; better therapeutic index than *d*-amphetamine with less reduction of appetite or increase in blood pressure; short duration of action
Pemoline	20–115 mg (37.5–150 mg)	16–18	Less sympathomimetic effect; milder stimulant; slower onset of action; a tendency for drug build-up; occasionaly produces liver toxicity; not a controlled substance
Mazindol[d]	2–6 mg (NA)	33–55	Weaker CNS stimulant effects; anorexia, dry mouth, irritability, headaches, gastrointestinal symptoms; reported to have less potential for abuse
Other Agents for treatment of EDS			
Modafinil	100–400 mg (NA)	8–14	No peripheral sympathomimetic action; headaches; nausea; reported to have less potential for abuse
Caffeine[e]	100–200 mg (NA)	3.5–5	Palpitations, hypertension; weak stimulant effect; 100 mg of caffeine roughly equivalent to one cup of coffee
MAO inhibitors with alerting effect			
Selegiline[b]	5–40 mg (NA)	0.15[f]	Low abuse potential; partial (10–40%) interconversion to amphetamine
Brofaromine	150 mg (NA)	12–19	Reversible MAOA selective inhibitor

[a]Dosages recommended by the ASDA (90) are listed in parentheses (usual starting dose and maximal dose recommended).
[b]Demonstrated anticataplectic effects in narcoleptic dogs.
[c]Methamphetamine is reported to have more central effects (38) and may predispose more to amphetamine psychosis (139). The widespread misuse of methamphetamine had led to severe legal restriction on its manufacture, sale; and prescription in many countries (112). Note that the molecular weight of this compound is about half that of *d*- and *l*-amphetamine; thus, methamphetamine contains twice as much active molecules as *d*- or *l*-amphetamine per mg dose. *L*-amphetaine (dose range 20–60 mg) is not available in the US, but probably has no advantage over *d*-amphetamine in the treatment of narcolepsy (slightly weaker stimulant).
[d]Demonstrated anticataplectic effects in humans.
[e]Caffeine can be bought without prescription in the form of tablets (NoDoz, 100 mg; Vivarin 200 mg caffeine) and is used by many patients with narcolepsy prior to diagnosis.
[f]Half-lives of metabolites (amphetamine and methamphetamine) are long.

TABLE 131.2. COMMONLY USED TREATMENTS FOR EXCESSIVE DAYTIME SLEEPINESS (EDS)

The clinical use of stimulants in narcolepsy has been the subject of a recent American Sleep Disorders Association (ASDA, now American Academy of Sleep Medicine) Standards of Practice publication (9). Typically, the patient is started at a low dose, which is then increased progressively to obtain satisfactory results (Table 131.2). Studies have shown that daytime sleepiness can be greatly improved subjectively, but that sleep variables are never completely normalized by stimulant treatment (92). Low efficacy compounds/milder stimulants (e.g., modafinil, or more rarely, pemoline) are usually tried first. More effective amphetamine-like stimulants (i.e., methylphenidate, *d*-amphetamine, and methamphetamine) are then used if needed. The final dose of stimulant medication used varies widely from patient to patient, depending on tolerance, personality, efficacy, and lifestyle (from no stimulant treatment to very high doses). Patient input and work environment is very important. Some patients prefer to use high doses of long-acting, slow-release preparations to stay awake all day long, whereas others combine lower doses and short half-life derivatives (e.g., methylphenidate) with scheduled napping. Stimulant compounds are generally well tolerated. Minor side effects such as headaches, irritability, nervousness, tremors, anorexia, palpitations, sweating, and gastric discomfort are common (Table 131.2). Cardiovascular impact such as increased blood pressure is possible considering established sympathomimetic effects in animals, but has been

remarkably difficult to document in human studies (145). Surprisingly, tolerance rarely occurs in this patient population and “drug holidays” are not recommended by the American Academy of Sleep Medicine (90). Rather, a slight increase in dosage is preferable. Exceptionally, psychotic complications are observed, most often when the medications are used at high doses and chronically disrupt nocturnal sleep.

Amphetamine was first used to treat narcolepsy in 1935 (120), only 8 years after Alles initially synthesized it (5). Both the *l*- and *d*-isomers have been used for the treatment of narcolepsy, either in isolation or as a racemic mixture (available in the United States). The *d*-isomer is a slightly more potent stimulant (113 ,115) and is most generally used. *L*-Amphetamine is occasionally used in some European countries (dose range 20 to 60 mg) (112). *D*-Amphetamine is the second most frequently prescribed narcolepsy treatment after methylphenidate (8). It is well absorbed by the gastrointestinal tract and partially metabolized in the liver using aromatic and aliphatic hydroxylation. This process yields parahydroxyamphetamine and norephedrine, respectively, both of which are biologically active (158). Amphetamine is metabolized into benzoic acid (23%), which is subsequently converted to hippuric acid or parahydroxyamphetamine (2%). This in turn is converted to parahydroxynorephedrine (.4%). Thirty-three percent of the oral dose is excreted unchanged in the urine. Importantly, urinary excretion of amphetamine and many amphetamine-like stimulants is greatly influenced by urinary pH. Amphetamine is a weak base and at a physiologic pH, it exists mainly as a charged amine [RNH3]+, which is poorly reabsorbed in the renal tubules. Acidifying the urine thus favors the excretion of the charged form of the amine (16), increases urinary excretion versus liver catabolism, and reduces the half-life. At urinary pH 5.0, the elimination half-life of amphetamine is very short (about 3 to 5 hours) but at pH 7.3 it increases to 21 hours (16). Sodium bicarbonate delays excretion of amphetamine and prolong its clinical effects, whereas ammonium chloride shortens amphetamine toxicity. Finally, dextroamphetamine is available as a sulfate-base derivative or as spansule (slow-release) capsules.

Methamphetamine is the most efficacious and most potent amphetamine derivative available. This compound is extremely useful in subjects with severe sleepiness who need high doses. The addition of a methyl group makes this derivative more lipophilic, thus increasing CNS penetration and providing a better central over peripheral profile. The widespread misuse of methamphetamine has led to severe legal restriction on its manufacture, sale, and prescription in many countries (112), but it is available in the United States. It should also be noted that the molecular weight of the most commonly used form of methamphetamine (hydrochloride) is about half that of *d*- and *l*-amphetamine salt (sulfate). Methamphetamine preparations thus contain twice as many active amphetamine molecules when compared to *d*- or *l*-amphetamine per mg dose. The simple chlorate to sulfate formulation difference largely explains the higher potency of methamphetamine.

Yoss and Daly introduced methylphenidate for the treatment of narcolepsy almost 50 years ago (160). It is now the most commonly prescribed stimulant medication in the United States, with 46% of narcoleptic patients using the compound on a regular basis (8). Part of its popularity is owing to its relatively short duration of action (approximately 3 to 4 hours). This property allows narcoleptic patients to use the compound on an as-needed basis while keeping open the possibility of napping. The compound is also reported to produce fewer psychotic complications at high doses (116). A slow release formulation is available but less frequently used.

Pemoline is generally better tolerated than methamphetamine or *d*-amphetamine but it is also less efficacious and less potent, and occasionally produces liver toxicity. After taking a therapeutic dose of pemoline (40 mg), peak levels in serum are reached within 4 to 6 hours. The half-life is 16 to 18 hours. Pemoline is partially metabolized by the liver. Metabolites include pemoline conjugates, pemoline dine, and mandelic acid. After oral administration of 40 mg of pemoline, 35% to 50% of the dose is excreted in the urine within 32 hours, and only a minor fraction is present as metabolites (41). The long duration of action of pemoline may be associated with a better compliance in narcoleptic patients (130). Pemoline most selectively blocks dopamine reuptake and only weakly stimulates dopamine release. Fatal hepatotoxicity has been reported and may be dose related (17 ,142). Pemoline should not be prescribed to patients with impaired hepatic function, and hepatic function should be carefully monitored during chronic drug administration. The recent introduction of modafinil, a novel wake-promoting agent with a similar profile and fewer side effects, has greatly diminished the use of this compound in narcolepsy.

Mazindol is less frequently used because of its weaker stimulant activity (58). It is a weak releasing agent for dopamine, but it also blocks dopamine and norepinephrine reuptake with high affinity (103). Mazindol is effective for both excessive daytime sleepiness and cataplexy (58). Mazindol is absorbed quantitatively at a medium rate from the gastrointestinal tract, and the peak blood concentration is reached after 2 to 4 hours. The half-life of clearance from blood was estimated at 33 to 55 hours (47).

Modafinil and Other Wake-Promoting Agents

Modafinil, a compound structurally distinct from amphetamines, has recently been approved in the United States for the treatment of narcolepsy and essential hypersomnia. This compound is also increasingly explored to treat other conditions, such as residual sleepiness in treated obstructive sleep

apnea or fatigue in multiple sclerosis. Modafinil has been available in France since 1986, and long-term follow-up suggests no remarkable side-effect profile and low abuse potential. Clinical trials in France and Canada have shown that 100 to 300 mg of modafinil is effective for improving daytime sleepiness in narcoleptic and hypersomnolent subjects without interfering with nocturnal sleep. It has limited efficacy on cataplexy and the symptoms of abnormal REM sleep (15 ,19 ,21). Recent double-blind trials on 283 narcoleptic subjects in 18 centers in the United States and on 75 narcoleptic subjects in 11 centers in Canada revealed that 200 and 400 mg of modafinil significantly reduced sleepiness and improved patients' overall clinical condition (1 ,26). However, it is also reported that patients who have been previously treated with methylphenidate may respond more poorly to modafinil (26). Modafinil is well tolerated by these subjects, and adverse experiences with modafinil use occur at rates comparable to placebo (1 ,26). In humans, modafinil exhibits a linear pharmacokinetic profile for doses ranging from 50 to 400 mg, with a terminal elimination half-life ($t_{1/2}$) of 9 to 14 hours (159). Modafinil is extensively metabolized to two major pharmacologically inactive metabolites, modafinil acid and modafinil sulfone, which are renally excreted. Less than 10% of the oral dose of modafinil is excreted unchanged, and 40% to 60% is excreted as unconjugated acid in urine (159).

The exact mode of action of modafinil is still uncertain. The wake promoting effects of the compounds have been suggested to involve α1-adrenergic stimulation (67) and/or serotonergic–GABAergic interactions (37). The compound interacts with the dopaminergic system at high doses and is neuroprotective in the MTPP model (37 ,39). Recent work by our group rather suggests that selective, but low-potency, dopamine reuptake inhibition mediates the wake-promoting effects of modafinil (84 ,103). In rats, modafinil acutely decreased both REM and non-REM sleep in rats for up to 5 to 6 hours without inducing a secondary rebound hypersomnolence (34). This contrasts with the intense recovery sleep seen after amphetamine administration (34). This unique feature of modafinil (wakefulness without rebound hypersomnia) may be explained by the pharmacokinetics profile of the compound (modafinil has a significantly longer half-life than amphetamine or methylphenidate) (159). Alternatively, this important difference may be owing to its unique pharmacodynamic profile, for example, dopamine uptake inhibition versus dopamine release effects for amphetamine (34).

Several factors make modafinil an attractive alternative to amphetamine-like stimulants. First, animal studies suggest that the compound does not affect blood pressure as much as amphetamines do (50) (potentially the result of its lack of effects on adrenergic release or reuptake). This suggests that modafinil might be useful for patients with a heart condition or high blood pressure. Second, animal data suggest no neurotoxic effects and no or less rebound hypersomnolence on withdrawal. Third, data obtained to date suggest that tolerance and dependence are limited with this compound (15), although a recent animal study reports a cocaine-like discriminative stimulus and reinforcing effects of modafinil in rats and monkeys, respectively (42). Finally, clinical studies suggest that the alerting effect of modafinil might be qualitatively different from that observed with amphetamine (15). In general, patients feel less irritable and/or agitated with modafinil than the amphetamines (15). In animal experiments, modafinil did not induce behavioral excitation, as measured by lack of locomotor activation (35). Considering the many advantages of modafinil over amphetamine treatment (fewer cardiovascular side effects, low abuse potential, lower levels of tolerance, and less rebound sleep), modafinil may replace amphetamine-like stimulants as a first-line treatment for excessive daytime sleepiness.

Caffeine, a xanthine derivative, may be the most popular and widely consumed stimulant in the world. The average cup of coffee contains about 50 to 150 mg of caffeine. Tea (25 to 90 mg/5 oz), cola drinks (35 to 55 mg/12 oz), chocolate (15 to 30 mg/1 oz), and cocoa (2 to 20 mg/5 oz) also contain significant amounts of caffeine. Taken orally, caffeine is rapidly absorbed, taking 47 minutes to reach maximum plasma concentration. The half-life of caffeine is about 3.5 to 5 hours (143). A slow-release soft gelatin caffeine capsule is also available with a mean delay to peak plasma concentration of 4 hours (143). The behavioral effects of caffeine include increased mental alertness, faster and clearer flow of thought, increased wakefulness, and restlessness (121). Fatigue is reduced, and the need for sleep is delayed (121). Physical effects of caffeine include palpitations, hypertension, and increased secretion of gastric acid and increased urine output (121). Heavy consumption (12 or more cups a day, or 1.5 g of caffeine) can cause agitation, anxiety, tremors, rapid breathing, and insomnia (121). The mechanism of action of caffeine involves antagonism of an adenosine (nonspecific) receptor and of adenosine-induced neuronal inhibition (121). Considering the fact that 100 mg of caffeine is roughly equivalent to one cup of coffee, caffeine does not possess the efficacy to counteract the pathologic sleepiness seen in narcolepsy. Nevertheless, caffeine in the form of tablets can be bought without a prescription (NoDoz, 100 mg caffeine; Vivarin, 200 mg caffeine), and is used by many patients with narcolepsy prior to diagnosis.

Antidepressants and the Pharmacologic Treatment of Cataplexy

Amphetamine stimulants have little effect on cataplexy, and additional compounds are most often needed to control cataplexy if the symptom is severe enough to warrant treatment. Since the 1960s, it has been known that imipramine is very effective in reducing cataplexy (2). Together with protriptyline and clomipramine, these tricyclic antidepressants

are now the most commonly used anticataplectic agents (8) (Table 131.3). Other antidepressant compounds of the tricyclic family have also been used with some success (Table 131.3). The use of tricyclic antidepressants in the treatment of cataplexy, however, is hampered by a number of problems. The first is the relatively poor side-effect profile of most tricyclic compounds. These are mostly owing to their anticholinergic properties, leading to dry mouth (and associated dental problems), tachycardia, urinary retention, constipation, and blurred vision (Table 131.3). Additional side effects are weight gain, sexual dysfunction (impotence and/or delayed orgasm), tremors, antihistaminergic effects leading to sedation and occasionally orthostatic hypotension owing to the α1-adrenergic blockade effects of some compounds. In this respect, protriptyline is often preferred because of its previously reported mild stimulant effect (49). Nighttime sleep might also become more disturbed because of increased muscle tone and leg movements (122 ,152). The cardinal pharmacologic property of tricyclic antidepressants is their ability to inhibit the reuptake of norepinephrine (and epinephrine) and serotonin (14). The degree of uptake inhibition of norepinephrine and serotonin is quite variable depending on the compound and the existence of active metabolites (mostly active on adrenergic uptake) (14). Additionally, some tricyclic compounds, such as protriptyline, are also weak dopamine reuptake inhibitors (14).

Antidepressant Compounds	Usual Daily Doses	Side Effects/Note
Commonly used compounds		
Imipramine	10–100 mg	Dry mouth, anorexia, sweating, constipation, drowsiness (51).
Desipramine	25–200 mg	Effects and side effects similar to those of imipramine demethylated metabolite of imipramine (51).
Protryptiline	5–60 mg	Some reports suggest improvement in vigilance measures (49), whereas other reports are negative (no improvement in performance or daytime sleepiness) (93).
Clomipramine	10–150 mg	Digestive problem, dry mouth, sweating, tiredness, impotence (45,140). Its active metabolite, desmethylclomipramine, is shown to be more potent in the canine model (97).
Fluoxetine[a]	20–60 mg	Nausea, dry mouth, fewer side effects, long half-life (60 hours); no anticholinergic or antihistaminergic effects; good anticataplectic effect but less potent than clomipramine (63).
Some clinical trials, but less commonly used		
Zimelidine[a]	100 mg	Less sedative effect; no anticholinergic or antihistaminergic effects; potent anticataplectic compound (94). Its active metabolite, norzimelidine, is shown to be more potent than zimelidine in the canine model (97).
Femoxitine[a]	600 mg	Fewer side effects than clomipramine but less potent (136) pharmacologic effects similar to fluoxetine.
Fluvoxamine[a]	50–300 mg	Gastrointestinal side effects (134). No active metabolities; pharmacologic profile similar to fluoxetine; less active than clomipramine.
Paroxetine[a]	20–60 mg	Less anticholinergic effects; cardiovascular side effects; effective on cataplexy (with yohimbine) (119).
Viloxazine	100–300 mg	Few side effects; selective but low potency adrenergic uptake inhibitor, active on human cataplexy and possibly sleepiness, but not available in most countries (40,43); effective anticataplectic agent in canines (85).
Venlafaxine	150–375 mg	New serotonergic and adrenergic uptake blocker; no anticholinergic effects, effective on cataplexy sleepiness in a small pilot study (146), low potency.

[a]Clinical trial results using these compounds (63,94,134,136) suggest that SSRIs are effective for the treatment of cataplexy or REM sleep related symptoms while inducing fewer side effects than classical tricyclic antidepressants. It is, however, still not conclusive whether SSRIs can be recommended as a first line of treatment, because SSRIs are usually less potent than tricyclic antidepressants (136).
SSRIs, selective serotonin reuptake inhibtors.

TABLE 131.3. ANTIDEPRESSANTS CURRENTLY USED AS ANTICATAPLECTIC AGENTS

The introduction of newer antidepressants with selective serotonergic uptake inhibition properties (e.g., SSRIs) and no anticholinergic effects, such as fluoxetine, fluvoxamine, paroxetine, sertraline, femoxitine, zimelidine, and trazodone has raised hope that the control of cataplexy could be achieved with fewer side effects. In general, however, clinicians have been less impressed with the potency of the serotonergic compounds on cataplexy (63 ,94 ,136). This experience parallels experiments in canine narcolepsy suggesting that adrenergic, not serotonergic, uptake inhibition mediates

the anticataplectic effects of most antidepressant medications (85 ,97). Among the SSRIs, fluoxetine is a viable alternative to tricyclic compounds (63). Fluoxetine has a good side-effect profile and may induce less weight gain, a significant advantage for some patients. Venlafaxine, a novel serotonergic and adrenergic reuptake blocker, also has been used recently with good success. Finally, the introduction of reboxetine, a specific adrenergic reuptake blocker, may offer a novel and more effective alternative to SSRIs and tricyclic antidepressants based on animal data.

In addition to the antidepressants listed in Table 131.3 , γ-hydroxybutyrate (GHB), a hypnotic compound discussed in more detail in the section on disrupted nocturnal sleep , has been shown to alleviate cataplexy during long-term administration. GHB is an endogenous constituent of mammalian brains, synthesized locally from GABA, which may play a role as an inhibitory neuromodulator (18). Monoamine oxidase inhibitors (MAOIs) are known to potently reduce REM sleep, and are therefore excellent candidate anticataplectic agents; however, these compounds are less often used owing to their poor safety profile. Selective or reversible MAOIs have recently become available, but clinical trials of these compounds at a large scale are still not available (104).

Treatment of Sleep Paralysis and Hypnagogic Hallucinations

The treatment of these two symptoms is not well codified. Hypnagogic hallucinations can be quite bothersome, and often occur in patients who also suffer from frequent nightmares. As they are a manifestation of sleep onset REM sleep, the compounds that suppress REM sleep are usually helpful in alleviating this symptom, and tricyclic antidepressant treatment has been reported to have some beneficial effects (149). Sleep paralysis only rarely requires treatment, but tricyclic antidepressants are also very effective for preventing this symptom. Recently, high doses (60 mg QD) of fluoxetine have been advocated as a very active treatment for isolated sleep paralysis (61). GHB is also effective in suppressing hypnagogic hallucinations, sleep paralysis, and cataplexy (72).

GHB and Treatment of Disturbed Nocturnal Sleep

Insomnia is a major complaint in narcoleptic subjects. Several studies reported that benzodiazepine hypnotics are effective in consolidating nighttime sleep in patients with narcolepsy (151). GHB, a compound with remarkable REM- and SWS-inducing properties, has also been used for consolidating nighttime sleep, an effect that leads to decreased sleepiness and cataplexy the following day (24 ,25 ,137 ,138). Large-scale double-blind placebo controlled clinical trials are in progress in the United States to re-establish GHB as a first line treatment for narcolepsy-cataplexy (104). The compound is especially useful in patients with severe insomnia and cataplexy who do not tolerate well the side effects of antidepressant medication on sexual potency. The mode of action of GHB on sleep and sleep-related symptoms is unknown, but may involve decreased dopaminergic tone after GHB (18). Because of its positive effects on mood and libido, its SWS-enhancing properties, and a subsequent increase in growth hormone release, the drug is widely abused by athletes and other populations (31 ,70); therefore, several states have passed legislation restricting access to GHB requesting by prescriptions for its use. The compound has also been reported to increase periodic leg movements in narcoleptic patients (27).

GHB is absorbed 15 to 20 minutes after oral ingestion, and peak plasma concentration occurs at 60 to 120 minutes. The elimination half-life is 20 minutes (111 ,157). Exogenous GHB is almost completely eliminated by oxidative biotransformation to carbon dioxide and water, less than 5% is detected unmetabolized in the urine (111 ,157). At low doses, GHB is anxiolytic and myorelaxant. At intermediate doses, GHB increases slow wave sleep and REM sleep (64). However, because of the short half-life of the compound, its effects on sleep architecture are short-lasting (about 3 to 4 hours) and administration thus has to be repeated two to three times during the night (20 to 40 mg/kg per night). Overdoses (a single dose of 60 to 100 mg/kg) induce dizziness, nausea, vomiting, confusion, agitation, epileptic seizures, hallucinations, and coma with bradycardia and respiratory depression (66). Death has been reported and the therapeutic window is narrow (LD_{50} = 5- to 15-fold the dose inducing coma). Although the compound is structurally related to GABA and is a natural metabolite of the neurotransmitter, its mode of action involves specific non-GABAergic binding sites (75). GHB and GABAB receptors may interplay functionally (71). GHB is also known to inhibit firing of dopaminergic neurons, dopamine release, and dopamine synthesis (156).

PHARMACOLOGY AND NEUROCHEMISTRY OF CANINE NARCOLEPSY

Part of "131 - Pathophysiological and Pharmacologic Aspects of the Sleep Disorder Narcolepsy "

Pharmacologic Control of Canine Cataplexy

The canine model of the disorder has been used to pharmacologically dissect the mechanisms involved in the control of cataplexy and alertness. These experiments led us to conclude that the control of cataplexy and REM sleep are very similar, although in several aspects, cataplexy is not identical to natural REM sleep muscle atonia (102). Activation of cholinergic systems using the acetylcholinesterase inhibitor physostigmine, for example, greatly exacerbates cataplexy (12 ,33). This cholinergic effect is mediated via muscarinic receptors because muscarinic stimulation aggravates cataplexy,

whereas its blockade suppresses it, and nicotinic stimulation or blockade has no effect (12 ,33). These results parallel data obtained on cholinergic systems and REM sleep control. (See refs. 144 and 148 for review.)

Monoaminergic transmission is also critical for the control of cataplexy. All therapeutic agents currently used to treat cataplexy (i.e., antidepressants or MAOIs) are known to act on these systems. Furthermore, whereas cholinergic neurons are activated during REM sleep, the firing rate of monoaminergic neurons in the brainstem, such as in the locus ceruleus (LC) and raphe magnus, are well known to be dramatically depressed during this sleep stage (10 ,153). In contrast, dopamine neurons of the ventral tegmental area (VTA) and substantia nigra (SN) do not significantly change their activity during the sleep cycle (89 ,154).

Although antidepressants and MAOIs enhance monoaminergic transmission, these compounds generally lack specificity and globally enhance serotonergic, adrenergic, and dopaminergic transmission. Using newer uptake inhibitors and releasing agents with selective monoamine effects, we have demonstrated that the presynaptic activation of adrenergic, but not dopaminergic or serotonergic, systems mediates the anticataplectic effects of currently available antidepressive treatments (85 ,97). This suggests that cataplexy, and possibly REM sleep atonia are more selectively modulated by adrenergic systems. Interestingly, presynaptic activation of dopamine transmission with dopamine uptake inhibitors had potent alerting effects (103) but no effect on cataplexy (85).

Receptor-Specific Regulation of Cataplexy: A Pathologic Model of REM Sleep Atonia

More than 200 compounds with various pharmacologic properties (cholinergic, adrenergic, dopaminergic, serotonergic, prostaglandins, opioids, benzodiazepines, GABAergics, and adenosinergics) have been studied in the narcoleptic canine model. (See ref. 104 for a recent review.) Although many compounds, such as M2 antagonists, α1-agonists, α2-antagonists, dopamine D2(3) antagonists, 5-HT1a agonists, TRH analogues, prostaglandin E2, and L type Ca^{2+} channel blockers reduce cataplexy, very few compounds significantly aggravate cataplexy. Because REM sleep can be easily disturbed nonspecifically in pharmacologic studies, aggravations in cataplexy are considered to be the most specific effect. The stimulation of muscarinic M2 (non-M1) receptors significantly aggravates cataplexy. Among monoaminergic receptors, the postsynaptic adrenergic α1b receptors (79 ,99) and presynaptic α2 receptors (100) were also found to aggravate cataplexy, a result consistent with a primary adrenergic control of cataplexy. It was also found that dopamine D2(3) agonists significantly aggravated cataplexy and induced drowsiness in these animals. To date, no other receptor ligands (e.g., adenosinergic, histaminergic or GABAergic) have been found to aggravate cataplexy (104).

The cataplexy-inducing effects of D2(3) compounds on cataplexy, however, are difficult to reconcile with the fact that dopaminergic uptake blockers and releasing agents have absolutely no effect on cataplexy (85). Interestingly, the aggravation of cataplexy by D2(3) agonists is blocked by adrenergic, but not dopaminenergic, uptake inhibitors (105), suggesting some functional interaction between the dopaminergic and adrenergic systems for the regulation of cataplexy.

Presynaptic Stimulation of Dopamine Transmission Mediates the EEG Arousal Effects of Amphetamine-like Stimulants

Amphetamine-like CNS stimulants currently used clinically for the management of sleepiness in narcolepsy presynaptically enhance monoaminergic transmission; however, these compounds also lack pharmacologic specificity. In order to study the mode of action of these compounds on daytime sleepiness, the stimulant properties of several dopaminergic and adrenergic uptake inhibitors were quantified and compared to the effects of amphetamine and modafinil using 6-hour daytime polygraphic recordings in the canine narcolepsy model (103). In spite of their lack of effects on cataplexy, all dopaminergic uptake inhibitors induced significant EEG arousal. In contrast, nisoxetine and desipramine, two potent adrenergic uptake inhibitors, had little effect on EEG arousal but significantly suppressed REM sleep, a finding that is consistent with their potent anticataplectic effects. Furthermore, the *in vivo* potency of dopamine uptake inhibitors on EEG arousal correlates well with the *in vitro* dopamine transporter (DAT), but not with the noradrenaline transporter (NET), binding affinities for individual compounds (103). These results are consistent with the hypothesis that presynaptic modulation of dopamine mediates the EEG arousal effects of these compounds. Interestingly, it was also found that modafinil binds to the DAT site with low affinity (84 ,103), similar to the affinity range for amineptine (a dopamine uptake inhibitor that also enhances EEG arousal in our model). Thus, DAT binding may also contribute to the stimulant properties of modafinil.

Midbrain Dopaminergic Systems Are Involved in the Regulation of Cataplexy and Excessive Daytime Sleepiness in Narcolepsy

The site of action for dopaminergic modulation of cataplexy recently has been identified using microdialysis experiments. D2(3) agonist injections into the ventral tegmental area (VTA) (126) and substantia nigra (SN) (53), two regions

where dopaminergic cell body autoreceptors are densely packed, was found to reproduce the effects of small intravenous doses of dopamine agonists or antagonists on cataplexy (98). An injection of the same compounds in the pontine reticular formation (PRF), where dopamine autoreceptors are less densely packed, has no effect (126). This suggests that the D2(3) effect is genuinely mediated by autoreceptor stimulation and that cataplexy may be modulated by changes in dopaminergic activity originating from the VTA and SN. The perfusion of dopamine uptake inhibitors in these midbrain dopaminergic nuclei does not modify cataplexy (53). Because various electrophysiologic and pharmacologic studies have demonstrated that dopamine reuptake is of physiologic importance in the limbic forebrain, striatum, and cortical hemispheres, but not in midbrain dopaminergic neurons (108), acting sites for the dopaminergic regulation of cataplexy and sleepiness may be anatomically different. This may explain why D2(3) agonists induce both cataplexy and sleepiness (53 ,126), whereas dopamine uptake inhibitors only induce significant EEG arousal but have no effect on cataplexy (105). In this model, enhancement of DA transmission at the terminal region may be sufficient to induce a wake-promoting effect; however, reduction in the activity of DA neurons and interactions with adrenergic systems may be required for the modulation of cataplexy (101 ,105).

Cholinergic Hypersensitivity and the Regulation of Cataplexy

The effects of cholinergic stimulation in various brain areas were also examined in narcoleptic and control canines. Local injection or perfusion of carbachol, a predominantly muscarinic agonist, into the PRF was found to aggravate canine cataplexy in a dose-dependent fashion (125). Acetylcholine release in the PRF was significantly elevated during the FECT when narcoleptic animals had multiple cataplectic attacks, while no increase in acetylcholine levels was observed in control animals (124). The results obtained in the PRF with cholinergic agonists and acetylcholine release were expected considering the well-established role of pontine cholinergic systems in the regulation of REM sleep. In this experiment, however, narcoleptic dogs were found to be consistently more sensitive to cholinergic stimulation than control animals (125). More surprisingly, however, it was also found that the local injection of carbachol unilaterally or bilaterally (2 to 10 nmol per site) into the BF (rostral to the preoptic area, in the vertical or horizontal limbs of the diagonal band of Broca and medial septum) also dose-dependently aggravated cataplexy (107). This manipulation induced long-lasting muscle atonia episodes with desynchronized EEG in narcoleptic canines (107). The same pharmacologic manipulation (10 nmol of carbachol) did not induce cataplexy in normal animals, but rather induced wakefulness, as previously reported in rats and cats (11). The BF is anatomically connected with the limbic system, which is regarded as a critical circuit for integrating emotions. Furthermore, BF neurons are known to respond to the arousing property of appetitive stimuli (131), which potently induce cataplexy in narcoleptic dogs. Considering the fact that emotional excitation is an alerting stimulus in normal animals, but induces cataplexy in narcoleptic animals, the BF may be involved in triggering a paradoxic reaction to emotions—atonia rather than wakefulness—in narcoleptic animals.

Monoaminergic/Cholinergic Imbalance and Hypocretin Deficiency

As detailed, cholinergic and monoaminergic imbalances are central to the pathophysiology of narcolepsy and the control of natural REM sleep. The fact that impaired hypocretin transmission is involved in both animal and human narcolepsy indicates that the hypocretin peptides must be tightly connected functionally with monoaminergic and cholinergic systems. Deficit in the production of the hypocretin ligand, as well as mutations in one of the receptors (Hcrtr 2), induces narcolepsy in mice and dogs, respectively (30 ,68). In humans, abnormalities in the production of the ligands are most likely to be the etiology of the disease in most cases (106).

De Lecea and associates first identified hypocretins using a subtraction technique aimed at the isolation of hypothalamic-specific transcripts (32). The same neuropeptide system was independently identified by Sakurai and associates and was named Orexin (133). These authors isolated two new neuropeptides, Orexin A and B, as endogenous ligands for previously poorly characterized orphan G-protein–coupled receptors (GPCRs). The hypocretin receptors are closely related to other neuropeptide GPCRs, such as the Y_2 neuropeptide Y receptor (26% identity) and the TRH receptor (25%). Hypocretin-1 and -2 correspond to Orexin A and B, respectively (132). These molecules are processed from the same precursor peptide (preprohypocretin). Hypocretins bind and activate two closely related GPCRs, the Hcrtr 1 (Ox1R) and Hcrtr 2 (Ox2 R) receptors (133). Hcrtr 1 is selective for hypocretin-1 (20 to 100 × higher affinity) whereas Hcrtr 2 exhibits similar affinity for both hypocretin-1 and -2 (133). Preprohypocretin mRNA and hypocretin-1 or -2 immunoreactivity colocalize in a small group of neurons located within and around the lateral hypothalamic area (LHA) in adult rat brains (32 ,118 ,133).

Hypocretins were initially believed to control appetite and food intake (thus the name Orexin, appetite in Greek) because of their discrete localization within the lateral hypothalamus. Similar to neuropeptide Y and leptin, hypocretins play a role in metabolic and endocrine regulation and have effects on food intake (95 ,133). The finding that hypocretin-containing neurons diffusely innervate numerous brain regions in addition to the hypothalamus (cerebral cortex,

limbic system, brainstem, and the spinal cord) (118), however, suggested that hypocretins might have other functions. Regulatory effects on blood pressure, body temperature, and the sleep-wake cycle were suggested (118). Hypocretin neurons in the LHA project to brain regions responsible for the regulation of vigilance (e.g., LC, VTA and the tuberomamillary histaminergic nucleus) and REM sleep (LC, dorsal raphe, and pontine cholinergic nuclei and PRF) (118). These anatomic and physiologic findings, taken together with the fact that deficits in hypocretin neurotransmission induce the narcolepsy phenotype, suggest that that hypocretins are the major neuromodulators for monoaminergic and cholinergic systems and hypocretins modulate sleep and sleep-related phenomena by interaction with these classical neurotransmitters.

PERSPECTIVES AND FUTURE DIRECTIONS

The discovery that a deficit in hypocretin neurotransmission, as revealed by the CSF hypocretin studies (106), frequently causes human narcolepsy opens the door to new diagnostic and therapeutic strategies. Measuring hypocretin levels in the CSF or other biological fluids may soon be used as a diagnostic test for narcolepsy. Early diagnosis may be critical for a disorder with peripubertal onset and a dramatic psychosocial impact. New therapeutic strategies should also be developed. All compounds currently used for the treatment of narcolepsy act symptomatically by enhancing monoaminergic transmission, likely downstream of the hypocretin neurotransmitter system (see section for monoaminergic/cholinergic imbalance and hypocretin deficiency). If reduced neurotransmission of hypocretin is a primary deficit in human narcolepsy and hypocretin receptors are still functional, supplementing transmission with hypocretins (and analogues) may have significant therapeutic effects in human narcolepsy (both on EDS and cataplexy).

Hypocretins are also likely to join acetylcholine and monoamines as critical sleep neurotransmitters. Basic research work relevant to the issue of sleep control will proceed at a rapid pace. Which hypocretin projections are most important for sleep control? How is the hypocretin system regulated across the sleep cycle? The preferential localization of Hcrtr2 on tuberomamillary and SN/VTA neurons suggests a preferential role for histaminergic and dopaminergic systems, but functional studies are lacking. Hypocretins are strongly excitatory in most cells studied, including monoaminergic cells (48 ,155). Removing an excitatory signal on these target cells could contribute to a monoaminergic hypoactivity. Similarly, the dense neuroanatomic distribution of Hcrtr2 in limbic structures such as the amygdala and the nucleus accumbens may explain cataplexy, a symptom triggered by emotions. Recent neuroimaging studies have shown that these regions are activated during natural REM sleep (74).

More work in the area of narcolepsy pathophysiology is also needed. Mutation screening studies of hypocretin genes indicate in narcolepsy-cataplexy very rare hypocretin system gene disease causing mutations, even in familial and non–HLA-DQB1*-0602 positive narcoleptic subjects (36). This indicates some degree of disease heterogeneity and the possibility that other neuronal systems closely related to the hypocretin/narcolepsy system still remain to be discovered. Does the observation that most cases of narcolepsy have undetectable CSF hypocretin levels indicate that hypocretin cells are destroyed in human narcoleptic brains? The finding that narcolepsy is tightly associated with HLA suggests a possible autoimmune process directed against these LHA cells. Autoantibodies against hypocretins or a substance closely related to the hypocretin system/LHA may secondarily cause narcolepsy. The relationship between feeding regulation, energy metabolism, and narcolepsy also should be explored. The role of the hypocretin system in the pathophysiology of narcolepsy without cataplexy remains to be investigated. Taking into account a recent, rapid gain in narcolepsy research, further progress in identifying the cause of human narcolepsy is likely to proceed at a rapid pace.

THEORIES OF HYPNOTIC ACTION

Part of "132 - Basic Mechanisms of Sedative/Hypnotics "

How compounds of a wide variety of chemical classes can have relatively similar effects in inducing sleep is an intriguing pharmacologic question. Probably the dominant theory—that these compounds exert their actions by altering the physical properties of lipids in neuronal membranes—comes from the alcohol and anesthetic literature (1). Although there are many viewpoints about which specific aspect of lipid properties is affected (i.e., fluidity, thickness, or surface tension), it is largely a physicochemical approach. Ultimately, it was found inadequate for a number of reasons; perhaps the most important is that there are very little or no detectable changes in lipid bilayers at the concentrations at which these compounds induce sleep or anesthesia (1). Ultimately, interest has turned to more specific mechanisms; by far the most satisfying one (and the focus of this chapter) is the notion that altering neurotransmitter-gated receptor channels induces sleep and anesthesia (2).

Another approach to understanding sedative/hypnotics has been to hypothesize that sleep results from drug-induced reduction in energy metabolism; barbiturates, for instance, decrease cerebral glucose metabolic rate in human positron emission tomography (PET) scan studies (3). On the other hand, the results of animal studies have been more variable, such that barbiturates may (4) and benzodiazepines may not (5) decrease cerebral metabolic rate of oxygen (CMRO2). A more cogent argument against the notion that hypnotics induce sleep by lowering metabolic rate is that it stems from a view of sleep as being a very passive process, which seems to contradict the more contemporary understanding of sleep as a multifaceted, actively regulated process (6). Indeed, at doses that induce sleep (and prior to achieving anesthetic doses), patients receiving most hypnotic medications demonstrate the alternating ultradian rhythm of NREM and REM sleep, which indicates an active regulatory mechanism. It seems more parsimonious, then, to hypothesize that sedative/hypnotics act at specific sites involved in sleep regulation, rather than producing a nonspecific “slowing” of the nervous system.

THE MOLECULAR LEVEL: THE CENTRAL $GABA_A$–BENZODIAZEPINE RECEPTOR COMPLEX

Part of "132 - Basic Mechanisms of Sedative/Hypnotics "

Background and Description

A major insight into the action of hypnotics began in the 1970s with the discovery of high affinity, stereospecific receptors for benzodiazepines in the central nervous system (7 ,8). $GABA_A$-benzodiazepine receptors are the most abundant inhibitory receptor system in the central nervous system (CNS) (9). They can be viewed as representatives of a large family of hetero-oligomeric ligand-gated ion channels (e.g., nicotinic acetylcholine, glycine, and serotonin-3 receptors) (10). Functionally, they contain three distinct but interacting moieties: recognition sites for GABA and benzodiazepines and a chloride ionophore (11). Binding of a benzodiazepine agonist to its recognition site results in increased chloride ion flux, which in turn hyperpolarizes the postsynaptic membrane at a level below that at which spike generation is possible.

Molecular cloning data indicate that the $GABA_A$-benzodiazepine receptor complex is comprised of at least five subunits; these in turn may have various isoforms (9). Each subunit is comprised of four membrane-spanning regions. The intracellular loops of some subunits contain phosphorylation sites, which have been hypothesized to be a locus of receptor modulation. It is possible, for instance, that the receptor system might respond to GABA differently in the phosphorylated versus dephosphorylated state. α- and γ-Subunits need to be present in order to be responsive to benzodiazepines, and a complete system of α, ß, and γ are

needed for a fully responsive receptor (12). Recent data using murine gene targeting techniques indicate that the α-1 isoform is not required for the anxiolytic actions of benzodiazepines, but may mediate sedation and ataxic effects; in principle, this might make it possible to develop anxiolytics with a more benign side effect profile than those currently available (13). The γ-1 subunit, which in some senses may be viewed as a marker of the subgroup of GABA receptors representing the $GABA_A$–benzodiazepine receptor complex, is found in 60% to 90% of GABA receptors (14). $GABA_A$-benzodiazepine receptors have also been divided into Type I and II (sometimes referred to as o-1 and -2), differing on the particular α subunit isoform; whether this distinction has pharmacologic significance in terms of effects of drugs that selectively bind to the Type I receptor is still under investigation. There are peripheral and "Valium-insensitive" receptors that appear not to be involved in sleep-related processes in addition to the central receptors (the focus here); hence, they are beyond the scope of this chapter.

Presynaptic Effects: Alterations in Calcium Channel Function

Although most work on the effector mechanism of benzodiazepine receptor agonists focuses on the postsynaptic mechanism of alterations in chloride ionophore function, it should be noted that there are also presynaptic actions involving calcium ion flux that have been less fully explored but that may have relevance to sedative/hypnotic properties. In rats, for instance, the dihydropyridine calcium channel blocker nifedipine given intraventricularly blocks the sleep-inducing property of systemically administered flurazepam, whereas BAY-K-8644, which facilitates calcium ion flux in dihydropyridine-sensitive channels, greatly augments the hypnotic effects of flurazepam (15).

The Role of GABA Agonists

One intriguing set of issues that has not been clearly resolved is that more specific $GABA_A$ agonists are relatively weak in their hypnotic effects, do not necessarily augment the effects of benzodiazepines, and may indeed have very different actions. The $GABA_A$ agonist muscimol when given IP to rats, for instance, has mild effects on reducing sleep latency and does not alter total sleep time (16). Analogously, the $GABA_A$ antagonist bicuculline slightly increases sleep latency without altering total sleep in the rat; neither interact with intraperitoneally administered triazolam (16). Muscimol has also been found to have effects on sleep different from midazolam in rats; the former increased both NREM and REM sleep, whereas midazolam increased NREM, decreased REM, and produced opposite effects on low-frequency EEG activity (17). Again, in contrast to triazolam, microinjection of muscimol into the medial preoptic area has been reported to have no effect on sleep in rats (18). The reasons for these differences are not clear; among the possibilities are that in the intraperitoneal administration studies muscimol produced nonspecific actions at GABA receptors throughout the brain, or that muscimol enters the CNS poorly (19); the lack of effects on sleep after microinjection directly into the MPA would seem to rule these possibilities out. It also appears that muscimol may alter chloride channel function in a manner different from GABA, activating channels for greater durations (20). It also may be that muscimol indiscriminately activates GABA receptors, whereas in contrast benzodiazepines may only alter function of receptors with specific compositions (21). Although this is still being assessed, the differences in effects of muscimol and benzodiazepines provide a cautionary note that it may be important not to equate the hypnotic actions of benzodiazepines with simple GABAergic effects.

The $GABA_A$–Benzodiazepine Receptor Complex as a Common Site for Diverse Pharmacologic Classes of Hypnotics

The affinities of various benzodiazepines were found to correlate well with their anxiolytic, anticonvulsant, and muscle relaxant properties in the early reports on central $GABA_A$–benzodiazepine receptors (7). Later evidence indicated that the receptor complex mediates the hypnotic actions of benzodiazepines as well. This role was clarified by studies of the inverse agonist 3-hydroxymethyl-ß-carboline (3-HMC), which induced awakening and decreased sleep in rats, an effect prevented by the benzodiazepine receptor blocker CGS 8216 (15). Similarly, the hypnotic properties of the clinically used benzodiazepine flurazepam were blocked by a low dose of 3-HMC that had minimal effects when given alone (22). The stereospecificity of the site was demonstrated by studies of the benzodiazepine B-10 enantiomers, in which the (+) compound induced sleep, whereas the (-) compound increased wakefulness (15). It became clear, then, that it was indeed interaction with this receptor complex that mediates the effects of benzodiazepines on sleep and waking.

The $GABA_A$-benzodiazepine receptor complex contains modulatory sites not only for benzodiazepines, but also for a number of other types of sedating compounds, including barbiturates, neurosteroids, and ethanol (23 ,24), etomidate (25), and the anesthetic propofol (26). The newer nonbenzodiazepine hypnotics zolpidem, zopiclone, and zaleplon bind to the type I benzodiazepine recognition site as well. The end result is thought to be an enhancement of chloride ion flux, as described. These compounds may achieve this effect by different means, nonetheless; hence, benzodiazepines may increase the frequency of channel opening (27), whereas barbiturates, for instance, may increase the duration of opening (28). Ethanol facilitates GABA-stimulated chloride flux at low concentrations, and directly enhances flux

at higher concentrations (29). Similarly, some cytokines such as interleukin-1 enhance GABA-dependent chloride influx into synaptoneurosomes (30).

We are beginning to gain insight into the problem we posed originally: how administration of sedative/hypnotic compounds from such diverse pharmacologic classes can result in sleep induction. It appears that most or all of them produce pharmacologic effects by altering the function of various moieties of the $GABA_A$-benzodiazepine receptor complex.

NEUROANATOMIC STUDIES

Part of "132 - Basic Mechanisms of Sedative/Hypnotics "

Microinjection of Hypnotics into the CNS

In some ways, it has been more challenging to determine the neuroanatomic sites of action of hypnotics than to assess their actions at a molecular level. The most parsimonious neuroanatomic approach would seem to be that hypnotics act at sites thought to be involved in physiologic sleep regulation, on the basis of lesion or stimulation studies. Using this reasoning, the author's laboratory set out some years ago to administer benzodiazepines into such sites, many of which were chosen on the basis of the classical studies of Hernandez-Peon (31). The compound chosen for these studies was the benzodiazepine triazolam, which was the most widely administered clinical hypnotic. Perhaps the most surprising finding was the absence of effects on sleep following triazolam microinjection into many loci thought to be involved in sleep regulation, including the locus ceruleus, horizontal limb of the diagonal band of Broca, lateral preoptic area, basomedial nucleus of the amygdala (32), and ventrolateral preoptic area (33). In contrast, microinjection at several sites—notably the dorsal raphe nuclei and medial preoptic area— profoundly altered sleep and waking. We examine these in turn.

The Dorsal Raphe Nuclei

The dorsal raphe nuclei, tubular structures in the upper pons and lower midbrain that contain most of the forebrain serotonin (34) send fibers via the medial forebrain bundle to a various areas including the hypothalamus, basal forebrain, septal area, striatum, hippocampus, and cerebral cortex (35 ,36). The heaviest innervation in the hypothalamus is in the medial preoptic area, suprachiasmatic nucleus, and dorsal and ventral premammillary nuclei (37), as well as in histamine-containing neurons of the tuberomamillary nucleus (38). Stimulation of the dorsal raphe has been demonstrated by the 2-deoxyglucose method to increase glucose utilization in the somatosensory cortex, thalamus, hypothalamus, and extrapyramidal system (39). Ascending fibers innervate the suprachiasmatic nucleus (34), raising the possibility that they influence circadian rhythm function. The dorsal raphe nuclei in turn receive descending fibers originating from the preoptic area (40), suggesting a kind of reciprocal innervation discussed in the following. The ventrolateral preoptic area (VLPO), which has been postulated to play a role in sleep initiation (41), sends GABAergic and galaninergic descending fibers to the dorsal and median raphe nuclei as well as the locus ceruleus, which might result in inhibitory action on ascending monoaminergic systems (42). In addition, dorsal raphe cells receive inhibitory serotonergic input from other local dorsal raphe neurons (43 ,44 ,45 and 46) as well as from the median raphe (43). Interestingly, microinjections of triazolam into the dorsal raphe *deceased* sleep in the rat—sleep latency was significantly increased and total sleep time was significantly reduced (47).

The Medial Preoptic Area

There has been considerable work on the role of the hypothalamus and adjacent structures in the regulation of sleep and waking, ever since pathological studies following the epidemic of encephalitis lethargica in the 1920s (48). Later lesion studies by Hess (49) and Nauta (50) suggested that the anterior hypothalamus is involved in sleep maintenance, whereas a more caudal area might promote wakefulness. Stimulation of a basal forebrain area, including the medial preoptic area (MPA), enhances (51) and lesions decrease (52) sleep in cats. Lesions of the medial preoptic area acutely decrease sleep in the rat, albeit subject to effects of ambient temperature (53). The MPA receives visual and auditory inputs, and contains neurons sensitive to glucose and steroids (54), osmotic and cardiovascular measures (55), and temperature (56). It is also a thermoregulatory site, and it may coordinate many processes in homeostatic and reproductive functions (36).

Cell bodies and fibers in the MPA cross react in immunohistochemical studies with a wide variety of neurotransmitters such as substance P and neuropeptide Y (57). Push-pull cannula studies of the MPA have documented release of catecholamines, GABA, and glutamate (58). GABA is uniformly found throughout the hypothalamus, and its synthetic enzyme GAD has very high concentrations in the preoptic area in particular (59). The MPA is also rich in some forms of the $GABA_A$-benzodiazepine receptor complex, suggesting that benzodiazepine hypnotic compounds might bind there (14). Neurons that become more active during NREM and REM sleep are inside the MPA (60). Its projections travel throughout the forebrain and brainstem (61) to the median and dorsal raphe nuclei, and possibly to the locus ceruleus (40). Stimulation of the MPA influences firing rates in the midbrain reticular formation (62 ,63). In summary, the preoptic area/basal forebrain appears to play an important role in the regulation of sleep and its integration with other processes; thus, it seems a likely candidate to be influenced by compounds that alter sleep and waking. Studies in the author's laboratory indicate that microinjections of pentobarbital (64), triazolam (65),

and propofol (66) into the MPA result in enhanced sleep in rats. Other groups have found similar results after microinjection of ethanol (67), adenosine (68), and prostaglandin D2 (69). Interestingly, the ability of adenosine to induce sleep when infused into the MPA is prevented by the benzodiazepine receptor blocker flumazenil (70).

Lesion Studies

One question that arises as a result of these studies is whether the MPA is the only site at which these compounds act to induce sleep; phrased somewhat differently, we know from the microinjection studies that the MPA is *sufficient*, but not whether it is *necessary*, for the hypnotic action of benzodiazepines. One way to approach this is to lesion the MPA, and then determine whether peripherally administered triazolam will still induce sleep. In order to assess this, we induced ibotenic acid lesions of the preoptic area in rats, and allowed 7 to 9 days of recovery in order for sleep to return to prelesion levels. We then administered triazolam .8 mg per kg intraperitoneally, and found that it still potently reduced sleep latency and increased total sleep (71). To put this finding in context, many of the studies of sleep physiology have suggested the presence of redundant mechanisms, which perhaps reflects the importance to the CNS of maintaining sleep/wake processes. One classic example, for instance, is that after anatomic or pharmacologic lesions of the dorsal raphe nuclei, sleep is initially greatly reduced, but then slowly returns to normal amounts (72 ,73). It seems likely, then, that although the MPA represents a common area at which a wide range of hypnotic compounds may act, there remain additional redundant mechanisms for sleep regulation, at which these agents can alter sleep in the absence of an intact MPA.

Do Hypnotics Induce Sleep by Altering Brain Temperature?

As we have described, the MPA contains warm- and cold-sensitive neurons, and is involved in thermoeffector activities (56). Typically, brain temperature decreases in NREM sleep compared to waking (74), and preoptic temperature drops in behaviorally defined sleep (75). It is known that peripherally administered benzodiazepines reduce rodent core (76) and brain (77) temperature. Thus, one interesting issue is whether the hypnotic effects of drugs such as triazolam are owing to “direct” effects on sleep regulatory mechanisms, or alternatively, whether the observed effects on sleep are secondary to drug-induced changes in temperature. In general, both rectal (78) and peritoneal (65) temperatures rise briefly following microinjection of triazolam into the MPA, but they do so equally in animals injected with vehicle. This transient rise in peripheral temperature, then, appears to be a nonspecific response related to the mechanics of injecting a fluid into the MPA. It is not clear whether brain temperature itself is altered by this microinjection procedure. In a recent study, cerebral brain temperature was measured following microinjection of triazolam .25 µg or vehicle into the MPA. Although sleep latency and waking time were significantly reduced, and total sleep increased in the 2 hours after injection, there were no changes in mean temperature in the first or second hour, temperature at sleep onset, or mean change from preinjection baseline (79). This suggests that the effects of triazolam microinjections into the MPA on sleep are not secondary to alterations in brain temperature, and raise the interesting possibility that pharmacologic and physiologic sleep initiation may differ in their relationship to temperature. Whether benzodiazepines induce subtler changes in hypothalamic temperature and play a role in sleep initiation remain to be determined.

CONCLUSION

Part of "132 - Basic Mechanisms of Sedative/Hypnotics "

Integrating Pharmacology of Hypnotics with Physiologic Sleep Regulatory Mechanisms

How should we picture the results of these microinjection and lesion studies in the context of what is known about the regulation of sleep? One of the most intriguing questions is: How does triazolam, which has a potent hypnotic effect when taken systemically, *reduce* sleep when injected into the dorsal raphe nuclei? The most likely explanation is that triazolam effectively inhibits raphe nuclei function. Benzodiazepines given systemically or iontophoretically have been reported to potentiate GABA inhibition of the dorsal raphe (80). Moreover, both depletion of serotonin by PCPA (81) or anatomic lesions of the dorsal raphe (82) greatly decrease sleep. Thus, it seems likely that the reduction in sleep seen after microinjection of triazolam mimics the effects of lesions of this structure.

As described, ascending fibers originating in the dorsal raphe travel via the medial forebrain bundle to various areas, including the hypothalamus (particularly the MPA and tuberomamillary nucleus), basal forebrain, septal area, striatum, hippocampus, and cerebral cortex (35). Descending fibers, in turn, travel to the dorsal raphe from the preoptic area. The dorsal and median raphe and the locus ceruleus also receive GABAergic and galaninergic innervation from the ventrolateral preoptic area (VLPO), which has an inhibitory influence on ascending monoaminergic systems (42).

Just as the MPA sends descending fibers to these specific monoaminergic brainstem nuclei, it also profoundly alters function of the reticular formation. This diffuse ascending system originates in the upper brainstem thalamic core, and projects largely through the intralaminar and other thalamic nuclei to the cortex, where it induces arousal (83). The main neurotransmitters involved in this process appear to be acetylcholine and glutamate (84). Stimulation of the MPA evokes inhibitory field potentials and suppresses neuronal

activity in the midbrain reticular formation, or MRF (62). Other stimulation data suggest that it induces an initial excitation followed by postexcitatory discharge suppression, suggesting that some actions of the basal forebrain on sleep might be mediated by alterations in activity in the MRF (63 ,85). In summary, we have described a system in which ascending monoaminergic pathways innervate the preoptic area, which appears to be an integrative center for sleep and a variety of physiologic processes, including thermoregulation and cardiovascular function, and at which microinjections of a wide range of classes of hypnotic compounds induce sleep. In turn, descending fibers from the preoptic area provide an inhibitory influence on both specific aminergic nuclei such as the dorsal raphe, as well as the midbrain reticular formation. We theorize that benzodiazepine hypnotics such as triazolam act by altering function of this reciprocal system of innervation between the hypothalamus/basal forebrain and brainstem structures.

Future Directions

Obviously, there are many potential areas to explore as possible sites of action of hypnotics. One possibility that has received little attention has been that classical hypnotics, such as benzodiazepines or barbiturates, might alter the ascending histaminergic arousal system, which is presumably the mechanism by which antihistamines produce sedating effects. Certainly one area of interest is the tuberomamillary nucleus, which lies adjacent to the mamillary bodies, just above the ventral surface of the hypothalamus (38). It is a histamine-producing cell group thought to be part of the ascending arousal system, with fibers going to the amygdala, hippocampus, and cortex (86). Data using the retrograde tracer cholera toxin subunit B indicate that the ventrolateral preoptic area (VLPO), which has been postulated to be involved in physiologic sleep initiation, innervates the histaminergic neurons in the tuberomamillary nucleus, via a GABAergic pathway (41 ,85 ,87). In principle, benzodiazepine or other hypnotic compounds might act by enhancing GABAergic inhibition of the tuberomamillary nucleus, decreasing its arousing effects. As described, the tuberomamillary nucleus also receives ascending serotonergic input from the dorsal raphe nuclei (38); therefore, it is conceivable that effects of hypnotics on sleep might also be mediated by their actions on the dorsal raphe, which in turn affect this structure.

INSOMNIA: DEFINITIONS, IMPACT, AND DIAGNOSIS

Part of "133 - Current and Experimental Therapeutics of Insomnia "

Definition of Insomnia Symptoms and Disorders

Insomnia can refer to either a symptom or clinical disorder. The *symptom* of insomnia is the subjective complaint of difficulty falling or staying asleep, poor quality sleep, or inadequate sleep duration, despite having an adequate opportunity for sleep. Two points in this definition deserve specific attention. First, insomnia is a subjective complaint not currently defined by laboratory test results or a specific duration of sleep or wakefulness. Second, the insomnia symptom occurs despite the individual having adequate opportunity to sleep. This distinguishes insomnia from sleep deprivation, which has different causes, consequences, and clinical presentations. As a *disorder*, insomnia is a syndrome consisting of the insomnia complaint, together with specific diagnostic features (either clinical or laboratory), significant distress or functional impairment, and the absence of specific exclusionary features.

Prevalence of Insomnia Symptoms and Disorders

Insomnia symptoms and disorders are widely prevalent. A number of recent epidemiologic studies indicate a prevalence of 30% to 45% for insomnia *symptoms* in the prior year (1 ,2 and 3). The specific prevalence depends on the definition of insomnia symptoms used. The prevalence of insomnia *disorders* is obviously much lower, in the range of 10% to 15% (4 ,5). Epidemiologic studies point to a consistent set of risk factors for insomnia. These include a previous history of insomnia, increasing age, female gender, psychiatric symptoms and disorders, medical symptoms and disorders, impaired activities of daily living, anxiolytic and hypnotic medication use, and low socioeconomic status. The increasing prevalence of insomnia with age may be explained in large part by increasing comorbidity with medical and psychiatric disorders and medication use. The incidence of insomnia also increases with age and is greater in women than men. On the other hand, remission of insomnia decreases with age and is less common in women. Together, prevalence, incidence, and remission data indicate that insomnia is often a chronic condition. Between 50% and 80% of individuals with insomnia at baseline have a persistent complaint after follow-up intervals of 1 to 3.5 years (1 ,6 ,7 and 8).

Impact of Insomnia

Studies in working populations show that individuals complaining of insomnia have more mood symptoms, gastrointestinal symptoms, headache, and pain (9). In addition, individuals with insomnia have greater self-ratings of role impairment, days of limited activity, days spent in bed, and higher total health costs (10). Health-related quality of life is significantly lower for individuals with insomnia than for those without (11). Individuals with insomnia may also have higher rates of serious accidents or injuries (12) and injurious falls (13). The economic costs of insomnia are also substantial. One recent estimate places the annual direct costs for insomnia-related problems at nearly $14 billion (including $11 billion related to nursing home care) (14). Insomnia has been identified as a significant risk factor for institutionalization in the elderly in some studies (15), but not in others (3). Despite these morbidities, insomnia does not appear to be an independent risk factor for mortality (3 ,16).

Perhaps the greatest morbidity associated with insomnia is an increased risk for psychiatric disorders. Several large,

carefully controlled studies have found that individuals with insomnia are at significantly increased risk for the development of depression, anxiety, and substance use disorders (4 ,17 ,18 ,19 ,20 and 21). These studies have included subjects from young adults to the elderly, and follow-up intervals from 1 to 35 years. Figure 133.1 shows data from the Breslau and associates study that are representative of these findings. The obvious—and unanswered—question is whether early identification and intervention in insomnia could prevent this costly outcome.

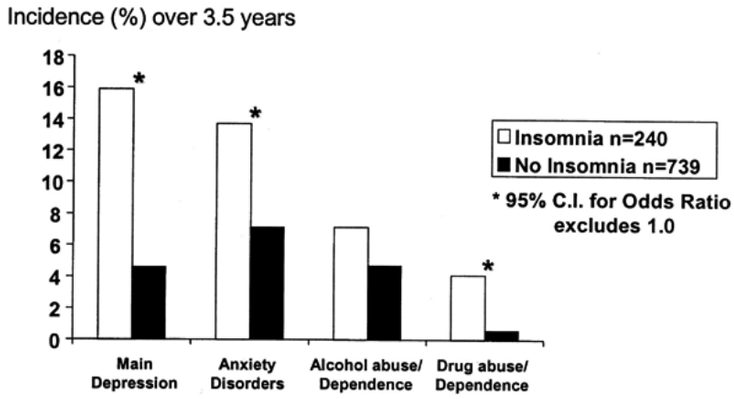

FIGURE 133.1. Insomnia is a risk factor for depression. Odds ratio's for developing new-onset psychiatric disorders among individuals with and without insomnia. Subjects were young adults in a health maintenance organization, interviewed at baseline, and at a 3.5-year follow-up. Baseline insomnia was a significant risk factor for incident depressive, anxiety, and substance use disorders. Data from ref. 19.

Differential Diagnosis

Insomnia can be the final result of many factors acting singly or in combination (Fig. 133.2). Many of these factors may lead to behaviors and conditioning that further reinforce the original problem. For instance, an individual who sleeps poorly may spend more time in bed in an effort to "catch up" on sleep. This extended time in bed occurring in an individual with impaired *ability* to sleep can further contribute to impaired sleep continuity and to the bed becoming a conditioned stimulus for wakefulness. Furthermore, most of the factors underlying insomnia contribute to increased physiologic arousal, which may constitute a final common pathway leading to insomnia complaints.

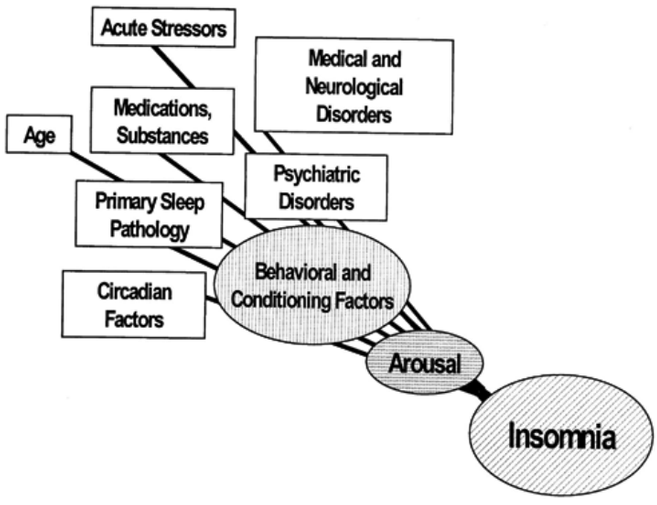

FIGURE 133.2. Causes of insomnia. Insomnia may result from many factors acting simply or in combination. Behavioral and conditioning factors often perpetuate insomnia that originally arises from other causes. Cognitive, affective, and somatic arousal may be the final common pathways leading to insomnia.

The differential diagnosis of insomnia disorders includes insomnia secondary to other medical, psychiatric, or substance use conditions; insomnia occurring during the course of primary sleep disorders; and primary insomnia. Insomnia secondary to psychiatric disorders is the most prevalent insomnia disorder, both in general population samples and clinically referred samples (5 ,22), accounting for 40% to 75% of all diagnoses. Virtually any psychiatric disorder can be associated with insomnia, although mood disorders (major depression, bipolar mood disorder, dysthymia) and anxiety disorders (generalized anxiety disorder, panic disorder, posttraumatic stress disorder) are the most common. Insomnia also may result from specific medical and neurologic disorders; those associated with pain, impaired mobility, and central nervous system (CNS) dysfunction are the most common. Common examples include arthritis, congestive heart failure, chronic obstructive pulmonary disease, and Parkinson's disease. A wide variety of drugs can also cause or contribute to insomnia, including alcohol, caffeine, decongestants, and other CNS stimulants, corticosteroids, and antidepressant medications, particularly selective serotonin reuptake inhibitors. Medications and substances can cause insomnia not only during the time they are being used, but also during withdrawal.

Insomnia also can be associated with specific sleep disorders. One common example is *restless legs syndrome* (RLS), which consists of an urge to move one's legs accompanied by uncomfortable dysesthesias, usually described as "creepy

crawly" or restless feelings. These sensations regularly increase at night, decrease during the day, and are temporarily relieved by movement. RLS is often associated with significant sleep onset insomnia. In addition, RLS is often accompanied by *periodic limb movement disorder* (PLMD), which consists of repetitive, short (.5- to 3.0-second) bilateral jerks in the toes, feet, ankles, and legs. These movements can lead to brief arousals and a complaint of nonrestorative sleep. *Sleep apnea syndromes* do not typically present with a complaint of insomnia. More often, sleep apnea presents within a syndrome of excessive daytime sleepiness, loud snoring, breathing pauses during sleep, and obesity or craniofacial abnormalities; however, a minority of patients, including older individuals, may present with insomnia complaints. *Circadian rhythm sleep disorders* often include prominent insomnia complaints. For instance, individuals with delayed sleep phase syndrome complain of difficulty falling asleep accompanied by difficulty awakening in the morning. Conversely, individuals with advanced sleep phase syndrome complain of early morning awakening and sleepiness in the evening hours. Jet lag and shift work sleep disorders are further examples of circadian sleep disorders that can present with insomnia problems.

Individuals who do not have other sleep disorders are diagnosed with primary insomnia. According to the DSM-IV, this syndrome is defined by a significant insomnia complaint; evidence of distress or impairment; and the absence of a concurrent psychiatric, medical, or sleep disorder that could explain the problem. Approximately 10% to 20% of individuals with significant insomnia are diagnosed with primary insomnia (5 ,22). This condition is broadly analogous to the term "psychophysiologic insomnia." The latter term invokes the etiologic factors of physiologic and cognitive arousal in association with the insomnia complaint.

Etiology and Neurobiology of Insomnia

Despite the prevalence and consequences associated with insomnia, relatively little is known regarding its neurobiology. One of the earliest and most enduring conceptualizations of insomnia is that of psychophysiologic arousal. Individuals with insomnia have several indicators of sympathetic and hypothalamic-pituitary-adrenal (HPA) axis activation, together with other peripheral indicators of "arousal." For instance, individuals with insomnia may have elevated temperature and muscle tone at sleep onset (23 ,24), elevated heart rate and sympathovagal tone in heart rate variability (25), and positive correlations among wake time after sleep onset and urinary norepinephrine, DOPAC, and DHPG (26). Studies of whole body metabolic rate, assessed by oxygen consumption, show elevated rates for individuals with insomnia compared to healthy controls, a difference which persists 24 hours per day (27). The psychologic arousal of insomnia is supported by higher rates of self-reported ruminations and intrusive thoughts among individuals with insomnia. It is less clear whether excess cognitive activity actually causes insomnia or is simply a byproduct of it. The cognitive hyperarousal may be the result of a ruminative, anxious personality style that also has been associated with insomnia.

Unfortunately, most studies identifying hyperarousal in insomnia are based on peripheral or "downstream" measures of arousal, rather than CNS arousal per se. Evidence for this type of arousal comes from electroencephalographic studies. Several investigators have demonstrated that individuals with insomnia have reduced sleep propensity not only at night, but also during the day. Individuals with insomnia also have lower δ EEG power (usually taken as an indicator of homeostatic sleep drive) and elevated amounts of ß EEG power (usually interpreted as evidence of EEG activation or cognitive activity) (28). In one recent investigation of depressed patients with insomnia, Nofzinger and colleagues found that ß EEG activity correlated positively with glucose metabolic rate in the medial orbitofrontal cortex, a region implicated in both behavioral and electroencephalographic activation (29). Behavioral evidence also supports the concept of increased cortical activity during sleep among individuals with insomnia. For instance, individuals with insomnia have better ability to recall auditory stimuli presented during the early sleep period relative to control subjects (30).

An integrative neurobiological model of insomnia should account for evidence of cortical activation during sleep, vulnerability to developing mood disorders, and evidence for sympathetic and HPA axis activation. It should also account for insomnia subjects' complaints of impaired concentration and memory, as well as their reduced propensity for sleep, even during daytime hours. Such a model may involve relative activation of ascending cholinergic and noradrenergic systems with diffuse projections to the cortex through thalamic and basal forebrain systems. The model may also involve reduced efficiency of processing in the frontal cortex, which may explain insomnia patients' complaints of poor concentration and attention. Another component of an integrative neurobiological model of insomnia would involve affective dysregulation. This might include amygdala activation or reduced activity in the subgenual anterior cingulate, similar to that observed in depression (31). Overactivity of ascending arousal systems, together with limbic system dysregulation, could lead to sustained activation of hypothalamic efferent systems, including activation of the sympathetic nervous system and HPA axis.

BEHAVIORAL AND NONPHARMACOLOGIC TREATMENT OF INSOMNIA

Part of "133 - Current and Experimental Therapeutics of Insomnia "

Rationale and Efficacy

Most behavioral and cognitive interventions aim to decrease or change factors that interfere with sleep, including maladaptive

sleep habits, cognitive or physiologic hyperarousal, and dysfunctional beliefs about sleep and insomnia. The ultimate goal of behavioral treatments for insomnia is to help patients manage their sleep and sleep habits more effectively. In addition to providing a safe alternative to pharmacotherapy, these nondrug treatments offer patients the potential benefit of a greater sense of control over their sleep problems. Most insomnia patients indicate that they would prefer a nonpharmacologic solution to their insomnia (32).

A comprehensive review of the efficacy of nonpharmacologic treatments for chronic primary insomnia, based on two metaanalyses and 48 individual treatment studies, showed reliable improvements in the main outcome measures of latency to sleep- and wake-time after sleep onset (33). Data consistently indicated that approximately 70% to 80% of insomniacs benefited from treatment. The magnitude of improvement was approximately 50%, with sleep latency reduced by about 30 minutes on average, from 60 to 30 minutes, and wake-time after sleep onset reduced from 70 to 38 minutes. Subjective report of sleep quantity and quality improved, based on sleep diary data. Relatively few studies have used PSG or actigraphy to document objective improvement. Improvements with behavioral treatment are well maintained over at least 6 months (34).

Good Sleep Practices (Sleep Hygiene Education)

Sleep hygiene education aims to promote environmental and lifestyle factors that are conducive to sleep, and to minimize those that affect sleep in a negative way, such as late-night caffeine consumption, sleeping with a television or radio on, or engaging in exercise in close proximity to bedtime. Many of these behaviors are not intrinsically problematic, but become detrimental to sleep if they are timed inappropriately. For example, exercise too close to bedtime can cause physiologic arousal that can impair sleep onset, whereas exercise during the late afternoon or earlier evening can have beneficial effects on sleep (35). Lifestyle factors alone are rarely the cause of chronic insomnia, but rather may complicate insomnia arising from other causes. Sleep hygiene modification is seldom considered sufficient treatment for chronic insomnia, and results from intervention studies support its limited efficacy. There is no single standard set of sleep hygiene recommendations; a sample of commonly reported elements is included in Table 133.1 .

Caffeine is a stimulant and should be discontinued 4–6 hours before bedtime.
Nicotine is a stimulant and should be avoided near bedtime and on awakening.
Alcohol is a depressant that can facilitate sleep onset, but can disrupt sleep later in the night. It should be avoided in close proximity to bedtime.
A heavy meal too close to bedtime can interfere with sleep and should be avoided. A light snack is all right.
Regular exercise in the late afternoon or early evening may deepen sleep, whereas exercise too close to bedtime may disrupt sleep.
Minimize light, noise, and excessive temperature during sleep.

Adapted from Morin (1990).

TABLE 133.1. SLEEP HYGIENE RECOMMENDATIONS

Stimulus Control Therapy

Stimulus control techniques (36) are based on the premise that insomnia is exacerbated or maintained by a maladaptive conditioned response to the bedroom environment and bedtime routine, which develops as a result of repeated difficulty sleeping. Whatever the initial cause of the insomnia, when an individual has experienced the frustration of lying in bed being unable to sleep, anxiety develops about the ability to sleep and the potential consequences of lack of sleep. Greater effort is made to lie in bed and consciously try to sleep. This behavior and effort are incompatible with sleep, cause further frustration and alertness, and result in “conditioned” insomnia.

The goal of stimulus control is to recondition cues such as the bedroom and bedtime routine to elicit relaxation and sleep as opposed to anxiety, frustration, and wakefulness. Stimulus control instructions are outlined in Table 133.2 . This is a paradoxic approach; the patient must accept the rationale of the treatment and trust the therapist enough to do something that does not make intuitive sense (i.e., get out of bed when he or she wants so desperately to sleep). Stimulus control requires effort and persistence, and often leads to initial resistance and temporary worsening before improvement. Consistency and motivation are important ingredients for a successful response. Quantitative reviews of controlled intervention trials consistently support the efficacy of stimulus control therapy.

Lie down intending to go to bed only when you are sleepy.
Use the bed and bedroom for sleep and sex only. Do not watch TV, listen to the radio, eat, or read in bed.
Get out of bed if you cannot fall asleep or go back to sleep within 10–15 minutes; return to bed only when you feel sleepy.
If you still cannot fall asleep, repeat the processing step as often as is necessary during the night.
Set your alarm and maintain a regular arising time in the morning, irrespective of how much sleep you got during the night.
Do not nap during the day.

Adapted from refs. 36 and 36a.

TABLE 133.2. STIMULUS CONTROL INSTRUCTIONS

Sleep Restriction Therapy

Patients with insomnia often try to compensate for lost sleep by getting into bed early or remaining in bed after awakening in the morning. Many individuals assume that bed rest may be restorative, even if no sleep is achieved. Unfortunately, the excess time in bed results in increased wakefulness in bed, which causes more frustration about difficulty sleeping and leads to even more pronounced insomnia. Increased time awake in bed can thus contribute to conditioned insomnia.

The goal of sleep restriction is to decrease time in bed in order to maximize the sleep efficiency of time spent in bed. Unlike stimulus control, sleep restriction addresses only the amount of time one spends in bed, rather than how the time in or out of bed is spent. This approach involves an initial curtailment of time in bed to the amount of time actually spent sleeping, based on sleep diary entries averaged over at least 1 week's time. Average sleep efficiency, which represents the proportion of time in bed spent asleep, is computed from sleep diaries. After sleep efficiency reaches desired levels (typically 90%), time allowed in bed can be increased by increments of 15 minutes until desired total sleep time at night is reached. If sleep efficiency remains low (<80%), after the initial restriction, time in bed is further curtailed by 15-minute increments until sleep continuity improves sufficiently. Time in bed is not changed if sleep efficiency is between 80% and 90%.

Relaxation and Biofeedback Therapies

Relaxation techniques target the cognitive or physiologic arousal that interferes with sleep, as discussed. A number of relaxation therapies have been used for insomnia, including progressive muscle relaxation and biofeedback to diminish physiologic arousal, and imagery techniques, autogenic training, and meditation to reduce cognitive arousal. Relaxation treatments may be most useful for sleep onset insomnia. In general, the magnitude of improvement seen with relaxation is smaller than for other behavioral approaches (37).

Cognitive and Multimodal Therapies

Insomnia often involves negative, unrealistic, or exaggerated beliefs about sleep and consequences of insomnia. These dysfunctional beliefs can cause emotional arousal and exacerbate the sleep problem (38). Cognitive restructuring has been used to help patients question the validity of automatic, maladaptive thoughts and reformulate them to make them more realistic and adaptive.

Many cognitive and behavioral techniques share common elements, and they are increasingly being used together within multimodal treatment protocols. It makes intuitive sense for some of the approaches to be combined, such as stimulus control and sleep restriction. The change in behavior advocated and the net result of each are similar, although the rationales are different. An adjustment in thinking, as can be accomplished with cognitive restructuring, can be helpful for successful completion of any behavioral or cognitive treatment. Effective, circumscribed, multicomponent therapies, such as that developed by Morin (39) combine several different treatment approaches within a limited number of treatment sessions to treat insomnia. The treatment protocol potentially can benefit a variety of patients who may respond differently to various aspects of the program. The treatments are integrated in a later session, and relapse prevention is addressed, promoting an overall focus on self-efficacy. From the existing literature, it is not clear that such combined approaches are more effective than the most effective of the individual techniques (e.g., stimulus control) used alone; however, such multifaceted therapies may have the added benefit of treating a broader range of patients without having to individualize treatment.

Other Nonpharmacologic Treatments

Phototherapy

As noted, insomnia associated with circadian rhythm sleep disorders results from problems related to the timing of sleep versus sleep itself. Because light is the most potent zeitgeber, or time cue, for the circadian timing system, phototherapy can be used as part of a treatment regimen to adjust the timing of the sleep/wake cycle and address a corresponding complaint of insomnia and/or sleepiness.

Exposure to bright light shifts circadian phase in a time-dependent manner (40). In general, bright light in the early morning hours shifts sleep and circadian rhythms to an earlier time (i.e., causes a phase advance); bright light in the evening hours shifts sleep and circadian rhythms to a later time (i.e., causes phase delays). Phototherapy can be delivered through artificial light, or by exposure to diffuse natural outdoor light. Artificial bright light has been shown to improve sleep maintenance insomnia in older adults (41) and younger adults with chronic insomnia (42); however, it is more typically used to treat circadian rhythm sleep disorders, such as delayed sleep phase syndrome. Practice parameters recently have been developed by the American Academy of Sleep Medicine (AASM) regarding use of phototherapy in the treatment of sleep disorders, including recommendations for light intensity and duration (43).

Exercise

The effects of exercise on sleep have been reviewed elsewhere (35 ,44). Exercise can increase sleep quality and slow-wave sleep, and reduce sleep latency in some individuals, including older adults (45). Individuals in good physical condition

observe the greatest effects on sleep with exercise in the late afternoon or early evening. Exercise performed in close proximity to bedtime, or by individuals who are unaccustomed to such exercise, can cause arousal. Exercise can be used as part of sleep hygiene recommendations or an overall training program potentially to improve sleep and health in general. Some of the effect of exercise on sleep may be mediated by changes in core body temperature. In particular, a rise in core body temperature with exercise may be followed by an exaggerated temperature decline during early sleep. This temperature decline may promote slow-wave sleep (46).

Passive Body Heating

Elevation of core body temperature by external body heating during the early evening also increases slow-wave sleep in both young and older individuals, and improves sleep continuity in older women with insomnia (47 ,48). Passive body heating involves immersion in hot water of at least 40°C for at least 30 minutes during afternoon or evening hours prior to bedtime. Although larger trials are needed, this procedure may constitute a relatively noninvasive, nonpharmacologic technique for treating insomnia.

PHARMACOLOGIC TREATMENTS FOR INSOMNIA

Part of "133 - Current and Experimental Therapeutics of Insomnia "

Several medication classes are used for the treatment of insomnia, although the strength of evidence regarding their efficacy and tolerability varies considerably. The major classes are benzodiazepine receptor agonists (BzRA), antidepressant drugs (AD), antihistamines, melatonin, and various herbal remedies including valerian root extracts. Of these medications, only BzRAs are formally approved for the indication of insomnia treatment in the United States. Nevertheless, physician-prescribing data show that prescriptions for BzRA hypnotics declined by 150% between 1987 and 1996, at the same time that benzodiazepine nonhypnotic prescriptions for insomnia remained stable, and antidepressant prescriptions increased by 150% (49). In particular, prescriptions for trazodone increased sixfold.

Benzodiazepine Receptor Agonists

Benzodiazepine receptor agonists (BzRAs) include the true benzodiazepines (e.g., triazolam, temazepam, estazolam, and lorazepam) as well as a structurally dissimilar group of nonbenzodiazepine agents, including an imidazopyridine (zolpidem), pyrazolopyrimidine (zaleplon), and cyclopyrolone (zopiclone). BzRAs are the only pharmacologic agents currently approved by the FDA for the treatment of insomnia, and they are labeled for short-term use (i.e., less than 4 weeks).

BzRAs share common pharmacodynamic actions, discussed in Chapter 68 . In summary, these agents bind at a specific recognition site in the benzodiazepine-γ aminobutyric acid (GABA)–chloride ion channel macromolecular complex. This binding is responsible for the hypnotic, anxiolytic, myorelaxant, and anticonvulsant actions of BzRAs. There is some evidence that the nonbenzodiazepine BzRAs, specifically zolpidem, may be relatively more specific for hypnotic effects relative to anticonvulsant and anxiolytic effects; this may be related to greater specificity for benzodiazepine type I receptors.

Specific BzRAs differ significantly in pharmacokinetic properties, including the rate of absorption, extent of distribution, and rate of elimination. BzRAs also range widely in elimination half-life, from 1 hour for zaleplon to 120 hours for flurazepam and its metabolites. Finally, these agents differ in terms of active metabolites, which may have longer half-lives than the parent compound. Table 133.3 outlines relevant pharmacokinetic properties for commonly used BzRAs.

Medication	Usual Adult Therapeutic Dose (mg)	Time to Onset (Minutes)	Terminal Elimination Half-Life (Hrs)	Active Metabolites
Marketed as hypnotics				
Estazolam	0.5–2.0	15–30	8–24	No
Flurazepam	15–30	30–60	2–5[a] 47–120[b]	Yes

TABLE 133.3. PHARMACOKINETIC PROPERTIES OF BENZODIAZEPINE RECEPTOR AGONISTS

BzRAs are efficacious in the short-term treatment of insomnia. Recent metaanalyses examined BzRA effects on sleep latency, sleep duration, number of awakenings, and sleep quality (50 ,50a). For each of these outcomes, the effect size d ranged between .55 and .75, indicating moderately large effect sizes and substantiating the superiority of these agents over placebo. Other data support a broader range of beneficial outcomes. For instance, treatment with zopiclone for both 14 days and 8 weeks of treatment was associated with greater improvements in quality of life measures, social activities, and professional activities compared to placebo (51). A telephone survey of patients with untreated insomnia and those receiving benzodiazepines showed that the later group reported fewer symptoms of feeling blue, down in the dumps, or depressed, and being easily upset compared to the former group (52).

BzRAs have consistent effects on PSG sleep measures. (See ref. 53 for review.) As expected, BzRAs are associated with reduced sleep latency and wakefulness during the night, and increased sleep duration and sleep quality ratings. Other specific PSG effects depend on the particular agent. For instance, zaleplon, with its very short half-life, has not been demonstrated to consistently affect sleep duration despite its effect on sleep latency. Traditional benzodiazepines reduce REM and stage 3 to 4 NREM sleep, whereas zaleplon and zolpidem are not associated with changes in sleep stages. In addition, BzRAs reduce the number of periodic limb movements and arousals associated with these movements (54). BzRAs can also lead to oxyhemoglobin desaturations during sleep and can theoretically worsen sleep apnea; however, in patients with moderate degrees of sleep apnea, the change in number of apneas and oxyhemoglobin saturation is felt to be clinically insignificant (55).

Although BzRAs have been studied primarily for short-term treatment of insomnia, insomnia is often a chronic

condition, and many patients take their hypnotics for longer periods of time. Some patients clearly developed tolerance with continued use of BzRAs, and some polysomnographic studies support this phenomenon (56); however, other PSG studies show continued efficacy over several nights of continued nightly administration. For instance, triazolam, zolpidem, and zaleplon have shown continued efficacy over a period of 4 to 5 weeks in double-blind, placebo-controlled studies (57 ,58 ,59 and 60), and single-blind studies have shown continued efficacy by PSG for as long as 6 months (61 ,62). Studies using self-ratings or observing-ratings have documented efficacy for even longer amounts of time. For instance, double-blind studies have shown continued efficacy for up to 24 weeks with no evidence of tolerance according to mean subject ratings (63 ,64) and single-blind studies have shown efficacy for up to 1 year of treatment (65 ,66); however, the role of BzRAs in long-term treatment or maintenance treatment of insomnia remains to be more clearly defined.

BzRAs can have significant adverse effects. The most common of these is a continuation of their desired therapeutic effect, sedation during the daytime. Daytime sleepiness is clearly more severe with longer-acting agents such as flurazepam, which has been documented in PSG studies (57 ,67). Similar PSG studies of short-acting hypnotics have not shown an increase in daytime sleepiness. BzRAs are also associated with dose-related anterograde amnesia that may even be partially responsible for their therapeutic affect (68 ,69). BzRAs can also impair other aspects of psychomotor performance, including reaction time, recall, and vigilance. Whether or not such deficits improve with this continuation of the drug is more controversial, with some studies noting improvement following discontinuation (70 ,71) and other studies failing to show such improvement (72).

BzRAs are significantly related to an increased risk of injurious falls and hip fractures in elderly people. In particular, risk seems to be increased with the use of long-acting agents, high doses, multiple agents, and cognitive impairment in patients (73 ,74). Data regarding automobile crashes are somewhat mixed. Self-report data have shown an increased rate of motor vehicle accidents in those taking hypnotics (12) but a case-control study in older individuals failed to show an elevated risk associated with benzodiazepines (75). Other studies have shown risk associated with long half-life drugs and recent initiation of treatment, but not with longer-term treatment (76). An analysis of data from over one million subjects in a national cancer database demonstrated an increased risk of all-cause mortality among older individuals using hypnotics, even after controlling for symptoms of insomnia, although the hypnotic drugs examined included barbiturate and other drugs as well as benzodiazepines (77). In fact, examination of two specific benzodiazepine agents in this cohort did not show an elevated mortality risk.

Several discontinuation phenomena have been examined in relation to BzRAs. *Rebound insomnia* refers to an increase in insomnia symptoms beyond their baseline level. Rebound is thought to be associated primarily with short-acting BzRAs, although recent evidence for zolpidem and zaleplon does not show this effect. Patients who demonstrate rebound insomnia tend to have worse baseline sleep and higher medication doses than patients without rebound (78 ,79). The behavioral aspect of taking a pill may contribute to rebound insomnia. Individuals who have shown a poor

response to treatment may show the greatest rebound (80). *Withdrawal* refers to the appearance of new symptoms on discontinuation of the drug. Withdrawal may occur in 40% to 100% of patients treated chronically with benzodiazepines, and can persist for days or weeks following discontinuation (81 ,82). Withdrawal symptoms can include dizziness, confusion, depression, and feelings of unreality. Cognitive and behavioral treatments can help patients discontinue chronic benzodiazepine use (83). The prevalence of true withdrawal phenomenon in any individuals treated with once-daily hypnotic doses of BzRAs is not well known. *Recurrence* is another potential discontinuance syndrome that has received little attention in insomnia. Given that insomnia tends to be chronic, it should not be surprising that many patients complained of their original symptom after discontinuation of an affected treatment. The role of recurrence in chronic BzRA treatment also remains to be well defined. Finally, *abuse* of BzRAs used for insomnia appears to be uncommon. One telephone survey showed no greater use of increased doses for BzRAs compare to antidepressants (84). Although data are difficult to obtain, benzodiazepines may be used by .5% to 3.0% of the population for nonmedical purposes in any 1 year (85). Among those who wish to discontinue chronic use of BzRAs, their pattern of use tends to suggest stability or declining doses over time as well as a tendency to intermittent rather than consistent dosing (86). Thus, among individuals with no prior substance use history, abuse of BzRAs appears to be uncommon.

Antidepressant Drugs

Although use of antidepressant drugs (AD) for insomnia has increased dramatically, evidence to support their efficacy is relatively sparse. The most commonly used ADs for insomnia include trazodone, tertiary tricyclic agents, and mirtazapine. These drugs clearly have diverse effects on neurotransmission, as reviewed in Chapter 79 . In general, the sedating properties of antidepressants are related to antagonism of serotonin 5-HT_2, histamine, and α_1-adrenergic receptors.

The effects of various antidepressant agents on sleep have been described primarily in the context of depression treatment. These effects are summarized in Table 133.4 and several recent reviews (87 ,88). As the table indicates, antidepressant drugs vary widely in their effects on sleep continuity, EEG delta activity and slow-wave sleep, and REM sleep. Sleep continuity effects are likely to be most important in the treatment of insomnia. Some antidepressant drugs also can cause or exacerbate insomnia problems. Selective serotonin reuptake inhibitors (SSRIs) bupropion, noradrenergic selective tricyclic drugs, and strongly serotonergic tricyclic drugs (e.g., clomipramine) are the most common agents to have such effects. In addition, serotonergic specific antidepressants can lead to anomalous sleep stages characterized by eye movements during NREM sleep and they can also cause or exacerbate restless leg syndrome and periodic limb movements (48). Antidepressants may also be associated with slight improvements in sleep apnea (89).

	Sleep Continuity	Slow Wave Sleep	REM Sleep
Tricyclic	↓ to ↑	→ to ↑	↓ to ↓↓↓
SSRIs, Venlafaxine	→ to ↓	→ to ↓	↓ to ↓↓
Trazodone, Nefazodone	↑	→ to ↑	→ to ↑
Bupropion	↓	→ to ↓	↑

→, No change.
↑, Increase.
↓, Decrease.

TABLE 133.4. EFFECTS OF ANTIDEPRESSANT DRUGS ON EEG SLEEP

Studies with small numbers of subjects and diverse inclusion criteria suggested the beneficial effects of trazodone 150 to 400 mg on sleep continuity measures, as well as a tendency to increase Stage 3 to 4 sleep and improve subjective sleep quality ratings, in insomnia patients (90 ,91 and 92). A more recent 2-week double-blind placebo-controlled study compared the effects of trazodone 50 mg and zolpidem 10 mg to placebo among individuals with primary insomnia (93). This study showed improvements in subjective sleep latency and sleep duration with both active drugs, although there was some evidence for superiority of zolpidem during the second treatment week. Both drugs were well tolerated. Other studies involving primary insomnia have shown beneficial effects of short-term treatment with low-dose doxepin (94) and trimipramine (95) compared to placebo. Finally, a recent open-label trial of paroxetine for primary insomnia in the elderly showed significant improvement in a multivariate measure of sleep quantity based on both diary and polysomnographic sleep measures (96). Small improvements were noted in diary-based measures of sleep quality and PSG measures of sleep efficiency; however, the greatest improvements were noted in daytime symptoms of mood and well being. Thus, it may not simply be the sedating properties of antidepressants that lead to improvements in insomnia.

Indirect evidence for the efficacy of antidepressants, and differential effects among agents, comes from studies in individuals with major depression. For instance, fluvoxamine has a relatively alerting effect relative to desipramine that in turn is more alerting than amitriptyline (97 ,98). A comparison of trimipramine and imipramine found that both drugs improve sleep quality, although trimipramine was associated with more positive effects on PSG sleep (99). A comparison of fluoxetine with trazodone showed that the later drug was associated with more improvements in insomnia

symptoms, but also with a greater percentage of sedating events during the daytime (100). A series of comparisons between fluoxetine and nefazodone has consistently shown that both drugs improve subjective sleep quality among depressed patients, although the change appears to be larger with nefazodone (101 ,102). Nefazodone also led to improvements in PSG sleep efficiency, whereas fluoxetine was associated with mild decrements.

Antihistamines

Antihistamines such as diphenhydramine and doxylamine are the most widely available over-the-counter preparations for insomnia. The mechanism of action of these drugs involves inhibition of histamine H_1 receptors. Histaminic neurons in the posterior hypothalamus promote wakefulness through interactions with ascending cholinergic nuclei and through projections through the thalamus. Inhibition of H_1 receptors leads to decreased alertness and subjective sedation. The elimination half-life of diphenhydramine ranges from 3 to 5 hours, within increases in elderly persons. In addition to their effects on histamine, these medications can also have antimuscarinic anticholinergic effects.

Despite their widespread use, a large body of well-documented research does not support the efficacy of antihistamines. Diphenhydramine 50 mg, improved subjective ratings of sleep quality, sleep time, sleep latency, and wakefulness after sleep onset in middle-aged subjects with insomnia (103). A more recent study comparing the effects of lorazepam versus a combination of lorazepam plus diphenhydramine showed a slight advantage for the combination preparation in terms of sleep latency and subjective sleep quality (104). On most sleep measures, the two drug preparations were fairly similar. Studies of antihistamines in elderly people demonstrate subjective sedative properties comparable in magnitude to those of benzodiazepines and confirmed by effects such as increased sleep time, decreased awakening, and shorter sleep latency (105 ,106).

Adverse effects of antihistamines include a range of cognitive and performance impairments (107). The anticholinergic effects of these medications may be of particular concern in elderly subjects. The relative safety and efficacy of antihistamines with more sustained use has not been examined.

Melatonin

Melatonin has been widely used as a “natural” sleep-promoting agent. Data regarding its efficacy and safety have been mixed. The study designs, doses, and outcome measures used in melatonin trials have been quite variable and may contribute to inconsistent findings (108). Melatonin is secreted by the pineal gland during hours of darkness in both diurnal and nocturnal mammals. Melatonin’s effect on sleep and wakefulness may result from interaction with specific receptors in the suprachiasmatic nucleus of the hypothalamus (109). In addition, melatonin shifts circadian rhythms according to a phase response curve (110 ,111). The half-life of endogenous melatonin is less than 1 hour. Exogenous melatonin is absorbed from the gastrointestinal tract, but a wide variety of preparations are commercially available, ranging from very short-acting to very long-acting agents, with half-lives ranging from several minutes to approximately 8 hours. Doses greater than 1 mg are likely to induce supraphysiologic concentrations. Clinical trials have employed doses ranging from .1 to 80 mg.

During daytime administration, melatonin causes sleepiness in fatigue and healthy subjects (112 ,113). When administered at night to healthy subjects, melatonin decreases sleep latency (114) and the number of awakenings, and improves sleep efficiency in an experimental insomnia paradigm (115).

Studies in insomnia patients have also yielded inconsistent findings. Single-night administration seems to produce very little effect (116). Subjective sleep ratings showed no effect in another trial of 5 mg for 1 week (117), whereas a 14-day trial of 75 mg resulted in increased subjective sleep time (118). Trials of melatonin in elderly people have ranged from 1 to 21 days. The most consistent effect is reduced sleep latency with some evidence as well for reduced nighttime wakefulness using sustained-released preparations (119 ,120 ,121 and 122). In a carefully designed 14-day crossover trial, immediate- and sustained-release melatonin were associated with shortened sleep latency, but no change in sleep time, sleep efficiency, wakefulness, or subjective sleep measures (123).

Adverse effects associated with melatonin have not been carefully evaluated. Melatonin has effects on reproductive cycles in several mammalian species, and reports have indicated the potential for worsening of sleep apnea and impaired cognitive and psychomotor performance during daytime administration. There are also some concerns regarding vasoconstriction as a potential side effect.

Valerian Extract

Valerian extract is one of the most widely used herbal remedies for insomnia. These extracts are derived from roots of the genus Valeriana, most often of the species *V. officinelis*. They contain a number of potentially active compounds, including sesquiterpenes and valepotriates. Valerian extracts show affinity for $GABA_A$ receptors, which may be related to the high amount of GABA itself that is often contained in these preparations (124 ,125). However, GABA does not cross the blood–brain barrier, so this is an unlikely mechanism of action. Other potential actions include affinity for serotonin and adenosine receptors.

Clinical studies with valerian extracts show mild sedative and anxiolytic effects. In particular, four double-blind placebo-controlled studies have examined doses of 400 to 900

mg of valerian extract over periods of time from 1 to 8 days, and in diverse subject populations ranging from healthy young adults to elderly insomniacs (126 ,127 ,128 and 129). Subjective effects include decreased sleep latency and improved sleep quality (126 ,127 ,129). One study also reported decreased subjectively rated awakenings (126). Polysomnographic studies have shown an increase in stage 3 to 4 NREM sleep and reduced stage 1 sleep (128), with no change in sleep onset time, awake time after sleep onset, or other measures of sleep continuity (128 ,129). Likewise, valerian was found not to influence the EEG power spectrum during sleep (129). Findings from these studies are hampered by small numbers of subjects, different inclusion criteria, and inconsistent findings. These studies do not demonstrate the efficacy of valerian extract in most groups of individuals with primary insomnia.

Clinical studies have suggested a generally favorable side effect profile for valerian extract; however, the sedative effects of valerian may potentiate the effects of other CNS antidepressants (125).

FUTURE DIRECTIONS

Part of "133 - Current and Experimental Therapeutics of Insomnia "

Although considerable progress has been made with regard to the epidemiology of insomnia, further work needs to be done regarding its consequences for health and role functioning. Individuals with insomnia complain not only of sleep disturbance, but daytime consequences as well. In addition, investigations into the neurobiology of insomnia are clearly needed. This will help to define the underlying pathophysiology of insomnia in the general sense, but also help to define the boundaries of specific insomnia disorders. Techniques from cognitive and affective neuroscience, as well as electrophysiology and psychophysiology, will lead to an improved understanding of this condition. Functional neuroimaging experiments will also contribute to our understanding of the circuitry involved in insomnia, and its boundaries with mood and anxiety disorders. To date, no animal model exists for insomnia that would also help to promote research in humans. Finally, genetic studies have been very useful for identifying abnormalities associated with narcolepsy and circadian rhythm sleep disorders. Similar genetic and genetic epidemiology strategies remain to be applied to a study of insomnia.

Several issues also remain with regard to treatment aspects of insomnia. First, the relative benefits and risks of treatment in terms of symptomatic relief, health-related quality of life, and morbidity remain to be defined. These issues are of considerable importance, given the potential for some insomnia treatments to cause significant adverse effects, such as cognitive impairment and injurious falls. The optimal duration of treatment and the conceptualization of potential “maintenance” treatments for insomnia is also an area open for further investigation.

With regard to behavioral treatments, one of the major challenges is designing well manualized and “exportable” treatments that can be applied more readily in a variety of treatment settings, including primary care settings. Several studies have begun to examine the optimal combination of behavioral and medication-treatment approaches. Some of the evidence suggests better durability of treatment effects with behavioral treatment alone (33); however, sequential treatments as well as concurrent treatments need to be investigated. In addition, treatment strategies for nonresponders to either behavioral or pharmacologic interventions must be developed.

Advances in the neurobiology of insomnia may come from basic neuroscience sources. For instance, recent evidence has accumulated regarding the role of adenosine as a modulator of sleep/wake states (130). Relative underactivity of adenosinergic neurotransmission could potentially result in reduced sleep drive. Another focus for dysregulation in insomnia may involve the ventrolateral preoptic area (VLPO) and its interactions with the tuberomamillary nucleus in the posterior hypothalamus (131 ,132). The GABAergic VLPO has been identified as one of the few “sleep active” areas of the brain; dysregulation in this nucleus and its efferent projections to histaminergic, cholinergic, and noradrenergic nuclei could conceivably shift the sleep/wake balance in the direction of wakefulness. Finally, recent findings regarding the role of orexin in sleep/wake regulation could have direct implications for the neurobiology and pharmacologic treatment of insomnia (133 ,134). Neuroscience and clinical studies can both inform the optimal management of insomnia disorders.

Sleep Disturbances Associated with Neuropsychiatric Disease

Eric A. Nofzinger

Matcheri Keshavan

Eric A. Nofzinger and Matcheri Keshavan: Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania.

Several observations suggest important links between sleep and mental disorders. From a psychological perspective, it has long been thought that trouble sleeping is related to a troubled mind, an intrusion of mental activity into the quiescence of sleep. Historically, this vein has fueled much of the interest in the relationship between sleep and mental disorders until the discovery of electrophysiologically defined sleep stages, particularly rapid eye movement (REM) sleep in the 1950s. Even after that time and into the 1960s and 1970s, this basic psychological tenet guided interest in uncovering relationships between REM sleep and mental disorders. Over time, interest shifted to defining the neurobiology of mental disorders. In this service, EEG sleep staging became a tool to be used in either diagnosis or validation of the biological nature of mental disorders. A second, nonpsychiatric, line of investigation during this time concerned itself with the physiology of normal sleep. This led to a significant expansion in our understanding of the brain mechanisms that govern basic sleep/wake, or behavioral state, regulation. Few attempts, however, have been made to bridge these diverging lines of investigation despite the complimentary information derived from each area. In part, this may be related to the vastly divergent levels of observation of the brain capable in preclinical and human studies. With the advent of advances in preclinical work defining the brain mechanisms underlying electrophysiologic oscillations measured at the brain surface and in human brain imaging work defining correlates of underlying functional neuroanatomy, these divergent fields are beginning to communicate in meaningful ways to enrich the discoveries made in each domain. Evidence of this evolution comes in the form of chapters in this volume devoted to neuropsychopharmacology by neuroscientists such as Allan Hobson and Emmanuel Minot and the inclusion in this clinical chapter of preclinical data that may guide interpretations of human electrophysiology and functional neuroanatomy.

As a guide, this chapter attempts to first distill aspects of preclinical work that may inform our understanding of findings in electrophysiology and functional neuroanatomy in clinical populations. We then review the subjective, EEG, and brain imaging work in the major mental disorders that help to define pathophysiology through a sleep window into brain function. Disorders that are highlighted are the major mood disorders, schizophrenia, and degenerative disorders of aging given the extensive sleep research conducted in each of these areas.

NEUROBIOLOGY OF HEALTHY SLEEP

Part of "134 - Sleep Disturbances Associated with Neuropsychiatric Disease "

Overview of the Sleep/Wake Cycle

Sleep can be conceptualized as a motivated behavior, something the organism “needs” to do in order to survive and for which there is a pressure to perform. Sleep propensity is lowest shortly after awakening, increases in mid-afternoon, plateaus across the evening, is greatest during the night and declines across sleep. Sleep has been subclassified polysomnographically into NREM and REM sleep states based on three measures: (1) electroencephalography (EEG), (2) electromyography (EMG), and (3) electrooculography (EOG). With sleep onset, the EEG frequency slows, the amplitude increases and the EMG decreases. This sleep is classified as NREM stages 1, 2, 3, or 4, which are distinguished by increasing amounts of low-frequency, high-amplitude EEG activity, also known as “delta” activity. Delta sleep decreases across the night. REM sleep follows the first NREM period and is characterized by low-amplitude, mixed high-frequency EEG, the occurrence of intermittent REMs, skeletal muscle atonia, and irregular cardiac and respiratory events. Across the night, brain function oscillates between the globally distinct states of NREM and REM sleep about three or four times, approximately every 90 minutes. Across successive sleep cycles within a night, stages 3 and 4 sleep decrease

and then disappear, whereas REM sleep and lighter NREM sleep stages increase.

Historical Development of Sleep Neurobiology

The current understanding that sleep and wakefulness are both active brain states that are generated and maintained from within the brain has its origins in the pioneering work of Berger (1930), Economo (1929), Bremer (1935), Moruzzi and Magoun (1949), and Jouvet (1962). Prior to the work of these investigators, the state of sleep was thought to represent an inactive period for the brain. Berger first described electrophysiologic patterns of brain electrical activity that correlated with changes in behavioral state. Other investigators discovered that the brain itself was responsible for generating its own intrinsic electrical activity and for switching between behavioral states. Clinicoanatomic clues came in the discovery by Economo (1929) that lesions to the posterior hypothalamus in encephalitis lethargica produced somnolence or coma, suggesting a role for the posterior hypothalamus in maintaining wakefulness. Moruzzi and Magoun defined the concept of a nonspecific ascending reticular activating system (ARAS) responsible for cortical activation following their discovery that electrical stimulation of the brainstem reticular formation suppressed high-amplitude EEG waves in the cortex. Finally, following the discovery of the behavioral state of REM sleep by Aserinsky and Kleitman (1), the French neurophysiologist Michel Jouvet (2) localized the generation of this sleep state to structures in the pontobulbar brainstem using rostropontine transections in cats. From these studies it is now recognized that behavioral state is intrinsically regulated and generated by the brain itself and manifested by electrical activity in the brain that can be recorded by EEG at the scalp.

An extensive preclinical literature has developed that describes the brain mechanisms of the distinct electrophysiologic oscillations that characterize the various behavioral states of waking, NREM, and REM sleep. Several features are important with respect to localizing the brain structures underlying slow wave sleep. First, the electrical oscillations observed at the macroscopic level are the end result of electrical oscillations involving widespread thalamocortical neurons that are synchronized in a global fashion. Second, widespread changes in these oscillations can result from state-dependent changes in modulatory systems such as the brainstem, hypothalamus, and basal forebrain. Third, slow oscillations in the 1 to 4 Hz delta range have both cortical and thalamic components. This line of research emphasizes that rhythmic oscillations are the end result, therefore, of integrated corticothalamic circuits and modulatory structures. Changes in delta sleep found in diverse neuropsychiatric disorders, therefore, may result from functional changes at one or more levels including the cortex, thalamus, and modulatory structures.

At the other end of the oscillatory spectrum are the fast oscillations in the beta and gamma frequencies (roughly > 20 Hz) that have been associated with increased vigilance and are most prevalent during waking and REM sleep (3 ,4). These fast rhythms are present in cortical and thalamic neurons and depend on neuronal depolarization characteristic of brain activation, a state in which neurons are maximally ready to respond to either external (in waking) or internal (in REM sleep) stimuli. These fast synchronous rhythms may serve a purpose of binding aspects of a stimulus into a global representation. Importantly, these fast rhythms as well as the slow rhythms are dependent on the level of excitability in local intracortical circuits as may be modulated by ascending activating modulatory systems such as the brainstem monoaminergic and cholinergic nuclei (5). Disturbances in these fast frequency oscillations in neuropsychiatric disorders may reflect pathology at one or more of these levels modulating these electrophysiologic rhythms.

Mechanisms Underlying Behavioral State Changes: Core Structures Related to Arousal

From the electrophysiologic preclinical literature, it has become apparent that the set point for electrical oscillations in widespread thalamocortical circuits can be modulated by global ascending activating influences. Identification of the structures that are important in providing this input, therefore, may provide clues as to the brain mechanisms leading to altered electrophysiologic activity in diverse neuropsychiatric disorders. Arousal and the maintenance of an aroused state is an active process requiring the integrated activity of a series of arousal systems shown diagrammatically in Fig. 134.1 . (See Robbins and Everitt, 1996 , for review and RMoore and colleagues , 2001, for a discussion of the relationship between the Orexin neurons and these arousal systems) (6 ,7).

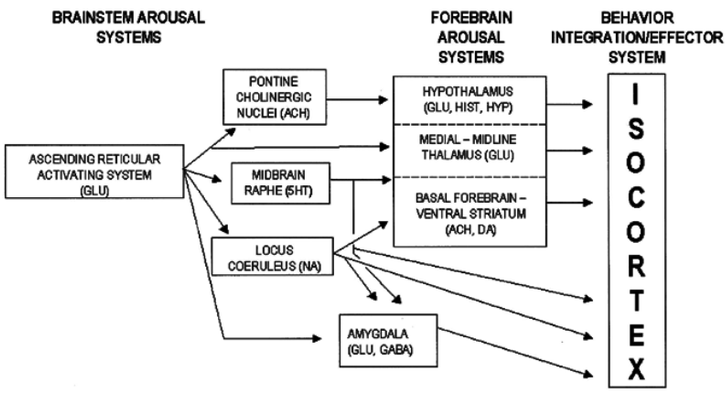

FIGURE 134.1. Arousal systems in the human brain (see text for description). The transmitters associated with each system are abbreviated. ACH, acetylcholine; DA, dopamine; GABA, γ aminobutyric acid; GLU, glutamate; HIST, histamine; HYP, hypocretin; NA, noradrenaline; 5HT, serotonin.

The central brainstem arousal system is the ascending reticular activating system (ARAS) (8 ,9). The ARAS projects into a series of specific brainstem systems including the pontine cholinergic nuclei, midbrain raphe nuclei, and the locus ceruleus, and into a series of forebrain structures involved in arousal. These include the midline and medial thalamus with widespread cortical projections and the amygdala, which has interconnections with isocortex and other areas involved in arousal, particularly hypothalamus and ventral striatum. The amygdala is particularly involved with autonomic regulation and the emotional component of arousal. There are two important components of the basal forebrain–ventral striatum system (10). One is the cholinergic neurons of the medial septum-nucleus of the diagonal band-nucleus basalis complex that innervates the entire forebrain. The second is the nucleus accumbens-ventral striatum complex that is involved in transmitting the arousing aspects of reinforcing stimuli. Until recently, the importance

of the hypothalamus was not fully recognized, but this is rapidly changing (10 ,11). First, we now appreciate that an important component of the circadian control of behavioral state is the maintenance of arousal by the circadian pacemaker, the suprachiasmatic nucleus (12). Second, there are extensive hypothalamic projections to isocortex, predominantly from posterior hypothalamus. These include a newly discovered projection from a group of neurons that produce a novel peptide hypocretin. This projection is of particular interest because the hypocretin neurons project not only over the entire isocortex but also to all of the arousal systems noted in Fig. 134.1 , including extraordinarily dense projections to locus ceruleus, raphe nuclei, pontine cholinergics, midline thalamus, nucleus basalis, and amygdala. (See ref. 7 for review.) The hypocretin projection has become of particular interest because a hypocretin gene knockout produces a narcolepsy-like syndrome in mice (13) and hypocretin is below detectable levels in CSF from narcoleptics in comparison to controls (14).

Mechanisms Underlying Behavioral State Changes: Core Structures Involved in REM Sleep

The nature of dreaming has led to extensive discussions about the relationships between REM sleep and mental disorders (9). The finding of EEG sleep staging abnormalities in REM sleep in certain mental disorders has also fueled discussions about the relationships between the biology of REM sleep and the pathophysiology of mental disorders; therefore, a brief review of brain structures that may have overlapping roles in REM sleep regulation and the pathophysiology of mental disorders may guide theoretical models of behavioral state regulation in diverse mental disorders (see Chapter 128 , Chapter 129 , Chapter 130 , Chapter 131 , Chapter 132 and Chapter 133). Evidence from a variety of approaches suggests that the laterodorsal and pedunculopontine tegmental cholinergic nuclei (LDT and PPT) in the pontine reticular formation underlie the phasic and tonic components of REM sleep (9). A reciprocal interaction hypothesis (9) claims that these cholinergic nuclei become disinhibited during the entry into REM sleep by the removal of tonic inhibition from noradrenergic and serotonergic nuclei as these monoaminergic nuclei slow or become silent in the transition from NREM to REM sleep (15). Modifications of this model now account for the influence of additional brainstem neurotransmitter systems such as GABAergic, nitroxergic, glutamatergic, glycinergic, histaminergic, adenosinergic, and dopaminergic; various peptide systems such as galanin, Orexin, vasoactive intestinal polypeptide, and nerve growth factor; and hormonal influences such as growth hormone-releasing hormone, prolactin, and corticotropin-releasing factor (9 ,11 ,16 ,17 and 18). Brainstem reticular nuclei include a dorsal pathway innervating the thalamus and a ventral pathway innervating the basal forebrain that thereby mediates widespread cortical arousal indicative of the REM sleep state. Human brain imaging studies of REM sleep show that the ventral pathway predominates during human REM sleep in activating anterior paralimbic structures (19 ,20).

Mechanisms Underlying Behavioral State Changes: Modulatory Structures

In large part, these preclinical studies have focused on the primary nuclei that may be generative centers for one behavioral state or another. Less information is available regarding structures that modulate activity in these centers and that may play a role in the abnormal modulation of behavioral states in various mental disorders (8 ,9). Recent work, for example, suggests that the amygdala has significant anatomic connections and recently established modulatory effects on the brainstem centers involved in REM sleep production (21 ,22). Similarly, other forebrain structures such as the hypothalamus (13) and basal forebrain (10 ,17) are

known to have both anatomic and functional relationships with brainstem centers thought to play a role in behavioral state regulation in addition to the primary roles they each play in cortical arousal. Although it is possible that certain disease states are associated with pathologic changes in discrete brain structures that generate discrete behavioral states, it is more likely (e.g., in the case of depression) that there are pathologic functions in brain structures that have modulating effects on these core brain structures in producing the behavioral state changes.

Mechanisms Underlying Behavioral State Changes: Evidence from Human Sleep Imaging Studies

The advent of brain imaging methods that can be used to study the functional neuroanatomy of human sleep has recently created a venue for linking preclinical work with human sleep electrophysiology. Findings from these new studies have enriched our understanding of the brain structures that are preferentially active across behavioral states and that may play a role in behavioral state regulation as well as functional roles for discrete behavioral states.

Global Changes in Brain Function across Behavioral States

In terms of global, or whole brain changes, from waking to NREM sleep, there are reductions in measures of cortical blood flow or metabolism (19). During REM sleep, global blood flow or metabolism ranges from 10% below to 41% above levels obtained during wakefulness (23 ,24). A recent report cited a positive correlation between waking global and regional cerebral blood flow and slow wave sleep measures from the subsequent night of sleep (25). The authors interpreted these findings as reflecting an energy conservation or restorative role for slow wave sleep.

Relative Regional Changes during NREM Sleep

In terms of regional relative changes during NREM sleep, blood flow has been shown to negatively correlate with the presence of NREM sleep in the anterior cingulate (19 ,26 ,27), pontine reticular formation (19 ,26 ,27), thalamus (19 ,26 ,27 and 28), basal forebrain/hypothalamus (19 ,26), amygdala (26), and orbitofrontal cortex (19 ,26 ,27). These changes are consistent with preclinical studies showing reductions in brainstem, basal forebrain, and hypothalamus sources of ascending activation. Declining function in the amygdala suggests the possibility that this structure modulates activity in ascending activating structures.

Relative Regional Changes during REM Sleep

In terms of regional relative changes during REM sleep, this state has been reliably associated with the selective activation of limbic and paralimbic structures including the amygdala, ventral striatum, anterior cingulate, and medial prefrontal cortex (19 ,20 ,23 ,29 ,30). This pattern of activation is superimposed on brainstem activation known to play a role in REM sleep generation on the basis of preclinical work.

Functional Brain Changes Associated with Sleep Deprivation

Several studies have discovered that sleep deprivation is associated with a global reduction in metabolism with some preference for the prefrontal cortex. This reduction is magnified with successive nights of sleep deprivation. These changes have recently been shown to play a role in the cognitive alterations associated with sleep deprivation (31).

THEORETICAL MODELS OF THE FUNCTION OF SLEEP

Part of "134 - Sleep Disturbances Associated with Neuropsychiatric Disease "

Homeostatic Function

Several models of sleep/wake regulation attempt to define parameters that may influence the probability at any point in the day that sleep may occur. One such model is the two-process model described by Borbely (32). One process, called process S, describes a homeostatic sleep process. Process S is thought to be dependent on the amount of prior wakefulness and is reflected by the amount of EEG slow wave (.5 to 4.5 Hz EEG) activity. As sleep deprivation increases, for example, process S increases and amplifies sleep propensity. The second process, process C, varies throughout the day in relation to a sinusoidal circadian phase across a 24-hour day. The intensity of this sleep propensity is unrelated to the amount of prior wakefulness. The sleep parameter most affected by this process is process C; nonsleep correlates of this process include core body temperature, plasma melatonin, and plasma cortisol levels. The regulatory structure for this process is the suprachiasmatic nucleus.

Sleep and Neuronal Plasticity

Several theorists have conceptualized distinct roles for the diverse sleep/wake states based on emerging knowledge regarding forebrain function in information processing. Buzsaki (33) emphasized a two-stage model of waking hippocampal memory trace formation and suggested parallels for two stages of memory processing during NREM and REM sleep. Karni and associates and Wilson and McNaughton have demonstrated direct evidence in support of memory processing during sleep for REM and NREM sleep, respectively.

Although the general states of neuronal activation have been described for NREM and REM sleep, little is known within these states about the relevance of this neuronal activation.

Llinas and Pare (34) suggest that wakefulness and REM sleep are fundamentally equivalent states of activation characterized by intrinsic oscillatory thalamo-cortical loops differing only in the degree to which external stimuli are capable of modulating the global brain state. They suggest that these oscillations serve the purpose of generating an internal representation of the world guided by innate predispositions of the brain to categorize and integrate the sensory world in certain ways. During REM sleep, these innate templates, which have been molded by experience, may be used to recreate world-analogues. During wakefulness, these templates are modulated by sensory events. Winson (35) suggested that, in humans, psychological experience essential to survival is integrated and further consolidated during REM sleep. He based this hypothesis on: (a) the presence of hippocampal theta during REM sleep; (b) the sole occurrence of hippocampal theta during species-specific survival-dependent behavior in nonprimates; and (c) the role of hippocampal theta in the induction of long-term potentiation (LTP), a model for the synaptic modulation underlying certain types of memory. Kavanau (36), reviewing data on synaptic events related to the formation of enhanced synaptic efficacy in the context of evolutionary biology, suggests that REM sleep may perform the service of repetitive activations of synapses in neural circuits that underlie essential adaptive behaviors. This “dynamic stabilization” is thought to ensure the efficacy of circuits that otherwise may suffer from a disuse atrophy. Although clearly these hypotheses require validation, the underlying premises are consistent with psychological theories that REM sleep and dreaming may play a role in affective adaptation; in the integration of recent, remote, and perhaps phyletic memory; maintaining or facilitating behavioral repertoires underlying crucial behavior; and the genetic programming of inherited behavior.

SLEEP IN MAJOR NEUROPSYCHIATRIC DISEASES

Part of "134 - Sleep Disturbances Associated with Neuropsychiatric Disease "

We turn now to characterizing the sleep disturbances in the major mental disorders. The vast majority of relevant data come from clinical and EEG sleep reports. Early findings from functional brain imaging studies are also reviewed.

DEPRESSION

Part of "134 - Sleep Disturbances Associated with Neuropsychiatric Disease "

Subjective Findings

The majority of patients with mood disorders describe difficulty falling asleep, staying asleep, and returning to sleep after early morning awakenings. Clinically, they report a paradoxic state of physical daytime fatigue, yet with persistent mental activity that makes it difficult for them to fall asleep at night. Subjective sleep quality has been measured with a validated instrument called the Pittsburgh Sleep Quality Index (PSQI) (37). In one study, subjective sleep quality was rated worse by patients with major depression than by patients presenting with a chief complaint of insomnia or other sleep disorder patients. Whereas insomnia characterizes the melancholia of middle age and elderly unipolar depression, younger patients and bipolar depressed patients often describe, atypically, difficulty getting up in the morning and hypersomnia during the daytime. This subjective hypersomnia, however, does not translate into an increased physiologic tendency to fall asleep when measured objectively by the Multiple Sleep Latency Test (MSLT).

EEG Findings

An extensive literature describes the changes in EEG sleep in patients with depression (38 ,39). Measures derived from the EEG sleep recordings that have been found to differ between healthy and depressed subjects include measures of sleep continuity, measures of visually scored EEG sleep stages, and automated measures of characteristics of the EEG waveform across the sleep period such as period amplitude or EEG spectral power measures.

The changes in subjective sleep complaints are paralleled by EEG measures of sleep. These include increases in sleep latency and decreases in sleep continuity. In terms of EEG sleep stages or “sleep architecture,” depressed patients often show reduced stage 3 and 4 NREM sleep (also known as “slow wave sleep” because of the presence of slow EEG delta activity during these stages). Several changes in REM sleep also have been noted. These include an increase in the amount of REM sleep, shortening of the time to onset of the first REM period of the night, shortened REM latency, and increase in the frequency of eye movements within a REM period.

In terms of quantitative EEG changes in sleep, many (40 ,41) but not all studies have reported reductions in the amplitude or a reduction in the number of low frequency (0 to 4 Hz) delta waves during sleep in depressed patients. Increased high frequency EEG activity has also been reported in depressed patients, including alpha (40) and beta. Importantly, sex differences have been found in these abnormalities. Depressed women appear to have relative preservation of delta sleep in relation to depressed men, despite elevations in higher frequency EEG activity in both groups (42).

Several observations regarding sleep disruption in depressed patients suggest that there may be a timing abnormality in the evolution of sleep across the night in depressed patients (38 ,41). A number of factors can influence the sleep EEG findings characteristic of depression. For instance, sleep continuity deteriorates, slow wave sleep decreases, and REM latency shortens with age, even in healthy subjects; however, age-related changes are more pronounced in patients

with depression (43). By contrast, sleep EEG measures are generally less abnormal in adolescents and prepubertal children with depression, and only appear consistently in those adolescents who are hospitalized and/or suicidal (44).

Other studies have shown that patients with psychotic depression have particularly severe EEG sleep disturbances and very short REM sleep latencies; patients with recurrent depression have more severe REM sleep disturbances than patients in their first episode; and sleep continuity and REM sleep disturbances are more prominent early in the depressive episode than later (45). Some studies suggest that patients with dysthymia and mania (surprisingly) have EEG sleep disturbances very similar to those observed in major depression.

Stressful life events also interact with EEG sleep. For instance, individuals who have severe stressful events preceding the onset of depression are less likely to have reduced REM latency than patients without such a stressor. Among older depressed patients, poor sleep is associated with shorter episode duration, older age, greater medical burden, the presence of life stressors, and a lower level of perceived social support (45).

EEG sleep findings help to inform our understanding of the neurobiology of longitudinal course and treatment outcome in depression. Although severely reduced REM latencies, phasic REM measures, and sleep continuity disturbances generally move toward control values after remission of depression, most sleep measures show high correlations across the course of an episode. Reduced REM latency is associated with increased response rates to pharmacotherapy (46) but not psychotherapy. Depressed patients with abnormal sleep profiles (reduced REM latency, increased REM density, and poor sleep continuity) are significantly less likely to respond to cognitive behavior therapy and interpersonal therapy than patients with a “normal” profile. Other studies have indicated that reduced REM latency and decreased delta EEG activity are associated with increased likelihood or decreased time until recurrence of depression in patients treated with medications or psychotherapy (47).

Sleep Neuroendocrine Findings

Cortisol secretion has been linked with the circadian cycle and growth hormone with slow wave sleep processes. In depressed subjects, studies have shown increases in cortisol secretion rates, a flattening of the circadian rhythms in cortisol, and elevated cortisol nadir. Secretion of growth hormone on the other hand, is reduced in the first half of the night in depressed subjects both in the acute phase and following remission from depression. Evidence such as this has been used to support hypotheses that a balance between the oppositional actions of CRF and GHRH may be shifted toward CRF in major depression. Given the activating qualities of CRF and its direct or indirect inhibition of GHRH, sleep would be shifted toward states of cortical activation, that is, either waking or REM sleep, and away from NREM sleep, which has been associated with the homeostatic function of sleep.

Sleep Neuropharmacologic Findings

Each of the major neurotransmitter systems shown to modulate the ascending activation of the cortex, that is, the cholinergic, noradrenergic, and serotonergic systems, have been implicated in the pathophysiology of mood disorders. The role of additional brainstem neurotransmitter systems such as GABAergic, nitroxergic, glutamatergic, glycinergic, histaminergic, adenosinergic, dopaminergic, and various peptide systems such as galanin, Orexin, vasoactive intestinal polypeptide, and nerve growth factor in the sleep disturbances in depression remain to be defined. Nearly all effective antidepressant medications show a pronounced inhibition of REM sleep including a prolongation of the first REM cycle and a reduction in the overall percent of REM sleep. (Exceptions include nefazodone [48] and bupropion, which do not suppress REM sleep [49].) Enhanced cholinergic function concurrent with reduced monoaminergic tone in the central nervous system has been proposed as a pharmacologic model for depression. In an exaggerated sense, the state of REM sleep mimics this formulation, that is, a cholinergically driven state with reduced firing of noradrenergic and serotonergic neurons. Cholinergic agents such as the muscarinic agonist RS 86, arecoline, physostigmine, and scopolamine produce exaggerated REM sleep effects in depressed patients in comparison with patients with eating disorders, personality disorders, anxiety disorders, and healthy controls (50). These studies suggest that there may be a supersensitivity of the cholinergic system driving REM sleep in mood disorders patients, although an alternative plausible hypothesis is that there may be reduced monoaminergic (5-HT and/or NE) inhibition of the brainstem cholinergic nuclei in mood disorders patients. Cholinergic activation may also play a role in the hyperactivity in the HPA axis and in the blunting of growth hormone secretion noted in depressed patients across the night, given the influence of cholinergic drugs on HPA activity and GH release.

Selective serotonin reuptake inhibitors are known to have prominent REM suppressing activity, most notably early in the night when enhances in REM sleep are most often seen in mood disorders patients (39). A tryptophan-free diet, which depletes central serotonin activity, is noted to decrease REM latency in healthy controls and in depressed patients (51) and ipsapirone, a 5-HT1a agonist, is noted to prolong REM latency in both normal controls and in depressed patients (52). Anatomically, 5-HT1a receptors have been conceptualized as the limbic receptors given their high densities in the hippocampus, septum, amygdala, and cortical paralimbic structures. The action in these structures has been shown to be largely inhibitory (hyperpolarizing).

Given the importance of limbic and paralimbic structures in REM sleep modulation, the influence of SSRI medications may be mediated by these limbic receptors. Importantly, in the brainstem LDT, a locus of cholinergic cells identified in the generation of REM sleep, bursting cholinergic neurons are inhibited by the action of 5-HT on 5-HT1a receptors. Finally, the effects of the 5-HT1a-antagonist pindolol on EEG sleep in healthy subjects was studied and noted to reduce REM sleep. This was interpreted as supportive of a reduction in raphe serotonergic autoregulation, resulting in increased serotonergic input to pontine cholinergic centers and inhibiting REM sleep.

Functional Neuroimaging Findings

Given the selective activation of limbic and paralimbic structures during REM sleep in healthy subjects, the study of the functional neuroanatomy during REM sleep in depressed patients

may provide clues as to alterations in limbic and paralimbic function related to the pathophysiology of depression. In contrast to healthy controls (4), depressed patients fail to activate anterior paralimbic structures (subgenual and pregenual anterior cingulate and medial prefrontal cortices) from waking to REM sleep. In contrast to healthy controls, depressed subjects show large activations in the dorsal tectum (superior colliculus and periaqueductal gray) during REM sleep. Finally, in contrast to controls, depressed subjects activate left sensorimotor cortex, left inferior temporal cortex, left uncal gyrus and amygdala, and left subicular complex during REM sleep. These findings suggest that depressed patients demonstrate uniquely different patterns of activation from waking to REM sleep than do healthy controls. In the context of neuroscience models relating forebrain function during REM sleep to attention, motivation, emotion, and memory, these results suggest that prior REM sleep abnormalities in mood disorders patients, therefore, likely reflect alterations in limbic and paralimbic forebrain function related to depression (Fig. 134.2).

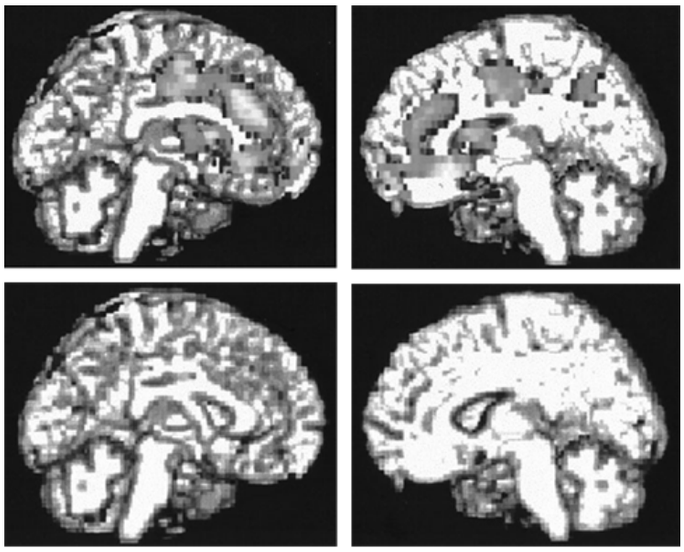

FIGURE 134.2. Healthy and depressed subjects' changes in relative glucose metabolism from waking to rapid eye movement (REM) sleep. The top two images are midsagittal sections showing areas of the brain that have greater relative glucose metabolism during REM sleep than during waking. These areas include anteriorly located paralimbic structures such as the ventral striatum, anterior cingulate cortex, and medial prefrontal cortex. The lower two images show the same comparisons, but in depressed patients. Of note is the absence of an increase in relative metabolism in any of these anteriorly located paralimbic structures in depressed patients from waking to REM sleep. See color version of figure.

Functional neuroimaging of NREM sleep in depressed subjects would be expected to provide evidence regarding the functioning of homeostatic mechanisms in mood disorders patients since this is a time of nonselective nonactivation of the cortex in which the buildup of a sleep dependent process, process S, is discharged and during which growth hormone secretion occurs. Ho and Gillin and colleagues (53) demonstrated that whole brain and regional cerebral glucose metabolism was elevated during the first NREM period of the night for depressed men in relation to healthy men. These findings are supportive of a deficiency of homeostatic mechanisms in mood disorders patients, perhaps secondary to cortical hyperarousal. Clark and associates (25) reported that reductions in delta sleep in depressed patients were associated with reductions in afternoon waking relative and global blood flow. This suggests that the elevations in glucose metabolism during NREM sleep in depressed patients are not related to a waking hypermetabolic state. Studies across waking and NREM sleep are needed in order to clarify this notion.

Nofzinger and associates (54) sought to clarify the neurobiological basis of variations in one aspect of central nervous system "arousal" in depression by characterizing the functional neuroanatomic correlates of beta EEG power density during NREM sleep. First, nine healthy (*N* = 9) subjects underwent concurrent EEG sleep studies and [^{18}F]2-fluoro-2-deoxy-D-glucose ([^{18}F]FDG) positron emission tomography (PET) scans during their first NREM period of sleep in order to generate hypotheses about specific brain structures that show a relationship between increased beta power and increased relative glucose metabolism. Second, brain structures identified in the healthy subjects were then used as *a priori* regions of interest in similar analyses from identical studies in 12 depressed subjects. Statistical parametric mapping was used to identify the relationship between beta power and relative regional cerebral glucose metabolism (rCMRglu) during NREM sleep. Regions that demonstrated significant correlations between beta power and relative cerebral glucose metabolism in both the healthy and depressed subjects included the ventromedial prefrontal cortex and the right lateral inferior occipital cortex. During a baseline night of sleep, depressed patients demonstrated a trend toward greater beta power in relation to a separate age- and gender-matched healthy control group. In both healthy and depressed subjects, beta power negatively correlated with subjective sleep quality. Finally, in the depressed group, there was a trend for beta power to correlate with an indirect measure of absolute whole brain metabolism during NREM sleep. This study demonstrated a similar relationship between electrophysiologic arousal and glucose metabolism in the ventromedial prefrontal cortex in depressed and healthy subjects. Given the increased electrophysiologic arousal in some depressed patients and the known anatomic relations between the ventromedial prefrontal cortex and brain activating structures, this study raises the possibility that the ventromedial prefrontal cortex plays a significant role in mediating one aspect of dysfunctional arousal found in more severely aroused depressed patients.

Wu and associates (55) characterized the functional neuroanatomic changes following sleep deprivation therapy in depressed patients. They found that depressed patients who demonstrated high pretreatment relative glucose metabolic rates in the medial prefrontal cortex were more likely to respond to sleep deprivation. Further, a reduction in relative metabolism in this region was found following sleep deprivation.

Depression and Alcoholism

Significant comorbidity exists between depression and alcoholism. EEG sleep studies have been used as a tool to explore the relationships between the neurobiology of the two disorders. Clark and colleagues (56) found that alcoholism played a more significant role in sleep disruption than depression. Increased REM density in primary alcoholics with and without a lifetime diagnosis of secondary depression predicted 3-month alcohol-related relapse rates. Drummond and co-workers (57) examined the relationships among sleep, natural course, and relapse in abstinent pure primary alcoholic patients. They found that the sleep was short, fragmented, and shallow early in abstinence with some incomplete improvements over the first year of abstinence. Further, the presence of sleep disruption at 5 months was shown to predict relapse by 14 months.

SCHIZOPHRENIA

Part of "134 - Sleep Disturbances Associated with Neuropsychiatric Disease "

REM Sleep

Early sleep EEG studies sought to test the intriguing hypothesis that schizophrenia is a spillover of the dream state into wakefulness. No evidence has accrued to support this prediction; however, subtle alterations in architecture of REM sleep may occur. REM latency was found decreased in seven of the 10 studies (58). It has been proposed that this may result from a deficit in SWS in the first NREM period leading to a passive advance, or early onset of the first REM period. An alternative explanation is "REM pressure." However, studies of the amounts of REM sleep have been conflicting with increases, decreases, as well as no change being found (58 ,59). Studies examining treatment naive schizophrenia patients show no increases in REM sleep (60 ,61); the increases in REM sleep observed in previously treated subjects may reflect effects of medication withdrawal and/or changes related to the acute psychotic state (61). It is unlikely that the observed decreases in REM latency in some schizophrenia patients result from primary abnormalities in REM sleep.

Slow Wave Sleep

Slow wave sleep is of particular interest to schizophrenia because of the implication of the prefrontal cortex in this disorder (62) and in generation of SWS (63). Several studies have shown a reduction of SWS in schizophrenic patients; SWS deficits have been seen in acute, chronic, as well as remitted states; and in never-medicated, neuroleptic-treated, as well as unmedicated patients (58); however, not all studies show these deficits. Studies that fail to find differences in SWS have generally used conventional visual scoring. Three studies that have quantified sleep EEG parameters have consistently shown reductions in SWS. Ganguli

and associates (60) observed no change in visually scored SWS, but instead, a significant reduction in delta wave counts in drug-naive schizophrenic patients, suggesting that visually scored SWS may not be sensitive enough, and automated counts may be a better marker of SWS deficiency in schizophrenia. Other groups have described similar reductions in delta counts. SWS deficits have been recently demonstrated in early course schizophrenia using sensitive approaches such as spectral analysis (64).

Sleep Deprivation Studies

Sleep deprivation provides a naturalistic, physiologic challenge for dynamic manipulation of sleep processes, and can help clarify the primary nature of sleep abnormalities. An intriguing reduction in REM rebound following REM sleep deprivation has been described in several studies in acute schizophrenia, but a normal or exaggerated REM rebound in remitted schizophrenic patients (58). This rebound failure in acute schizophrenia has been attributed to a possible “leakage” of phasic REM events from REM sleep into NREM sleep, although no systematic investigation has supported this hypothesis.

Sleep deprivation studies can also help clarify whether SWS abnormalities in schizophrenia are secondary to pathology in neuronal circuits in this disorder, or whether they reflect primary homeostatic disruption in sleep processes. There is evidence (65) that following total sleep deprivation, recovery of Stage 4 sleep is diminished in schizophrenia. SWS deprivation is known to consistently cause impaired attention, prolonged reaction time, verbal learning, and vigilance similar to what is seen in frontal lobe dysfunction and schizophrenia (66). A defect in SWS recovery might be consistent with impairments in critical cognitive processes such as psychomotor vigilance observed in schizophrenia. Such a defect might also suggest impairment in trophotropic or restorative processes in schizophrenia.

Relation between Sleep Abnormalities and Clinical Measures in Schizophrenia

The neurobiological correlates of the psychopathological dimensions are critical for our understanding of the pathophysiology of psychiatric disorders. Research during the past decade has focused increasingly on the positive and negative syndromes, a conceptual distinction of particular importance to pathophysiology of schizophrenia. A number of studies have examined the association between REM sleep parameters and clinical parameters. Tandon and associates (61) reported an inverse association between REM latency and negative symptoms. No association has been seen between sleep abnormalities and depressive symptoms (61), but two studies have shown that increased REM sleep may correlate with suicidal behavior in schizophrenia (67 ,68).

It is important to understand the longitudinal nature of sleep abnormalities in schizophrenia, in order to elucidate their significance for pathophysiology. Stage 4 does not appear to improve while other sleep stages change following 3 to 4 weeks of conventional antipsychotic treatment (69). In a longitudinal study, alterations of SWS appeared to be stable when polysomnographic studies were repeated at 1 year, but the REM sleep parameters appeared to change. These observations suggest that SWS deficits in schizophrenia might be trait-related (70). Consistent with this view, delta sleep abnormalities have been found to correlate with negative symptoms (60) and with impaired outcome at 1 and at 2 years (71).

An association between attentional impairment and SWS deficits also has been reported in early studies (72). The thalamus plays a crucial role in attention and gating of information because it is the major relay station receiving input from the reticular activating system and limbic and cortical association areas. A defect in this structure could explain much of the psychopathology of schizophrenia and alterations in SWS.

Relation Between Sleep Findings and Neurobiology in Schizophrenia

Some clues to the possible pathophysiologic significance of SWS deficits in schizophrenia may derive from the studies of the ontogeny of sleep during normal adolescence, in the context of a neurodevelopmental framework for schizophrenia. Converging evidence suggests a substantial reorganization of human brain function during adolescence; a marked decline in synaptic density is seen in the postmortem prefrontal cortex during adolescence. Pronounced reductions in cortical gray matter volume and regional cerebral metabolism also have been seen during adolescence. Polysomnographic studies show major changes in EEG sleep patterns in adolescence; the amounts of SWS decrease (73) across the age span from childhood to late adolescence. The time courses for maturational changes in SWS, cortical metabolic rate, and synaptic density during the postnatal phase of human development are strikingly similar; Feinberg (74) suggested that cortical neurons, after birth, go through a phase of initial overproduction and subsequent regression (pruning) of neural elements. Thus, the maturational processes in sleep EEG, cortical synaptic density and regional cerebral metabolism might reflect a common underlying biological change (i.e., a large-scale synaptic elimination).

It is instructive to examine the polysomnographic abnormalities in schizophrenia in relation to the brain maturational parameters discussed in the preceding. In addition to SWS deficits, consistent alterations in structure and function of cortical and subcortical brain regions have been observed in schizophrenia. Cross sectional studies of the correlations between such alterations and sleep are valuable to better understand the pathophysiologic substrate of schizophrenia.

Altered Neuroanatomy

Reductions in cortical gray matter are seen in schizophrenia, perhaps more prominently in the frontal and temporal cortex as well as in thalamic volume (75). SWS generation appears to be regulated by a complex neural system involving the anterior brain regions and the thalamus. The relationship between alterations in these brain structures and SWS, therefore, is interesting. SWS tends to be inversely correlated with anterior horn ratio, a measure of frontal lobe size (76), and positively correlated with lateral ventricular volume (77). These observations may reflect reductions in subcortical structures such as the thalamus, which forms a substantial part of the ventricular boundaries. A correlation between thalamic volume and SWS deficits may be predicted, and is consistent with the former's critical role in generation of SWS.

Altered Neurochemistry

What are the neurochemical mechanisms involved in SWS deficits? SWS may result from several neurochemical processes that produce neural inhibition, functional differentiation, and EEG synchrony. Activation of the cholinergic system facilitates arousal and hastens REM sleep. Cholinergic hyperfunction postulated to underlie schizophrenia, therefore, could account for SWS and REM latency reduction in schizophrenia sleep (78). Interestingly, schizophrenic patients show supersensitive REM sleep induction with the cholinergic agonist R5 86 (79), suggesting cholinergic hyperfunction. Nicotinic receptors may also be involved; sensory gating deficits as evidenced by P50 event-related potentials, which are possibly related to central nicotinergic system alterations, are reversed following sleep in schizophrenia (80). Alternatively, serotonergic abnormalities may also be involved, as indicated by an inverse correlation between serotonin metabolites in the CSF and SWS in schizophrenia (81). Disturbances in catecholaminergic mechanisms may also underlie SWS deficits in schizophrenia. Norepinephrine, which is presumed to be hyperfunctional in schizophrenia, is inhibitory to REM; therefore, it may be argued that cholinergic and monoaminergic abnormalities mediate the constellation of reduced REM latency and SWS deficit without increases in REM sleep amounts in schizophrenia (78).

The possible relation between hormonal substances and delta sleep has also received some attention. Van Kammen and associates (82) showed an association between reduction in delta sleep induction peptide, a putative endogenous sleep modulator, and SWS decrements. Adenosine, an amino acid neuromodulator has drawn increasing interest in recent years as a possible endogenous sleep-promoting agent, as it tends to accumulate during waking hours (83). Adenosine agonists have been proposed as possible therapeutic agents in schizophrenia (84).

Altered Physiology

Some evidence, albeit modest, for decreased frontal lobe metabolism has been documented in schizophrenia using a variety of techniques, including PET, single photon emission computed tomography (SPECT), 31P MRS, and xenon 133 inhalation technique. It may be instructive to examine SWS deficits in the context of such physiologic alterations. An association has been demonstrated between SWS deficits and reduced frontal lobe membrane phospholipid metabolism as examined by 31P MRS (85).

Decreased synaptic density, postulated to underlie schizophrenia, could result in reduced SWS by decreased membrane surface (fewer dendrites per neuron), causing a smaller voltage response to the synchronizing stimulus. Recent studies in cats using single cell recordings (86) have shown that slower (<1 Hz) synchronized oscillations originate mainly in the neocortex, whereas delta waves (1 to 4 Hz) arise primarily from activity of thalamocortical neurons. A finer analysis of these oscillations may clarify the nature of pathophysiology in schizophrenia. Preliminary analysis of this question using period amplitude analyses suggested more prominent deficits in the <1 Hz range in schizophrenia, pointing to a thalamocortical dysfunction (64). This finding deserves further study and replication.

Effects of Antipsychotic Drugs on Sleep

Studies of the acute effects of neuroleptics have consistently shown improvements in sleep continuity, as reflected by reduced sleep latencies, improved sleep time, greater sleep efficiency, and prolongation of REM latency (58); however, changes in SWS have been less consistent. Studies that have examined the sedative effect of conventional neuroleptics have reported either no effects or modest increases in SWS. A recent study showed a robust increase in SWS with olanzapine following acute administration (87). On the other hand clozapine increases stage 2 sleep, but may actually decrease stage 4 sleep (88). These studies have frequently used small sample sizes; few studies have examined sleep variables in relation to acute versus long-term treatment with neuroleptics in a longitudinal design.

Attempts to examine polysomnographic characteristics of schizophrenia have to consider potential effects of neuroleptic discontinuation on sleep EEG. Neylan and associates (89) reported significant worsening of REM and non-REM sleep in a series of schizophrenic patients undergoing controlled neuroleptic discontinuation. Patients experiencing relapse has larger impairments in sleep. The effects of neuroleptic discontinuation continued to worsen from 2 to 4 weeks of a neuroleptic-free condition, and did not correlate with clinical change (90). These findings highlight the importance of controlling for medication state in investigation of EEG sleep in schizophrenia.

Future Directions

New knowledge on brain mechanisms of sleep is likely to open new avenues to investigate the pathophysiology of schizophrenia. First, functional brain imaging studies suggest distinct patterns of regional brain activation in SWS and REM sleep; such studies can provide clues to the pathophysiology of schizophrenia, especially used in conjunction with physiologic perturbation paradigms such as sleep deprivation (31). Second, sleep architecture changes dramatically during development; sleep studies during development in health and disease can shed considerable light on developmentally mediated neuropsychiatric disorders (91). Finally, sleep changes are often the earliest signs of disturbance, and may even represent trait-related vulnerability markers for psychiatric disorders; sleep studies of individuals at risk for schizophrenia are likely to be fruitful (92).

GERIATRIC DISORDERS

Part of "134 - Sleep Disturbances Associated with Neuropsychiatric Disease "

Late Life Depression

Assessments of the timing and quality of NREM and REM sleep cycles through EEG sleep studies have proven to be particularly useful indicators of homeostatic and adaptive physiologic processes during successful and pathologic aging in humans. In a study of healthy “old old” and “young old,” Reynolds and colleagues (93) reported: (a) a small age-dependent decrease in slow-wave sleep, in contrast to the stability of REM sleep measures from “young old” to “old old”; (b) much better preservation of slow wave sleep among aging women than men, particularly in the first NREM period of the night, but no sex-related differences in REM sleep measures; (c) greater stability of sleep maintenance among aging men than women; and (d) longer REM sleep latencies among aging women than men. In comparison with 20 year olds, 80 year olds have significant reductions in both REM sleep percent and latency, as well as a slower recovery from the effects of acute sleep loss. Elderly people show greater rigidity in sleep patterns, with less intersubject and intrasubject variability in habitual sleep times compared to the young (94); therefore, although some loss of REM and slow wave NREM sleep characterize the aging process, successful aging is associated with a relative stability of sleep states over the later years. One explanation for these findings may be some mild losses in both homeostatic as well as adaptive physiologic mechanisms that result in NREM and REM sleep decrements, respectively. Alternatively, information processing related to both homeostatic and adaptive behavior may be more stable and efficient in the elderly, especially in those for whom the aging process has been bridged successfully.

EEG sleep studies have also provided insights into the pathophysiology of disorders in which affective adaptation is significantly stressed in late-life, that is, in response to significant losses or in acute depressive episodes. In a study of elderly volunteers who had lost a spouse, Reynolds and colleagues were able to distinguish EEG sleep changes discriminating subjects who did from those who did not develop an episode of major depression. Bereaved subjects with depression had significantly lower sleep efficiency, more early morning awakening, shorter REM latency, greater REM percent, and lower rates of delta-wave generation in the first NREM period, as compared to nondepressed bereaved volunteers. These findings are similar to those of elderly patients with recurrent unipolar depression. In a subsequent longitudinal study of bereaved elders who did not become clinically depressed, only increases in phasic REM activity and density (compared to normal controls) were observed throughout the first 2 years of bereavement (95). These findings are similar to those of Cartwright for depressed versus nondepressed divorcing women, suggesting that short REM latency and slow wave sleep are correlates of depression during stressful life events, whereas increased REM activity may correlate with successful recovery from stress in the absence of major depression. Given the selective activation of limbic and paralimbic structures during REM sleep, that is, structures related to affective adaptation, the increase in REM activity in the successful resolution of stressful events may relate to the activation of brain structures mediating adaptation to these stressful events. A failure to terminate this normal adaptive response, similar to the failure of counterregulatory neuroendocrine events in the generalized stress response, appears to result in a shift of central neurophysiologic events favoring cortical activation. This results in shifts away from homeostatic NREM sleep states, and toward more activated waking and REM sleep cortical states. In the EEG these are manifested by reductions in intrinsic, nonactivated thalamocortical synchronous EEG waves of NREM sleep, and an early entry into desynchronized REM sleep. Subjectively, this may relate to depressed patients complaints of both increased fatigue, or anergy (loss of homeostatic mechanisms) and increased internal “arousal” (shifting toward a more continuous on-line state of readiness to process salient stimuli).

Alzheimer’s Disease

Disturbances in sleep commonly accompany Alzheimer’s disease (AD) (96). These disturbances are a significant cause of distress for caregivers, often leading to institutionalization of these patients (97). The changes in sleep often parallel the changes in cognitive function in demented patients (98). Also, daytime agitation has been associated with sleep quality at night (99). A large-scale community based study of AD patients reported that sleeping more than usual and early morning awakenings were the most common sleep disturbances in noninstitutionalized patients. Nighttime awakenings, however, were more disturbing to caregivers.

Nighttime awakenings were associated with male gender, and greater memory and functional declines. Three groups of subjects were identified in association with nocturnal awakenings: (a) patients with only daytime inactivity; (b) patients with fearfulness, fidgeting, and occasional sadness; and (c) patients with multiple behavioral problems including frequent episodes of sadness, fearfulness, inactivity, fidgeting, and hallucinations.

In terms of sleep laboratory-based evaluations, sleep continuity disturbances in these patients include decreased sleep efficiencies, increased lighter stage 1 NREM sleep, and an increased frequency of arousals and awakenings. Sleep architecture abnormalities include decreases in stages 3 and 4 NREM sleep and some reports of decreases in REM sleep (100). Loss of sleep spindling and K complexes have also been noted in dementia. Sleep apnea has been observed in 33% to 53% of patients with probable AD (101). It is unclear if there is an increased prevalence of sleep apnea, however, in AD patients in relation to age- and gender-matched controls. Nocturnal behavioral disruptions, or “sundowning” are reported commonly in the clinical management of AD patients, although specific diagnostic criteria for a “sundowning” episode have been difficult to define (96 ,102). Despite extensive clinical research in this area, the pathophysiology of sundowning, including its relationship with brain mechanisms that control sleep/wake and circadian regulation remain unclear. Overall, the literature on sleep in AD suggest that the primary defect in this disease is the more general neurodegenerative changes that lead to the profound cognitive and functional declines of this disease and that the sleep changes are secondary manifestations of the disorder. If sleep is viewed as generated by core sleep systems that then require an intact neural structure throughout the rest of the brain for expression of behavioral states, then the sleep changes in AD are most likely related to end-organ failure as opposed to pathology in key sleep or circadian systems themselves.

Parkinson’s Disease

Light, fragmented sleep occurs frequently in Parkinson’s disease (PD) patients. Sleep problems have been reported in as many as 74% to 96% of patients (103). Complaints include frequent awakenings, early awakening, nocturnal craps, pains, nightmares, vivid dreams, visual hallucinations, vocalizations, somnambulisms impaired motor function during sleep, myoclonic jerks, excessive daytime sleepiness, REM sleep behavior disorder, and sleep-related violence leading to injury (103 ,104 ,105 and 106). These changes may result from the disease itself, or to complication from treatment with dopaminergic agents (103 ,104 and 105 ,107). Additionally, depression is common in PD and the sleep disruption may in part be related to this comorbid disorder (103).

Sleep architecture abnormalities include increased awakenings, reductions in stages 3 and 4 sleep, REM sleep, and sleep spindles (107 ,108). Reductions in REM latency have been observed. Increased muscular activity, contractions and periodic limb movements may prevent slow wave sleep and foster light fragmented sleep. Disorganized respiration also is found (109).

FUTURE DIRECTIONS

Part of "134 - Sleep Disturbances Associated with Neuropsychiatric Disease "

As one of the earlier tools available to psychiatric research for discovering the biological basis of mental disorders, EEG sleep recordings have been used extensively to characterize alterations in brain function across diverse mental disorders. This literature now forms the background for new research that can uncover the brain mechanisms that underlie these descriptive changes. Tools available for such purposes include refinements in electrophysiologic recordings using automated EEG and the concurrent use of electrical recordings of cognitive processes such as evoked responses to characterize changes in information processing during sleep in relation to mental disorders. Extensive advances in functional neuroimaging that are currently available, as well as in development, promise to provide us with dynamic images of brain function as it transitions throughout the sleep/wake cycle. In this manner, the functional neuroanatomic basis of the electrophysiologic abnormalities can be determined and interventions designed targeting not only specific neurotransmitter systems but systems that are specific to a discrete brain region that is responsible for the sleep/wake disturbance. The discovery of the genetic basis of narcolepsy brings the dream of uncovering the genetic basis of sleep disruption into closer view. Application of the advances in cognitive neuroscience to sleep also promise to define the importance of sleep in shaping cognitive function as well as the role of pathological sleep in disrupting waking cognitive activity.
