Preface

The current (Sixth Edition) *Principles and Practice of Clinical Virology* consists of 39 chapters and 968 pages, contrasting with the 16 chapters and 590 pages in the First Edition, published in 1987. This is a manifestation of not only the wealth of new knowledge acquired on those virus infections listed in the First Edition, but also the discovery of newly-recognized emerging infections, the improvement or development of new vaccines, for example human papilloma virus vaccines, and an increasing repertoire of antiviral agents for treatment. Molecular techniques are now increasingly used for the diagnosis and monitoring of viral infections but their use and assessment is dependent on having a clear understanding of some of the basic virology covered in each of the chapters.

All chapters have been thoroughly revised and there are a number of new contributors, joining the cadre of internationally-recognized experts. Of particular note is a new chapter on vaccinology, covering the principles

relating to the development and use of vaccines generally, which will be a useful complement to the specific vaccines described, where appropriate, in the various chapters. The two chapters on nosocomial infections have been rewritten and enlarged and will be particularly useful for those having to advise on the management of hospital-acquired infections. There are chapters on virus infections common in developing countries, including zoonoses which, because of climate change and speed of travel by air, may need to be identified and managed in resource-rich countries.

This edition emphasizes the rapid accumulation of new information in such fields as retroviruses, particularly HIV, SARS, hepatitis C and influenza, including avian influenza.

As in previous editions, attempts have been made to limit references to key publications of historical importance and to recent review articles.

October 2008

Past, Present and Future of Clinical Virology: an Overview

Medical virology is an eclectic science, born a century ago of the germ theory of disease and the realization that pathogenic microbes smaller than bacteria must exist. The circumstances surrounding its birth are exemplified by the early study of influenza. Epidemic influenza had first been clearly documented in the years 1889–1891, and this led to the description of *Haemophilus influenzae* as its causative agent. That organism proved to be a secondary invader, however, and by the time the next influenza pandemic appeared in 1918 few believed that it was responsible for influenza. By then, too, there was a growing conviction that influenza and several other common diseases such as measles and herpes simplex were due to a different life form, one that passed through bacteria-retaining filters and could not be propagated in the laboratory on inert growth media.

Although the word ‘virus’ had been loosely used for many years previously, the first clues about the life form that eventually took that name came with the independent description around 1915, by Twort and d’Herelle, of bacteriophages. These were viruses observed to cause patches of lysis on lawns of bacteria grown on agar, a phenomenon that could then be reproduced with high dilutions of filtrates derived from the same patches. About the same time comparable observations were being made on plants with filtrates derived from lesions on their leaves. In respect to human viruses, though, the first quarter of the twentieth century can be regarded as a Dark Age in which there was accurate observation of virus diseases but little understanding of their pathogenesis and none at all of the biology of the viruses that caused them.

Fortunately, veterinary studies were more instructive; both investigations of viral infections of animals that might be analogous to human ones, and others in which animal susceptibilities to human viruses were beginning to be used for clinical diagnosis and vaccine development. Into the former class fell the studies by Loeffler and Frosch on Foot and Mouth Disease (around 1900). These showed that very highly dilute filtrates derived from acute

lesions of cattle readily transmitted the infection. Into the latter class fell the successful transmissions of measles (1908), polio (1909) and yellow fever (1926) infections to rhesus monkeys, of vaccinia and herpes simplex to rabbits (around 1915), and of influenza to ferrets (1933). As has continued to be the case, such transmissions were very instructive; but they were inconvenient as a routine and have since become increasingly controversial, both in their use of animals and, in the case of primates, in their impact on endangered species. Moreover, animal studies have not been forward-looking, harking back as they do to the nineteenth century propagation of vaccinia on the flanks of calves and of attenuated rabies virus in the spinal cords of rabbits. Though this was the bedrock on which clinical virology was built, inoculation of animals with human viruses has proved to have distinct limitations.

The next recognizable phase in the development of clinical virology saw the first applications of tissue culture to the propagation of viruses and the adoption of fertile eggs as a convenient substrate for virus growth. Before antibiotics the former was hopelessly prone to contamination, but the latter much less so. A pioneer (around 1930) in the use of fertile eggs was the American biologist Ernest Goodpasture, and his technique was soon applied by Macfarlane Burnet to the study of influenza viruses and by Max Theiler to the production of yellow fever vaccine.

Meanwhile, physicians were using convalescent and immune sera in the prevention and treatment of infections such as measles, and applying increasingly sophisticated serological techniques to diagnose virus infections in the laboratory, based on the host immune response. As well as having a therapeutic role, sera had become both routine diagnostic specimens and standard diagnostic reagents.

In Germany in the late 1930s electron microscopy was first used to examine structured virus particles. Staining and light microscopy had previously been used to visualize ‘elementary bodies’ including pox virions, but with the electron microscope viruses smaller than these could be visualized if suspended in electron-dense salt solutions.

This 'negative' staining did not find diagnostic applications until the 1960s, but it meant that for the first time viruses were being seen with certainty, and 'seeing was believing'. Demonstrably, viruses were particulate intracellular micro-organisms, capable of limited survival outside the living cell but of growth only within it. It might seem obvious now, but it had taken over half a century to arrive at that conclusion.

World War II was a stimulus to the study of virology, particularly in respect of those diseases, such as infectious hepatitis, that in several theatres of war put troops out of action for weeks at a stretch. For reasons that only came to be understood later, hepatitis afflicted both those newly exposed to battlefield or other insanitary conditions and, after a longer interval, those transfused with plasma to treat blood loss. The next period in the development of virology saw, from 1950, the introduction of *in vitro* monolayer cell culture as the substrate of choice for the isolation and propagation of viruses. This was greatly enabled by the availability of antibiotics to suppress contamination, and its eventual impact on virology was as far-reaching as, in the 1880s, had been Koch's use of semi-solid media to isolate pathogens on the development of bacteriology. A swathe of human and animal viruses was grown on monolayers, and cell culture transformed both virus diagnostics and vaccine manufacture. Outstanding was the development and distribution of cell-grown killed and attenuated polio vaccines, followed, in the 1960s, by measles, mumps and rubella vaccines.

As the pace of virus discoveries slackened at the end of the 1960s it became apparent that there were diseases for which isolation of a causative virus in cell culture was difficult, if not impossible. Prominent among these refractory viruses were the agents of hepatitis and gastroenteritis, and these were the centre of attention in a further phase of virological development in the 1970s and 1980s. It was also a time of rapid expansion of diagnostic services, benefitting from the discovery of Australia antigen (the surface antigen of hepatitis B virus), of Epstein-Barr virus and its association with human lymphatic and pharyngeal tumours, and of the two very prevalent human gastroenteritis viruses, rotavirus and norovirus. None of these agents could be grown in conventional cell monolayers, yet they were responsible for much acute and chronic disease. Their detection was added to the diagnostic repertoire, first in the developed, then in the developing world, where they were particularly important pathogens.

The same era saw the eradication of smallpox, based on exhaustive case finding, contact observation, vaccination and, where necessary, the use of diagnostic tools such as electron microscopy. The magnitude of that global health achievement is now more fully appreciated as

international bodies struggle with the complexities of a second generation of virus-eradication schemes, against polio and measles.

It is difficult to set recent events in a proper historical context, but the most significant developments since the mid 1980s have probably been the emergence of novel infections, the impact of molecular biology and the synthesis and use of effective, relatively nontoxic, antiviral substances. HIV is a virus with a profound effect on the immune system; hepatitis C is an insidious infection whose varied pathogenesis remains poorly understood; and the infectious zoonotic form of dementia, vCJD (which is almost certainly not due to a virus), points to the possibility of finding other unusual pathogens that will fall within the ambit of clinical virology. Some of these may be more common than vCJD has so far proved to be. All the most important recent technical innovations in virology have been based on molecular biology, including the expression of synthetic virus proteins, for example the antigens of hepatitis B, hepatitis C and papilloma viruses, and the ability through the polymerase chain reaction (PCR) to amplify virus oligonucleotides for diagnostic purposes. Other applications of PCR have allowed virus 'fingerprinting', entire genome sequencing and even the synthesis of whole viruses. Antivirals have facilitated successful transplantation and transformed the prognosis for HIV and hepatitis patients. They may have a role in mitigating the impact of epidemic influenza.

The history of a subject gives context to the state it is currently in, but it does not necessarily show how it will develop in the future. It is for instance predictable that as national vaccination programmes against hepatitis B and high-virulence papilloma viruses are rolled out, the incidence of two important viral cancers will slowly decline; but the foregoing also offers examples of developments in virology that were wholly unpredictable. It cannot be said when pandemic influenza will next occur, or whether a comprehensive vaccine will ever be devised against HIV, let alone what new viruses might soon emerge. Quite likely other forms of intracellular parasite than the presently-recognized viruses will appear, and they may possibly be shown to be responsible for 'orphan' diseases, not least important chronic ones such as multiple sclerosis. Virologists, aware of the rapid and somewhat haphazard development of their subject to date, should avoid the hubristic notion that almost all there is to know has already been found out. Instead they should look forward to the surprises the future holds with an open mind, curiosity and even relish.

Further reading: there is as yet no comprehensive history of virology, but original reports of discoveries since 1900 are easily found in the series of various learned journals. Textbooks, from *Filterable Viruses* (1928), edited by

Thomas Rivers, through to more modern ones such as the continuing series first published in 1953 and also early on edited by Rivers, demonstrate in their successive editions how the subject has advanced. A scholarly attempt at an historical approach was A.P. Waterson and L. Wilkinson's *Short History of Virology* (1977), but it has not been

brought up to date since. More popular and discursive is *The Virus Hunters* by Greer Williams (1978). Williams was a professional journalist who interviewed some of the leading virologists of the mid twentieth century and reported what he learned from them in accessible prose. That book, too, deserves to be brought up to date.

Diagnostic Approaches

Katie Jeffery¹ and Emma Aarons²

INTRODUCTION

Human virus infections may affect all ages and assume any degree of severity. They may be acute or chronic, be recurrent or elicit lifelong immunity. They are acquired through various routes via contact with humans, animals or the environment. They present as various syndromes involving fever, rash, arthralgia/myalgia, respiratory or gastrointestinal disorders and occasionally serious organ malfunction with deaths from pneumonia, cardiac, liver or kidney failure or encephalitis. They have to be rapidly distinguished from bacteriological and other infectious and non-infectious diagnoses if the appropriate clinical management is to be given.

Host factors are crucial to the outcome of virus infections. For any virus infection, age may be critical to determining outcome, those at extremes of age being more vulnerable as a consequence of lack of immunocompetence, inexperience of vaccination and waning of immunity. For some infections, gender and race may confer advantages or disadvantages, but malnutrition, pre-existing organ damage and social neglect are always potentially disadvantageous. Thus, in assessing prognosis and deciding on the investigation, management and treatment of virological infections, the individual patient must be carefully considered in their medical and social context. Any natural tendency towards spontaneous immune-mediated clearance of a virus is likely to be compromised if factors such as these are unfavourable.

A substantial part of clinical virology is taken up with the investigation and treatment of patients either constitutionally or iatrogenically immunosuppressed, or suffering from an existing immunocompromising infection, such as

human immunodeficiency virus (HIV). These patients often need pre-emptive and continuing investigation if intensive treatment for other conditions is not to be nullified by overwhelming virological and other opportunistic infections. The management of these patients must be planned and rigorous, and will differ from that of other virological patients.

Because virus infections are contagious, diagnosis cannot be confined to a consideration of the individual patient. Two questions may be crucial: where did the infection originate? And who may contract it next? Each question clearly gives rise to the potential for wider investigation and possible action to protect contacts through behaviour modification, isolation or prophylaxis with drugs or vaccines. If the infection is sufficiently contagious or is life-threatening, more extensive public health measures may be required and the clinical diagnosticians must not lose sight of the possible implications of their conclusions for the wider community.

Clinical virology in the 1980s was characterized by the widespread use of enzyme-linked immunosorbent assay (ELISA) technology, and in the 1990s by the entry into routine diagnostic use of molecular methods for virus detection. During the early years of the twenty-first century real-time polymerase chain reaction (PCR) and virus quantification have come of age, alongside increasing automation of molecular diagnostics. Concurrently, the emphasis and priorities of diagnostic virology laboratories have shifted. This is in response to the availability of rapid diagnostic methods, the identification of new viruses many of which are non- or poorly cultivable, the increasing availability of effective antiviral agents, the emergence of antiviral resistance, the increasing number

of immunocompromised patients in whom opportunistic viral infections are life-threatening, and the cost pressures on pathology services.

This chapter will provide, firstly, an overview of diagnostic techniques set against this background and presented in order of historical development. Secondly, it will highlight the ways in which these techniques may be applied to arrive at accurate diagnosis thereby facilitating effective management of virus infections, including prevention of their onward spread.

ELECTRON MICROSCOPY

Electron microscopy (EM) is the only technique available for directly visualizing viruses, and therefore has many applications beyond purely diagnostic ones. With the advent of alternative diagnostic methods, EM retains a limited role in the clinical setting for the diagnosis of viral gastroenteritis and examination of skin lesions for herpes and pox viruses.

Preparation of specimens for EM and the technique of negative staining are straightforward and quick, and the method is a 'catch-all' approach to detecting viruses. However, it has a limit of sensitivity of approximately 10^6 viral particles per millilitre of fluid, making negative results unreliable. Vast numbers of virions are present during acute skin and gastrointestinal disease and a diagnosis is easily made, but later in the course of infection viral shedding is reduced below the level of detection. Although sensitivity can be enhanced by antibody-induced clumping of virus (immune EM) or ultracentrifugation, it is unrealistic to undertake these methods routinely. The advantages and disadvantages of EM are summarized in Table 1.1.

The survival of EM within the routine clinical virology laboratory hinges on the emergence of alternative, more sensitive methods of diagnosis. Many centres now use latex agglutination for rotavirus diagnosis, and PCR is more sensitive than EM for detection of herpesviruses in vesicular fluid (Beards *et al.*, 1998) and for the detection of noroviruses (previously called Norwalk-like

viruses) (O'Neill *et al.*, 2001). Thus, the future of EM in clinical virology is in some doubt. However, one of the first indications for EM was for the rapid diagnosis of smallpox and, in the era of bioterrorism, EM may continue to play a role in specialist centres in the event of a bioterrorist attack.

HISTOLOGY/CYTOLOGY

Direct microscopic examination of stained histology or cytology specimens can on occasion provide the first indication that a virus may be responsible for a pathological process, for example the intranuclear (early) or basophilic (late) inclusions seen in interstitial nephritis in renal transplant biopsies due to BK virus, changes in cervical cytology seen in association with human papilloma virus (HPV) and the nuclear inclusions seen in erythroid precursor cells in Parvovirus B19 infection. Moreover, the particular viral aetiology can be confirmed by specific antigen/genome staining using labelled antibody or *in situ* hybridization techniques (see below).

VIRUS ISOLATION

Many of the advances in clinical virology have come about because of the ability to grow viruses in the laboratory. Historically, viruses were propagated in laboratory animals and embryonated eggs, but most virus-isolation techniques now rely on cultured cells. With appropriate specimens and optimal cell lines, this technique can be highly sensitive and specific, with a presumptive diagnosis made on the basis of a characteristic cytopathic effect (CPE). The particular diagnosis can then be confirmed by haemadsorption (certain viruses, influenza and measles for example, cause adherence of erythrocytes to infected cells in a monolayer because the viral antigens expressed include a haemagglutinin) or by immunofluorescence (IF) using a virus-specific antibody labelled with a fluorescent dye. The judicious selection of two or three cell lines, such as a monkey kidney line, a human continuous cell line and a human fibroblast line will allow the detection of the majority of cultivable viruses of clinical importance, such as herpes simplex virus (HSV), Varicella zoster virus (VZV), cytomegalovirus (CMV), enteroviruses, respiratory syncytial virus (RSV), adenovirus, parainfluenza viruses and influenza viruses. In addition, the ability to grow virus from a clinical specimen demonstrates the presence of viable virus (albeit viable within the chosen cell line)—this is not necessarily the case with detection of a viral antigen or genome. For example, following initiation of antiviral therapy for genital herpes, HSV antigen can be detected from serial genital swabs for longer than by virus

Table 1.1 Electron microscopy

Advantages	Disadvantages
'Catch-all'	Requires skilled staff
Detects unculturable viruses	Large capital outlay
Economical running costs	Poor sensitivity
Adaptable, for example immunoelectron microscopy confirms cytopathic effect	
Rapid (same day)	

propagation in cell culture. This implies that antigen is persisting in the absence of viral replication and underlines the importance of correct interpretation of laboratory results. However, failure to isolate a virus does not guarantee that the virus is not present. Virus isolation has also been shown to be diagnostically less sensitive than molecular amplification methods such as PCR for HSV and several other viruses (see below), for example for the diagnosis of herpes simplex encephalitis.

The benefits of virus isolation (Table 1.2) include: the ability to undertake further characterization of the isolate, such as drug susceptibility (see later) or phenotyping; and the identification of previously unrecognized viruses, for example human metapneumovirus (van den Hoogen *et al.*, 2001), severe acute respiratory syndrome (SARS)-associated coronaviruses (Drosten *et al.*, 2003) and human enteroviruses 93 and 94, associated with acute flaccid paralysis (Junttila *et al.*, 2007). On the other hand, routine cell culture techniques available in most laboratories will not detect a number of clinically important viruses such as gastroenteritis viruses, hepatitis viruses, Epstein–Barr virus (EBV), human herpesvirus 6, 7 and 8 (HHV-6, -7, -8) and HIV. Other than HSV and some enteroviruses, most isolates of which will grow in human fibroblast cells within three days, the time taken for CPE (or, for example, haemadsorption) to develop for most clinical viral isolates is between 5 and 21 days, which is often too long to influence clinical management. For this reason, a number of modifications to conventional cell culture have been developed to yield more rapid results. These include centrifugation of specimens on to cell monolayers, often on cover slips, and immunostaining with viral protein-specific antibodies at 48–72 hours post inoculation (shell vial assay) (e.g. Stirk and Griffiths, 1988). Such techniques can also be undertaken in microtitre plates (O’Neill *et al.*, 1996). Certain changes, for example in haemadsorption or pH, may precede the CPE and therefore can be used to expedite detection of virus. Similarly, PCR techniques (see later) can be used to detect virus in cell culture supernatants before the appearance of CPE.

Table 1.2 Virus isolation

Advantages	Disadvantages
‘Catch-all’ (as long as viable within the chosen cell line(s))	Only detects ‘viable’ virus
Sensitive	Slow (conventional cell culture)
Generates isolate for further study, for example phenotyping	Multiple cell lines required
Can be adapted for a more rapid result	Labour intensive and requires skilled staff
	Safety concerns, laboratory security

The role of conventional cell culture for routine diagnosis of viral infections has been a subject of active debate within the virology community (Carman, 2001; Ogilvie, 2001). Many laboratories are discontinuing or downgrading virus isolation methods in favour of antigen or genome detection for the rapid diagnosis of key viral infections, for example respiratory and herpes viruses. Nevertheless, it is important for certain reference and specialist laboratories to maintain the ability to employ this methodology to obtain live virus isolates and allow unexpected and emergent viruses to be grown and recognized.

SEROLOGY

This term is often used to refer to diagnostic tests for the detection of specific antibodies. More properly, the term encompasses any testing of blood serum samples for the presence of a specific antigen or antibody. However, as both antigen and antibody assays are often applied to whole blood or plasma, or indeed to body fluids other than blood (e.g. cerebrospinal fluid (CSF), oral crevicular fluid), it is helpful to use the term to span all such testing. As will be seen, most of the techniques used for viral antigen detection can also be used for detection of specific antibody, and vice versa.

Antigen Detection

Immunofluorescence

IF is one of the most effective rapid diagnostic tests. Direct IF involves the use of indicator-labelled virus-specific antibody to visualize cell-associated viral antigens in clinical specimens. The indirect method utilizes a combination of virus-specific antibody (of a nonhuman species) and labelled anti-species antibody. Usually, the label used is fluorescein. The indirect method is more sensitive, since more label can be bound to an infected cell. Results can be available within 1–2 hours of specimen receipt. The success of the technique depends on adequate collection of

Table 1.3 Antigen detection by immunofluorescence

Advantages	Disadvantages
Rapid (same day)	Labour intensive and requires skilled staff
Sensitive for some viruses (e.g. RSV)	Dependent on high-quality specimen Interpretation is subjective

cells in the particular sample to be examined, for example epithelial cells for respiratory virus antigens or peripheral blood mononuclear cells (PBMCs) for CMV. An advantage of IF is that microscopic examination of the fixed cells can determine the presence of adequate cell numbers for analysis (Table 1.3). Whenever it is employed, however, a trained microscopist is required to interpret results, which remain subjective.

The most common use of this technique is for the diagnosis of respiratory viral infections. A panel of reagents can be used to detect RSV, parainfluenza viruses, influenza A and B, metapneumovirus and adenovirus in multiple wells of a microscope slide. Compared to cell culture this technique is rapid and sensitive, especially for detection of RSV. The ideal specimen is a nasopharyngeal aspirate or a well-taken throat/nasal swab, most usually obtained from infants with suspected bronchiolitis, in whom a rapid result is invaluable for correct clinical management and implementation of infection control measures. There is increasing evidence that community- or nosocomial-acquired respiratory viruses lead to severe disease in immunocompromised patients (reviewed in Ison and Hayden, 2002), and it is important that bronchoalveolar lavage specimens from such patients with respiratory disease are also tested for these viruses, in addition to bacterial and fungal pathogens.

IF has been used widely for the direct detection of HSV and VZV in vesicle fluid, and has advantages over EM in both sensitivity and specificity. Detection and semi-quantification of CMV antigen-containing cells in blood can also be undertaken by direct IF (CMV/pp65 antigenaemia assay). This technique involves separating PBMCs and fixing them on a slide, followed by staining with a labelled monoclonal antibody directed against the matrix protein pp65. The frequency of positive cells can predict CMV disease in the immunocompromised patient (van der Bij *et al.*, 1989) and has been used quite extensively, though it is labour intensive. It needs large numbers of PBMCs, making it unsuitable for some patients. In addition, it requires a rapid processing of blood specimens if a reduction in sensitivity of detection is to be avoided (Boeckh *et al.*, 1994). PCR has therefore

become the method of choice for qualitative and quantitative detection of CMV as well as several other viruses.

Enzyme-linked Immunoassay (EIA), Chemiluminescent and Fluorescence-based Immunoassay

Solid-phase systems for antigen detection are still used widely. EIA is based on the capture of antigen in a clinical specimen to a solid phase (such as the base and walls of a well in a microtitre plate, or multiple magnetic microparticles/beads) via a capture antibody, and subsequent detection uses an enzyme-linked specific antibody that produces a colour change in the presence of a suitable substrate. EIA is also readily used for the detection of specific antibody as well as antigen (see later).

Elaboration of capture and detector antibody species has increased the sensitivity of EIA antigen-detection assays, which are widely used for hepatitis B virus (HBV) surface antigen (HBsAg) and 'e' antigen (HBeAg) detection and for HIV p24 antigen detection. Neutralization of the antigen reactivity by the appropriate immune serum can be used to confirm the specificity of the antigen reactivity. In primary HIV infection, HIV p24 antigen is present in the blood prior to the development of antibodies. Therefore, assays which detect this antigen in addition to anti-HIV antibodies reduce the diagnostic 'window period', that is the time from acquisition of infection to its first becoming detectable (Hashida *et al.*, 1996). Similar assays that detect hepatitis C core antigen in addition to anti-HCV (hepatitis C virus) antibodies have been proposed for testing donated blood.

Molecules with chemiluminescent properties, for example acridinium ester, which produces chemiluminescence in the presence of hydrogen peroxide, can be conjugated to antibodies/antigens and used instead of enzymes for immunoassay detection. Fluorescent labels are another alternative. The fluorescence emissions of chelates of certain rare earth metals—lanthanides, for example Europium—are relatively long-lived. Thus, the presence of an antigen or antibody labelled with a lanthanide chelate can be detected by measuring fluorescence intensity at a delayed time point after excitation, background fluorescence having completely died away. This is the principle of the time-resolved fluorescence assay (TRFA). Both chemiluminescent and TRF methods are very sensitive and highly amenable to automation in commercial systems.

Particle Agglutination Assays

Small latex particles coated with specific antibody will agglutinate in the presence of antigen, and their clumping together can then be observed by the naked eye. This

rapid assay can be used for rotavirus diagnosis, with an equivalent sensitivity to EM.

Immunochromatography

Several immunochromatography or ‘dipstick’ tests have been developed commercially as point of care tests (POCTs) that can be used either in the laboratory, in the clinic or at the patient’s bedside for specific antigen detection. Examples include tests for influenza A and for rotavirus. Such dipstick tests require no special expertise and are quick to perform.

A detector reagent (virus-specific antibody conjugated to a coloured indicator) is impregnated at one end of a base membrane in a disposable ‘dipstick’. A capture antibody is coated on the membrane at the test region. When the clinical specimen is added to the sample pad, any viral antigen present in the specimen binds to the detector reagent and is carried along the membrane by capillary action. As the specimen passes over the test region coated with capture antibody, the viral antigen-bound detector reagent is immobilized. A coloured band proportional to the amount of virus present in the sample develops. The excess unbound detector reagent moves further up the membrane and is immobilized at the control band by an anti-detector antibody, and a second coloured line appears. Thus, two coloured lines on the test stick indicate the presence of virus. In the absence of virus in the patient’s sample only the control band appears.

Antibody Detection

Viral infections generate a host immune response, and this can be used for diagnostic purposes. The classical response pattern following an acute infection is illustrated in Figure 1.1. The functional nature of this response is extremely variable. In some instances the antibodies are neutralizing and can be assessed for this activity (e.g. polioviruses). Other infections are controlled more effectively by T-cell responses, though the detection of antibody may still be used diagnostically.

Traditional methods of antibody detection did not distinguish between IgG and IgM responses, and diagnosis was simply based on seroconversion or a significant rise in antibody titre between acute and convalescent samples (10–14 days apart). The complement fixation test (CFT) was widely used in this way, though assay insensitivity and the cross-reactivity of many antigens used within the assay limited its clinical usefulness and, importantly, the diagnosis could only be made a week or more after the acute illness. The principle of complement fixation is that a specific reaction between an antigen and an antibody takes up complement. If a measured amount of complement is added to a reaction

Figure 1.1 Typical evolution of antibody responses following an acute viral infection.

in which both antigen and specific antibody are present, the uptake of complement can be detected by a second ‘detector’ reaction in which sensitized red cells are added to the system. Failure to lyse the red cells signals that complement fixing antibody has been detected, giving a positive test result. Currently, complement-fixation assays are mostly used for the retrospective diagnosis of ‘atypical’ pneumonia (*Chlamydia psittaci/pneumoniae*, coxiella, influenza or mycoplasma).

Serum or plasma is the specimen of choice for antibody detection, but oral crevicular fluid (obtained by rubbing an absorbent sponge around the gums) can be used as a non-invasive alternative. This may be useful for outreach surveillance studies (Hope *et al.*, 2001; MMWR, 2007) or in children (Holm-Hansen *et al.*, 2007). In patients with viral central nervous system (CNS) infections, the CSF may be tested for virus antibodies, and the antibody concentration compared with serum to confirm intrathecal antibody synthesis.

Enzyme-linked Immunoassay (EIA) for Antibody Detection

Solid-phase enzyme immunoassays (EIAs), in which one of the reagents is immobilized on a plastic or other surface (e.g. magnetic beads), are used extensively in diagnostic laboratories. The use of synthetic peptides or recombinant antigens instead of whole viral lysates, and improvements in signal detection, have led to more sensitive, specific and rapid methods for measuring virus-specific antibody levels. The immunoassay format is versatile, and new assays can be designed quickly to cope with clinical demands, for example the investigation of new viruses such as SARS-associated coronaviruses. As indicated above, several non-isotopic, non-enzymatic reagent labelling and detection methods have been developed, such as chemiluminescence- and fluorescence-based methods. These are very sensitive, very rapid and highly amenable to incorporation into commercial automated systems.

Solid-phase immunoassays for the detection of antibody are essentially of three types (Figure 1.2):

- *Indirect assays.* Viral antigen is immobilized on to a solid phase. Specific antibody in the patient serum sample binds to this antigen and, after a washing step, is detected by an enzyme-labelled anti-human immunoglobulin. In this way, either specific IgG or IgM can be detected, depending on the indicator immunoglobulin (Figure 1.2a,b). Detection of IgM species is dependent on the prevailing level of IgG, and a high level of specific IgG may reduce the sensitivity of an IgM assay for the same virus. If rheumatoid factor is present in the clinical sample it may lead to false-positive IgM reactions (Figure 1.2c).
- *Capture assays.* IgG or IgM species are captured on to the solid phase by anti-human immunoglobulin, after which antigen and then labelled antibody is added. This is the preferred method for IgM assays, as it reduces the potential for interference by rheumatoid factor (Figure 1.2d).
- *Competitive assays.* In this case, a labelled antibody in the EIA system competes for binding to immobilized antigen with antibody in the clinical sample. This assay may improve the specificity of the assay diagnosis (Figure 1.2e).

Other Antibody Detection Methods

Immunoblot (western blot) methods can be useful for confirmation of certain infections, such as human T lymphotropic virus (HTLV) and HCV infection. These are based on the detection by antibodies within a serum sample of multiple antigenic epitopes previously separated and blotted onto a membrane. Nonspecific reactions within EIAs can be clarified in these systems, since the nonspecific antibodies will react with the nonviral antigenic epitopes, and the specific ones with the viral epitopes. Immunoblot assays are expensive and technically demanding.

Other antibody-detection techniques include haemagglutination inhibition, latex agglutination (in which antibody is captured by antigen-coated particles) and IF (most widely used for EBV diagnosis), and these techniques still have a significant role in clinical laboratories.

The diagnosis of acute infection by detection of specific antibody in body fluids is particularly suited to situations in which detection of the virus itself is difficult and time-consuming, or where virus excretion is likely to have ceased by the time of investigation, such as hepatitis A, rubella and parvovirus B19. There are situations, however, where IgM is produced over a prolonged period, or in response to re-infection, as is the

Figure 1.2 EIA formats (a) indirect IgG assay; (b) indirect IgM assay; (c) rheumatoid factor interference in IgM assay (indirect); (d) IgM capture assay; (e) competitive assay. Note that the solid horizontal lines represent the solid phase.

case for CMV. In these cases, past infection can better be distinguished from recent infection by antibody avidity tests. These are based on the principle that antibody responses mature over time, with high-avidity antibodies predominating at the later stage. By using a chaotropic agent (e.g. urea) during the EIA washing stage, low-affinity antibodies (representing recent infection) will be preferentially dissociated from antigen compared to higher-affinity antibodies (Blackburn *et al.*, 1991).

Antibody detection is also essential for diagnosis of, and screening for, persistent infections where antibodies are detectable in the presence of virus replication, such as HIV and HCV. The availability of sensitive and specific assays allows widespread screening for immunity against, for example, HBV, rubella, VZV and hepatitis A.

Despite recent advances in antibody-detection techniques, there remain inherent limitations to this form of virological diagnosis (Table 1.4). It is highly dependent on the ability of the individual to mount appropriate immune responses to infection. Thus, these methods have a limited role for diagnosing viral infections in severely immunocompromised patients (Paya *et al.*, 1989). Every effort must then be made to detect the virus itself. Transfusion or other receipt of blood products may lead to spurious serological results; for instance, leading to a false interpretation that a seroconversion, indicating acute infection, has occurred. The major role of antibody-detection tests in transplant patients is in identifying immune status at the baseline in order to forecast the risk of primary infection, re-infection or reactivation during subsequent immunosuppression (see later).

Interpretation of Serological Assays

Viral serology should take account of the patient's history and symptoms, and sometimes additional information may need to be sought. For example, the detection of very low levels of HBsAg in the absence of any other markers of hepatitis B infection might be explained by very recent immunization (because the vaccine itself is recombinant HBsAg) rather than hyperacute infection with this virus. The diagnosis of a primary virus infection can be made by demonstrating seroconversion from a negative to a positive specific IgG antibody response, or by detecting virus-specific IgM. A fourfold rise in IgG antibody titre between acute and convalescent samples can also be indicative of a primary infection (e.g. by CFT). Detection of virus-specific IgG without IgM in a single sample, or no change in virus antibody titre between acute and convalescent phase sera, indicates exposure to the virus at some time in the past. Results of antibody-detection assays can be complicated by a number of factors: the age of the patient (the production of serum IgG or IgM antibodies can be absent or impaired in the immunocompromised, neonates and the elderly), receipt of blood products with passive antibody transfer, maternal transfer of IgG antibodies and nonspecific elevation of certain virus antibodies due to recent infection with other viruses. The last phenomenon is particularly common with herpes virus infections, which have group-specific cross-reacting epitopes. IgM antibodies may persist for extended periods of time following primary infection, and may also be produced as a result of reactivation of latent infection, although not reliably so (e.g. CMV, EBV). The production of

Table 1.4 Serology

Advantages	Disadvantages
Specific IgG assays good indicator of prior infection	Retrospective (e.g. rising CFT titres). CFTs insensitive, especially to assess previous infection
Capture IgM assays good indicator of recent infection	Cross-reactivity and interference
May allow retrospective diagnosis if no acute specimen obtained	Poor sensitivity for diagnosing some congenital infections, for example CMV
Readily automated	Not appropriate for the immunocompromised
Rapid (same day)	Spurious results possible following receipt of blood products
Diagnosis of unculturable or poorly culturable viruses, for example hepatitis B	
Can use non-invasive samples such as saliva or urine	

CFT = complement fixation test.

virus-specific intrathecal antibody (requiring demonstration of an intact blood–brain barrier) can confirm the diagnosis of viral CNS infection, for example subacute sclerosing panencephalitis. Antibody-detection assays may be complemented and confirmed by molecular assays, for example PCR for HCV RNA in the presence of hepatitis C antibody or PCR for HIV provirus, used for the investigation of infants born to HIV-infected mothers.

MOLECULAR AMPLIFICATION TECHNIQUES

This is the most rapidly developing area in diagnostic virology, providing both qualitative and quantitative results. PCR and other molecular amplification techniques have now been applied to the diagnosis of virtually all human viruses and, in general, the sensitivity of these assays far exceeds that of other virus detection systems. However, the interpretation of results in a clinical setting may be difficult. A number of commercial kits and automated systems are now available, with the advantages of improved quality control and reduced inter-laboratory variability. The advantages and disadvantages of molecular techniques are summarized in Table 1.5. These issues will be discussed following a brief review of the techniques available.

The Principle of the Polymerase Chain Reaction (PCR)

This technique uses a thermostable DNA polymerase to extend oligonucleotide primers complementary to the viral DNA genome target (Saiki *et al.*, 1988). Consecutive cycles of denaturation, annealing and extension result in an exponential accumulation of target DNA. This is

Figure 1.3 Polymerase chain reaction.

limited only by substrate (nucleotide) availability and possible competition between target genome and nontarget amplicons for reaction components (Figure 1.3). RNA genomes require transcription to complementary DNA (reverse transcription) prior to the PCR reaction. Undertaking a second round of PCR on the first-round amplicon can increase the overall sensitivity of detection (nested PCR). The second round uses a different set of PCR primers internal to the first set, and can therefore act as confirmation that the correct amplicon was produced by the first-round reaction.

Table 1.5 Molecular assays

Advantages	Disadvantages
Speed—results available in a few hours	Commercial assays expensive (but becoming relatively less so)
High sensitivity—gold standard for many viruses	High set-up costs (equipment) for ‘in-house’ assays
Wide range of applications/versatility	Susceptible to contamination
Increasing availability of automation	Rigorous quality-control systems required for ‘in-house’ molecular diagnostics
Increasing availability of commercial assay kits with built-in quality control	Some assays lack clinical validation
Increasing availability of external quality-assurance programmes	Lack of availability and expertise outside specialist centres
Amplicon can be used for sequencing/genotyping	No isolate available for phenotyping
Can be highly specific to viral subtype	Target sequence must be known and highly conserved
Quantification readily possible	
Detection of uncultivable viruses (e.g. acute HCV infection)	
Can use non-invasive samples, for example urine, saliva	

Primers

The correct choice of primers is an important determinant of the success of any PCR. The nucleic acid sequence of at least a part of the viral genome needs to be known, and primers must target a very well-conserved region. This can be done using multiple alignment programs; however, the final success of the PCR depends on the availability of sequence data from a range of different viral isolates. Otherwise, unusual viral variants may not be detected. This issue is as important for commercial assays as it is for 'in-house' assays, as was demonstrated by suboptimal HIV subtype detection by a commercial quantitative PCR (qPCR) assay (Arnold *et al.*, 1995). Other important aspects of primer design include the avoidance of secondary structure or complementarity between primers (leading to so-called primer-dimer amplification artefacts). Computer programs used to design primer sequences address these problems.

Preparation of Clinical Specimens for PCR

Viral gene detection methods do not rely on persistence of viral infectivity within the clinical specimen and in one respect this is a major advantage over traditional methods of virus detection. Specimens should be transported and stored in the refrigerator or freezer prior to analysis, but less meticulousness is required than to achieve virus isolation. However, viral RNAs are susceptible to nucleases, present in all biological material, and certain specimen types (e.g. intraocular fluids (Wiedbrauk *et al.*, 1995) and urine (Chernesky *et al.*, 1997)) contain inhibitors of PCR. PCR is therefore susceptible to false-negative results, and specimens for qualitative and especially qPCR require careful preparation. Each assay needs to be evaluated for individual specimen type and patient group. For blood samples, the anticoagulant heparin is contraindicated because it inhibits the PCR reaction. It is generally recommended that for viral quantification ethylenediamine tetraacetic acid (EDTA) anticoagulated blood is separated as soon as possible, after which the plasma can be stored frozen until analysis. If multiple tests are to be undertaken on one sample, it should be aliquoted on receipt to avoid multiple freeze-thawing. A number of different nucleic acid extraction methods are available. The choice depends on the nature of the clinical specimen and whether the target is RNA or DNA.

Detection of Conventional PCR Product

The PCR product of any specific reaction has a known size, and can therefore be detected on an agarose gel, usually by staining with ethidium bromide (or other, potentially safer, fluorescent stains such as SYBR Green) in comparison with a molecular weight ladder. However,

more than one specific band may be seen, or the band may not be of the expected size. For this reason, detection of the product by hybridization with a specific nucleic acid probe is desirable. A microtitre plate format with a colorimetric end point read by a standard spectrophotometer may be used, for example (Gor *et al.*, 1996). Many commercial PCR assays employ this system. The addition of such a step enhances the specificity of the assay, and may improve sensitivity.

Multiplex PCR

Since more than one viral target is frequently sought in each specimen, multiplex assays have been devised in which multiple sets of primers (against different targets) are combined within one PCR reaction (for example Dingle *et al.* 2004). Each set of primers requires specific conditions for optimal amplification of the relevant target, and the development of a multiplex system requires a detailed evaluation of these conditions to ensure that the efficiency of amplification for any one target is not compromised. Identification of the specific product in this system may be based on the different size of amplicons, or the use of different probes. Figure 1.4 illustrates a multiplex PCR for RSV A (RA), RSV B (RB) and human metapneumovirus with agarose gel-based detection. Increasingly, conventional multiplex PCR has been replaced by multiplex real-time PCR (see below).

Quantification

Conventional PCR is inherently a qualitative assay. Initial attempts to quantify with PCR involved the simultaneous analysis of samples with a known target genome copy number and comparing the intensity of bands on an agarose gel with that of the test specimen. However, the efficiency of amplification within any one PCR reaction can be exquisitely sensitive to changes in reaction conditions and inhibitory factors present in the clinical specimen. It is therefore important that internal standards (within the same PCR reaction) are used for quantitative competitive (qcPCR) assays. These control sequences should mimic the target genome as closely as possible, yet be detectable as a distinct entity on final analysis. This can involve the incorporation of restriction enzyme sites at which the control amplicon, but not the target sequence, can subsequently be cleaved (Fox *et al.*, 1992), or involve use of a control sequence of different size (Piatak *et al.*, 1993). Commercial assays often use a jumbled sequence as a control, with subsequent use of probes against both control and target sequences. In all cases, since the number of input control genomes is known, simple proportions can be applied to the signals to generate a quantitative value for the clinical specimen (Figure 1.5a). Real-time

Figure 1.4 A 2% agarose gel of ethidium bromide-stained products from an internally-controlled nested multiplexed reverse transcriptase PCR for RSV A (RA), RSV B (RB) and human metapneumovirus (M). Lanes 1–20 represent 20 clinical samples; L size markers; +ve positive control; –ve negative control. Each clinical sample has been spiked with an internal control from the hepatitis delta genome. The internal control reaction is out-competed by the amplification of target genome in this assay. The asterisk indicates the position of the internal control when target viruses were not detected. (Source: Based on a figure in Dingle *et al.*, 2004.)

PCR methods, as described in the next section, have now largely replaced these qcPCR assays.

Real-time PCR

The conventional PCR method described above aims to maximize the amplification reaction and depends on end-point detection of product. More sensitive detection methods allow the kinetics of the amplification to be measured, and may require fewer cycles of amplification for the product to be detected.

Real-time PCR systems allow the reactions to be undertaken within a closed system, and fluorescence generated

by the assay can be measured without further manipulation. Some of these systems produce very rapid temperature cycling times and, by also abandoning post-PCR detection procedures, this means that PCR tests can be completed within minutes. Many of the signalling technologies (reviewed in Mackay, 2004) rely on energy transfer between a donor fluorophore and a proximal acceptor molecule (fluorescence resonance energy transfer, FRET). The simplest of these involves the use of molecules, such as SYBR green, which spontaneously intercalate into dsDNA and then fluoresce when exposed to a suitable wavelength of light. Specificity of the PCR reaction for the correct product (rather than artefacts) is provided by analyzing a decrease in fluorescence at the melting (denaturation) temperature specific for that product.

5' nuclease or TaqMan oligoprobes (see Figure 1.6a) utilize the intrinsic 5' → 3' endonuclease activity of *Taq* DNA polymerase. A short target-specific probe, in which the fluorescence of the fluorophore at the 5' end is quenched by the fluorophore at the 3' end, binds to the relevant amplicon, and subsequent hydrolysis of this probe increases fluorescence (Morris *et al.*, 1996).

The method of choice for amplicon detection in the LightCycler system employs linear oligoprobes (or 'kissing' probes: see Figure 1.6c), one bearing a donor fluorophore and the other an acceptor fluorophore. Adjacent hybridization of the two probes on the denatured amplicon DNA results in a FRET signal due to interaction between the donor and acceptor.

Somewhat similarly to 5' nuclease probes, hairpin oligoprobes (see Figure 1.6c) carry a fluorophore and quencher at opposite ends. The labels are held in close proximity by homologous base-pairing of the distal ends of the oligonucleotide into a hairpin structure. Hybridization of the probe to the target separates fluorophore and quencher, resulting in increased fluorescence. The self-fluorescing amplicon concept is similar to that of the hairpin oligoprobe except that the fluorophore and quencher are attached to opposite ends of a primer (rather than a probe), distal complementary sequences of which

Figure 1.6 Oligoprobe chemistries. (a) 5' nuclease oligoprobes. As the DNA polymerase (pol) progresses along the relevant strand, it displaces and then hydrolyzes the oligoprobe via its 5' → 3' endonuclease activity. Once the reporter (R) is removed from the extinguishing influence of the quencher (Q, open), it is able to release excitation energy at a wavelength that is monitored by the instrument and different from the emissions of the quencher. Inset shows the non-fluorescent quencher (NFQ) and minor groove binder (MGB) molecule that make up the improved MGB nuclease-oligoprobes. (b) Hairpin oligoprobes. Hybridization of the oligoprobe to the target separates the fluorophore (F) and nonfluorescent quencher (Q, closed) sufficiently to allow emission from the excited fluorophore, which is monitored. Inset shows a wavelength-shifting hairpin oligoprobe incorporating a harvester molecule. (c) Adjacent oligoprobes. Adjacent hybridization results in a FRET signal due to interaction between the donor (D) and acceptor (A) fluorophores. This bimolecular system acquires its data from the acceptor's emissions in an opposite manner to the function of nuclease oligoprobe chemistry. (d) Sunrise primers. The opposite strand is duplicated so that the primer's hairpin structure can be disrupted. This separates the labels, eliminating the quenching in a similar manner to the hairpin oligoprobe. (e) Scorpion primers. The primer does not require extension of the complementary strand; in fact it blocks extension to ensure that the hairpin in the probe is only disrupted by specific hybridization with a complementary sequence designed to occur downstream of its own, nascent strand. Inset shows a duplex scorpion that exchanges the stem-loop structure for a primer element terminally labelled with the fluorophore and a separate complementary oligonucleotide labelled with a quencher at the 5' terminus. (Source: Reproduced from Mackay *et al.*, 2002. *Nucleic Acids Research* 30(6) pp. 1292–1305 Figure 3 (A-E), with permission from Oxford University Press.

keep the fluorophore and quencher in close proximity (see Figure 1.6d). On hybridization of the primer to its target, the fluorophore and quencher are separated from one another, and irreversibly incorporated into the PCR product.

Due to the limited number of fluorophoric labels available and the significant overlap in their emission spectra, quantification of multiplex reaction products is difficult and often not possible for more than two or three targets. Moreover, one channel is required for the detection of an internal control in order to confirm satisfactory extraction and amplification (see 'Quality Control', later). Nevertheless, a recent study reported a 'pentaplex' assay using 5' nuclease probes for four viral targets (influenza A, influenza B, adenovirus and enterovirus) together with an internal control sequence (Molenkamp *et al.*, 2007). Development of novel chemistries and improvements in real-time instrumentation and software should allow more fluorophores to be multiplexed and enhance real-time PCR assays.

The major advantage of real-time PCR is that it is inherently semi-quantitative: the quantity of target sequence present in the initial reaction mixture determines the number of temperature cycles required for a threshold fluorescence signal to be reached. An external standard curve is used to determine the relationship between cycle threshold (Ct) and input target copy number. An example of real-time detection of a calibration series for the detection of hepatitis C is shown in Figure 1.7. The dynamic range of real-time PCR of at least eight log₁₀ copies of template surmounts the problem encountered by many qPCR reactions of inability to quantify high virus loads if sensitivity at the lower end of the assay is also to be maintained

(Garson *et al.*, 2005). In addition, intra- and inter-assay variability is reduced in comparison with qPCR (Abe *et al.*, 1999; Locatelli *et al.*, 2000).

The disadvantages of real-time PCR compared with conventional PCR include an inability to monitor the size of the amplicon or to perform a nested PCR reaction without opening the system; incompatibility of some systems with certain fluorescent chemistries; and (as discussed above) relatively limited capability for multiplexed reactions because of the few non-overlapping fluorophores available. In addition, the start-up costs of real-time PCR may be prohibitive. Despite these difficulties, real-time PCR is now used routinely in many diagnostic virology laboratories, for both qualitative and quantitative applications. As with conventional PCR, real-time PCR has proven cost-effective in high-throughput laboratories when compared with traditional culture-based methods of viral diagnosis.

PCR Contamination and Control Reactions

PCR is highly susceptible to contamination from amplified products generated in a previous reaction, from target sequences cloned in plasmid vectors and from other infected clinical specimens. By contrast, a false-negative result can arise from inadequate nucleic acid extraction from a sample, or from inhibitory factors in the PCR reaction; or the sensitivity of the assay, though reduced, may not be completely inhibited. Relevant controls within each PCR run are essential for a correct interpretation of a positive or negative result, and these are highlighted in Table 1.6. The limit of sensitivity for each assay must be assessed. This can be undertaken by serial dilutions

Figure 1.7 Real-time PCR detection of a hepatitis C calibration series from 10 million IU/ml down to 10 IU/ml in 1 log steps. x axis = cycle number; y axis = log fluorescence. The sample with the highest virus load (10^7 IU/ml) requires 39 cycles of PCR before reaching a detectable level. Results obtained by Dr Jeremy Garson.

Table 1.6 PCR—recommended controls

Negative controls	
Extraction control	to control for contamination during extraction (use negative clinical material)
Reagent control	to control for contamination of reagents (use solvent in which extracted nucleic acid is suspended)
Positive controls	
Extraction control	Use positive clinical material
Control genome/run control	To control for PCR efficiency, specifically to assess sensitivity
Alternate target/internal control	to control for inhibition of reaction

of a tissue culture supernatant of known median tissue culture infective dose (TCID₅₀) or virion concentration (as measured by EM), or of a preparation of purified viral genome provided at a standardized concentration. Alternatively, plasmid containing the target genome may be used, but many laboratories are reluctant to introduce plasmids into the molecular biology area because of the risk of widespread contamination with plasmid amplicons.

There are two specific procedures designed to reduce PCR contamination. Firstly, extraneous DNA contaminating PCR reagents can be inactivated by subjecting 'clean' PCR reagents to ultraviolet irradiation. This introduces thymidine dimers into the DNA chain, rendering it unamplifiable. More effective is the substitution of dUTP for dTTP in the PCR reaction (Longo *et al.*, 1990); this does not affect specific product detection. The use of uracil DNA glycosylase in any subsequent PCR reaction prevents DNA polymerization of any uracil-containing DNA, but has no effect on thymidine-containing DNA template. Thus any contaminating DNA from a previous reaction is not amplified.

Physical Organization of the Laboratory for PCR

The physical requirements for undertaking 'in-house' PCR reactions are demanding (Victor *et al.*, 1993). A 'clean room' is required for preparation and aliquoting of reagents. This must be protected from any possible contamination with viral nucleic acid. A separate area is also required for nucleic acid extraction, although this can be undertaken in a diagnostic area. A dedicated PCR room is required for setting up reactions and siting thermal cyclers. Finally, another room is required for any post-PCR analyses, such as running gels. Dedicated laboratory coats and equipment are required for each of these areas, and strict adherence to protocol by all staff is essential.

The provision of such a dedicated set of rooms for molecular biology is a challenge for busy, crowded, diagnostic virology laboratories. Nevertheless, it is paramount that diagnostic PCR reactions are undertaken with the

risk of contamination minimized, and every effort must be made to provide the relevant space if such assays are to enter the routine diagnostic armamentarium. Some of the newer automated commercial assays incorporate several of the above steps within a self-contained machine. However, it is unwise to use such assays outside of a laboratory environment in which staff are well trained in this type of work.

The Range of Other Amplification Systems

Other, mostly commercial, amplification systems include the ligase chain reaction (LCR), which, as with PCR, requires a thermal cycler. Nucleic acid sequence-based amplification (NASBA), transcription mediated amplification (TMA), strand displacement amplification (SDA) and branched chain DNA (bDNA) do not require any specialized thermal cycler. A number of newer technologies particularly suited to the simultaneous detection of multiple viral (and nonviral) targets in individual samples are also coming into use.

Ligase Chain Reaction

LCR involves hybridization of two oligonucleotide probes at adjacent positions on a strand of target DNA, which are joined subsequently by a thermostable ligase. The reaction also takes place on the complementary strand so multiple rounds of denaturation, annealing and ligation lead to an exponential amplification of the viral DNA target (Hsuih *et al.*, 1996). RNA targets require prior reverse transcription.

Nucleic Acid Sequence-based Amplification

This technique uses RNA as a target, utilizing three enzyme activities simultaneously: reverse transcriptase (RT), RNase H and a DNA-dependent RNA polymerase (Guatelli *et al.*, 1990). A DNA primer incorporating the T7 promoter hybridizes to the target RNA and is extended by RT. RNase degrades the RNA strand, and the RT then

utilizes a second primer to produce double-stranded DNA. Subsequently, T7 polymerase forms multiple copies of RNA from this DNA template. This method is suited to the detection of RNA viruses, or mRNA transcripts of DNA viruses. In addition, it can be turned into a quantitative assay using internal controls (Figure 1.5b). Different detection formats for the amplified RNA product have been developed, including electrochemiluminescence and molecular beacon detection technologies, and adapted for rapid detection of various viruses, for example West Nile and St Louis encephalitis (Lanciotti and Kerst, 2001). TMA techniques are very similar. Commercial TMA systems have been used to detect and quantify HIV and HCV nucleic acid sequences.

Strand Displacement Amplification

In this technology, an oligonucleotide primer containing a restriction enzyme site binds to its complementary (target) nucleic acid. An exonuclease-deficient DNA polymerase is used in the presence of dGTP, dATP, dUTP and a dCTP containing an α -thiol group (dCTP α S) to produce double-stranded DNA containing a restriction enzyme site. Upon binding, the restriction enzyme nicks the strand without cutting the complementary thiolated strand. The exo-DNA polymerase recognizes the nick and extends the strand from the site, displacing the previously-created strand. The recognition site is repeatedly nicked and restored by the restriction enzyme and exo-DNA polymerase, with continuous displacement of DNA strands containing the target segment. The process becomes exponential with the addition of an antisense primer containing the appropriate recognition site. SDA technology has been established in a fully-automated system known as BDProbeTec.

Hybridization Methods

These methods are based on the hybridization of a labelled oligonucleotide probe to a unique complementary piece of viral genome, and can be undertaken either on a solid phase or *in situ*. The short probes are 20–30 bases in length and can be RNA (riboprobe) or DNA. The bDNA assay is a modification of the probe assay principle and, unlike the other molecular methods described so far, it uses a *signal* amplification system rather than amplifying a *target* genome. A single-stranded genome (RNA or DNA) is hybridized to an assortment of hybrid probes, which in turn are captured on to a solid phase by further complementary sequences. Branched DNA amplifier molecules then mediate signal amplification via enzyme-labelled probes with a chemiluminescent output. This method can also provide quantitative results (De-war *et al.*, 1994; van Gemen *et al.*, 1993) (Figure 1.5c).

The hybrid-capture assay is another hybridization-based signal-amplification system in which riboprobes hybridize with DNA targets. These RNA-DNA hybrids are captured and detected by means of a labelled monoclonal antibody, which has been developed commercially and used extensively for the detection of HPV genome in cervical brushings/washings.

New Molecular Techniques

Loop-mediated Isothermal Amplification Assay

The loop-mediated isothermal amplification assay (LAMP) is another method for rapid amplification of DNA under isothermal conditions. It is based on the principle of autocycling strand-displacement DNA synthesis (Notomi *et al.*, 2000). The enzyme required is a DNA polymerase with high strand-displacement activity. A high degree of target specificity is achieved by the use of two outer primers and two inner primers, with each of the inner primers recognizing independent target sequences. The LAMP reaction results in the production of a mixture of stem-loop DNAs of different stem lengths, and cauliflower-like structures comprising multiple loops. These products can be detected by gel electrophoresis and appropriate staining, or (because pyrophosphate ion is a by-product of DNA synthesis) by monitoring the accumulation of precipitated magnesium pyrophosphate in a simple turbidometer (Mori *et al.*, 2004). Further assay refinements include the employment of an initial RT step, so as to be able to apply the technique to an RNA target, and the use of an additional pair of 'loop primers' to accelerate the LAMP reaction (Nagamine *et al.*, 2002). Very sensitive, specific and fast LAMP assays have been reported for detection of West Nile virus (Parida *et al.*, (2004)) and noroviruses (Yoda *et al.*, 2007). As the technique does not require sophisticated equipment, it is potentially valuable for use in resource-poor countries.

Microarrays

Microarrays consist of arrays of single-stranded DNA oligonucleotide probes spotted on to specific locations on a small glass slide, membrane or coated quartz microchip surface. Tens of thousands of spots can be contained on one microarray. DNA and RNA is extracted from experimental or clinical samples, and then target sequences are amplified and labelled with fluorescent markers. When these labelled nucleic acids are hybridized to complementary sequences in the array, the amount of label can be monitored at each spot, thereby indicating whether or not the complementary nucleic acid sequence was present in the original sample. Microarrays, for example the Pneu-moVir from GENOMICA SA are now entering routine

laboratory use for the diagnosis of multiple viral respiratory tract pathogens at reasonable economic cost compared with multiple multiplexed conventional PCR-based assays. In the future it is likely that they will be developed for the simultaneous detection of multiple infectious agents—bacterial, viral and fungal—in individual patient samples. By detecting specific target sequences, not only should they be able to detect the presence of a specific pathogen but they should also determine whether that pathogen demonstrates genotypic drug resistance.

Micro-bead Suspension Array Multiplex PCR

This technology combines multiplex PCR for simultaneous amplification of multiple target sequences with a coloured micro-bead detection system. For each pathogen, target-specific capture probes are covalently linked to a specific set of colour-coded beads. Labelled PCR products are captured by the bead-bound capture probes in a hybridization suspension. A dual-laser detection device identifies the colour of each bead (corresponding to a particular pathogen) and determines whether labelled PCR product is present on the bead or not, so indicating the presence or absence of the particular pathogen in the original sample. The technology offers the potential for the rapid simultaneous detection and quantification of up to 100 different analytes within a single sample. Recent studies have applied it successfully to respiratory virus diagnosis (Mahony *et al.*, 2007) and to determination of HPV type (Schmitt *et al.*, 2006).

Quality Control for Molecular Methods

Compared to more traditional virological methods, molecular biological ones are expensive. There have recently been initiatives to make all molecular assays in Europe compliant with the *in vitro* diagnostic directive (IVDD). However, many laboratories in the United Kingdom and elsewhere continue to use well-validated molecular assays developed in-house. This makes it difficult for each laboratory to evaluate each molecular assay, and there is likely to be considerable inter-assay and inter-laboratory variation (Valentine-Thon, 2002). If a noncommercial assay is employed, the critical reagents should be batch tested, and it is vital that a known low-level positive ‘run control’ is used to monitor within- and between-analytical run variability. To supplement these internal quality control measures, it is very important to participate in external quality assessment (EQA), since major clinical and therapeutic decisions are made on the basis of molecular assay results. An EQA service sends participating clinical laboratories samples on a regular basis, which they test as if they had come from patients. Results are returned to the EQA centre, which provides a report that compares

a participant’s performance with that of all laboratories and/or groups of laboratories using similar test methods. These may be commercial assays or developed ‘in-house’. Programmes such as Quality Control for Molecular Diagnostics (www.qcmd.com) provide EQA schemes for blood-borne viruses and other pathogens such as CMV, enterovirus and respiratory viruses. Participation in such schemes represents a significant but essential expenditure for diagnostic laboratories.

Automation of Molecular Techniques

With the use of highly-sophisticated robotics, the component processes of molecular assays—extraction of nucleic acid, real-time PCR reaction set-up, amplification and detection—can also be automated. Thus, it is possible for a single machine to perform a specific diagnostic nucleic acid test on a patient sample and deliver a very rapid result without any technical expertise being required at all, for example the GeneExpert System. Such self-contained, fully-integrated systems are currently very expensive however, prohibiting widespread use.

Clinical Value of Molecular Techniques

The application of qualitative and quantitative molecular analysis to human viral infections has provided new insights into the natural history of infections such as HIV, HBV, HCV and the herpesviruses. This includes the nature of viral persistence and latency, viral replication and turnover rate, and an understanding of the response to antiviral therapies. Molecular diagnostic assays have not merely increased sensitivity over alternative methods; they have resulted in the identification of a number of new viruses associated with respiratory disease: coronaviruses NL63 (van der *et al.*, 2004) and HKU1 (Woo *et al.*, 2005), and human bocavirus (Allander *et al.*, 2005).

Diagnosis of Virus Infection and Disease

Infection is revealed by the detection of virus in a clinical specimen. The infection may be asymptomatic or symptomatic (disease). However, the key determinant for correct diagnosis is the sensitivity of the assay, with a goal of detecting viral genome if it is present. A sensitive qualitative assay is relevant, for instance, in the diagnosis of HIV in infants (proviral DNA in PBMCs) (Lyll *et al.*, 2001) or acute HCV (plasma/serum RNA) infection (Aarons *et al.*, 2004). Before introducing such an assay into routine use, the sensitivity and specificity of the new test must be established, according to the formulae in Table 1.7. Note that in this instance, these parameters are compared to an existing gold standard assay (true positives or negatives) and therefore relate purely

Table 1.7 Evaluation of a new diagnostic assay

Parameter	Description	Formula
Sensitivity	Proportion of true positives correctly identified by test	$\frac{\text{true positive results}}{(\text{true positives} + \text{false negatives})}$
Specificity	Proportion of true negatives correctly identified by test	$\frac{\text{true negative results}}{(\text{true negatives and false positives})}$
Positive predictive value	Proportion of patients with positive test results who are correctly diagnosed	$\frac{\text{sensitivity} \times \text{prevalence}}{\text{sensitivity} \times \text{prevalence} + (1 - \text{specificity}) \times (1 - \text{prevalence})}$
Negative predictive value	Proportion of patients with negative test results who are correctly diagnosed	$\frac{\text{sensitivity} \times (1 - \text{prevalence})}{(1 - \text{sensitivity}) \times \text{prevalence} + \text{specificity} \times (1 - \text{prevalence})}$
Likelihood ratio	Indicates how much a given diagnostic test result will raise or lower the pretest probability of the target disorder	$\frac{\text{sensitivity}}{(1 - \text{specificity})}$

to a comparison between assays. Since molecular assays are usually more sensitive than existing assays, it is often necessary to confirm by other means that the samples positive solely by the molecular assay are indeed true positives. This can be done by confirming the identity of the PCR product, or by correlation with another marker of infection (for instance, seropositivity, where appropriate) or with the clinical background. Thus, an expanded gold standard, including positives by both existing and new assay, is used for sensitivity and specificity calculations. A useful concept in evaluating a diagnostic test is the likelihood ratio (Table 1.7), which indicates how much a given diagnostic test result will raise or lower the pre-test probability of the target disorder (Altman and Bland, 1994).

As discussed above, the nature of viral disease has had to be redefined in the light of qualitative and quantitative molecular data. Increasingly, it is possible to detect the presence of virus at low genome copy number in the absence of symptoms. This may make the interpretation of positive results problematic, and requires close clinical–virological liaison. Two approaches are possible:

1. *Qualitative detection of viral genome at a site that is normally virus-free.* A good example is the diagnosis of viral encephalitis, in which detection of HSV, CMV, VZV or enterovirus genome is diagnostic (Jeffery *et al.*, 1997). Qualitative PCR offers significant advantages in terms of speed over traditional methods of viral diagnosis and, indeed, it has been very difficult traditionally to propagate herpesviruses in cell culture from CSF samples. It is unclear whether this is a reflection of a low level

of virus, or whether there is a preponderance of disrupted, non-infectious virus produced from brain tissue into the CSF. Early diagnosis and treatment of CNS infection can improve prognosis in herpes simplex encephalitis (Raschilas *et al.*, 2002), or can reduce unnecessary treatment and hospitalization as in the case of enteroviral meningitis (Nigrovic and Chiang, 2000).

2. *Qualitative detection of virus without an exquisite level of sensitivity.* This is useful where low-level viral shedding may occur in the absence of disease. An example is the use of PCR for HSV1 and HSV2 to determine the cause of oral/genital ulceration (do Nascimento *et al.*, 1998). Another example is the diagnosis of viral gastroenteritis by detection of rotavirus, norovirus or faecal adenovirus genome in stool samples (O'Neill *et al.*, 2002).

Staging of Infection and Prediction of Disease

For many persistent virus infections with transient or continual low-level viraemia, the onset of symptomatic disease is associated with a higher viral replication rate. This provides the rationale to identify the levels of viraemia that are predictive of disease. Quantitative molecular data on CMV disease in allogeneic bone-marrow transplant patients (Boeckh *et al.*, 1996) and AIDS patients (Spector *et al.*, 1998), and similar molecular data on BK polyomavirus-associated nephropathy in renal transplant recipients (Limaye *et al.*, 2001) demonstrate the usefulness of this approach. The

capacity of a positive laboratory test to predict disease must be established by detailed prospective surveillance protocols, in order to generate positive and negative predictive values (Table 1.7). Since the natural history of viral infections (relationship between replication and disease) may be influenced by factors such as the length and nature of immunosuppression, these parameters should be determined separately for different patient groups, such as human stem cell transplant (HSCT) recipients, solid organ recipients and patients with AIDS. Large prospective studies are therefore required in each case. Standardization within commercial assay systems and/or against international unitage standards will help in this respect.

qPCR for CMV has emerged as the preferred screening method for detection of CMV viremia in patients following allogeneic stem cell and solid organ transplant. Although there are currently no universally-accepted qPCR treatment thresholds at which to start pre-emptive therapy, evidence suggests that one of $\geq 10\,000$ copies/ml whole blood is a safe and effective strategy in clinically stable patients (Verkruijse *et al.*, 2006).

Data from the Multicentre AIDS Cohort Study (MACS) has shown that a high virus load predicts a faster rate of decline of CD4+ cells (Mellors and Rinaldo, 1996). This became a guideline for initiating antiviral therapy. However, more recently the British HIV Association (BHIVA) has moved away from recommending initiation of therapy based primarily on plasma HIV RNA load. It recommends that therapy for asymptomatic established infection should be deferred until the CD4+ cell count is between 200 and 350 cells/ μ l (Gazzard *et al.*, 2006). For hepatitis B infection, there is evidence that a high viral load predicts progression to cirrhosis (Iloeje *et al.*, 2006) and the development of hepatocellular carcinoma (Ohkubo *et al.*, 2002).

Genetic Subtyping (Genotyping)

HCV is a genetically heterogeneous virus with six major genotypes (Simmonds *et al.*, 1993). Some genotypes (namely types 2 and 3) have a more favourable response to interferon-based treatment than others (Chemello *et al.*, 1994; Hadziyannis *et al.*, 2004) and genotyping therefore affects the management of HCV infection. Sequencing is the reference method of HCV genotyping. Alternative methods include a line probe assay (in which biotinylated PCR product from the 5' untranslated region (UTR) is hybridized with subtype-specific oligonucleotide probes attached to a nitrocellulose strip and detected with a streptavidin-alkaline phosphatase conjugate), subtype-specific PCR and restriction fragment length polymorphism (RFLP).

Hepatitis B is a similarly heterogeneous virus. Several studies have shown that genotype B (prevalent in the Far

East) is associated with both a better overall prognosis (Kao *et al.*, 2002; Sakugawa *et al.*, 2002) and a higher rate of interferon-induced HBeAg clearance than hepatitis B genotype C (Wai *et al.*, 2002). HBV genotyping is likely to be used clinically in future, for example in guiding appropriate antiviral treatment. In HBeAg negative, antiHBe positive patients with discordantly high viral loads (2000 IU ml⁻¹), sequencing of HBV for the presence of pre-core and core promoter mutations is becoming a common request.

Over 70 genotypes of HPV are recognized, but not all of these types have the potential to cause lesions that may progress to malignancy. A hybrid capture technique (see above) is widely used to detect the DNA of 'high-risk' (HR) HPV genotypes in cervical brushings/washings, and there is evidence that women with minor cytological disorders can be excluded from colposcopy following a negative HR HPV result (Guyot *et al.*, 2003).

Monitoring Antiviral Therapy

In recent years, viral genome quantification to monitor the effect of specific viral therapy has become part of the clinical management of patients infected with HIV, HBV, HCV and those at risk of developing CMV disease (Berger and Preiser, 2002).

For HIV, regardless of the baseline viral load, a level of 1000 copies/ml has been found to be achievable in the majority of people by four weeks from start of highly active antiretroviral therapy (HAART). Failure to achieve this is strongly associated with failure to depress viral load below 50 copies/ml within 24 weeks (Gazzard *et al.*, 2006). Clinical trial data suggest that reduction of viral load to below 50 copies/ml predicts durability of antiviral response (Montaner *et al.*, 1998; Powderly *et al.*, 1999). Thereafter the purpose of regular monitoring of plasma HIV RNA levels is to monitor the success of therapy, and current protocols recommend subsequent tests at three to four month intervals (see Chapter 39).

Three- to six-monthly monitoring of HBV DNA level is an important tool in assessing response to antiviral treatment as most guidelines propose that suppression of HBV replication is a major therapeutic goal. It may be appropriate to use shorter monitoring intervals (every three months) for lamivudine monotherapy than for other nucleoside/nucleotide analogues because of the propensity for lamivudine resistance to arise (Valsamakis, 2007).

Evidence suggests that a lower baseline hepatitis C viral load predicts a more favourable response to combination therapy (pegylated interferon and ribavirin) for chronic infection (Yuki *et al.*, 1995), and that the required duration of treatment may be shorter (Shiffman *et al.*, 2007). Moreover, HCV RNA quantification has become vital for monitoring the response to therapy. In genotype

1 and 4 infections, if the HCV RNA load has not fallen 100-fold after 12 weeks of treatment, the likelihood of viral RNA remaining undetectable six months after completion of therapy, that is of achieving a sustained viral response (SVR), is very low (negative predictive value: 97–98%) and treatment should be discontinued (NICE, 2004). This leads to cost savings and a reduction in the inconvenience and side effects of treatment (Davis, 2002). Patients who become HCV RNA negative after only four weeks of treatment have the best chance of achieving SVR (as reviewed in Poordad *et al.*, 2008).

Virological monitoring of patients receiving anti-CMV therapy is important. Not only does a high viral load predict CMV disease in a number of risk groups such as solid organ transplant recipients (Fox *et al.*, 1995), HIV infected patients (Spector *et al.*, 1998) and congenitally infected newborn infants (Revello *et al.*, 1999), but persistent viraemia following onset of therapy or virological relapse on therapy is associated with continuing disease. Conversely, in stem cell transplant recipients treated with ganciclovir pre-emptively, clearance of viraemia can be an indicator to stop therapy (Einsele *et al.*, 1995). In all cases of antiviral drug monitoring using qualitative or quantitative molecular assays, a rebound in viral load or failure to suppress viral replication may reflect reduced drug susceptibility. In these cases, it may be appropriate to undertake drug susceptibility assays (see below).

Prediction of Transmission

It is reasonable to assume that a high viral load will predict a propensity to transmit infection. Studies on vertical HIV transmission suggest that the mother's viral load is a better indicator of the risk of vertical transmission than CD4 cell count (O'Shea *et al.*, 1998). The plasma HIV load has been shown to be the main predictor of heterosexual transmission in a study of HIV discordant couples in Uganda (Quinn *et al.*, 2000), and a high HIV load in genital secretions is also associated with efficient heterosexual HIV transmission (Chakraborty *et al.*, 2001). Mother-to-infant hepatitis C transmission is associated with a high HCV load (Dal Molin *et al.*, 2002) and similarly, in a study of 155 HIV and HCV co-infected women, the maternal plasma HCV RNA was significantly higher in those who transmitted HCV to their offspring than in those who did not (Thomas *et al.*, 1998). HBeAg has long been used as a surrogate marker of a high HBV virus load and therefore of high risk of mother-to-infant transmission in pregnant women; but increasingly studies are detecting significant levels of HBV DNA in HBeAg-negative individuals (Berger and Preiser, 2002). Following a number of incidents of transmission

of hepatitis B from HBeAg-negative health care workers (HCWs) to patients, guidance (HSC 2000/020) extended the role of HBV DNA monitoring in the United Kingdom to exclude HCWs with a DNA load of $>10^3$ genome equivalents/ml from practising exposure-prone procedures, whatever their HBeAg status. More recent guidelines allow HBeAg-negative individuals with a baseline DNA load of between 10^3 and 10^5 genome equivalents/ml to practice while on antiviral therapy if their DNA load is reduced to $<10^3$ genome equivalents/ml and is monitored under careful supervision every three months (Department of Health UK, 2007).

Viral Genetic Analysis of Transmission Events

Viral genome sequencing is now a standard method for studying transmission events. Relatedness between viruses is examined against a background of genetic variation ('viral quasispecies'). In such investigations, the choice of gene targets to amplify and sequence is important, and results must be subject to the correct statistical and phylogenetic analysis for reliable evidence of a transmission event. This approach has been particularly important in the investigation of HCWs infected with blood-borne viruses such as HBV (Nguu and Teo, 1997; Zuckerman *et al.*, 1995) and HIV (Blanchard *et al.*, 1998).

Sequence-relatedness between different virus isolates is also essential for virus classification. The data used to generate phylogenetic trees are usually derived from conserved genes, such as those coding for viral enzymes or structural proteins. This type of analysis has been used recently to develop a new classification of the *Retroviridae* (www.ncbi.nlm.nih.gov/ICTVdb/Ictv/fs_retro.htm).

Detection of Antiviral Resistance

Resistance has been documented for virtually all compounds with antiviral activity, and so the emergence of antiviral resistance in clinical practice should come as no surprise. Drug susceptibility depends on the concentration of drug required to inhibit viral replication and so drug resistance is not usually 'all or none', but relative. The genetic basis of resistance is becoming better understood, and specific viral genetic mutations have been associated with resistance.

As the use of antiviral drugs increases, there will be more pressure on diagnostic laboratories to provide assays to determine the causes of treatment failure, of which drug resistance is one. Laboratory assays for drug resistance fall into two major categories: phenotypic and genotypic. Their relative advantages and disadvantages are summarized in Table 1.8.

Table 1.8 Advantages and disadvantages of phenotypic and genotypic antiviral drug resistance assays

	Advantages	Disadvantages
<i>Phenotype</i>	Represents sum of all mutations Quantitative assessment of resistance (IC ₅₀ , IC ₉₅)	Expensive Labour-intensive Slow
	Can assess cross-resistance	Selection of culture-adapted strains (not with recombinant virus assay)
<i>Genotype</i>		
(a) Selective (e.g. point mutation assay, line probe)	Quick Relatively inexpensive (PMA) Semiquantitative (PMA)	Difficult to interpret single mutation in absence of other information
(b) Sequencing	Rapid Comprehensive information Background polymorphisms detected	Expensive Labour-intensive Expertise in genomic analysis required Simultaneous mutations not necessarily on same genome

Phenotypic Assays

Though phenotypic assays have been largely replaced by genotypic methods, the plaque reduction assay remains the gold standard for detecting HSV, CMV and VZV drug resistance. A specific titre (plaque-forming unit) of virus is inoculated on to a permissive cell monolayer, usually within a multiwell plate. These monolayers are overlaid with increasing concentrations of drug in a semisolid medium, thus preventing extracellular virus spread. The plaque reduction associated with drug inhibition can then be calculated, with results expressed as IC 50 or IC 90 (concentrations of drug required to inhibit virus production by 50 or 90%). Alternative methods for HSV include the dye uptake method, which quantifies viable cells within a viral-infected monolayer. The time-consuming nature of VZV and CMV culture techniques has led to the development of rapid culture methods, using viral antigen detection or genome detection to assess drug efficacy (Pepin *et al.*, 1992). All these assays produce different IC 50 values on the same isolates, and standardization is therefore required.

For HIV-resistance testing, recombinant virus assays have been developed. In these, a PCR product amplified directly from plasma virus is recombined with an HIV clone lacking the relevant gene (Hertogs *et al.*, 1998). The fragments can include the RT gene, protease gene and gag cleavage sites, and the resulting recombinant can then be screened for susceptibility to a range of drugs. Since the background clone of virus used grows rapidly in culture, this method is faster than conventional phenotypic assays.

With the development of CCR5 entry inhibitors such as Maraviroc to treat HIV infection, it has become important to be able to determine whether a potential recipient already harbours CXCR4-using (X4) viral quasiespecies. Such viruses will be resistant to a CCR5 inhibitor drug and their increasing predominance in the viral 'swarm' is associated with more rapidly advancing HIV disease. The Trofile™ co-receptor tropism assay measures the ability of a patient's virus envelope gene to mediate entry into cells expressing CXCR4 or CCR5.

Phenotypic assays are clearly important since they reflect global determinants of drug resistance, but they require propagation of a virus stock before the assay is undertaken. This process is itself selective, and may lead to the final susceptibility assay being carried out on an unrepresentative species. On the other hand, phenotypic assays based on PCR suffer from the same genetic selection limitations as genotypic methods.

Genotypic Assays

An understanding of the genetic basis of drug resistance and the availability of automated and nonradioactive methods of nucleic acid sequencing have enabled widespread assessment of viral isolates with reduced drug susceptibility. With the increasing use of antiviral medication for a number of infections, most notably HIV and hepatitis B, these assays have become part of a routine diagnostic repertoire. Genotypic assays for drug resistance in CMV have also been developed (Bowen *et al.*, 1997) and mutations associated with multidrug resistance are now recognized (Scott *et al.*, 2007).

Sequence-based methods have largely replaced selective PCR (or point mutation assays, PMAs), line probe assays and RFLP assays for specific mutations associated with resistance. Recent advances in automated nucleic acid sequencing, such as the use of capillary sequencers, allow rapid high-throughput sequencing within a clinical laboratory setting. This has been most widely utilized for HIV and hepatitis B drug resistance assays, but it has other applications, for example the study of nosocomial transmission events. The biggest challenge of this technique is the manipulation and analysis of the data generated. Sequence editing and interpretation is required. With regard to HIV drug resistance, the identification of key resistance mutations depends on interpretation of variable drug susceptibility patterns and on the software systems utilized. When based on a product PCR amplified from the plasma, these techniques provide information only on the majority population within the quasispecies. They cannot exclude different mutations existing on separate genomes.

'Virtual phenotyping', a technique developed by Virco (www.vircolab.com), is a method of interpreting genotypic HIV resistance information with the aid of a large database of samples with paired genotypic and phenotypic data. By searching the database, viruses with genotypes similar to the patient's virus are identified and the average IC 50 of these matching viruses is calculated. This information is then used to estimate the likely phenotype of the patient's virus.

RECOMMENDED DIAGNOSTIC INVESTIGATIONS

Making an accurate virological diagnosis is critically dependent on receiving adequate specimens with information relating to the onset of symptoms and the clinical presentation. Swabs and tissue samples should be collected by trained staff and placed into virus transport media. If sample transport is delayed, samples should

be stored at 4°C or on wet ice (for a maximum of 24 hours). Assays for quantifying virus in blood require rapid specimen transport and appropriate processing and storage prior to analysis. It is the role of the clinical virologist to decide on the most appropriate investigations for any given clinical scenario. Laboratory request forms are important in this respect, and should encourage full documentation of clinical details. The practice of sending a serum sample to the virology laboratory with a request for a general 'screen' should be strongly discouraged. Instead diagnosis should be built upon the concept of syndromic presentation, its initial and continuing investigation, and appropriate management developing out of clinical progress, diagnostic findings and response to treatment. If the clinical presentation proves to be due to a virus infection, the virologist may have a leading role, but liaison with haematological, radiological, pharmacological and other clinical colleagues must be appropriate and continued.

Test Selection

Much of the work presenting to a virology laboratory is straightforward, taking the form of a particular screen (Table 1.9). But in other cases clinicians are presented with a patient whom they suspect may have a viral infection, yet they are unsure which tests to request. In some cases, they may request inappropriate tests. One of the most important roles of the laboratory staff, both technical and medical, is to assist the clinician in obtaining the correct diagnosis by choosing appropriate tests. In some cases sufficient clinical details on request forms will allow test selection in the laboratory (not necessarily the tests requested by the clinician!). In other cases, further information and possibly additional and different sample types will be needed. Many virology laboratories also provide serological testing for nonvirological infections, for example syphilis, toxoplasma and chlamydia (serological and nucleic acid-based testing).

Table 1.9 Examples of suggested screening assays for specified patient groups

Pre-stem cell transplant screen (donor and recipient)	HIV (i.e. combined testing for anti-HIV 1 and 2 and for HIV 1 p24 antigen), anti-HCV, HBsAg, anti-HBcore, anti-HTLV 1, CMV IgG, EBV EBNA IgG, VZV IgG, anti-HSV, syphilis, toxoplasma-Ab
Renal dialysis patients	HIV (i.e. combined testing for anti-HIV 1 and 2 and for HIV 1 p24 antigen), anti-HCV, HBsAg pre-dialysis Anti-HCV, HBsAg three-monthly. HIV repeat testing based on risk assessment
Antenatal screening	HIV (i.e. combined testing for anti-HIV 1 and 2 and for HIV 1 p24 antigen), HBsAg, Rubella IgG, syphilis

Table 1.10 Suggested testing strategy for the investigation of hepatitis and abnormal LFTs, with or without jaundice

First line	HAV-IgM, HBsAg and HBcore IgM, anti-HCV
Second line	EBV-IgM, CMV-IgM, HCV-RNA, hepatitis E IgM (any could be first-line, depending on history)
Third line	Dengue, yellow fever, leptospirosis, enterovirus, adenovirus and others depending on age, clinical details, travel history and so on

In the UK, the Health Protection Agency has proposed a number of national standard operating procedures (www.hpa-standardmethods.org.uk) that can help in suggesting a strategy for testing (e.g. VSOP 6: Hepatitis, jaundice and abnormal LFTs); but as illustrated in Table 1.10, the individual patient needs to be taken into account in order to select a cost-effective strategy for testing. There are also many situations where tests will be requested for which there is no evidence

base or recommendation to support testing, and many laboratories have developed brief clinical/educational comments explaining why such testing is thought not to be appropriate. Examples are given in Table 1.11. Clinical liaison leads to samples being used more appropriately, for example proposing hepatitis C antibody testing for a fatigued ex-drug user. Screening requests such as 'TORCH' should be discouraged in favour of test selection in response to specific clinical details. Testing for congenital and perinatal infection is complex, and for a neonate/infant is likely to require access to earlier stored samples such as the maternal antenatal booking sample or the infant's dried blood spot taken at birth (the Guthrie card). Exposure to rash illness in pregnancy is very common (e.g. chickenpox, B19 virus) and national guidelines exist on rash illness and exposure to rash illness in pregnancy (www.hpa.org.uk/infections/topics_az/pregnancy/rashes/default.htm).

Table 1.12 illustrates some suggested first-line serological tests for common clinical requests in the United Kingdom. Selecting an appropriate repertoire of serological tests for a routine diagnostic laboratory and achieving an appropriate balance between testing samples in-house and sending samples to other laboratories

Table 1.11 Examples of comments for samples where serological testing may not be clinically indicated

Request	Comment
Chronic fatigue screen	Serological tests are of low value for investigating chronic fatigue. We are happy to discuss individual cases. Sample stored
Meningitis/encephalitis screen	Viral serology in the first week of meningitis or encephalitis is usually unhelpful. The sample has been stored. CSF is the best sample
?HSV infection	Serological testing is unlikely to be helpful. Please send appropriate sample (CSF, or swab of skin/mucosal lesion in viral transport medium) for viral culture \pm PCR
Abdominal pain/diarrhoea. Viral screen please	There are no useful serological tests for viruses that cause primarily vomiting, diarrhoea or abdominal pain
Intrauterine death (IUD)/miscarriage with 'TORCH' screen requested	Serological tests are not routinely performed in cases of IUD/miscarriage unless there are clinical features suggesting a viral aetiology. If this is the case please contact the laboratory
Measles/mumps/rubella (MMR) screen	The assays that measure IgG to measles and mumps have not been validated for the determination of protection against these diseases: they were designed to assist in the diagnosis of acute infection. Therefore, it is not appropriate to use these assays for the purpose of excluding the need to give MMR
Atypical pneumonia/influenza	Testing acute samples for atypical and influenza serology does not contribute to acute patient management. Sample stored. If legionella infection is suspected, please send a urine sample for legionella urinary antigen

Table 1.12 Suggested first-line serological tests for common clinical requests in the United Kingdom

Clinical details	First-line tests
Arthralgia/joint pains	B19 IgM, HBsAg, Rubella IgM. Consider toxoplasmosis IgM if myalgia
Atypical pneumonia/influenza	Acute sample store. See above suggested comment. Testing of convalescent samples provides retrospective diagnosis and epidemiological data
Chronic fatigue	Samples not tested until discussed with clinician
Encephalitis	As indicated by clinical details. See HPA protocol QSOP 48
Endocarditis (culture negative)	Q fever, bartonella, chlamydia species, others as indicated
Glandular fever/lymphadenopathy	EBV-IgM, CMV-IgM, consider toxoplasma IgM and HIV test, bartonella if cat scratch a possibility
Hepatitis/abnormal LFTs	See Table 1.10 (also HPA VSOP 6)
Pregnancy and congenital infection—illness in the mother, abnormal fetal ultrasound findings or possible neonatal infection	Strategy depends on nature of illness, clinical findings and local protocols. ‘TORCH’ screening should be discouraged
Rash illness—maculopapular	Depends on local epidemiology. Consider B19, rubella, measles
Rash illness—vesicular	Depends on local epidemiology. HSV and VZV infections usually best diagnosed with a vesicle swab for PCR-based direct virus detection
Rash illness—exposure in pregnancy	See HPA protocols VSOP 33 and www.hpa.org.uk/infections/topics_az/pregnancy/rashes/default.htm

will depend on the size of laboratory, the population served, ease of testing and the throughput of tests. Many assays are best performed in batches, and in order to maintain an acceptable turnaround time it is not practical to provide a comprehensive repertoire in every laboratory. However, the increasing availability of multiple analyser systems that provide a wide range of cross-discipline immunoassays, random access facilities and automation allows even the smaller laboratory to offer a wide range of serological assays. This has to be balanced against the savings that can be made with economies of scale. In addition, obtaining a battery of immunoassays from a single commercial company may mean that compromises have to be made with certain tests not having the optimum sensitivity and specificity for the particular local population.

FUTURE TRENDS

In the light of rapid assay development and the continuing identification of new viruses, clinical protocols require constant updating. The era of retrospective viral diagnosis is over, replaced by rapid techniques which impact directly on clinical management. Competition for health care resources has meant that new techniques have replaced more traditional methods with limited clinical

value. Clinical virologists have to work closely with their clinical colleagues to establish new diagnostic criteria, develop protocols for use of antiviral drugs and monitor patients with persistent infections. The diversity of diagnostic methods now available makes communication between physicians and clinical virologists more important than ever before. The present multiplicity of traditional and new diagnostic techniques, as described above, suggests that a rationalization is now overdue. This will involve the abandonment of some older technologies, more discriminatory use of newer, especially molecular, ones, and technical collaboration with other pathology disciplines to improve efficiency and shorten turnaround times. Laboratories will need to embrace the electronic patient record (EPR) and remote requesting (‘order communications’), which, if well managed, will improve the quality of service provided by the laboratory, improving patient care. Laboratory information management systems will have to be fully integrated with the EPR in order to maximize the benefits from new information technologies.

A special emphasis must be placed on the needs of the immunocompromised patient population. They may experience life-threatening viral infections, which can present atypically. Ongoing antiviral prophylactic therapy may distort the nature and timing of presentation. Routine monitoring of transplant recipients is important

so that pre-emptive or early therapy can be initiated or immunosuppressive therapy modified as appropriate. Precise monitoring protocols will depend on the patient group concerned, availability of laboratory facilities and budgetary constraints. Nevertheless, in the context of high-risk patients such as those receiving long-term chemotherapy or transplants, the relative cost of virological investigations will be small. This population is constantly changing and expanding with new procedures and immunosuppressive agents, and the range of organisms to be monitored is likely to increase.

Alongside the increase in laboratory automation there is an increase in the integration of clinical virology with clinical microbiology laboratories. A step further is more extensive automation that integrates diagnostic immunoassay facilities across pathological specialities. This leads to economies of scale, though it may reduce the skill base and number of individuals trained in traditional virological techniques such as tissue culture and EM. Already, the distinctions between bacteriology and virology diagnostic techniques are becoming blurred, both providing opportunities for those skilled in molecular diagnostics and strengthening the practice of molecular diagnostics. With increasing automation in molecular techniques, the majority of general microbiology laboratories in the United Kingdom now offer at least a limited repertoire of molecular assays. For example, nucleic acid-based testing for *Chlamydia trachomatis* and other commercially-available assay systems are also being used for presurgery methicillin resistant *Staphylococcus aureus* (MRSA) screening and the detection of bacteria in sterile site samples by a PCR for 16S ribosomal RNA. Microbiology laboratories of the future may have to participate in bioterrorism surveillance for multiple infectious pathogens and collaborate in the rapid development of tests for new diseases of high social impact, as recently shown for the SARS caused by SARS-CoV (Raoult *et al.*, 2004).

There is a corresponding change in the training of medical staff in the United Kingdom, with broader based training across the infection specialities. There is a new cohort of physicians qualified to practice both as infectious disease clinicians and as laboratory-based staff. With possible future centralization and 'factory style' diagnostic testing facilities, laboratory-based specialists need to strengthen their role in clinical consultation and front-line management of patients, for example in hepatitis and HIV clinics and on transplantation ward rounds. For some, this broad-based training in infection demands a radical change in attitude and outlook.

We live in a global village, with rapid international travel and communication and the possibility of major environmental transformation due to climate change. Deforestation and expanding urban development facilitates

epidemic spread of infection by bringing human and animal populations closer together, allowing pathogens to 'jump' species. The threat of bioterrorism must not be neglected. These factors make human and animal populations more vulnerable than ever before to the epidemic spread of novel (as well as well-known) viruses, as seen in recent years with SARS-CoV and avian H5N1 influenza. In recognition of this, the World Health Organization (WHO), within the framework of the International Health Regulations, has developed a vision that '*every country should be able to detect, verify rapidly and respond appropriately to epidemic-prone and emerging disease threats when they arise to minimize their impact on the health and economy of the world's population*'. This should be achieved by focusing on three principles: contain known risks, respond to the unexpected and improve preparedness (www.who.int/csr/about/en/#strategy).

In rural, resource-poor areas of the world such as parts of South East Asia and Africa, little is known about the epidemiology of many viral infections. The burden of viral disease in such areas is likely to be considerable, but the infrastructure to implement the cross-sectional epidemiological studies necessary to define the causes of infectious disease is not available, largely due to economic constraints. Research in such resource-poor areas is fragmentary and often focuses on the interests of a specific individual or group. The developed world has been able to embrace the recent advances in diagnostic virology and improve clinical care, but in resource-poor areas basic diagnostic facilities which could go some way towards delivering the WHO vision are not available. For example, basic laboratory testing to support the roll-out of highly active anti-retroviral therapy (HAART) is often lacking in resource-poor settings. An important challenge for the infection community is to develop cost-effective and robust diagnostic and monitoring assays for use in the developing world. The discipline required to do this may also bring benefits by helping to rationalize the congested work schedules in laboratories in the developed world.

Viral Transmission: Infection Acquired by the Blood-borne Route

Will Irving

University of Nottingham and Nottingham University Hospitals NHS Trust, Nottingham, UK

INTRODUCTION

Blood (or other bodily fluids, Table 2.1) is a potential infection source, mediating transmission of viruses from one individual to another. Although humans are not often exposed to each others' blood, blood-borne transmission can arise in a variety of settings, some perhaps more obvious than others:

- transfusion of blood or blood products from an infected individual;
- organ or tissue transplantation from an infected donor;
- sharing or re-use of blood-contaminated needles and syringes, whether for medicinal or recreational purposes, or through activities such as acupuncture, tattooing or body piercing;
- accidental inoculation injuries with blood-contaminated needles/sharps;
- exposure to blood splashes, or to blood-contaminated objects and instruments; and
- exposure to contaminated maternal blood, either ante- or peri-natally.

Blood-borne transmission of infection is a particular concern in the context of the provision of health care. Blood/blood-product transfusion is an obvious potential hazard for the recipient, but blood sampling or instrumentation of infected individuals is also commonplace in health-care settings, resulting in potential contamination of both sharps and the environment, and thereby creating possibilities for nosocomial spread. The literature is replete with outbreaks of infection with a variety of viruses,

but particularly the 'big-three' blood-borne viruses (BBVs) of human immunodeficiency virus (HIV), hepatitis B virus (HBV) and hepatitis C virus (HCV), arising from blood-borne transmission in a health-care setting. As these risks have become recognized, so it has become necessary to devise policies and guidelines to prevent, or at least minimize the chances of, such outbreaks occurring.

It is useful to consider three particular circumstances under which BBV transmission may occur within health-care settings:

- patient-to-patient transmission;
- patient-to-health-care worker (HCW) transmission; and
- HCW-to-patient transmission.

Table 2.1 Body fluids which should be handled with the same precautions as blood

Cerebrospinal fluid
Peritoneal fluid
Pleural fluid
Pericardial fluid
Synovial fluid
Amniotic fluid
Semen
Vaginal secretions
Breast milk
Any other bodily fluid containing visible blood, including saliva in association with dentistry

Adapted from (Department of Health, 1998).

Strategies designed to minimize the risks of nosocomial transmission of BBV need to address:

1. prevention of exposure to blood or other bodily fluids through the establishment and maintenance of high standards of infection control; and
2. prevention of infection through the implementation of policies for the pre-exposure prophylaxis (where possible) and post-exposure management of patients and HCWs should a needlestick or other exposure happen.

PREVENTION OF EXPOSURE THROUGH INFECTION CONTROL

Good infection control practice provides a firm basis for limiting all nosocomial BBV transmission. General principles of infection control have been elaborated in detail in UK guidance (Department of Health, 1998). Specific guidance for reducing the risk of percutaneous and mucocutaneous exposure during surgical procedures is also given in this document, including measures to reduce eye and other facial exposure. Other general measures which should be taken to prevent HCW exposure to BBVs include adequate sterilization, disinfection and cleaning of equipment and work surfaces (Department of Health, 1996).

Approaches to reduce hazardous exposures of HCWs to BBVs can be categorized as (i) the taking of special precautions for patients or specimens known or suspected to be infected or (ii) the adoption of universal precautions to cover all patients and specimens, the principle of which is that the level of precautions taken depends on a risk assessment of the procedures being undertaken, rather than on the patient's infection status. In recent years there has been a major shift towards the latter (Department of Health, 1996), one of the main reasons being that for every patient known to be infected with a BBV, there will be many more in routine clinical practice where this status is not known or even suspected. There is also evidence to suggest that knowledge of a patient's high-risk status may not reduce the risk of blood exposures during surgical procedures (Gerberding *et al.*, 1990), whilst practicing universal precautions does reduce the frequency of blood exposures among trained HCWs (Beltrami, 2000; Fahey *et al.*, 1991).

Other possible approaches to prevent the occurrence of inoculation injuries include the development of safer surgical techniques, avoidance of the use of sharp instruments where alternatives exist (e.g. when suturing), better training of junior surgeons using surgical rigs, effective systems for collecting and disposing of used sharps, and the design of safer needle and syringe combinations

which reduce needle handling and automatically protect the needle after use.

PREVENTION OF INFECTION THROUGH SPECIFIC PRE- AND POST-EXPOSURE POLICIES

The nature of pre- and post-exposure interventions differs depending upon which of the three transmission circumstances is being considered.

PATIENT-TO-PATIENT TRANSMISSION

This may arise in several ways.

Transfusion of Contaminated Blood/Blood Products

Blood transfusion services have adopted several measures to protect the blood supply, including rigorous procedures for selection of donors, and appropriate testing of donors for evidence of infection. The importance of donor selection cannot be over-emphasized. The World Health Organization (WHO) asserts that blood donation should be 100% voluntary and free of incentives. Countries which have never used paid donors have a much better record in terms of BBV transmission by blood or blood-product transfusion than those where donors have been paid—the latter process discouraging individuals from declaring risk factors in case of rejection. Anyone wishing to be a donor in the United Kingdom is given an explanatory leaflet which asks them to self-defer if they have identifiable risk factors. In addition, first-time donor interview reduces the infectious risk 100-fold. The safety of repeat as compared with first-time donors shows a significant difference (Table 2.2).

All individual donations should be tested—in the United Kingdom it is mandatory to screen for evidence of HIV, HBV, HCV, human lymphotropic virus (HTLV)-1 and syphilis infection. According to the WHO, failure to introduce donor testing results in up to 16 million HBV, 5 million HCV and 160 000 HIV infections worldwide per year (Editorial, 2007). The modality of testing differs for each organism and between countries. Current practice in the United Kingdom is:

- HIV—combination anti-HIV and antigen enzyme immunoassay (EIA) testing of all donors; pooled (48 members) nucleic acid testing (NAT) of all donors.
- HBV—hepatitis B surface antigen EIA testing.
- HCV—anti-HCV EIA testing of all donors; pooled (48 members) NAT of all donors.

Table 2.2 Risks of BBV transmission by UK blood donors

Incidence	Per million donations			1 per <i>x</i> million donations		
	All	New	Repeat	All	New	Repeat
HIV	0.24	0.58	0.20	4.22	1.72	5.01
HCV	0.03	0.13	0.02	35.52	7.92	57.41
HBV	0.80	2.51	0.61	1.25	0.40	1.63

HTLV—anti-HTLV (I and II) EIA testing on pools of 48 samples.

syphilis—TPHA, TPPA or EIA testing.

Some donations are also tested for antibodies to cytomegalovirus, malaria and *Trypanosoma cruzi*. Donors with a tattoo or skin piercing since their last donation are deferred for six months and then screened for anti-hepatitis B core.

Despite all of the above, BBV transmission by transfusion still occurs. In the United Kingdom, from 1995 to 2006 there were a total of sixty infections and thirteen deaths arising from transfusion. Twelve recipients acquired HBV infection from eleven infected donors, two acquired HCV infection (two donors) and four acquired HIV infection (two donors). In the same period there were thirty-three bacterial transfusion transmitted infections (TTIs), with eight deaths (CDR, 2007). One cause of TTI is the presence of window-period donors; that is, individuals with recent infection, in whom there is not yet a detectable antibody response, or in whom the HBsAg antigen level is below the detection limit of currently available assays. The development of sensitive HIV antigen detection assays resulted in some closure of the window period for this infection. Much attention has been paid recently to the use of NAT as a way of reducing the window period even further. HIV and HCV NAT testing has been introduced in the United States, resulting in an estimated prevention of about five HIV and fifty-six HCV infections per year at an average cost of around \$2 million per infection prevented (Goodman, 2004). Currently, only HCV NAT is used on all donations in the United Kingdom. In the first two years since its introduction in 1998, about 7 million donations were tested and three window-period donors identified, considerably less than anticipated. The estimated cost per quality-adjusted life year (QALY) gained by HCV NAT screening is in excess of £7 million (Simmonds *et al.*, 2002). The cost-effectiveness of NAT is thus the subject of some debate. The development of HCV combined antibody and antigen EIA assays may offer a cheaper alternative to NAT, albeit at the expense of some loss in sensitivity.

Two possible strategies for the reduction of HBV TTIs have been proposed, but both have drawbacks.

Screening for antibodies to HBV core antigen (anti-HBc) may identify donors who are HBsAg negative but have low levels of HBV DNA. This pattern of reactivity may arise after acute infection, when the individual is in the process of clearing infection (i.e. this is not 'window-period' infection). However, anti-HBc assays may yield significant numbers of false-positive reactions (poor specificity), and deferral of all anti-HBc positive donors would also lead to significant losses of safe donations from individuals who had truly cleared infection. HBV NAT testing is also possible, but is likely to be of limited benefit in countries, such as the United Kingdom, which use extremely sensitive HBsAg assays, capable of detecting around 0.1 ng ml^{-1} HBsAg, equivalent to the sensitivity of 24 sample minipool HBV NAT for the identification of window-period infections. Individual NAT may have an increased sensitivity, but would also increase costs considerably.

Infection risks from transfusion may also be reduced by the use of viral inactivation steps such as heat or solvent-detergent treatment. These methods have been used for many years on pooled fractionated products such as factor VIII or immunoglobulin solutions, rendering them safe from HIV, HBV and HCV transmission. Application of these, or other, inactivation procedures to labile blood products, including cellular components, is of interest, but technically difficult (Council of Europe Experts Committee in Blood Transfusion Study Group on Pathogen Inactivation of Labile Blood Components, 2001).

Thus, even with all the above precautions, transfusion of blood or blood products can never be guaranteed to be free of the risk of BBV transmission. For some agents transmitted by this route, there are no appropriate validated screening tests currently available, for example prion diseases. For other infections, it is deemed not to be cost-effective to screen, for example parvovirus B19 and hepatitis A virus. Even for the big-three BBVs, where screening is performed there remains a residual risk of transmission, of the order of 1 in 2 million donations for HIV and HCV in the United States, for example (Stramer *et al.*, 2004). The residual risks of infection from transfusion in the United Kingdom are given in Table 2.2.

Organ/Tissue Transplantation

Prevention of BBV transmission by organ or tissue transplantation is achieved largely through screening organ and tissue donors. Requirements for microbiological testing of donors are set out in official UK guidance (Department of Health, 2000). Selection of organ donors cannot be as rigorous as for blood donors, particularly in near-death settings. Thus, as a generality, organ donors are more likely to have a BBV infection than blood donors. There are also additional difficulties in testing when the only donor samples available for screening are taken post-mortem.

Organs and tissues may also be donated to, or accepted from, countries abroad. In addition to local guidelines, there are also European Union directives covering the technical requirements for the donation, procurement and testing of human tissues and cells (European Union Directive, 2006). These may differ from, and therefore supersede, national guidelines. One example of discrepancy is the need for anti-HBc testing, which in the UK guidance is only necessary where liver transplantation is being considered, but is required for all donated organs and tissues in the EU directive.

Exposure to Blood-contaminated Instruments/Environments

Blood sampling of a BBV-infected patient creates an immediate opportunity for nosocomial transmission of that infection. Common errors in infection control leading to outbreaks of infection include the use of multidose vials, or re-use of improperly sterilized sharps or instruments. The largest recorded nosocomial outbreak of HCV infection was in a haematology/oncology outpatients department, involving 99 transmissions, most probably arising because of the practice of using shared saline bags to flush through intravenous lines (Macedo de Oliveira *et al.*, 2005). However, in many instances, the precise route of transmission in a particular outbreak cannot be identified with certainty.

Nosocomial BBV transmission has been a particular concern in the context of renal haemodialysis units, and thus specific guidelines have been produced and updated to minimize this risk (Department of Health, 2002a). The principles of these are:

- strict adherence to universal precautions (defined above);
- immunization of patients (and staff) against HBV infection;
- regular (e.g. three-monthly) screening of all patients for evidence of HBV, HCV or HIV infection;
- segregation of patients returning to the unit who have been dialysed outside the United Kingdom ('holiday

dialysis'), until such time as they have been shown to be negative for HBsAg, anti-HCV and HCV RNA;

- enhanced surveillance for one or more BBV and/or continued segregation for patients returning from dialysis abroad, the precise details of which will depend on a risk assessment;
- known HBV-infected patients should be dialysed in isolation on dedicated machines; and
- known HCV-infected patients should be segregated from the main unit when undergoing dialysis. Segregation of HIV-infected patients should be considered, based on a local risk assessment.

Exposure to Infected Maternal Blood

Whilst not a cause of nosocomial BBV transmission, this is nevertheless an important route whereby BBV may be transmitted from one individual to another. Detailed discussions of the management of such transmission can be found in the relevant virus-based chapters.

PATIENT-TO-HCW TRANSMISSION

Epidemiology

Blood exposure incidents are, unfortunately, all too common for HCWs in a hospital setting. It is estimated that more than 380 000 needlestick injuries occur in US hospitals each year (Gerberding, 2003). Studies of sharps injuries in operations report rates of 1–7% (Camilleri *et al.*, 1991; Gerberding *et al.*, 1990; Hussain *et al.*, 1988; Williams, 1997). Risk factors include long procedures, high blood loss, major operations and wound closure with staples. Needlestick injuries are also more common after a night on-call (Ayas *et al.*, 2006). By their final year in training, 99% of surgical residents in a survey in the United States had suffered a needlestick injury, and in over half, the injury had involved a high-risk patient (Makary *et al.*, 2007). Other potential exposures include splashing of contaminated blood or bodily fluids onto mucous membranes (conjunctivae, oropharynx) or skin. Whilst intact skin is impermeable to HIV, HBV and HCV, transmission through this route has been reported in individuals with non-intact skin, for example those with chronic dermatitis or with cuts and abrasions.

In the United Kingdom, a surveillance system was established in 1996 for the reporting of significant occupational exposure incidents. The period 2002–2005 saw a 49% increase in such incidents. The greatest proportion of percutaneous exposures was to HCV. Numerically, the largest number of incidents involved nursing staff, but proportionately more injuries were suffered by doctors and dentists. Between 1997 and 2005, over a third

(607/1669) of all incidents were deemed to have been preventable had there been proper adherence to universal precautions and safe disposal of clinical waste (Health Protection Agency, 2006).

Hepatitis B

Serological surveys conducted prior to the introduction of HBV vaccination clearly identified an increased prevalence of HBV markers in HCWs exposed to blood and bodily fluids, for example in the United States the overall risk to persons employed in health-related fields was four times that of the general adult population, with even higher risks in physicians and dentists (5–10-fold), and surgeons and laboratory workers (greater than 10-fold) having frequent contact with blood samples (West, 1984). Similar conclusions can be drawn from surveillance of acute hepatitis B infections in the United Kingdom. Whilst the average annual rate of infection in men in the whole population between 1980 and 1984 was 6 per 100 000, this rose to up to 37 per 100 000 for HCWs (Polakoff, 1986). Again, surgeons and laboratory workers were the subgroups with the highest rates of infection.

The risk of HBV transmission after accidental inoculation of infected blood is 19–31% from HBeAg-positive source patients, compared to 1–6% for HBeAg-negative sources (Grady *et al.*, 1978; Masuko *et al.*, 1985; Seeff *et al.*, 1978; Werner and Grady, 1982). Data to allow estimations of the risk of HBV transmission after other types of exposure are not available, but there must also be at least a theoretical risk of transmission by exposure of mucous membranes to blood splashes. There are no reports of transmission of HBV via blood contact with intact skin. Hepatitis B transmission has been reported following human bites (Cancio-Bello *et al.*, 1982; Hamilton *et al.*, 1976; MacQuarrie *et al.*, 1974), presumably related to inoculation of the biter's blood-stained saliva. This sort of exposure may be experienced by workers with mentally-disturbed or subnormal patients, or by police and prison officers.

Hepatitis C

In contrast to HBV, serosurveys for evidence of HCV infection conducted in a variety of different countries and health-care settings do not consistently show strikingly higher rates of infection amongst HCWs compared to the general population (reviewed in Irving and Harling, 2005). However, there are well-documented examples of acquisition of HCV infection by HCWs through needlestick injury, some of which have been confirmed by molecular evolutionary analysis, and transmission by a blood splash into the conjunctiva has been reported (Sartori

et al., 1993). There are no reports of transmission of HCV via blood contact with intact skin.

An extensive review of published data described 39 acquisitions of HCV infection by HCWs from 2506 needlestick exposures, a rate of 1.6% (Henderson, 2003). The Centers for Disease Control (CDC) guidelines in the United States quote a similar figure of 1.8% (Centers for Disease Control, 2001).

The UK surveillance scheme referred to above has identified 11 HCWs who acquired HCV infection following a needlestick injury. At least five of these exposures occurred through noncompliance with appropriate policies for infection control and disposal of sharps. The first nine of these HCWs are known to have cleared infection, either spontaneously or following therapy.

Human Immunodeficiency Virus

The risk of HIV transmission after a percutaneous exposure to known HIV-infected blood, in the absence of post-exposure prophylaxis, is of the order of 0.3%. Mucocutaneous exposure carries a risk of around 0.09% (95% confidence interval, 0.006–0.5) (Centers for Disease Control, 1991). Table 2.3 shows data relating to factors influencing the risk of needlestick transmission, derived by the CDC from a large retrospective survey (Cardo *et al.*, 1997).

Table 2.4 shows the number of documented and possible transmissions of HIV from patient-to-HCW reported in the world literature to December 2002 (HPA, 2005). These data are derived from countries with established surveillance systems, and therefore there may be significant under-reporting from South East Asia, the Indian subcontinent and Africa. 96/106 documented cases arose as a result of percutaneous exposure. Nurses and clinical laboratory workers account for 69% of documented cases, whilst 13% are doctors (including medical students). Only one case was in a surgeon.

Table 2.3 CDC case-control study of HIV seroconversion in HCWs after percutaneous exposure. Data sourced from Cardo *et al.*, NEJM 1997; 337; 1485–90

Risk depended on	Odds ratio	95% CI
Deep injury	15	6.0–41
Injury with device visibly contaminated with blood	6.2	2.2–21
Needle from vein or artery	4.3	1.7–12
Source patient died within two months	5.6	2.0–16
PEP (zidovudine)	0.19	0.06–0.52

Table 2.4 Documented and possible occupational acquisition of HIV infection

	USA	Europe (UK)	Rest of world	Total	
Documented seroconversion	57	35	(5)	14	106
Possible occupationally-acquired infections	139	85	(14)	14	238

Prevention of BBV Transmission from Patient to HCW

Pre-exposure

The importance of adhering to strict infection-control policies has been referred to above. All HCWs, including students, should be educated about the potential for and the risks of occupational exposure to infectious patient-derived material, and fully trained in the general principles of infection control. They should be aware of institutional protocols and policies for the management of needlestick or other exposure incidents, including the recommended initial first-aid measures to be taken, and to whom any such incidents should be reported for urgent advice and management, both within and outside normal working hours.

There are no prophylactic vaccines available to protect individuals against either HIV or HCV infection. In contrast, there are highly effective vaccines for the prevention of HBV. It is World Health Organization and European Union policy that HBV vaccines should be adopted as universal vaccines of childhood. The United Kingdom is in a decreasing minority of countries which maintain instead a selective vaccination policy, aiming to target vaccine to those subgroups of the population that are identifiably at increased risk of acquisition of HBV infection. The UK Department of Health vaccination guidance (Department of Health, 2006) lists a large number of such subgroups, one of which covers HCWs including students and trainees.

It is important that HBV-vaccinated HCWs should have their anti-HBs response checked, in a sample taken 6–10 weeks after the last dose. About 10% of adults do not mount any anti-HBs response to current vaccines and are therefore not protected against infection. Such individuals can nevertheless be protected against needlestick acquisition of infection by passive immunization with hepatitis B immunoglobulin (HBIg). Definitions of a protective response to vaccination vary—official US guidelines specify >10 IU/L (Centers for Disease Control, 1991). UK guidelines are more conservative, stating that it is preferable to achieve >100 IU/L. HCWs with a sub-optimal response

of 10–100 IU/L should be given a further dose of vaccine (Department of Health, 2006). There is some controversy regarding the need for booster doses of vaccine to maintain protective immunity over long periods of time, as immune memory will persist despite decline of anti-HBs levels below detectable levels (European Consensus Group on Hepatitis B Immunity, 2000). The UK recommendation is for a single booster dose five years after the initial course.

Post-exposure

Risk assessment It is incumbent on any HCW who suffers an exposure to a patient's blood (or blood-stained bodily fluids) to report the incident promptly so that appropriate action may be taken on their behalf. This in turn means that every health-care institution needs to have definitive protocols and easily-identifiable lines of responsibility for the management of such incidents.

The first step in managing an exposure incident is to perform a risk assessment, taking into account a number of relevant factors (Table 2.5). For ALL exposure incidents, it should then be a universal policy to approach the source patient and ask for a blood sample on which to test for markers of HBV, HCV and HIV infection. This normalizes the process, so that individual patients do not feel discriminated against. The approach should be made by a member of the team responsible for the care of the source patient, but NOT the recipient of the exposure incident. It is helpful if there are guidelines available which can help HCWs not familiar with seeking permission for BBV testing to explain to the source patient the reasons for and benefits of being tested. It is unusual for patients to refuse permission for testing if approached in an appropriate manner.

The individual responsible for the post-exposure management of the incident must decide initially on the basis of the risk assessment whether or not any further action should be recommended, and if so, what. This decision may later be reviewed in the light of the results of testing the source patient for evidence of BBV infection.

Table 2.5 Post-exposure risk assessment

Source patient
BBV infection status (including drug therapy)
If status unknown, risk factors for acquisition of BBV infection
The incident
Type of exposure (e.g. percutaneous, mucosal, skin)
Type of needle (blunt or hollow-bore)
Source of needle (intramuscular, parenteral, etc.)
The recipient
Degree of injury
BBV infection status (including HBV vaccination)

All HCWs who report a BBV exposure incident should be appropriately followed up and tested for evidence of infection. In the United Kingdom, only 20% of HCWs reporting an exposure to HCV received the recommended follow-up testing—the biggest default being the absence of anti-HCV and HCV RNA tests taken at six months post-exposure (Health Protection Agency, 2006). It is conceivable that some of those HCWs did indeed acquire HCV infection, and by not being tested, were denied the opportunity of curative early therapy.

Hepatitis B Virus Table 2.6 shows the UK algorithm for management of an HBV-exposed HCW (PHLS Hepatitis Subcommittee, 1992), taking into account the nature of the exposure and the HBV status of both donor and recipient. A significant exposure is defined as one which is percutaneous (needlestick or sharps injury, bite), mucocutaneous (non-intact skin, conjunctiva or mucous membrane) if involving blood, or sexual. The actions to be taken vary from nothing through to administration of HBV vaccine and HBIG. HCWs should be tested for HBV markers at six months after exposure.

Hepatitis C Virus There is no vaccine for either pre- or post-exposure active immunization, nor any preparation approved for passive immunization. Management is therefore based on the observation that treatment of patients with recently-acquired HCV infection is highly successful in achieving sustained virological responses (SVRs) (Jaeckel *et al.*, 2001). At-risk recipients should be tested at 6 weeks for HCV RNA, and 12 and 24 weeks for both anti-HCV and HCV RNA. Early therapy should be considered if there is any evidence of acquisition of infection. For genotype 1 infection, treatment with pegylated interferon alone, for a minimum of six months, should begin as soon as possible, as delay of onset of therapy significantly reduces SVR rates. For genotype 2 or 3 infection, delay of therapy up to 20 weeks does not impact on SVR rates, so it may be sensible initially to see if spontaneous clearance occurs. Treatment of these genotypes may require only 12 weeks of therapy (Kamal *et al.*, 2006a, 2006b).

Human Immunodeficiency Virus The mainstay of management of an HIV-exposure incident is post-

Table 2.6 HBV post-exposure prophylaxis for reported exposure incidents

	Significant exposure			Non-significant exposure		
HBV status of person exposed	HBsAg positive source	Unknown source	HBsAg negative source	Continued risk	No further risk	
≤ 1 dose HB vaccine pre-exposure	Accelerated course of HB vaccine* HBIG × 1	Accelerated course of HB vaccine*	Initiate course of HB vaccine	Initiate course of HB vaccine	No HBV prophylaxis. Reassure	
≥ 2 doses HB vaccine pre-exposure (anti-HBs not known)	One dose of HB vaccine followed by second dose one month later	One dose of HB vaccine	Finish course of HB vaccine	Finish course of HB vaccine	No HBV prophylaxis. Reassure	
Known responder to HB vaccine (anti-HBs > 10mIU/ml)	Consider booster dose of HB vaccine	Consider booster dose of HB vaccine	Consider booster dose of HB vaccine	Consider booster dose of HB vaccine	No HBV prophylaxis. Reassure	
Known non-responder to HB vaccine (anti-HBs < 10mIU/ml 2–4 months post-immunisation)	HBIG × 1 Consider booster dose of HB vaccine A second dose of HBIG should be given at one month	HBIG × 1 Consider booster dose of HB vaccine A second dose of HBIG should be given at one month	No HBIG Consider booster dose of HB vaccine	No HBIG Consider booster dose of HB vaccine	No prophylaxis. Reassure	

*An accelerated course of vaccine consists of doses spaced at zero, one and two months. A booster dose may be given at 12 months to those at continuing risk of exposure to HBV. Source: PHLS Hepatitis Subcommittee (1992).

exposure prophylaxis. This strategy is supported by data from animal models, and also indirectly by the CDC retrospective case-control study of needlestick injuries, which demonstrated an 81% reduction (95% confidence interval (CI) 43–94) in risk in those HCWs given post-exposure prophylaxis (PEP) (at that time, consisting solely of zidovudine monotherapy); see Table 2.3 (Cardo *et al.*, 1997). However, there are no data from a randomized control trial to prove this contention, and nor will there ever be. The protective effect of PEP is less than 100%; at least 24 HCWs have acquired HIV infection following occupational exposure despite appropriate administration of PEP (HPA, 2005).

The taking of PEP is not without risk to the HCW; serious events are rare but can be life-threatening. In particular, nevirapine is not recommended, following reports of serious adverse events, including twelve cases of hepatotoxicity, one of which required liver transplantation. Thus, PEP should only be recommended to HCWs if, after full risk assessment, they have had a significant occupational exposure to blood or other high-risk fluid from a known, or high-risk, HIV-infected source. PEP should be started as soon as possible after an incident, and therefore an emergency supply pack must be available within all health-care settings for out-of-hours access. Source testing of the latter should enable a specific decision to be made as to the need to continue PEP. A particular concern regarding emergency access to PEP relates to medical students going to high HIV-prevalence areas for their elective studies. Most but not all medical schools in the United Kingdom recommend students to take a PEP starter pack with them, which will give them time to seek expert advice and follow-up should an exposure incident occur (Tilzey and Banatvala, 2002).

Current recommendations for PEP in the United Kingdom (Department of Health, 2008) are shown in Table 2.7 (these may be modified in individual circumstances, for example if the source patient is known to have drug-resistant virus). It is to be taken for four weeks, initiated as soon as possible after the exposure, and preferably within one hour (Department of Health, 2004). No antiretroviral drugs are licensed for PEP—their use on an ‘off-label’ basis therefore requires written, informed consent from the HCW.

Table 2.7 UK recommended starter pack for HIV PEP

One Truvada tablet (300 mg tenofovir and 200 mg entricitabine) once a day plus Two Kaletra film-coated tablets (200 mg lopinavir + 50 mg ritonavir) b.d.
--

Table 2.8 Summary of patient-to-HCW transmission

Virus	Risk (%)	Pre-exposure	Post-exposure
HBV	19–31	Vaccination	HBIg, vaccination
HCV	1–3	None	Monitor and early therapy
HIV	0.3	None	PEP

All drugs used for PEP have side effects, and HCWs will require support and counselling in order to comply with the full four-week regimen. In the United Kingdom surveillance of occupational exposure scheme, 77% (233/303) of HCWs exposed to an HIV-positive source patient began HIV PEP, 34% within an hour of exposure and 89% within 24 hours. Earlier data from the same scheme showed that where the source was subsequently shown not to be HIV infected, 71/173 HCWs had taken PEP for more than one day, and 17 for more than one week, indicating an unnecessary exposure to potentially toxic drugs with unpleasant side effects, arising from delays in source patient HIV testing (Health Protection Agency, 2006).

Reassurance of the absence of HIV transmission can only be provided once an exposed HCW has been shown to be anti-HIV negative at least six months after cessation of PEP.

Risks and strategies for prevention of patient-to-HCW transmission of BBV are summarized in Table 2.8.

HCW-TO-PATIENT TRANSMISSION

The risks of and policies governing possible HCW-to-patient transmission vary significantly depending on which virus is being considered. However, all prevention policies are based on the concept of ‘exposure-prone procedures’ (EPPs), a term coined in 1991 by the CDC to describe procedures where there is a risk of percutaneous injury to the HCW, and where, if such an injury does occur, the worker’s blood may contact the patient’s tissues or mucous membranes (Centers for Disease Control, 1991). This is more likely when manipulation of needles or other sharp instruments in a body cavity without clear vision or in a restricted space is necessary.

Hepatitis B

Transmission of HBV from Infected Health-care Workers

There are over 45 reports of HCW-to-patient transmission of HBV in the literature, with over 400 infected patients and transmission rates of 6–15% (Mele *et al.*, 2001). In

the United Kingdom, between 1975 and 1990 there were 12 outbreaks of HBV infection associated with infected HCWs, with 91 infections identified (reviewed in Hep-tonstall, 1991). In 11/12 instances, the HCW was HBeAg positive (the status of the 12th was unknown). In five outbreaks where tracing and testing of exposed patients was performed (i.e. lookback), acute icteric HBV infection occurred in 1–2% of patients, with an overall transmission rate (including asymptomatic cases) of 4–9%. In a report of 20 such outbreaks in the United States involving over 300 infected patients, all 17 surgeons who were tested were HBeAg positive (Centers for Disease Control, 1991).

Prevention of Transmission of HBV from Health-care Workers

Guidelines for the prevention of HCW-to-patient transmission of HBV were first introduced in the United Kingdom in 1981. There have been a number of revisions since, each being more restrictive than the last. Guidelines released in 1993 resulted in the banning of HBeAg-positive HBV-carrier HCWs from performing EPPs, a decision based on the extensive evidence available at that time that HBV-transmitting HCWs were all HBeAg positive (where testing had been performed).

Subsequently, there have been 9 HCWs who have transmitted infection to at least 15 patients, 3 of whom died of fulminant HBV infection (reviewed in Irving and Harling, 2005). All anti-HBe positive surgeons harboured pre-core mutants and had high levels of HBV DNA (Incident Investigation Team and Others, 1997). Further restrictions on HBsAg-positive HCWs were therefore introduced in 2000 (Health Service Circular, 2000), specifying that HCWs without HBeAg should be further tested for HBV DNA. A cut-off value of 10^3 copies per ml was set; only HCWs with DNA levels below this level were allowed to continue to perform EPPs, subject to annual testing of their HBV DNA levels. The HBV DNA assays are performed in only two designated laboratories. Two samples from each HCW are required, taken a few days apart.

There are controversial aspects to this policy. The cut-off value was set bearing in mind known HBV DNA levels in anti-HBe-positive HCWs who transmitted infection (Corden *et al.*, 2003), possible variations in viral load within individuals (Tedder *et al.*, 2002) and assay performance characteristics, but is, nevertheless, arbitrary. Other countries have adopted a higher value, for example the Netherlands: $>10^5$ copies per ml (Gunson *et al.*, 2003). With the advent of drugs which can effectively suppress HBV replication, it is possible that an HCW whose HBV DNA level is above the cut-off may wish to take such medication purely for the purposes of allowing them to continue their chosen career. In recognition of this, guidance was released in 2007 which sanctions this course of

action, limited to those HCWs with initial viral loads of 10^3 – 10^5 copies per ml, and subject to stringent controls, including HBV DNA viral load assays every three months (Department of Health, 2007b).

Policies which allow known HBV-infected HCWs to continue to perform EPPs should emphasize that any needlestick or sharps injury to the HCW received whilst performing an EPP must be reported appropriately, regardless of the HCW's HBV DNA level. The transmission risk to the patient is not simply dependent on the HBV DNA load of the HCW—other factors, such as the amount of blood to which the patient is exposed, are important. A risk assessment must therefore be performed to determine whether or not to offer post-exposure prophylaxis (HBIG and/or HBV vaccine) to the patient.

It should be noted that HBsAg-positive individuals may harbour low levels of anti-HBs (Shiels *et al.*, 1987; Tsang *et al.*, 1986). Thus, for HCWs who will perform EPPs, it is preferable to test for HBsAg before vaccination. Otherwise it is possible that HCWs tested post-vaccination and found to be anti-HBs positive will erroneously be allowed to perform EPPs. This has happened in the United Kingdom—one of the nine surgeons to have transmitted since 1993 achieved an anti-HBs level of 252 IU/L after nine doses of vaccine, and ultimately transmitted infection to three patients, one of whom died.

Hepatitis C Virus

Transmission of HCV from Infected Health-care Workers

Several HCW-to-patient transmissions of HCV have been reported (reviewed in Irving and Harling, 2005). In the United Kingdom, at least seven surgeons have transmitted HCV infection to patients. Taking all reports together, the transmission rate per patient operated on by an HCV-infected surgeon is around 1 in 400, or 0.25%.

In addition, there are a number of transmissions associated with anaesthetists. Numerically, these far outweigh the surgeon-to-patient transmissions. Most have arisen through a small number of anaesthetists who have contaminated vials of narcotics intended for patient use with their own blood in the process of illicitly 'sharing' the dose with the patient, although some have undoubtedly been through non-adherence to good infection-control practice, such as the re-use of multi-dose vials.

The magnitude of risk of transmission from infected workers has been estimated in the United Kingdom (Department of Health, 2002b), on the basis that 1 in 200 surgeons currently practising in the United Kingdom is infected with HCV (i.e. the same prevalence as in the general population), and that an infected surgeon transmits infection in 1 in 400 operations. The chances of an

individual patient acquiring infection from a surgeon of unknown status is then 1 in 80 000. Thus, if half a million exposure-prone procedures are performed annually, somewhere between 5 and 10 patients per year will acquire HCV infection through this route.

Prevention of Transmission of HCV from Health-care Workers

Guidelines have been introduced to try to reduce the incidence of HCW-to-patient transmission of HCV (Department of Health, 2002c). Again, there are elements of controversy in these, as they represent a compromise between two extreme strategies—on the one hand, take no action; on the other, screen all HCWs performing EPPs and ban any who are HCV RNA-positive. HCWs who are known to be infected with HCV are banned from performing EPPs. There is no recommendation for blanket screening of all HCWs performing EPPs, although any HCW with reason to suspect they might be infected by way of having a risk factor for infection is encouraged to be tested. However, screening is introduced for all HCWs entering training in a specialty which requires them to perform EPPs. The aim of this is to block the recruitment of HCV-infected individuals into the pool of HCWs who perform EPPs, at a stage in their career when it is reasonable for them to make an informed career choice. Implicit in this policy is the realization that a small number of patients (5–10 per year) will acquire HCV infection from infected HCWs.

A later refinement of the above guidance appeared in 2007, extending the testing of HCWs for HCV infection to ‘new HCWs’ (Department of Health, 2007a). ‘New HCWs’ encompasses those ‘moving into training or posts involving EPPs for the first time’ and those ‘returning to work in the NHS (National Health Service) . . . who may have been exposed to serious communicable diseases while away’. Examples of the latter include those ‘returning from research experience, electives, voluntary service with medical charities, sabbaticals, exchanges, locum and agency work or periods of unemployment spent outside the UK’.

Human Immunodeficiency Virus

Transmission of HIV from Infected Health-care Workers

HCW-to-patient transmission of HIV is exceedingly rare. The first documented cases arose from an HIV-infected dentist in Florida, USA, six of whose patients acquired infection. Despite intensive investigation, the precise route(s) of these transmissions has never been determined (Ciesielski *et al.*, 1994). One French orthopaedic surgeon,

who himself is believed to have acquired HIV infection from a needlestick exposure in 1983, is thought to have transmitted infection to a patient in 1992 (Lot *et al.*, 1999). A Spanish gynaecologist transmitted infection to one patient undergoing Caesarian section (Bosch, 2003). Evidence for HCW-to-patient transmission in both of the latter incidents included detailed molecular epidemiological studies.

Lookback studies performed on patients operated on by surgeons subsequently discovered to have HIV infection confirm the scarcity of transmission events. Lookbacks from at least 44 infected HCWs in the United States and 22 in the United Kingdom, covering 22 759 and 7000 patients respectively, have failed to identify a single additional transmission (Gerberding, 1999).

Prevention of Transmission of HIV from Health-care Workers

Despite the above data indicating that the risk of transmission from a known HIV-infected HCW is extremely low, the guidelines governing this situation are the most draconian of those for any BBV. Known HIV-infected HCWs are not allowed to perform EPPs (Department of Health, 2005). This is irrespective of the disease status, viral load or antiretroviral status of the individual HCW concerned.

Up until 2007 there was no compunction for UK HCWs who performed EPPs, or who were training in specialties involving EPPs, to be tested for HIV infection. However, guidance introduced in March 2007 stipulates that ‘new HCWs’ (explained above) who will perform EPPs should be screened for HIV infection (Department of Health, 2007a). This guidance has, not unexpectedly, attracted controversy, given that it introduces compulsory HIV testing for the first time for certain categories of HCW.

Viral Transmission: Infection Acquired by All Other Routes (Respiratory, Eye–Nose–Mouth, Inoculation and Faeco-orally)

Philip Rice

Department of Virology, St. George's Hospital Medical School, London, UK

INTRODUCTION

This chapter will cover the important clinico-pathological aspects of all the major groups of human viruses, including relevant epidemiological characteristics, with the aim of providing the practical knowledge to enable microbiologists and virologists to prevent and contain the spread of virus infections in hospital. The entire subject of nosocomial virus infection has not had the prominence it deserves. It has been neglected in part because of the preference to measure nosocomial bacterial infection. This is somewhat surprising since bacteria, perhaps with the exception of *Legionella*, do not have the capacity to close wards and entire hospitals that certain viruses have, norovirus and varicella zoster being just two examples. Indeed, an analysis of the literature that exists regarding ward closure (Outbreak database, www.outbreak-database.com) performed in 2005 showed starkly that of the six virus types in the database, four (noroviruses, rotavirus, hepatitis viruses, influenza/parainfluenza virus; 67%) were significantly associated with ward closure. This compares with only 3/14 (*Acinetobacter* and *Streptococci*; 22%) bacterial genera (Hansen *et al.*, 2007). This is due largely to the fact that viruses may be spread quickly among patients and staff by aerosol and droplet routes in addition to direct contamination by unwashed hands, which

is the principal way nosocomial bacterial infections occur.

Hospitals may also act as centres of virus amplification for the further spread of virus in the wider community. This has been exemplified recently in the case of severe acute respiratory syndrome (SARS), and previously with Ebola virus outbreaks centred in hospitals in Africa, and appears to be happening again with measles. There is also an ever-increasing burden of extremely vulnerable patient groups, including pre-term neonates and those with immunodeficiency secondary to human immunodeficiency virus (HIV) or solid organ and bone-marrow transplants (BMTs). Global travel has also meant that the staff who work in health services come from all over the world. This brings with it other unique problems, such as increased susceptibility rates to chickenpox if staff are from equatorial climes.

The prevention of nosocomial virus infections requires a team effort. Very often virology is able only to prevent secondary cases where the incubation period is relatively long, for example 10–14 days for measles, chickenpox and so on. Preventing the nosocomial spread of viral respiratory and gastrointestinal pathogens with very short incubation periods of sometimes only hours to a few days, however, relies heavily on the staff admitting the patient recognizing the potential for transmission and adhering strictly to basic infection-control measures

such as hand washing. The admission to single rooms of patients experiencing viral prodromal illness of, for example, parvovirus or measles during epidemic seasons or local upsurges, along with cohort nursing, is very effective but requires thought from admitting teams. To facilitate this approach, clear, concise guidance from the virology, infection-control and occupational health departments on how to manage individual virus infections and staff exposures to them is required. In other ways, however, the prevention of hospital-acquired virus infection should be considerably easier than it is for the vast majority of multiply-resistant bacteria, because of the success of many viral vaccines. For these preventative measures to work and with regard to vaccine-preventable disease, for example measles, mumps, varicella and influenza, which may easily establish a hospital-based outbreak, it is essential that a robust method for identifying and vaccinating susceptible staff is in place and functioning, as shown by regular audit of the uptake of vaccination within the hospital and across a country. Such information must be prospectively gathered prior to an outbreak in order to prevent transmission of vaccine-preventable infections. Given that it is not acceptable for any patient to acquire such a nosocomial virus infection, it is incumbent on the management teams of hospitals to give strong consideration to making certain immunizations mandatory prior to acceptance of any future student or employee unless there are genuine contraindications to its use in that individual.

Control of virus infections in hospitals must be a proactive process. Although rapid diagnosis and excellent communication with staff in the clinical areas are essential if nosocomial infection is to be prevented, anticipating recurring problems, for example the annual norovirus and respiratory syncytial virus (RSV) winter epidemics, by informing staff through continuous education programmes and proactively if local outbreaks are occurring, is of additional benefit.

We will illustrate the problems and some of the solutions to controlling viruses spread by all routes and means of contact other than blood. Practical measures that should be taken to prevent or control an outbreak including data on virus survival, the activities of different disinfecting agents and additional epidemiological information is provided in Tables 3.1, 3.2 and 3.3 respectively. Guidance on the management of staff susceptible to particular agents will also be given.

MEASLES, MUMPS AND RUBELLA

Measles

The risk for measles infection in medical personnel is estimated to be 13-fold higher than that in the general

population (Atkinson *et al.*, 1991; Davis *et al.*, 1986). Approximately 5–10% of all notified cases of measles are reported to have been acquired in a medical setting and over 33% of cases acquired in hospitals are in health-care workers (HCWs), mostly (>85%) previously unvaccinated (reviewed in Centers for Disease Control and Prevention, 1997; Farizo *et al.*, 1991).

In African countries it is a much more serious issue, as shown in 1989 by Cotton, who examined paediatric patients admitted for their risk of acquiring a nosocomial infection (Cotton *et al.*, 1989). Overall, 193/1350 (14.3%) children admitted to hospital developed a nosocomial infection; of these 28/193 (14.5%) were measles, resulting in seven deaths. Moreover, because already-hospitalized patients have by definition an illness, the mortality rate in nosocomial measles may be considerably higher (50% vs 2%) when compared with community acquisitions (Reynolds and Klein, 1987). Such nosocomial outbreaks are also a threat to the eventual elimination of measles, as hospitals act as amplifiers of infection (Marshall *et al.*, 2003).

Measles virus infection is now a particular problem, partly because of the success of MMR vaccination. Whilst this has dramatically reduced the incidence of infection in the community, the clinical skills required to diagnose measles have also waned. Moreover, as the population of immunosuppressed patients has continued to grow (organ/bone-marrow transplantation, intensive care and HIV), atypical presentations are more likely to occur and the diagnosis is more likely to be missed (Kidd *et al.*, 2003). Thus, as measles virus has a reproduction rate of 14 : 1, it can easily re-emerge in developed countries, due largely to importation of measles from countries with less well-developed measles vaccination programmes (Ramsay *et al.*, 2003). This becomes even more of a problem if the MMR uptake rate falls, as indigenous ongoing transmission will then occur (Thomas *et al.*, 1998).

There are two ways of containing measles virus infection within hospitals. Firstly, it is essential that all staff involved in the care of patients and ideally all staff in a hospital are aware of their measles immune/vaccine status and have taken appropriate steps to ensure that they do not pose a risk to others. Secondly, one must have guidelines for clinically suspected measles. A useful acronym already in use in the United Kingdom, which currently stands for Consultant in Communicable Disease Control (CCDC), may also be used to assist in measles diagnosis by substituting the following words: ‘a febrile patient with two of the following: Cough, Coryza, Diarrhoea and Conjunctivitis’. When after a few days this is accompanied by a rash, the diagnosis is virtually certain, and in the context of a community-wide outbreak or an epidemiological link with other cases, 100% accurate. Sometimes a history of travel abroad or contact with

recently-returned travellers also increases the likelihood of the diagnosis, as does having had no or only one dose of MMR. Other clues to the diagnosis are lymphopenia $<0.8 \times 10^9 \text{ l}^{-1}$, slight thrombocytopenia $<150 \times 10^9 \text{ l}^{-1}$ and biochemical hepatitis (ALT 3–5 \times normal). Patients should be admitted to a single room and be cared for only by staff who know their measles immunity status. A strict gloves, aprons and hand-washing policy must be adhered to if further infection in staff or patients is to be avoided. Rapid diagnosis may be by serum IgM (often positive), serum IgG (often negative) or by monoclonal antibody fluorescence on a urine sample. If real-time polymerase chain reaction (PCR) is available, this may be applied to an oral fluid sample or to urine.

Transmission is by droplet infection, though fortunately the degree of infectivity reduces quickly after the rash appears and lasts for only a few days (4) afterwards. The incubation period may be as short as 7 days, but more typically 10–13 days. However, because it may be as long as 18 days, susceptible staff are excluded from work for 5–21 days after contact.

Problems continue to arise in the United Kingdom as it has only just introduced a formal policy of establishing measles immunity for all new staff (Salisbury *et al.*, 2006). The recommendations are that an individual should have either detectable measles IgG or have received two doses of a measles-containing vaccine after their first birthday. However, these guidelines have been in place in the United States for some time, and despite high levels of vaccine coverage across the US, in 2005 it experienced the largest documented outbreak of measles since 1996, from a single individual who had acquired infection overseas (Parker *et al.*, 2006). As a result of this community-wide outbreak, almost exclusively in unvaccinated individuals, a hospital employee (a phlebotomist) contracted measles. Due to the extensive movements of that member of staff the hospital had to administer 210 doses of immunoglobulin in addition to 317 doses of MMR vaccine; the total accrued costs were \$113 647, spent in efforts to prevent further infection and severe disease. The staff member had only received one dose of measles vaccine after her first birthday and had never had her antibody tested.

It used to be acceptable that a cut-off year of 1957 was used as a proxy for immunity to measles, as people born before this year are very likely to have had measles infection as a child. However, as the susceptibility rate in this age group is still 5%, individuals in this group who cannot provide evidence for physician-diagnosed measles must undergo antibody testing and, if susceptible, given two doses of MMR (Braunstein *et al.*, 1990; Schwarcz *et al.*, 1992; Uckay *et al.*, 2007).

Even pre-exposure vaccination is not always successful, however, as shown in the Netherlands, where there was

measles transmission to susceptible hospital staff where the level of immunity in health-care workers was 98.5% (de Swart *et al.*, 2000). Nevertheless it must be remembered that vaccination is not only highly efficacious, as shown by two primary school outbreaks where the attack rate in unimmunized children ranged from 26 to 46% yet was only 0.4% in children who had had MMR (Richardson and Quigley, 1994), but is also our only defence against infection as measles is untreatable.

It is a responsibility of hospital facilities to ensure that their staff have made all practicable efforts to eliminate the risk of measles transmission to patients. This is because given recent reductions and continued low uptake rates of MMR, we may be creating a cohort of children, at least in the United Kingdom, which will become large enough to not only sustain local virus transmission, but also be a source for susceptible infants who have yet to receive MMR. This is because most mothers now have vaccine-induced immunity and there is a lack of circulating virus to create natural boosters, so it is much more likely that measles antibody will have disappeared in infants by nine months. Infection under a year of life presents a much greater risk of developing SSPE later in life. The absence of natural boosting may also increase the rate of breakthrough infection in adults who have received only one dose of the original measles vaccine in the 1970s–1980s. Indeed, I have seen a case of breakthrough infection recently in an adult aged 45 years who transmitted virus to his son, who was only old enough to have received one dose of MMR.

To contain measles in a hospital the only effective measure is to isolate the patient, but the focus should be on maintaining high uptake rates of primary immunization. Even post-exposure vaccination is of dubious merit. When administered in an epidemic setting the efficacy can be as low as 4% (King *et al.*, 1991). Our experience has been very similar when attempting to prevent an outbreak in infants at a nursery. The same day the case was notified, which was the day of the rash in the index case, five of the six contacts (all aged less than two years and previously unimmunized with MMR) were vaccinated. Ten to fourteen days later all six children developed clinical measles, confirmed by detection of wild-type virus in one of the vaccinees (Rice *et al.*, 2004). Thus it is essential to achieve the highest possible level of staff immunity before an outbreak.

Failure to do so will eventually result in ward closure and death in unimmunized immunocompromised patients (Kidd *et al.*, 2003).

Mumps

Mumps virus infection in the post-vaccine era has until recently not been a problem for most developed countries,

due to the success of MMR immunization programmes. During 2006 in the United States and 2004–2005 in the United Kingdom, extensive community outbreaks of mumps were seen in age-limited cohorts (Dayan *et al.*, 2008; Gupta *et al.*, 2005; Savage *et al.*, 2005). In the pre-vaccine era mumps was an almost universal infection acquired by the end of secondary schooling (16 years). Since the 1970s in the United States and 1988 in the United Kingdom, mumps vaccine has been in widespread use in the childhood vaccination programmes. Dramatic reductions in mumps incidence were seen following vaccination, and these reductions have been maintained for 15 years in the United Kingdom and almost 30 years in the United States.

The United Kingdom has had a particular problem in recent years with individuals born between 1982 and 1990, who are likely to have received at best only one dose of MMR. As the efficacy of single-dose MMR is estimated at 80%, this is not sufficient to contain transmission in closed communities. However, the United States has had about 90% vaccine coverage with two doses. The US outbreak was again age-limited (18–24 years) and geographically localized to the Midwestern states, but there it was thought that multiple factors played a role in generating and sustaining it. These were waning immunity, high population density and contact rates in colleges, and incomplete herd immunity despite the extensive two-dose vaccine coverage. Such herd immunity is estimated to be 88–92%; so individual vaccine efficacy of about 80%, even with exceptional coverage rates of 95% for both doses, will only achieve herd immunity of about 90%. This is only at the limit to prevent widespread epidemics (Dayan *et al.*, 2008).

Whilst these factors might explain outbreaks in closed communities they do not explain why there is a lack of described outbreaks in hospitals. Two factors are likely to play a role. Mumps infection is relatively frequently asymptomatic and as such these patients will not present to health-care services. Secondly, health-care workers aged 30 years or older will very likely be immune from natural childhood infection in the pre-vaccine era. Mumps outbreaks in closed communities including hospitals have been described, especially when there are many opportunities for close contact (Wharton *et al.*, 1990). One such outbreak occurred at trading floors in Chicago in 1987, with over 100 cases (Kaplan *et al.*, 1988). The reason for an increase in cases in young adults is because of the success of MMR vaccination. This has led to fewer exposures for a cohort of young adults who were ineligible for immunization and so have escaped natural infection.

Controlling mumps virus in hospitals is still necessary because of the risk of meningitis and subsequent sensorineural deafness. A high index of clinical suspicion,

hand washing and admission to a single room with droplet precautions remain the main ways that transmission is prevented in hospitals. For staff, it is necessary to test those exposed for mumps IgG and to immunize seronegative individuals. As mumps virus excretion in saliva commences five to six days prior to symptom onset and MMR vaccine or normal immune globulin given post-exposure is entirely ineffective in preventing secondary cases, it will be necessary to furlough from work staff requiring vaccination for a period of 10 days, starting 12 days after the first contact with a case (Aitken and Jeffries, 2001).

Rubella

Outbreaks of rubella in hospitals are now rare, due largely to effective staff and student antibody screening and immunization (Greaves *et al.*, 1982). As a history of rubella infection is not reliable and voluntary immunization has been shown not to prevent outbreaks it is now accepted by staff that they have to be rubella-immune before being allowed to work in high-risk areas, namely obstetrics (Heseltine *et al.*, 1985). The susceptibility rates in staff in the 1970s and 1980s varied from 5 to 18% depending on age (Polk *et al.*, 1980). Thus, with such high rates it was possible for rubella virus to circulate in hospitals. Staff susceptibility rates are now much lower, such that if transmission to a member of staff does occur it is just as likely that this merely reflects a larger community-wide outbreak. However, individuals born in developing countries without rubella vaccination programmes are at increased risk of infection in hospital if a health-care worker develops rubella. They can then pose a risk to those they live with at home. It is essential that staff from such countries are identified by screening procedures, as hospitals with a large number of such staff may become the amplifier of an outbreak that spreads back into the wider community. This has been shown recently in other types of workplace, where attack rates were almost 100-fold greater than the general population (Danovaro-Holliday *et al.*, 2000). In this particular outbreak, though not in a hospital, 6/24 (25%) pregnant women became infected. In health-care settings, of particular concern are women (patients and staff) from south Asia and Africa, where susceptibility rates may be almost 20% in those of childbearing age (Devi *et al.*, 2002; Miller *et al.*, 1990). Indeed, in the last three years I have seen three cases of rubella in the first sixteen weeks of pregnancy, all resulting in fetal loss, where the woman was from a country without well-organized childhood rubella vaccine programmes (Mauritius, Philippines and Russia) and had travelled back to her country of origin for family celebrations.

Furthermore, infants with congenital rubella syndrome (CRS) are a potential source of infection for susceptible staff and other infants due to the excretion of high-titre

virus in urine for prolonged periods of about two years (Aitken and Jeffries, 2001). Indeed, the first demonstration of a baby with CRS infecting another baby was shown in a London hospital, when a baby with CRS infected a baby in a neighbouring cot (Sheridan *et al.*, 2002). The only way that transmission could have taken place is by non-adherence to hand washing by staff after dealing with urine and other bodily fluids from the baby with CRS. The best way to prevent nosocomial rubella is to fully investigate staff members with rash illness, remembering that in the first three days after the rash has appeared they may be IgG and IgM negative. Once identified, colleagues in close daily contact should be tested for rubella IgG, with the focus on pregnant staff <18 weeks gestation. Although post-exposure rubella vaccination is ineffective in preventing infection, any nonpregnant susceptible staff should then be immunized and tested two to three months later for a response.

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is one of the easiest viruses to control in hospital yet probably causes more anxiety, especially among pregnant staff, than any other virus excluding HIV. The anxiety usually results from the identification of a baby or infant with congenital infection, often on the neonatal unit. As congenitally-infected babies excrete virus at high titre ($>10^6$ ml⁻¹), staff are, understandably, concerned at the risk these babies pose to pregnant members of staff or to other babies on such units. At this stage HCWs are sometimes offered CMV screening, by other staff or occasionally by occupational health departments, principally as a means of providing reassurance. However, such screening tests are offered in ignorance of the data concerning the risks of transmission to staff and are erroneously believed to be capable of determining if a person is 'immune' to CMV infection. Moreover, the potential implications and consequences of commencing CMV antibody testing in pregnant members of staff are never considered by those requesting the tests. Indeed, the first contact between a clinical virologist and the staff member is when the pregnant member of staff contacts them to discuss the results of their CMV serology and its significance. This is where the difficulties arise. As discussed in the chapter on CMV, the concept of CMV immunity, especially in relation to pregnancy, is incorrect as reactivation and re-infection may lead to congenital infection and occasionally disease in newborns.

Though the CMV serology may indicate past infection or susceptibility, occasionally CMV IgM is detected, which produces considerable anxiety. Further tests, such as IgG avidity, are then required, as well as a hunt for

earlier samples to try and determine, as accurately as possible, the timing of any CMV infection. Furthermore, when past infection is shown, the potential for re-infection or reactivation has then to be discussed.

If the member of staff is susceptible, the discussion widens to include the potential benefit and harm of follow-up testing, prenatal diagnosis and the possible outcomes for the baby if a primary infection is demonstrated.

It is obvious from this outline that screening of staff for CMV is a big undertaking and should only be done after a prolonged and informed discussion with the clinical virologist and an obstetrician. The advice that should be given to the staff member is that if they have been adhering to universal precautions and have washed their hands after dealing with patients, serological testing for CMV should not take place. This is because there are several well-conducted studies which all conclude that there is no evidence that CMV excreted by hospitalized patients poses a significant additional risk for pregnant staff (Balcarek *et al.*, 1990; Balfour and Balfour, 1986; Dworsky *et al.*, 1983).

The incidence of CMV infection in hospital staff is approximately 1–2% and there is no difference between various occupational groups within and the general population outside hospital. Balcarek *et al.* (1990) showed, for example, that there was no difference in the rate of infection in staff regardless of area of work, job type (nurse, doctor, support services, administrative staff) or number of patient contact hours of between 10 and 40 hours per week. Moreover, when the rates of CMV excretion by patients are known in different areas of the hospital, this has no effect on the rate of transmission to staff. Demmler *et al.* (1987) demonstrated this when rates of CMV excretion varied from 3% in newborns to 16% in a chronic care unit for children, many with severe neurological and physical handicap, a proportion of whom would have had congenital infection and be excreting high-titre virus in urine.

Further proof that patients are not the source of infection has come from studies that have examined virus strains detected in staff who are shown to seroconvert at work. In these cases either the strains of virus in staff and patient have been different or another source outside of hospital, often a sexual partner or child at home for example, has been shown to be shedding an identical virus (Demmler *et al.*, 1987; Onorato *et al.*, 1985). Such virus sequencing has also been used to disprove suspected nosocomial infection between babies, with staff as the likely vector of infection, on a neonatal unit (Stranska *et al.*, 2006).

The single study which did show an increased incidence of infection among staff demonstrated this only for student nurses on their first placement in paediatrics (Haneberg *et al.*, 1980). Such staff were reportedly

observed to kiss drooling infants while feeding them. Indeed, this paper highlights the fact, as stated by others, that intimate and prolonged contact is required for CMV transmission to occur (Onorato *et al.*, 1985). Hence the increased rate of infection seen in pregnant mothers with a young child at home or in staff employed in child day care, where the transmission rate may be 10–25% per annum (Adler, 1989).

CMV, being an enveloped virus, does not survive well on inanimate surfaces or on hands. This was shown clearly in a study in a paediatric hospital, where the virus was not isolated from any equipment, toys or hard surfaces, and although not isolated from the dry hands of staff members, was removed completely by hand washing with soap and water (Demmler *et al.*, 1987). Simple hygienic measures and washing of surfaces with household detergent are sufficient to remove infectious material from the environment.

It is certainly not advisable to routinely screen staff after a possible exposure occupationally to CMV as considerable anxiety is experienced whilst waiting for the results and there can be difficulties in interpreting them correctly. Indeed, where this was attempted in a hospital in the United Kingdom some years ago, it was a ‘disaster’ and led to ‘public relation, psychological and management problems’ (reviewed in Young *et al.*, 1983). Staff should be educated about how the virus is transmitted (sexually, kissing, lapses in hand washing especially after changing nappies) and about the many pitfalls of antibody testing. If a staff member has requested to be tested after an exposure, ideally the virologist should see them to discuss all of the issues relating to the possible outcomes. The issues to be discussed would be the fact that CMV infection is ubiquitous, staff are at no increased risk of infection, transmission is interrupted easily by hand washing and CMV serology can be fraught with difficulties if low- or even high-level IgM is detected.

VARICELLA ZOSTER VIRUS

Preventing patients and staff from contracting chickenpox in hospitals forms a significant part of the workload of a clinical virologist. Aside from the excess costs that nosocomial varicella zoster virus (VZV) infection imposes (estimated to be £5–10 million in the NHS of England and Wales annually), it causes significant disruption to wards, even occasionally entire hospitals, increases the workload of clinical virology laboratories at very short notice, and leads to considerable disruption when susceptible staff have to be excluded from work after exposure. Chickenpox can also occur at any age; I have witnessed primary infection in two 65-year-olds, a 78-year-old and a man of 92 years!

In recent years, however, and solely as a result of varicella vaccination in susceptible staff, the rate of hospital-acquired VZV has dramatically reduced. Nevertheless, it is still important to understand the peculiar problems that hospitals have hitherto faced with this virus, because the United Kingdom still has not embraced routine childhood vaccination and a 2004 survey of UK clinical virologists revealed a disappointingly low rate of implementation of just 14% of using the vaccine in susceptible staff (Breuer, 2005). Until this rate improves and/or VZV vaccine is made part of childhood immunization schedules, clinical virologists and microbiologists need to be knowledgeable in the peculiarities of VZV infection in hospitals.

When a patient or staff member with VZV infection is identified, all staff in contact must know their immune status. Indeed, knowledge of such status is part of routine occupational health screening. A well-taken history of previous chickenpox correlates very well with immunity (99%) and, even for those who are unsure if they have had chickenpox in the past or claim never to have had chickenpox, 60% will have evidence of past infection. However, a history may be less reliable in those born in countries where varicella is less common in childhood, essentially in the tropics, and some have advocated testing of all staff born in such countries. For reasons currently unknown, individuals born in hotter climates, particularly the Indian subcontinent, Africa and the Caribbean islands are much more likely to be susceptible. Indeed, of the VZV-susceptible staff employed at St George’s who developed chickenpox in the last three years, >50% were born in these countries (Devi and Rice, 2002).

It is thus important for staff to appreciate the problems that VZV transmission may cause and for susceptible staff to report any contact with virus. This is especially so for staff who have children, as approximately 50% of susceptible staff who develop chickenpox do so after a home exposure.

The VZV transmission rate to susceptible staff after contact has been estimated to be between 4.7 and 29% (Langley and Hanakowski, 2000; Myers *et al.*, 1982; Wreghitt *et al.*, 1996). As there are several factors that affect this rate and most are difficult to quantify, guidelines on the degree of exposure can be helpful in deciding to what extent exposure has occurred. Examples of significant exposures have been defined as a face-to-face contact for at least 15 minutes or being present in the same room for 1 hour with an individual with chickenpox or disseminated/uncovered zoster (Salisbury *et al.*, 2006). An intermediate risk occurs when exposure has taken place in a multi-room setting; that is, an area with beds separated by doors, partitions or curtains. In a prospective study by Langley and Hanakowski 2000, they found

that transmission risks of varicella for single-room and multi-room settings were 11.8% (4/34; 95% CI 3.3–27.5) and 0% (4/89; 95% CI 1.2–11.1) respectively.

At the other end of the exposure spectrum, however, the likelihood of transmission taking place from cases of covered zoster, for example thoraco-lumbar, is remote. Although airborne transmission on open wards has been described, the evidence for airborne spread of VZV is very limited, and complicated by the difficulty in reliably excluding droplet transmission.

Although chickenpox is much more infectious than zoster, most of the practical problems involved with control of infection arise from patients who have zoster. This is simply because chickenpox is much more easily recognizable and such patients are admitted immediately into a single room. Zoster, however, often develops in a patient who has been on the ward for several days or even weeks and the rash is often present for several days before the diagnosis is suspected. Thus, many more staff and patients are exposed to VZV after contact with patients who have zoster than those with chickenpox. This was demonstrated clearly in a study from Cambridge, UK. During a five-year period, only 1/28 (3.6%) of susceptible staff developed chickenpox after an exposure to varicella, compared with 5/29 (17.2%) after exposure to zoster (Wreghitt *et al.*, 1996).

It is wise to remember, however, that chickenpox can be mistaken for other vesicular exanthems due to enteroviruses, measles or even allergy, contact dermatitis or eczema. If you are presented with the information that a member of staff, patient, visitor or relative, for example on the neonatal unit, has developed chickenpox, the implications for the unit are considerable. Multiple doses of varicella zoster immune globulin (VZIG) will almost certainly need to be administered, staff will need to be sent home, visiting may become restricted and it is possible that the unit will have to be closed to new admissions. Thus, although it is an extreme example of what might happen, before embarking on the above course of action it is essential that the diagnosis of chickenpox be confirmed by an experienced virologist or microbiologist with access to laboratory facilities capable of providing rapid results either by direct immunofluorescence or by real-time PCR.

If a susceptible member of staff has been exposed, the simplest way to manage the exposure is to exclude them from day 8–10 after contact until day 21 after the first exposure. This is because cases of chickenpox are infectious two days prior to rash onset. Another option used quite commonly is to allow staff to remain at work providing that they feel well and are afebrile (Haiduvén, 2003; Josephson *et al.*, 1990; Weber *et al.*, 1996). While at work they should wear a mask and take their temperature twice daily, and they should remain at

home or leave work if they become unwell/febrile as this could be the first sign of a prodromal varicella illness. This measure is used more frequently in key staff whose absence from a clinical area would be detrimental to patient care. Alternatively, the individual could perform duties that do not involve patient contact, though the usefulness of this approach for an experienced ward sister, for example, is questionable.

All of the preceding was much more applicable in the pre-VZV vaccine era. Now, the most cost-effective long-term way of managing such staff is through active vaccination against VZV either before or after an exposure (MMWR, 1999).

Live attenuated varicella vaccine has been in use for more than 20 years in Japan and the Far East and almost a decade in the United States, but only recently have two varicella vaccine products been licensed for susceptible individuals >12 years of age in the United Kingdom.

Both products, one from Glaxo Smith Kline, the other from Aventis-Pasteur, are highly effective at preventing chickenpox prior to exposure, and produce a seroconversion rate of >95% after a two-dose schedule (Sharrar

Table 3.1 Persistence of viruses in the environment

Type of virus	Duration of persistence (range)
Adenovirus	7 d to 3 mo
Astrovirus	7–90 d
Coronavirus	3 h
SARS associated virus 7	2–96 h
Coxsackie/ECHO virus	1 to >2 wk
Cytomegalovirus	8 h
HSV types 1 and 2	4.5 h to 8 wk
Influenza virus	1–2 d
Norovirus	8 h to 7 d
Papillomavirus	16 h to >7 d
Papovavirus	8 d
Poliovirus	4 h to <8 d
RSV	Up to 6 h
Rhinovirus	2 h to 7 d
Rotavirus	6–60 d
Vaccinia	3 to >20 wk

Various factors influence virus survival. Low temperature appears to favour virus persistence, especially for those acquired faeco-orally and HSV. Humidity, however, gives conflicting results. The initial inoculum and the presence of faeces appear also to increase the chances of persistence. The role of environmental contamination appears to be important for rota- and rhinoviruses and probably for noroviruses, especially when vomiting has occurred. In experimental studies using a bacteriophage as a marker of the transferability of infectivity, it has been shown that contaminated hands may pass virus to 5 or more surfaces and are capable of passing to 14 additional people when not disinfected. (Adapted from Kramer *et al.* 2006.)

Table 3.2 Physical characteristics of viruses and resistance and sensitivity patterns to agents of disinfection

Virus family	Nucleic acid	Enveloped: yes/no	Resistant to	Sensitive to
<i>Herpesvirus</i> (HSV, VZV, CMV, EBV)	dsDNA	Yes	No disinfecting agents	Low pH, desiccation, lipid solvents, ^a detergents, chlorine-based agents, alcohols
<i>Adenovirus</i> (all types)	dsDNA	No	Mild acid conditions, lipid solvents	Chlorine-based agents, ^b >56°C for 10 min
<i>Parvovirus</i> (B19)	ssDNA	No	pH 3–9, lipid solvents, 56°C for 10 min	Formalin, β-propiolactone, hydroxylamine, oxidizing agents, for example chlorine-based agents/iodine
<i>Polyomavirus</i> (BK/JC)	dsDNA	No	Lipid solvents, pH 2–3, 50°C for 60 min	Chlorine-based agents
<i>Papillomavirus</i> (all types)	dsDNA	No	Lipid solvents, pH 2–3, 50°C for 60 min	Chlorine-based agents
<i>Rotavirus</i> (all types)	ds-segmented RNA	Partially (mature particles: No)	pH 3–9, relatively stable to 50°C, lipid solvents (absence of envelope in mature particle)	β-propiolactone, formalin, chlorine-based agents, phenol, alcohol solutions NB 95% solution in water
<i>Astrovirus</i> (all types)	ssRNA	No	pH 3, 50°C for 60 min, 60°C for 5 min, lipid solvents, non-ionic detergents	Chlorine-based agents
<i>Calicivirus–Norovirus</i> (all types)	ssRNA	No	pH 3, 50°C for 60 min, 60°C for 5 min, lipid solvents, non-ionic detergents	Chlorine-based agents
<i>Picornavirus</i> (Enterovirus)	ssRNA	No	Stable at acid pH, lipid solvents, non-ionic detergents	Chlorine-based agents
<i>Picornavirus</i> (Rhinovirus)	ssRNA	No	Stable at pH 5–6, lipid solvents, non-ionic detergents	Low pH, chlorine-based agents
<i>Paramyxovirus</i> (Measles, Mumps, RSV, Metapneumovirus, Parainfluenzavirus)	ssRNA	Yes	No disinfecting agents	Heat, lipid solvents, ionic and non-ionic detergents, formaldehyde, oxidizing agents; that is, chlorine-based agents
<i>Orthomyxovirus</i> (Influenza A and B)	ss-segmented RNA	Yes	No disinfecting agents	Heat, lipid solvents, ionic and non-ionic detergents, formaldehyde, oxidizing agents; that is, chlorine-based agents
<i>Coronavirus</i> (SARS and other types)	ssRNA	Yes	No disinfecting agents	Heat, lipid solvents, ionic and non-ionic detergents, formaldehyde, oxidizing agents; that is, chlorine-based agents

Table 3.2 (Continued)

<i>Togavirus</i> (Rubella)	ssRNA	Yes	No disinfecting agents	Heat, lipid solvents, ionic and non-ionic detergents, formaldehyde, oxidizing agents; that is, chlorine-based agents
----------------------------	-------	-----	------------------------	--

ds, double-stranded; ss, single-stranded.

^aExample of lipid solvent possibly in use in hospital setting: acetone.

^bThe effectiveness of chlorine-based disinfectants is compromised by excessive amounts of organic materials.

Alcohol rubs should be used only on visibly clean hands and at a concentration of 70% since the mode of action is to denature proteins, which is best at that ratio of alcohol to water.

et al., 2000). Although pre-exposure vaccination has been shown to be cost-effective, this has been assessed only in mathematical models and there are several important practical considerations before advising a staff-wide vaccination policy (Gray *et al.*, 1997). These include how to manage staff working in high-risk areas, as a small proportion of vaccinees will develop a rash both at the site of vaccination and outside of the injection area, and there is a measurable rate of breakthrough infection after exposure to wild type virus and the potential for ongoing transmission. The arguments for and against use of VZV vaccine in health care are detailed in Table 3.4.

The rate of vesicular rash post-vaccine is about 8% (Arbeter *et al.*, 1986). However, in the majority the rash is only maculo-papular; in only 30% of these is it vesicular and even then the average number of lesions is only 14. The nature of the rash and the lack of evidence for pharyngeal excretion of virus probably explain why transmission of vaccine virus to another healthy susceptible individual occurs only extremely rarely. Nevertheless, to take account of this problem staff employed in high-risk areas should take particular care in the two to four weeks after both doses and report to occupational health immediately a possible varicella-like rash develops. Breakthrough infection, however, is potentially more troublesome as this is a long-term problem and occurs at a rate of 5–8% after an exposure (Arbeter *et al.*, 1986; Watson *et al.*, 1993). The average timing for such breakthrough infections is 30 months post-vaccination (Watson *et al.*, 1993).

Despite breakthrough cases of infection being described after exposure to VZV at work, where presumably the degree of exposure is less intense compared with at home, transmission of wild-type virus from cases of breakthrough infection to susceptible contacts within the home is only 12% (Watson *et al.*, 1993). This should be compared with a household transmission rate of 80–90%. The lower rate of breakthrough infection as a result of work-based exposures was also demonstrated in a prospective study of 120 HCWs, in whom such infection developed 6 months to 8.4 years after vaccination. The attack rates following exposure at home or work were 18% (4/22) and 8%

(6/72) respectively. The illness was universally mild, with a mean of just 40 vesicles. Thus, although this might represent a risk for onward transmission to susceptible patients, it presents a considerably lower risk as the mean number of lesions seen in wild-type varicella is 250–500. Although it is possible for breakthrough infections to occur after a documented seroconversion to VZV vaccine, in a study by Gershon, 9/12 (75%) of staff experiencing breakthrough were shown to be seronegative after their initial vaccination (Gershon *et al.*, 1988). It is possible therefore that this group could be offered a booster dose of vaccine post-exposure and retested in seven days to assess the response. If antibody was detected they could almost certainly continue to work uninterrupted. VZV vaccine as post-exposure measure is also highly effective, provided it is given within three days of contact with infectious material.

A study from Asano *et al.* (1977) examined 26 contacts in 21 families who were immunized within three days of the index case developing chickenpox. None of the vaccinees developed a rash. However, a control group of 19 unimmunized contacts in 15 families were all infected. In the same study Asano also gave vaccine to 34 healthy siblings within three days of the index case rash; 2/34 (5.8%) got varicella (Asano *et al.*, 1977). The protective efficacy of post-exposure vaccination is therefore >90%. Whilst this approach may not necessarily allow the member of staff to remain at work in very critical areas such as bone-marrow transplantation units, the exposure that led to use of VZV vaccine as post-exposure should be the individual's last time, where they need to be sent home from work for two weeks.

For the three years 2000–2002 at St George's Hospital all cases of varicella in staff and students notified to the medical microbiology and occupational health departments have been documented. A total of 25 cases have been notified across all staff/student disciplines. Of these 25 cases, 13/22 (59%) occurred in individuals born outside of the United Kingdom where the country of birth was known. If pre-exposure vaccination had been adopted at SGH even amongst only the nursing and medical staff

Table 3.3 Incubation periods, communicability and transmission modes for common virus infections

Virus	Mode of transmission	Incubation period	Duration of shedding	Risk of transmission in hospitals ^a	Prevention	Adverse outcomes
Rubella	Respiratory droplet	15 to 20 d	-7 before to +2 d after rash	Low	Screening and vaccination	Congenital Rubella Syndrome
Measles	Respiratory droplet	7 to 18 d	Greatest before rash onset -1 before prodrome to +4 d after rash	Low	Notification Screening and vaccination	SSPE Death in I/C pts
Mumps	Respiratory droplet	14 to 19 d	-6 before to + d after symptoms (maybe up to 9 d)	Low (may increase in certain cohorts)	Notification Screening and vaccination	Meningitis Deafness
Chickenpox	Respiratory droplet Physical contact Airborne, possibly	10 to 21 d (normally 14)	-2 to +7 (maximum in children) (or until scabbed)	Moderate	Notification Screening and vaccination	Congenital chickenpox Death in I/C pts ^b
Parvovirus	Respiratory droplet	13 to 18 d	-6 to -3 d before symptoms	Low/moderate	Reporting	Miscarriage Aplastic crises Chronic anaemia Severe neonatal disease
Enteroviruses	Faecal-oral Fomites Airborne	5 to 7 d	1 to 8 weeks	Low/moderate	Reporting	Death (I/C, elderly) Ward closure
Influenza	Respiratory droplet Airborne, possibly	2 to 3 d	-1 to 7 d	High	Reporting vaccination	Ward closure Death in I/C
Parainfluenza	Respiratory droplet	1 to 7 d	7 to 21 d	Very high	Reporting	Death in neonates
RSV	Respiratory droplet	1 to 5 d	7 to 21 d	High	Reporting	Death in I/C
HSV	Saliva Physical contact Fomites	Few d (mean = 6)	1 to 8 weeks	High if breakdown in hand washing/ personal hygiene	Reporting	Death in neonates
CMV	Physical contact with virus at mucosal surfaces	1 to 2 wk	week	Low	Hand washing	None
Rotavirus	Faecal-oral Respiratory	2 to 4 d	6 to 10 d	High	Isolation Hand washing	Prolonged stay in hospital
SRSV	Faecal-oral Airborne, via vomiting	1 to 3 d	Up to 2 weeks (allow back to work 48 h after symptoms resolved)	Very high	Reporting Isolation	Ward and hospital closure

^aRefers to overall risk of transmission, modified by level of immunity in the population.^bI/C pts, immunocompromised patients.

Table 3.4 Arguments for and against use of varicella vaccine for health-care workers

For vaccine use	Against vaccine use
Eliminate varicella from staff	Vaccine costs £80 (€/\$150) per person
Of great use, especially in high-risk areas (paediatrics, HIV, transplant, neonatal, Obs and Gyn)	Administration costs and potential for post-vaccine antibody testing
Much lower risk of transmission to pregnant staff and patients in hospital	Vaccine-associated rash
Reduce potential for nosocomial transmission	Durability of immunity, especially after exposure
Very good safety record; in use for about 30 years	Possible need to send off or restrict to nonclinical work after intense exposure
Lower incidence of shingles in vaccines	Inadvertent immunization of immunosuppressed staff
Lower rate of vaccine-related events compared with natural infection	Latent virus reactivation (zoster)
Durable immunity with natural boosters	
Virtually no risk of transmission from one healthy person to another	
Less worry for final exams in students (about 5–10% intake susceptible)	
May be used post-exposure (recent US and UK license)	
Potential case for complaint if transmission of wild-type virus occurred from a susceptible staff member to vulnerable patient	

and students, 85% of chickenpox cases would have been prevented (Devi and Rice, 2002). Since having used the vaccine for all susceptible staff, we have seen a dramatic decline in the number of staff developing varicella, having witnessed just one case of breakthrough infection. At the same time, we have found that about 10% of 130 vaccinated staff in the three years since receiving vaccine have reported exposures to VZV either at home or in the workplace, with only one developing breakthrough disease (Shin, G., personal communication). This represents a considerable financial saving to a hospital with 5000 employees, of whom 3–5% will be susceptible to chickenpox when starting work.

Two other problems with the issue of immunizing staff against chickenpox are that as it is a live attenuated vaccine it may reactivate causing zoster later in life, and that it may be inadvertently given in pregnancy. The issue with accidental use of vaccine in pregnancy is clearly ideally avoided, but the data that exist suggest that it presents a very low/theoretical risk to the developing fetus. In 629 prospectively-enrolled women who received vaccine whilst pregnant, among the 131 babies born to seronegative mothers 3 had major defects (rate, 3.7% (95% CI 0.8–10.7)) yet there was no evidence of congenital varicella syndrome. Though the number of women followed up is too small to exclude a very low risk, the data collected so far do not support a causal role of the vaccine in birth defects (Wilson *et al.*, 2008).

The vaccine probably offers benefit over wild-type infection because the rate of zoster with reactivated vaccine virus is about 50% lower than after wild-type infection, as evidenced by the fact that reactivation of the Oka strain occurs five to seven times less commonly than wild-type virus (Saiman *et al.*, 2001). The key problem with a widespread staff immunization policy, even though it is established that vaccinating susceptible staff will reduce considerably the risk to patients from chickenpox, is that immunity to infection after vaccination is not guaranteed as it is after natural chickenpox, and that it is not possible to identify which staff may be at risk of breakthrough infection after an exposure.

The decision has to be made what to do with immunized staff in these circumstances. The data indicate that whilst transmission of breakthrough wild-type varicella infection may occur, especially in immunosuppressed patients, this is much less likely than after natural varicella. If a staff-wide vaccination policy were to be instituted, it should be accompanied by a concerted effort to immunize simultaneously the most vulnerable patient groups.

HERPES SIMPLEX VIRUS

The prevention of nosocomial herpes simplex virus (HSV) infections relies entirely on good standards of personal hygiene. Though virus may be shed in genital tract and in

saliva without clinical lesions, adhering to hand washing with soap and water or alcohol-based gels is sufficient to destroy infectious virus. The main reason for concern over nosocomial HSV infections is the potential for transmission to neonates born either pre-term or term, as neonatal HSV infection still has extremely high rates of mortality and morbidity even with the prompt use of antivirals (Francis *et al.*, 1975; Hammerberg *et al.*, 1983). Approximately one-third of cases of neonatal HSV infection are thought to be acquired from a nonmaternal source. It is vital therefore that staff employed on delivery suites, post-natal wards and neonatal units understand the importance of hand washing and of the absolute requirement to absent themselves from work if they develop a herpetic whitlow. A herpetic whitlow in a midwife/doctor/nurse working on the delivery suite, post-natal or neonatal units is an extremely serious matter as transmission can be very efficient. An extensive outbreak of herpetic gingivostomatitis with a transmission rate of about 40% was described in a dental practice after the dental hygienist was found to be at work and suffering from a herpetic whitlow (Manzella *et al.*, 1984).

It is important to note, however, that although nosocomial transmission has been proven by restriction enzymatic digestion analysis of cultured isolates, often the identity of the presumed common source has remained undiscovered (Linnemann *et al.*, 1978).

Virus has also survived for more than 60 hours on a cot which had been used for a baby who died from disseminated HSV infection. Further transmission was entirely preventable, since more than 60 hours after this baby died the cot was reused without any form of decontamination. A second neonate was then nursed in it. Twelve days later this infant also died (Sakaoka *et al.*, 1986).

Herpetic whitlow is also an occupational hazard, especially for those working in intensive care when handling parts of respiratory equipment, which may be contaminated with HSV as a result of a silent reactivation secondary to intercurrent illness. In some reports there is circumstantial evidence of HSV nosocomial pneumonia in such patients. Evidence for this has been provided by the presence of typical viral inclusions from the fluid obtained at bronchoscopy and a dramatic response to aciclovir. However, in such reports although the assertion was made that HSV transmission between patients is possible, the same unit was unable to determine which bronchoscope was used on which patient (Mohan *et al.*, 2006). Moreover, isolation of HSV from the respiratory tract of patients in intensive care may be as high as 31%, so its causation in nosocomial pneumonia is uncertain (Daubin and Vincent, 2005).

NOROVIRUSES

Of all the viruses capable of causing nosocomial infection, noroviruses probably present the greatest challenge to clinical virologists and infection-control teams. Though initially termed 'winter vomiting disease' after a school outbreak in Norwalk, Ohio in 1966, these agents are now known to circulate all year round. To an individual they are of little consequence as the illness is short-lived, self-limiting and only in exceptional cases does it lead to any complications. In hospitals, nursing and residential care homes, however, when outbreaks occur, almost without exception, either the ward or occasionally the entire hospital must close. Moreover, fatalities are described. Between 1992 and 2000, a total of 43 fatal cases were seen in 38 such outbreaks in England and Wales (Lopman *et al.*, 2003). Of particular note with these viruses is their propensity for considerable spread to contacts, resulting in an attack rate of more than 50%. There are many factors, both host and viral, that lead to this. Norovirus outbreaks are notoriously disruptive to the normal functioning of the hospital, resulting in closure of key units and cancellation of elective operations and often attracting unwanted media attention. In terms of cost alone it has been estimated that the NHS in England spends £115 million (US\$230 million) on outbreak control of gastroenteritis annually (Lopman *et al.*, 2005).

The highest outbreak rates have been seen in general medical units, followed by geriatric and orthopaedic units, in units with shorter average lengths of stay and in those with high levels of activity. All this points to continued and repeated introductions of susceptible hosts (patients) to fuel transmission. Indeed, acute hospitals almost certainly have a role in providing further impetus to enable virus to be transmitted back into the community from recently discharged patients. Units which have experienced a previous outbreak, especially within the past month, are also more at risk of subsequent outbreaks (Lopman *et al.*, 2005).

It is known from volunteer studies and outbreak investigations that the incubation period is short, often 12–48 hours. Indeed, volunteers exposed to infectious virus orally have been found to be shedding virus in faeces only 15 hours later. The illness commences abruptly with projectile vomiting in over half of cases and profuse watery diarrhoea. However, because the occasional case of vomiting and/or diarrhoea is not unusual among patients, this may be overlooked initially. The environment can then become contaminated quite quickly; as the infectious dose is 10–100 particles it has even been suggested that a single episode of vomiting is sufficient to generate between 300 000 and 3 000 000 infectious doses (Caul, 1995). This is further exacerbated by the fact that

viral particles are capable of resisting low-dose chlorine disinfection and temperatures of 60°C so that any breakdown in hand washing leading to secondary cases occurs via the faeco-oral route. Fomite transmission is also possible because of its environmental stability and it has been suggested that infection may occur via airborne transmission (Marks *et al.*, 2003). Evidence from PCR detection of viral RNA indicates that virus excretion persists for longer than previously thought. Although virus shedding in stool is maximal at 24–72 hours after exposure, virus can be detected for almost two weeks in both symptomatic and asymptomatic persons. The epidemiological significance of these new findings is unclear. Finally, because of the strain diversity among the noroviruses, there is incomplete cross-protection and no long-term immunity (Lopman *et al.*, 2008). Repeated infections throughout life are therefore common.

The main focus of infection control should be that after notification of an outbreak on a ward, whilst attempts can be made to stop the virus from spreading to other patients or staff on that ward, maximum effort must be to stop it affecting other wards in the hospital. An outbreak described in Salford, United Kingdom in 1994 is illustrative. By the time the problem was highlighted to microbiology, over 80% of the eventual total number of cases on the first ward to be affected were either symptomatic or incubating the infection.

Establishing an early aetiological diagnosis of norovirus gastroenteritis with laboratory techniques has been difficult as the sensitivity of the traditional technique of electron microscopy is as low as 20% and decreases rapidly in time from symptom onset as the diarrhoea, which is often short-lived, improves. Whilst use of enzyme immunoassays offers an alternative approach, as they are significantly less sensitive than real-time PCR, they are still useful only in outbreaks when the sensitivity of a clinical diagnosis is already high. However, real-time reverse-transcriptase polymerase chain reaction (RT-PCR) is becoming much more widely available, is extremely sensitive and is applicable to testing of individual specimens. This can be both useful and problematic at the same time because whilst increases in test sensitivity are welcome, asymptomatic infection is being detected (Adamson *et al.*, 2007; Galimore *et al.*, 2004; Pang *et al.*, 2004). As the significance of such a finding is presently unclear it still presents problems with regard to the clarity of infection-control advice.

With more laboratories being able to confirm suspected norovirus infections in real time, this may have a positive impact on infection control of this virus, but this remains to be seen. Indeed, in a prospective study of the epidemiology and costs of nosocomial gastroenteritis in England

in 2002–2003, the most important act to limit the spread of infection was prompt closure of the affected wards. Outbreaks in which the affected unit was closed within three days of the first case were contained in a mean of 7.9 days compared with 15.4 days for units where closure took place more than three days after the first case was identified (Lopman *et al.*, 2004).

Fortunately, to aid rapid identification a clinical diagnosis of a norovirus outbreak is usually reliable if the following criteria are adhered to: stool samples are negative for bacterial pathogens, the percentage of cases with associated vomiting is >50%, the duration of illness is short (one to three days), the incubation period, if available, is only 24–48 hours and both patients and staff are affected.

All affected patients should either be nursed in single rooms or cohorted. Strict hand washing must be observed and gloves and gowns must be worn. The risk of infection has been shown to increase in a linear fashion with the number of patient contacts or exposure to nearby vomiting. Although there is no evidence that the wearing of masks reduces the risk of infection, they could be considered for individuals who clear up and dispose of vomit and faeces. All dirty linen should be disposed of with minimal agitation (to prevent further environmental contamination), horizontal surfaces and floors should be cleaned with 1000–5000 ppm of available chlorine, approximately equivalent to about a 10% solution of household bleach. It is also important to remove visible faecal matter using a detergent prior to disinfection with hypochlorite solution as norovirus RNA was detected on up to almost a third of surfaces which had been treated with bleach only (Barker *et al.*, 2004). There is no need to clean walls unless visibly contaminated. This environmental cleaning should continue once the outbreak has subsided. As the number of staff affected is often high, personnel shortages may lead naturally to ward closure. If they do not, however, the ward must be closed to new admissions for a period of 72 hours after the last case. Furthermore, the staff on the ward at onset of the outbreak must not work on other wards and neither should patients be transferred to other areas unless it is medically necessary to do so. Even then consultation should take place with the infection-control team. Staff must be made aware of the critical importance of not coming to work unless well. Visitors too must be made aware of the necessity for hand washing before and after entering the ward and non-essential staff should be excluded. To prevent outbreaks it is also worth remembering that regular staff education in a variety of formats (public lecture, e-mail, information with payslips, hospital web site, public notices at hospital entrances) is to be encouraged.

ROTAVIRUS

Rotavirus infection is universal in childhood so it is not surprising that it can be spread in hospital and health-care settings, though the exact burden of nosocomial rotavirus infection remains unknown. The available literature makes it very difficult to give an accurate incidence; the rate varies between studies from 1–2 to as high as 50 per 1000 hospital days (Chandran *et al.*, 2006). Infection in the community is seasonal, with a winter peak normally among children aged three months to three years; in cases of nosocomial infection the same winter seasonality is seen but neonates, older children and the elderly may all be affected, with outbreaks described in hospitals, day-care centres and nursing homes. In neonatal infection the disease may often be mild or asymptomatic and may even protect against symptomatic disease in later childhood. Breast-feeding may offer protection in this particular patient group.

Controlling infection is difficult. Experimental infection in volunteers was shown to require only low virus inocula (via the faeco-oral route) and the mature virus particle is not enveloped and as such is resistant to detergents and many disinfectants (Sattar *et al.*, 2000; Ward *et al.*, 1986). It can survive in the environment for many days or weeks, making fomites such as toys into vehicles for transmission, and transfers by hand to and from inanimate surfaces has been proven (Ansari *et al.*, 1988; Sattar *et al.*, 1986). On hands it can persist for at least four hours and effective removal requires high concentrations of alcohol-based solutions (>80% alcohol) or chlorine-based compounds at 800 ppm. Nevertheless, concerted campaigns can reduce the rate of nosocomial infection (Zerr *et al.*, 2005).

Ultimately the reintroduction of two new rotavirus vaccines into childhood vaccination programmes in some developed countries may lead quickly to the disappearance of severe infection in childhood infection and so should, along with good hand-hygiene practice, lead to a reduction in the nosocomial burden, as children will be much less likely to require hospital admission. Whether or not a reduction in nosocomial rotavirus infection will occur depends on the full potential of the vaccine being demonstrated and the necessary resources and infrastructure in developing countries becoming available.

PARVOVIRUS B19

Infection with human parvovirus B19 occupies a unique place among nosocomial virus infections. This is because once a single case of symptomatic infection has been identified in a member of staff, secondary cases have probably

already been infectious for several days and infected tertiary cases, who, in turn, will be infectious in the next few days. When stated thus, it would appear that infection with parvovirus would be universal in childhood and that the vast majority of adults would be immune. This is not the case. Indeed seroprevalence of parvovirus B19 IgG among adults reaches only 50–60%. For reasons unknown, parvovirus B19 is not as infectious as most other childhood virus infections. This can create problems when patients are admitted to hospital with parvovirus infection or when a member of staff develops infection. However, the problems are largely illusory, as proven nosocomial transmission is in my opinion an uncommon event.

When the index case (patient or staff member) is identified they pose no further risk of infection to others; the potential for spread of infection lies with the contacts (staff and patients) whose infectivity or immunity status is unknown. There are two reasons for this. Firstly, the typical symptoms of rash and arthralgia manifest only when virus antigen–antibody complexes are formed; thus the index case presents when no longer infectious. Secondly, volunteer studies have shown that the period from exposure to such symptoms is normally between 13 and 18 days (maximum 21 days), yet the period from exposure to infectiousness is only 7 days. In addition, as an estimated 20–30% of adult cases are symptomless, it would appear likely that virus transmission could pose significant problems within hospitals.

Such nosocomial transmission may also be especially hazardous as there are particularly vulnerable patient groups at risk of adverse outcomes, namely pregnant women, the immunocompromised and those with reduced red blood cell survival, who may develop a life-threatening transient aplastic crisis.

The available information, however, suggests that whilst hospital outbreaks do occur, they are uncommon. Moreover, before ascribing cases detected within a hospital to be nosocomial, they need to be examined carefully in the context of a wider community epidemic that may be occurring concurrently.

Indeed, a pseudo hospital outbreak was described in a maternity unit after several cases among staff and patients during the preceding weeks had been notified (Dowell *et al.*, 1995). However, when cases of acute infection on other wards, different hospitals and even healthy control subjects were sought for it was demonstrated that the percentage of individuals with recent infection both in and out of hospital was not significantly different; 23–30% in all locations or wards. The most likely explanation put forward was the presence of the largest community-wide parvovirus outbreak for 18 years (Dowell *et al.*, 1995).

Furthermore, a formal evaluation of the risk of nosocomial transmission was performed among 87 HCWs

exposed to two patients admitted with aplastic crises who were not placed in isolation, compared with a control group of 88 HCWs who were unexposed to the cases (Ray *et al.*, 1997). The level of previous infection in the two groups was almost identical, as was the rate of transmission among the non-immune-exposed group and those unexposed; 1/32 (3.1%) and 3/37 (8.1%) respectively. The rates of transmission moved even closer with a subgroup analysis of the most heavily exposed, which showed a transmission rate of 5.8% (1/17) (Ray *et al.*, 1997).

When hospital outbreaks are described they appear initially to be explosive since they are noticed only after many cases in staff and patients have occurred, often over a period of several days. This is demonstrated by the attack rate of 27–50% in susceptible individuals, both staff and patients (Bell *et al.*, 1989; Lui *et al.*, 2001; Miyamoto *et al.*, 2000; Pillay *et al.*, 1992; Seng *et al.*, 1994). What is less clear is whether or not any infection-control measures can prevent further virus transmission. This is important since the measures proposed are potentially very costly in terms of staff absences or redeployment and possible ward closure. Indeed, to limit the spread of infection some authors have proposed ward closure, transfer of only immune staff to any affected ward and preventing the nursing staff from working on other wards. (Pillay *et al.*, 1992). However, by the time an outbreak has been notified it is highly likely that the majority of virus transmissions that are going to occur have already taken place. This was clearly demonstrated in an outbreak at a London, England teaching hospital (Seng *et al.*, 1994). Over a one-month period on a single ward a total of 18 cases of acute parvovirus B19 infection were detected in 15 staff, of whom 12 were symptomatic; 3 patients were also affected. However, of the 12 symptomatic staff and the 3 affected patients, all who had dates of symptom onset, 10 either were or had recently been symptomatic prior to outbreak notification. Moreover, of the 5 further cases that were going to occur, only 4 had developed symptoms within 8 days of notification of the index case. Thus only 1 case was possibly preventable by the institution of infection-control measures (Seng *et al.*, 1994). Another outbreak on a paediatric ward demonstrated, however, that 50% of cases might have been prevented had notification to the infection-control team been made earlier (Pillay *et al.*, 1992). These hospital outbreaks mirror the experience from community outbreaks, for example in schools. Nevertheless, the high transmissibility of parvovirus B19 was shown in an outbreak investigated in a UK primary school for children aged 3–11 years during the epidemic year of 1994 (Rice and Cohen, 1996). This showed that 75% of the total number of cases had already occurred by the time the first few cases had been notified, and of the remaining 25% most had been infected and were

incubating the infection by this time. Any efforts to limit the spread of the infection would thus have had little effect on limiting the outbreak.

The high infectivity of parvovirus in an outbreak setting is also illustrated by demonstrating that after this single outbreak in the school the prevalence of parvovirus IgG rose from 15 to 60–70%, that is to an adult level of immunity (Rice and Cohen, 1996). It is my experience that when single cases of infection are identified among staff, further transmission among staff occurs probably only as a result of social contact. This was also raised as one of the reasons for the extensive ward outbreak referred to earlier (Seng *et al.*, 1994). Moreover, given the reasonably high attack rate in close, social and household contacts of approximately 50% and the long incubation period, it is possible to detect virus in susceptible contacts by PCR or even by using standard electron microscopy. This is an additional measure which may be undertaken to limit the spread of infection.

Nosocomial transmission is a particular problem from patients with aplastic crises, since they present earlier in the course of their illness when they are still infectious. This was clearly demonstrated in a paediatric ward outbreak where 12 health-care workers were infected, most probably as a result of a failure to recognize the infection early enough (Bell *et al.*, 1989). This outbreak was, however, probably made more likely by the fact that in the two outbreaks only 12% and 31% had pre-existing immunity. Transmission has also been described from immunocompromised patients with chronic infection, due to an inability to clear the viraemia and who presumably still shed oro-pharyngeal virus (Lui *et al.*, 2001). However, absence of transmission has also been documented from those with transient aplastic crises and chronically-infected patients whose titres of viraemia are likely to be very significantly different because of the different nature of the two disease syndromes (Kozioł *et al.*, 1992; Ray *et al.*, 1997).

Despite the conflicting evidence as to the real risk of nosocomial parvovirus infection, as significant harm to vulnerable patient groups and pregnant staff can occur, the following appear to be reasonable precautions to prevent virus spread:

Patients with reduced red cell survival should have their antibody status assessed and, if non-immune or unknown, should be admitted to a single room if they experience a sudden drop in haemoglobin consistent with a possible transient aplastic crisis. Acute infection should be assumed, especially if the reticulocyte count is normal or low, indicating a shutting down of erythropoiesis. They should not be nursed by pregnant staff and hand washing should be re-emphasized. A case can be made for routine staff screening for those working in particular high-risk

areas, namely paediatric haematology (Bell *et al.*, 1989; Crowcroft *et al.*, 1999; Pillay *et al.*, 1992).

Any staff with rash and especially those with arthralgia should be investigated for parvovirus and rubella, and their household and close social contacts should be offered testing for recent or past infection. However, not all laboratories offer testing and those that do may only perform tests in weekly batches, and it will often be necessary to make a judgement on whether or not staff should be redeployed or furloughed before test results are available. Those who are found to be susceptible, however, can then be tested for the presence of viraemia by real-time PCR. Decisions may then be made about furloughing of such staff.

Pregnant staff who are at less than 20 weeks gestation are at increased risk of miscarriage or fetal hydrops. However, the rate of transmission in the community during an outbreak is likely to be very similar to that seen in hospital and they should be advised accordingly. They should be advised before testing of the low probability of any adverse outcome due to the low transmissibility, moderate levels of adult immunity and low risk of miscarriage. However, advising what an individual staff member may wish to do will also be influenced by other factors, including whether or not the pregnancy was achieved using IVF.

RESPIRATORY VIRUSES

The respiratory viruses are well established as agents capable of nosocomial transmission. They are particularly well suited for many reasons. They are highly infectious with reproduction rates of 5–15 : 1, can spread by both droplet and aerosol routes and have short incubation periods. Explosive outbreaks are thus possible. Furthermore, during the epidemic season high community attack rates of 10% for influenza and 40% for RSV in the groups at highest risk of infection make possible multiple introductions into the hospital. They are capable of survival on surfaces and unwashed hands for hours, and among immunocompromised patients infectious virus may be shed for weeks. Finally, vaccination is available only for influenza and effective antiviral agents are available for only two genera (RSV and influenza). They represent a significant financial burden on hospitals by prolonging hospital stays, increasing mortality in vulnerable patient groups and causing staff absences, with the need to hire of temporary replacements at additional cost. Ward closure may sometimes be necessary to terminate an outbreak.

There are also no tests for checking the immune status of staff. Indeed, for influenza and RSV, re-infection is common. To prevent outbreaks, close cooperation between the microbiology department and the

infection-control team is essential. A key element of this is rapid communication of positive results on all patients in a hospital, especially at the start of the winter season. To facilitate this, rapid diagnostic assays should be employed. A variety of methods are available, but regardless of sensitivity and specificity their proper use is the key to success in controlling infection. Near-patient testing, if used properly, has sensitivity approaching that of conventional immunofluorescent tests, but it still requires knowledgeable staff capable of collecting an adequate specimen. Whilst near-patient tests offer a result within minutes of sample collection, they are less sensitive. Newer PCR protocols involving real-time assays are capable of providing results as fast as IF with enhanced sensitivity. A recent paper demonstrated that real-time PCR using the light cycler could generate a result in less than two hours after specimen receipt and it was significantly more sensitive in older children and adults (Whiley *et al.*, 2002). This study showed that out of 77 samples positive by LC-RT-PCR, 7 were negative by IF testing. Of these 7, however, 6 were from adults or children aged >12 years. This is compatible with lower viral loads in these individuals, most probably as a result of re-infection. Thus PCR offers advantages over IF testing in certain groups, for example less cooperative children, who may be harder to sample, and adults.

Influenza

Influenza is a particular problem in hospitals because of the explosive nature of outbreaks and the especially vulnerable patient groups that are heavily exposed during the epidemic season. During the winter up to 10% of the general population is infected; in hospitals during outbreaks the attack rate may be as high as 50% in patients on affected wards and up to 20% in the general hospital population. All types of ward have been affected and whilst the mortality can be low, in geriatric wards it can be as high as 16% (Gowda, 1979) and in transplant centres mortality due directly to influenza is between 30 and 60% (Weinstock *et al.*, 2000). These figures are particularly worrying since it has been estimated that up to 70% of influenza infections in transplanted patients are nosocomial in origin. Staff are also at high risk of infection, with transmission rates of 11–60% in those caring for patients with influenza (reviewed in Salgado *et al.*, 2002). In hospitals with a particular interest in influenza and a well-developed strategy for preventing nosocomial infection, however, the attack rate in staff is significantly reduced to only 2% (reviewed in Salgado *et al.*, 2002).

Influenza viruses are notable for their antigenic diversity. They are also, however, capable of undergoing sudden shifts in their external glycoproteins, exemplified

by the global spread of two novel avian influenza types (H7N7 but most notably H5N1) which have caused serious infection in humans, with a mortality of >50% in healthy adults. We are currently fortunate in that their person-to-person spread appears to be very inefficient, although it is essential to maintain vigilance since they may become better adapted to the human host and may, like avian influenza viruses, be capable of transmission faeco-orally (Gambotto *et al.*, 2008; Wang *et al.*, 2008).

There is good evidence that influenza viruses are capable of surviving for varying amounts of time in artificially-generated aerosols and that when such aerosols are applied to animals and human volunteers virus transmission is reasonably efficient, with a transmission rate of about 20% (Alford *et al.*, 1966). This would suggest that airborne transmission might be responsible for natural infection. This is an important consideration when advising on infection-control procedures since it would mean that wearing a face mask, and preferably an N95 mask, would be necessary to prevent patient-to-staff transmission.

However, the evidence that airborne spread is important is weak in three key areas. The particle size of the artificial aerosols is significantly greater than that produced naturally by coughing or sneezing; particles are much smaller in experimental conditions, with a diameter of about 5–6 μm or less, with <10% being 8 μm in size. This compares with 99.9% of the naturally-produced particles, being >8 μm in diameter. Particles of the larger size would fall quickly to the ground and so would not be available for aerosol spread. Some of the experimental studies are also flawed in that they have had to use equipment to agitate the ambient air in order to maintain the aerosol. Finally, the infectious dose is considerably lower (10–100 fold) when delivered by artificial aerosol compared with intranasal inoculation. As this does not, in the opinion of certain authors, reflect the natural history of influenza transmission it is uninterpretable with respect to virus transmission in the natural state (reviewed in Brankston *et al.*, 2007).

Although there are nine observational studies reporting on airborne spread, the most frequently quoted paper demonstrating such a transmission route concerned a 72% attack rate in passengers in the cabin of an aeroplane with an inoperative ventilation system (Moser *et al.*, 1979). The four individuals who decided to leave the plane escaped infection. However, those remaining were free to move around the passenger compartment and so large particle droplet infection is very likely to have occurred. Nevertheless, two other studies have suggested that airborne transmission may occur based on a higher rate of infection in unirradiated departments of 19%, compared with a rate of just 2% in those areas that had upper-air UV disinfection, a known virus sterilizer. Additionally, units

with efficient ventilation systems saw that virus transmission was less common (9–16% patients became infected when between 30 and 70% of the room air was replaced with outside air, compared with <2% transmission with 100% such air exchange between the room and outside (reviewed in Brankston *et al.*, 2007).

The six other studies were more consistent with a droplet route or contact transmission. Indeed, the one study that reported on control measures which were not biased by pre- or post-exposure prophylaxis reported control of an outbreak on a neonatal intensive care unit (NNU) by cohorting patients and staff and instituting droplet or contact control measures. Airborne precautions were not applied (Munoz *et al.*, 1999).

The only time that it would be sensible to consider influenza as an airborne pathogen would be if aerosol-generating procedures were going to be used; that is, in the collection of naso-pharyngeal or broncho-alveolar lavage specimens. It would seem sensible to take precautions against both inhalation and droplet spread by the wearing of a facemask and eye protection.

Influenza virus is stable for 24–48 hours after aerosolization and for at least 5 minutes on unwashed hands. Virus shedding begins one day prior to symptom onset and continues for four to seven days in immunocompetent patients, though extended periods of virus excretion of several weeks are seen in the immunocompromised.

Preventing influenza spread in hospitals is difficult because of the multiple routes of entry of virus in staff, patients and visitors. However, low nosocomial transmission rates are achievable through a concerted action by all staff and the infection-control and occupational-health departments. Staff must understand that they should not report for work if they are ill and will be sent home if they develop an influenza-like illness. The ethos should be one of protecting patients as well as working as a team.

There are essentially three major ways by which the incidence and overall disease burden of nosocomial influenza may be brought under control. The first is to immunize children, as they commonly experience infection and are often seen in hospital. Secondly, the groups at high risk of complications should similarly be vaccinated. Lastly, staff should be immunized on an annual basis. However, staff uptake rates are low; in the United States about 10–40%. There are many reasons for this, mostly based around the lack of knowledge concerning the illness itself and the effectiveness/safety of the vaccine.

This is unacceptable as the importance of influenza vaccine in preventing nosocomial transmission has been shown both ways; outbreaks in hospitals and long-term care facilities have been associated with low vaccination rates in staff Cunney *et al.*, 2000; Saito *et al.*,

2002), whilst units with higher uptake rates have demonstrated a lower incidence of nosocomial infection (Carman *et al.*, 2000; Potter *et al.*, 1997; Salgado *et al.*, 2004); in a unit where the vaccine uptake rate increased from 4 to 67% between 1987 and 2000 the proportion of laboratory-confirmed cases of influenza in staff fell from 42 to 9%, whilst in hospitalized patients the rate of nosocomial infection decreased from 32% to zero (Salgado *et al.*, 2004).

The way to increase uptake rates is to educate staff. Since self-protection is an efficient motivator they should be told about the benefits of vaccination and the risk that influenza poses to them, their families and, finally, their patients. This can be achieved, for example, by posters and messages via hospital e-mail or in pay slips. When senior medical and nursing staff act as role models, their staff have higher vaccine acceptance rates.

Improving access to vaccine is seen as a vital step to increase staff coverage. This can be done by offering the vaccine in as convenient a form as possible, for example by immunizing staff in their workplace, during conferences or in out-of-hours clinics at the end of the working day. By adopting such an approach, uptake rates can increase from 10 to 70% (reviewed in Salgado *et al.*, 2002). Finally, the vaccine coverage should be measured regularly and reported, including posting the rates of vaccination in different areas of the hospital and among different occupational groups. This could also be used as a measure of the quality of care an individual hospital provides (Pearson, 2006).

The overall efficacy of vaccine in patients and healthy staff is 70–90%. Vaccination of staff is probably the most effective measure in reducing mortality in hospital from influenza, as shown in a study from Scotland, especially as some studies in elderly institutionalized patients have demonstrated much lower rates of efficacy, of 30–40%, for preventing infection (Carman *et al.*, 2000).

Patients who are admitted with suspected influenza should be placed in a single room and put on respiratory precautions; that is, plastic apron, gloves, hand washing and mask. Specimens for rapid diagnosis should be sent as soon as possible so that cohorting is possible if the demand for single rooms becomes too great. There is no need to place such patients in negative pressure as the experience over a 15-year period from a hospital in Virginia, USA, has been that admitting patients with influenza to private rooms at slight positive pressure has not resulted in temporally-related secondary cases (reviewed in Salgado *et al.*, 2002).

If there appears to be an increase in the number of cases of proven influenza or influenza-like illnesses on a particular ward, consideration should be given to immunizing staff as rapidly as possible. Whilst this takes effect,

antiviral prophylaxis might also be considered. Amantadine, the oldest of the antiviral agents active against influenza, was shown many years ago to be an effective prophylactic regimen. However, it does suffer from three major problems: it is inactive against influenza B, shows rapid development of drug resistance and has significant CNS toxicity. Even during a short treatment course of only two to five days, up to one-third of influenza virus isolates will have developed resistance. These are as transmissible as wild-type virus and have been known to cause fatalities. CNS toxicity is also problematic and 18% of patients suffered from CNS side effects, compared with just 2% taking Rimantadine. The newer neuraminidase inhibitor agents, Zanamivir and Oseltamivir, given by inhalation and orally respectively, have an improved side effect profile and so are better tolerated. Furthermore, when used in the home as post-exposure prophylaxis they are extremely effective in preventing influenza illness, with efficacies of 74 and 90% respectively. Nevertheless, with increasing use it has become apparent that high-level resistance to Oseltamivir has been seen in influenza isolates across Europe and in the United Kingdom. Indeed, I have seen such an occurrence with virus transmission involving an NNU where all four of the five patients with clinical evidence of infection and a sufficient sample had the key mutation (H274Y) in neuraminidase detected.

Parainfluenza Virus

Like other respiratory viruses parainfluenza virus may cause outbreaks on nurseries, neonatal units, long-term care facilities and BMT units. It is important to remember that infection in high-risk patients has considerable mortality, approximately 40–50% in BMT patients (Zambon *et al.*, 1998); specific antiviral compounds do not exist and often the only way to terminate an outbreak is for the affected unit to be closed to admissions. When outbreaks occur it is always in the context of a wider community epidemic, which for parainfluenza virus usually runs from May to September each year. Thus it is possible that what may appear to be an outbreak is merely the result of multiple introductions of virus into the ward by patients, staff and visitors. However, the available data from two large outbreaks, one on a paediatric ward, the other in a BMT unit, showed the introduction of one PIV strain and its spread and propagation from person to person (Karron *et al.*, 1993; Zambon *et al.*, 1998). How virus may be transmitted is not easy to determine with absolute confidence, but transmissions by unwashed hands, contaminated fomites and large droplets are all possible. In a report from the United Kingdom, one of two outbreaks on a BMT unit started nine weeks after the index case had been identified, who was still shedding infectious virus (Zambon *et al.*, 1998). This

emphasizes the absolute necessity for extreme vigilance when adhering to hand washing and for prolonged periods when patients are immunocompromised. Indeed, virus excretion for four months has been demonstrated in this patient group (Zambon *et al.*, 1998). This may be one reason why symptomatic surveillance and patient isolation have been shown not to terminate outbreaks in such units (Nichols *et al.*, 2004). What was also clear from this study and from another in Canada is that parainfluenza virus outbreaks can, unlike influenza virus outbreaks where the median duration is only seven days, be protracted and ultimately only terminated by closure of the unit to new admissions (Moisiuk *et al.*, 1998). When the first case of a parainfluenza virus is discovered on a ward with high-risk patients, full adherence to all necessary infection-control measures (gowns, gloves, patient cohorting and hand washing), including reiterating the standing instructions to staff not to come to work if unwell, must be rigorously enforced. It has now been established that all four types of human parainfluenza virus are capable of causing prolonged outbreaks with nosocomial spread (Lau *et al.*, 2005).

Adenovirus

Adenovirus is a leading cause of epidemic keratoconjunctivitis in adults and conjunctivitis in children as well as community-acquired upper and lower respiratory tract infection and gastroenteritis. Nosocomial transmission has been described in different hospital and care settings, for example paediatric, neonatal, haematology and chronic psychiatric facilities, but most notably in ophthalmic wards and departments (Chaberny *et al.*, 2003; Klinger *et al.*, 1998; Montessori *et al.*, 1998; Warren *et al.*, 1989). Whilst other areas of the hospital may be affected, the original source of virus is often associated with contaminated ophthalmic equipment (Percivalle *et al.*, 2003). Whilst the original route of acquisition may be from improperly disinfected equipment by the use of isopropyl alcohol (Montessori *et al.*, 1998) or from contaminated solutions for instilling into the eye, the propagation of an outbreak is also from inadequately decontaminated hands of hospital staff (Montessori *et al.*, 1998; Percivalle *et al.*, 2003). Large outbreaks may also occur and be problematic to bring under control, especially if there is an upsurge in community-acquired infection. One important aspect of an effective infection-control strategy is to triage and cohort patients with suspected conjunctivitis so that they can be treated by staff who are assigned only such patients (Montessori *et al.*, 1998; Warren *et al.*, 1989).

The outbreaks that cause most concern are those that affect the immune-suppressed, as infection has a significant excess mortality and with the possible exception of cidofovir, no truly specific antiviral agent

is currently available. It is also particularly troublesome since it resists desiccation, especially on nonporous surfaces, surviving for up to 35 days (Nauheim *et al.*, 1990); it is only effectively disinfected by chlorine-based agents and may be shed for prolonged periods from conjunctiva and the gastrointestinal and respiratory tracts. Sharing of toilets and bathrooms may exacerbate virus spread (Jalal *et al.*, 2005).

Severe Acute Respiratory Syndrome Coronavirus (SARS-CoV)

The spread of severe acute respiratory syndrome coronavirus (SARS-CoV), now known to be caused by a previously unknown coronavirus, has highlighted the extreme dangers that are posed by emerging, particularly respiratory, pathogens to virgin-soil populations. During 2003, over 30 countries in 5 continents were affected with great rapidity. Over 8000 cases were diagnosed, resulting in 774 deaths. Though it commenced as a zoonosis, originally from the horseshoe bat (*Rhinolophus* sp.), it became apparent quite quickly that it was capable of person-to-person spread. It also disappeared almost as quickly, only to briefly reappear in late 2003 upon resumption of the wildlife food market, at which time it was found to be present in the horseshoe bat. Thus vigilance is necessary as it could re-emerge again, especially since not only are coronaviruses are capable of genetic recombination but there is a culture of the consumption of exotic animals in southern China.

In man, the virus is present in the respiratory secretions, faeces, urine and tears of affected individuals. It became apparent that nosocomial transmission was facilitated by the use of nebulizers, bronchoscopy and suctioning procedures, and cardiopulmonary resuscitation. All of these activities result in the generation of a large quantity of droplets containing infectious virus particles. It was also unfortunate that hospitals were unwittingly involved in amplifying the spread of the epidemic (Tomlinson and Cockram, 2003). This was seen very clearly in the Prince of Wales Hospital in Hong Kong, China. Within just three weeks of admission of the index case, 156 further cases had been diagnosed, all capable of being traced back to this single case. The major reasons given for the spread of infection in this hospital were failure to apply appropriate isolation precautions to cases not yet identified as SARS-CoV and breaches of such precautions. Staff were also appearing for work with mild fevers, so potentially exposing other patients and staff. Of especial importance in the rapid dissemination of infection in this hospital was the use of a nebulized bronchodilator in the index case, hugely increasing the droplet contamination of the patient's environment.

A case control in five Hong Kong hospitals demonstrated that adhering to such precautions as use of a mask, gloves, gowns and hand washing resulted in no secondary cases in 69 staff who followed these prevention-of-infection measures. However, all of the 13 staff who became infected after caring for SARS-CoV cases reported not adhering to at least one of these measures (Seto *et al.*, 2003). When each of the four infection-control measures was examined, however, only the wearing of N95 masks was shown to be essential for protection against infection. This agrees with the principal mode of spread of SARS being by respiratory droplets. Unlike most of the other respiratory viruses, wearing an N95 mask, capable of trapping 95% of all particles, adds a further level of protection to staff. The wearing of simple paper masks did not afford any protection.

The WHO has since given recommendations to control the spread of SARS-CoV should it reemerge. It is essential that these are adhered to as there is neither vaccine nor antiviral agent; preventing infection is the only option. The recommendations are centred around rapid case identification, triage and immediate isolation, with droplet and if necessary airborne precautions. Thus when a suspected case enters a hospital, these conditions must be strictly enforced, the patient must be isolated in a single room and, if procedures which may generate an aerosol are necessary for patient diagnosis and management, this should be a negative-pressure room. If mechanical ventilation becomes necessary, this must take place in such a room. However, if the only patient requires supplemental oxygen, the use of nasal cannulae is believed to reduce the risk of airborne spread compared with a high-flow face mask. If no additional oxygen is required, patients who are proven or who may represent possible cases of SARS-CoV should be given a face mask to wear, preferably one that filters exhaled air, in order to prevent the spread of SARS-CoV in hospitals. Furthermore, after discharge the patient must be told to adhere to strict personal hygiene. The staff involved in the initial contact must wear a mask, for example N95 with 95% filter efficiency and goggles. They must wash hands before and after contact and wear gloves. Standard disinfectant solutions such as household bleach and alcohol gel preparations should be readily available in the immediate vicinity of the patient as the virus is easily inactivated. Further infection-control measures include restricting visitors and supervising them in the use of protective equipment. It has also been suggested that the wearing of footwear that can be easily decontaminated should be considered. The removal of linen should be done by staff wearing full protective equipment (goggles, N95 or N100 masks, gloves, disposable gowns/aprons). The linen must be placed in biohazard bags and destroyed by incineration. As virus

has been shown to survive in faeces and respiratory secretions for 4 and >7 days respectively, room cleaning should take place using a broad-spectrum disinfectant, for example household bleach.

Respiratory Syncytial Virus

RSV, like all other seasonal pathogens, is problematic for a brief period of time, during which the paediatric wards soon become full because of infants with bronchiolitis. Whilst this is expected and normal for winter, RSV can unexpectedly lead to disastrous outbreaks on paediatric intensive care units (PICU)s and NNUs, and among BMT recipients. In one such NNU, leaving aside potential excess mortality, the cost of an outbreak was estimated at US\$1.15 million (Halasa *et al.*, 2005). It is an especially serious infection in the immune-suppressed and those with chronic cardiac and pulmonary pathology when the mortality is high. The most effective methods for preventing nosocomial infection with RSV are regular hand washing by staff, parents and visitors, the wearing of gloves and gowns, and either the cohorting of infected patients or admission directly into single cubicles. This directly limits virus spread, as it has been shown that direct contact with contaminated secretions plays the key role in transmission (Hall and Douglas, 1981). Hand washing is important because it helps irradiate the culture among all involved in patient care. Indeed, the effectiveness of such a measure has been shown by several studies. Isaacs *et al.* 1991 studied hospital-acquired infection among children with congenital cardiac and lung disease. They showed a nosocomial infection rate of 35% prior to the introduction of the enhanced infection-control measures of hand washing and patient cohorting. Not only were they able to demonstrate a 66% reduction in the rate of nosocomial RSV but among patients admitted for >14 days, the rate was even higher. During the year prior to the intervention of 11 patients staying longer than 14 days in hospital, 8 (73%) developed nosocomial RSV, compared with 2/77 (2.6%) during the period of intervention.

Conversely, when a breakdown in barrier precautions takes place a rapid upsurge in nosocomial infection may result. A large outbreak occurred in a PICU, probably as a result of just such a breakdown in basic droplet precautions and the fact that some children became persistent shedders of infectious virus for as long as 27 days (Thorburn *et al.*, 2004). Indeed, in this outbreak it was demonstrated that droplet precautions (strict hand washing, single-use aprons and education) played a more important role than isolation in a single room, since nosocomial spread was reduced despite all available cubicles

being occupied and infectious cases being treated in open ward areas (Thorburn *et al.*, 2004).

Although others have suggested a role for Palivizumab in controlling neonatal RSV transmission, this is still unclear (Abadesso *et al.*, 2004).

Prevention of infection is paramount on BMT units, where the mortality from LRTI RSV infection may be 30–100% (Harrington *et al.*, 1992). Moreover, since infected patients shed virus for longer they act as potential reservoirs for the maintenance and cascading of infection in the ward.

Rapid virus diagnosis may assist in reducing the rate of nosocomial transmission but the beneficial effect of testing all symptomatic infants for RSV infection remains to be demonstrated (Goldmann, 2001). Indeed, whether cohorting is required on the basis of specific virus type or on respiratory symptoms alone is debatable. It was noteworthy in the study by Madge *et al.* (1992) that where children were initially cohorted on the basis of respiratory symptoms alone, no symptomatic child initially placed in an RSV-infected cohort but subsequently shown to be RSV negative became infected as a result of this contact (Madge *et al.*, 1992). The underlying reason for this must be the protective effect of viral interference in the upper and lower respiratory tracts. Indeed, with the increasing use of real-time multiplex PCR for respiratory virus diagnosis, cohorting patients infected with two or more viruses is, practically speaking, impossible.

Emerging Virus Infections

Brian W.J. Mahy

National Center for Preparedness, Prevention and Control of Infectious Diseases, CDC Atlanta, GA, USA

INTRODUCTION

Although infectious disease mortality declined sharply throughout the twentieth century, apart from a dramatic increase following the 1918 pandemic of influenza virus, in the last 20 years a small but noticeable increase in mortality from infectious diseases can be observed (Armstrong *et al.*, 1999; Mahy, 2000; Figure 4.1). The start of this increase roughly coincides with the appearance in the population of human immunodeficiency virus (HIV) infection and associated cases of acquired immune deficiency syndrome (AIDS), but there is good evidence suggesting that many factors contributed to this situation.

In 1991, the Institute of Medicine (IOM) of the US National Academy of Sciences convened a multidisciplinary committee to consider emerging infectious diseases and the factors responsible for them, and to make recommendations for future actions to be taken in response to their threat to public health (Lederberg *et al.*, 1992). In 2001, the IOM convened a new committee on Microbial Threats to Health in the Twenty-First Century (Smolinski *et al.*, 2003), with a similar mandate to review the situation 10 years later. It is noteworthy that during the period covered by the two sets of recommendations more than 60 new viruses were recognized in the human population, and four years later, in 2007, this number reached 80 (Figure 4.2). These range from hepatitis C virus (HCV), first recognized in 1988, to the new human coronavirus, first recognized in 2003, which is responsible for severe acute respiratory syndrome (SARS). As with most emerging virus infections, these are examples of world diseases that threaten public health throughout the world and are not limited in their potential geographic range. As pointed out in the first report on emerging infections, in

the context of infectious diseases, there is nowhere in the world from which we are remote and no one from whom we are disconnected (Lederberg *et al.*, 1992).

FACTORS CONTRIBUTING TO EMERGENCE

Considering infectious diseases as a whole, the committee of the IOM recognized 13 factors contributory to emergence, and these are listed in Table 4.1. Some of these are natural events that can be responded to but not prevented from occurring, such as microbial adaptation and change, and climate and weather. Others are societal and political in origin and could be eliminated, such as the breakdown of public health measures, and poverty and social inequality. Finally, 'intent to harm' refers to acts of bioterrorism, an example of which might be the deliberate release of smallpox (variola) virus (Mahy, 2003).

This chapter reviews the factors responsible for the emergence of new virus infections under four broad headings: (i) virus evolution; (ii) human demographics, susceptibility to infection and behaviour; (iii) improved technology for the detection of virus infection; and (iv) increased contact with vectors of virus infection. By considering examples of virus emergence under each category, the factors responsible for the remarkable global increase in human virus infections over the last 20 years (Figure 4.2) will become clear.

Virus Evolution

There are a number of different mechanisms by which viruses may evolve. In general, RNA viruses are much more likely to evolve by genome changes than DNA

Figure 4.1 Infectious disease mortality in the United States, 1900–1996. (Reproduced from Armstrong, Conn and Pinner (1999) *Journal of the American Medical Association*, 281, 61–66, Copyright © 1999, American Medical Association.)

viruses, and this in part reflects the proofreading functions present in the host cell that preserve the integrity of DNA. Such proofreading mechanisms do not exist for RNA, and so RNA viruses are much more mutable.

Table 4.1 Factors in emergence.

Microbial adaptation and change
Human vulnerability
Climate and weather
Changing ecosystems

Mutation

The most obvious mechanisms for evolution involve point mutations in the genome RNA nucleotide sequence, either random (spontaneous) or in response to a selective pressure, such as inhibition by an antibody or an antiviral drug. For example, influenza viruses undergo frequent

Figure 4.2 Emergence of viruses affecting humans.

mutations in response to humoral antibodies against influenza which exist in the general population; this phenomenon produces 'antigenic drift'.

Another example is HIV, which, in the presence of a drug which prevents DNA replication, such as zidovudine (azidothymidine), generates rapidly mutant viruses that are resistant to the drug.

Reassortment

A second mechanism for genetic change is reassortment, which is a common feature of those viruses that have a segmented genome, such as influenza viruses and rotaviruses. In cases where two viruses of distinct genetic lineage infect the same cell, it is possible for exchange of genome segments to occur, giving rise to a new reassortant virus that may have altered properties of transmission or pathogenesis. This is of particular importance clinically with the influenza viruses, and it has been clearly demonstrated that both the 1957 'Asian' influenza pandemic and the 1968 'Hong Kong' influenza pandemic resulted from viruses that were apparently generated by reassortment between human and avian influenza virus strains (Webster and Kawaoka, 1994).

Recombination

The third most common mechanism of virus evolution is recombination between the genomes of two different viruses. Although not absolutely proven, it seems most likely that rubella virus was originally generated in this way, and we see many examples of recombination in action, especially with the picornaviruses, such as poliovirus. For example, an outbreak of poliomyelitis in Hispaniola in 2001 was caused by a recombinant virus between the live Sabin poliovirus vaccine strain and an enterovirus, which restored the pathogenicity of the vaccine virus (Kew *et al.*, 2002).

As a general rule, recombination events seem to be much more common with viruses having a positive-strand RNA virus genome, and such events are rarely reported for negative-strand viruses, although they certainly can occur.

Human Demographics, Susceptibility to Infection and Behaviour

Changes within host populations have contributed greatly to the emergence of virus diseases during the past 20 years.

Increases in World Population and Global Travel

The rapid increase in the world population has combined with the greatly enhanced opportunity for global travel

to increase the opportunity for persons to come into contact with virus diseases formerly considered to be exotic to the developed world (such as Lassa fever, which causes 5000 deaths per year in West Africa; in 1989 a patient died from Lassa fever in a hospital in Chicago (Holmes *et al.*, 1990). The patient was an American citizen who had visited Nigeria to attend his mother's funeral, and became ill two days before his return to Chicago. Although 102 people had contact with him in the Chicago hospital, fortunately none of these contacts became infected.)

Global travel also provides the opportunity for very rapid movement of a newly emerged virus, as we witnessed when SARS was first recognized in Guangdong Province, China, on 16 November 2002, where it had caused 300 cases of unknown aetiology and 5 deaths. This was reported to the World Health Organization (WHO) on 11 February 2003, and then on 26 February a WHO official working in Hanoi, Vietnam, Dr Carlo Urbani, reported an unusual case of severe acute respiratory disease to the WHO. Other cases were soon identified in Hanoi and in Hong Kong, and many of these were health-care workers. On 12 March 2003 the WHO issued a global alert about these cases, and on 14 March cases of a similar disease syndrome were reported by Canada. Over the next few weeks it became clear that all these cases of severe respiratory disease could be linked to a hotel in Hong Kong (Hotel M), where the index case of the disease, a 65-year-old medical doctor from Guangdong Province in China, had arrived on 21 February. He had noted his onset of symptoms on 15 February, and he was hospitalized on 22 February and died the following day. Although he only stayed in the hotel one night to attend a family wedding, this single individual infected 12 other guests in the hotel, and from them several hundred persons in widely disbursed geographic areas became infected within a few weeks, resulting eventually in more than 300 deaths between February and June 2003. By the end of the epidemic in August 2003, the WHO reported more than 8000 probable cases of SARS worldwide, of whom 10%, some 800 persons, died (World Health Organization, 2003). Most of those who died were elderly patients (Centers for Disease Control and Prevention, 2003).

Increased Numbers of Elderly Persons

This brings us to another demographic change that is affecting the emergence of infectious diseases. The elderly population is growing faster than any other segment of society in most highly-developed countries, but elderly people may have impairment of normal defence mechanisms against infection, resulting in greater susceptibility to disease.

Immunosuppression

Other factors that affect susceptibility to infection include immune suppression, due to genetically-inherited traits, malnutrition, use of immunosuppressive drugs following organ transplantation or as part of cancer treatment, or infection with HIV. Worldwide, many millions of persons are now infected with HIV, and this has created a large segment of the global population in which emerging virus infections may spread and become amplified. In addition, a person infected with HIV may also suffer from reactivation of latent virus infections that are normally held in check by the immune system. These latent infections may include several members of the herpesvirus group, such as cytomegalovirus, or the human polyomavirus JC, which may cause progressive multifocal leukoencephalopathy.

Human Behaviour

Human behaviour is a major factor in the emergence of virus diseases. HIV, for example, would not spread within the human population if obvious precautions were taken by all individuals to prevent transmission. In addition, disease outbreaks have been recognized as resulting from unusual human behaviour. The emergence of monkeypox in the United States in 2003 is an example of a disease that only emerged because of the demand by US citizens for importation of exotic animal pets. In this case, the importer brought in several African rodents—giant pouched rats (*Cricetomys* spp.), rope squirrels (*Funisciuris* spp.) and dormice (*Graphiurus* spp.)—all of which were found to be infected with monkeypox virus (Hutson *et al.*, 2007). These African rodents were housed together with other animals, especially prairie dogs, burrowing rodents of the genus *Cynomys*, which are a popular pet animal in Midwest America. The prairie dogs proved to be highly susceptible to monkeypox virus, and the virus then spread from them to children and adults who handled these pets. This incident raised concern about the possible development of a wild rodent reservoir of monkeypox virus in the United States, but fortunately this did not happen. One or more of the African rodents was infected

with monkeypox virus, which spread to the prairie dogs, and from them to people (Hutson *et al.*, 2007).

A more serious example of virus emergence due to human behaviour occurred in the early 1980s, when a decision was made to alter the production process of bovine meat and bone meal, a dietary supplement for young calves, by omitting a lipid extraction phase. As a result, a new prion disease, bovine spongiform encephalopathy (BSE), became established in the UK cattle population and eventually led to human cases of the disease, called new variant Creutzfeldt–Jakob disease (nvCJD) (Collinge *et al.*, 1996). The exact mechanism by which humans acquire this disease remains uncertain, but it is believed to be the result of eating meat from an infected bovine animal. Certainly the virus found in the brains of humans who have died of nvCJD is identical to the virus causing BSE (Almond and Pattison, 1997).

Improved Technology for the Detection of Virus Infection

In recent years a variety of molecular techniques, especially the polymerase chain reaction (PCR), have been used to identify viruses causing a variety of diseases that were formerly of unknown aetiology. Examples of these are listed in Table 4.2.

Screening cDNA Expression Libraries

One of the most important discoveries that used molecular technology was the identity of the virus causing hepatitis non-A non-B, now known as Hepatitis C virus. It had long been recognized that an important cause of serum-transmitted hepatitis was neither hepatitis A nor hepatitis B virus. In 1988, Bradley at the Centers for Disease Control and Prevention (CDC) collaborated with workers at Chiron Corporation. They used the blood of a chimpanzee that had been experimentally infected with a preparation known to transmit non-A non-B hepatitis. RNA extracted from the chimpanzee's blood was reverse-transcribed using random primers to make cDNAs, which were then cloned into a bacteriophage expression vector. The resultant bacterial colonies were then

Table 4.2 Examples of molecular approaches to pathogen discovery

Virus	Type of approach	Reference
Hepatitis C virus	Expression library	Choo <i>et al.</i> 1989
Sin Nombre virus	Consensus PCR	Nichol <i>et al.</i> 1993
Human herpesvirus 8 and KS	RDA	Chang <i>et al.</i> 1994
GB hepatitis viruses	RDA	Simons <i>et al.</i> 1995
TT virus	RDA	Nishizawa <i>et al.</i> 1997
Human metapneumovirus	RAP-PCR	van den Hoogen <i>et al.</i> 2001
Human bocavirus	DNase-SISPA	Allander <i>et al.</i> 2005

screened using sera from patients with non-A non-B hepatitis. Thousands of clones were screened in this way, until one was found that reacted with antibodies in the sera of infected patients. DNA from the positive clone was then used to screen other clones by DNA hybridization, and eventually the full-length sequence of HCV was elucidated (Choo *et al.*, 1989). This enabled the development of diagnostic tests that are crucial to screening the blood supply, and to preventing transmission of hepatitis C by blood transfusion. A very similar molecular approach was used later to identify hepatitis E virus, responsible for occasional large outbreaks of water-borne viral hepatitis (Purdy and Krawczynski, 1994).

Consensus PCR

Direct application of the PCR technique proved very valuable when an outbreak of cases of acute respiratory disease syndrome occurred in the south-western United States, initially on a Navajo Indian reservation. Initial serological studies suggested that the serum of patients who had experienced the disease contained antibodies that cross-reacted with Hantaan virus, a bunyavirus that was a known pathogen transmitted by rodents and causing haemorrhagic fever with renal syndrome (HFRS) in Asian countries such as Korea, but Hantaan virus was not suspected of causing fatal pulmonary disease in the United States.

Because of the serological cross-reaction, the known nucleotide sequence of Hantaan virus was used to make consensus primers for PCR amplification, and by this means a new group of hantaviruses, causing severe pulmonary distress syndrome (hantavirus pulmonary syndrome (HPS)), was identified (Nichol *et al.*, 1993). Once the consensus primers had amplified the RNA genome of the new hantaviruses, more specific primers could be designed, based upon sequence analysis of the new hantaviruses. The prototype virus of what has proved to be a very large group of viruses present in rodents of the subfamily *Sigmodontinae* was named Sin Nombre virus. So far, rodents transmitting HPS have only been found in the Americas.

Random Primer PCR

In 2001, a Dutch group reported the isolation of a new respiratory virus from young children which had sequences, amplified by random primer PCR, which resembled a pneumovirus of turkeys that differed from respiratory syncytial virus (RSV), and was classified as avian metapneumovirus (van den Hoogen *et al.*, 2001). They named the new virus human metapneumovirus, and serological studies showed that all children tested in the Netherlands were exposed to the virus by five years of age, and that

the virus has been circulating in the population for at least 50 years. The disease caused by this virus is similar to infection by RSV, and it has now been reported throughout the world (van den Hoogen *et al.*, 2004).

Representational Difference Analysis

In addition to PCR, sequence representational difference analysis (RDA) was used to identify human herpesvirus 8 (HHV8), a rhadinovirus found in association with Kaposi's sarcoma (KS), a rare skin tumour found in AIDS patients. In this technique, DNA extracted from KS tissue was compared with DNA extracted from normal tissue, and DNA sequences of a new herpesvirus were only found in the Kaposi's sarcoma tissue (Chang *et al.*, 1994; Moore *et al.*, 1996). Similar virus sequences were subsequently detected in tissue from patients with multicentric Castleman's disease and the rare primary effusion lymphoma, and HHV8 is believed to be associated causally with these tumours.

The RDA approach has also been successfully used in the identification of other viruses which are apparently common human infections but for which no clear association with disease has been found (Mushahwar, 2000). Three viruses, known as GBV-A, GBV-B and GBV-C, were found as a result of studies on the serum from a surgeon (George Barker) with acute non-A non-B hepatitis. When injected into marmosets (tamarins) of *Saguinus* spp., his serum caused hepatitis which could be serially passed in marmosets; the causative virus was distinct immunologically and structurally from the known hepatitis A, B, C and E viruses. Two viruses (GBV-A and GBV-B) were isolated from serum of the infected marmoset using the RDA technique and found to be new members of the family *Flaviviridae*, and associated with GB agent hepatitis.

A third newly-discovered flavivirus, GBV-C, was identified in human sera by reverse transcription and consensus PCR, using primers based upon the GBV-A, GBV-B and HCV helicase gene, and appears to be identical to a virus that was independently isolated and called hepatitis G virus (Linnen *et al.*, 1996; Simons *et al.*, 1995). For this reason, the virus is usually called GB virus C/hepatitis G virus. This latter virus is widely distributed in the human population, but has not been shown to cause hepatitis. It seems able to infect both liver and spleen cells without causing obvious disease symptoms.

The RDA approach was also used to identify a completely different class of viruses in the human population. Once again, the initial discovery of the virus occurred during attempts to isolate a new agent causing transfusion-related hepatitis that was not due to hepatitis viruses A, B, C, D, E or G. Using RDA, DNA clones

were isolated from a patient (initials T.T.) before and after transfusion. The differential DNA analysis revealed a small non-enveloped virus with a DNA genome, and it was named TT virus (TTV) after the initials of the patient (Nishizawa *et al.*, 1997). Although no association of TTV has been found with any human or nonhuman primate disease, the virus appears to be ubiquitous in the healthy human population, with multiple variants (Hino and Miyata, 2007; Khudyakov *et al.*, 2000; Mushahwar *et al.*, 1999; Okamoto *et al.*, 2000). The name *Anellovirus* has been proposed to describe this large genus of viruses that have a circular, single-stranded, negative-sense DNA genome approximately 3850 nucleotides in length. Analysis of a large collection of TTV genomes showed nearly 50% of them to be recombinant (Worobey, 2000).

DNase-SISPA

Recently, a new screening approach was developed that involved treating human samples with DNase to remove any DNA, then amplifying the remaining RNA by sequence-independent single primer amplification PCR (Allander *et al.*, 2001). By this means, RNA sequences of several previously unknown human viruses were found.

The first to be reported was a new human parvovirus, which had a sequence similar to bovine and canine parvoviruses, which belong to the new genus *Bocavirus*. The new human virus was found in respiratory secretions and has been named 'human bocavirus'. As soon as it was reported, virologists worldwide found that it was present in respiratory secretions of children under five years of age in all continents, and appeared mainly to be associated with bronchiolitis, though the exact disease associations are still being examined (Allander *et al.*, 2007b; Sloots *et al.*, 2006).

Subsequently this technique was used in the detection of two new human polyomaviruses, KI and WU, in human respiratory secretions (Allander *et al.*, 2007a; Gaynor *et al.*, 2007). Some 30% of their genome differs from human polyomaviruses BK and JC. Their role in disease, if any, remains unknown.

Conclusions Regarding Molecular Techniques

It seems likely that as molecular techniques continue to be applied in this manner, many more viruses that have no obvious association with pathogenesis will be found in the human population. In addition, it is likely that, using molecular approaches, a number of diseases presently of unknown aetiology will prove to be associated with causative viruses that have yet to be discovered.

Despite the availability of these sophisticated molecular approaches for the identification of emerging viruses, the

most recently identified emerging virus pandemic—a human coronavirus causing SARS—was found by the classical technique of electron microscopy of the virus growing in cell culture (Ksiazek *et al.*, 2003). Only once the virus was identified by electron microscopy were molecular techniques used to establish that it was a newly-identified coronavirus not hitherto seen in the human population.

Increased Contact with Vectors of Virus Infection

As the global human population continues to expand, there is increased opportunity for human contact with natural virus vectors, such as arthropods, birds or rodents, and in recent years we have seen the emergence of a number of new virus diseases, as well as a resurgence of other diseases that were formerly well controlled. Indeed it has been postulated that many major infectious diseases arose in the human population as the result of transfer from animals (Wolfe *et al.*, 2007). Some instances involve the invasion by humans of a new ecological niche which brings them into closer contact with animal or arthropod vectors. As an example, in South America deforestation of large land areas may deprive rodents carrying arenaviruses or hantaviruses of their usual habitat, resulting in infestation of houses and closer contact with the human population. Although there has been no large pandemic of influenza since 1968, it is highly likely that reassortment of an avian influenza virus with a human one, as happened in the last two pandemics, will occur again. There is a vast reservoir of influenza viruses in the avian population (Webster and Kawaoka, 1994) and our ability to control such a pandemic, if it occurs, has not significantly improved in the last 30 years.

Arthropod-borne Viruses

Another important factor that has contributed to the emergence of virus diseases is the vector population density. This is particularly true of mosquito-borne viruses. Once well controlled, the mosquito population, including *Aedes aegypti* and *Aedes albopictus*, has expanded greatly since the cessation of the use of DDT, resulting in increasing cases of dengue fever worldwide (Figure 4.3) and in particular a resurgence of dengue haemorrhagic fever, a severe form of dengue involving infection with two or more serotypes of dengue virus.

Translocation of a vector-borne virus into a new geographical region can result in the emergence of a dramatic disease outbreak. In 1999 there was an outbreak of West Nile viral meningoencephalitis, first detected in New York City. This virus had only been detected previously in Africa and the Middle East, and once the virus found in New York was sequenced, it was found to be identical in sequence to a virus isolated from diseased birds

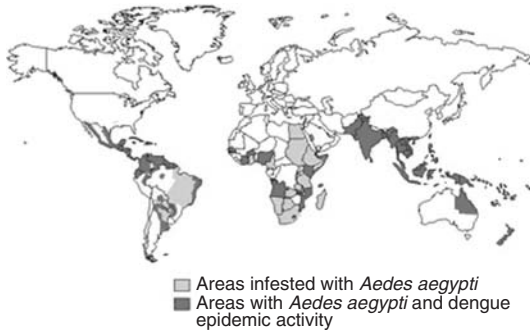

Figure 4.3 World distribution of dengue, 2005.

in Israel. How the virus was imported into the United States is unknown—an infected person, a mosquito or a bird are all possibilities. However, once established in a virgin population with the appropriate vector, the virus soon spread both south and west from New York, and has now moved south into the Caribbean and Mexico and north into Canada. By 2002, West Nile virus had spread to 39 states and DC, and caused 2741 human cases of meningoencephalitis and 263 deaths. More than 124 000 dead birds were reported, as well as more than 12 000 cases in horses. The virus was recovered from 37 species of mosquito, and is now an endemic disease requiring considerable public health efforts for its control.

Rodent-borne Hantaviruses

In 1993 an epidemic of acute respiratory disease occurred in south-western United States, and was identified as HPS, a new clinical disease of high mortality (40%), spread by a virus in the deer mouse (*Peromyscus maniculatus*) population in the area. It soon emerged that climatic conditions in the summer of 1993 had favoured an explosion in the population of deer mice, and this was the major factor which had contributed to a large number of HPS cases from which the epidemic became recognized. Once recognized, other hantaviruses were identified in both North and South America, many causing severe and often fatal HPS in the human population (Figure 4.4).

Although most rodents worldwide appear capable of housing and transmitting hantaviruses, the only cases of severe HPS have been associated with rodents of the subfamily *Sigmodontinae*, which is confined geographically to the western hemisphere, in North and South America. In other parts of the world, hantaviruses cause milder disease, with few fatalities.

Bats as Virus Vectors

Another important group of animals that act as vectors for virus diseases are bats, which make up a fifth of all

Figure 4.4 New world hantaviruses (2007). Dark yellow represents viruses causing hantavirus pulmonary syndrome, and cream represents rodent isolates not associated with disease in humans. (Courtesy of James Mills, CDC, Atlanta, GA, USA.)

living mammalian species (Wilson and Reeder, 2005). In the United States, insectivorous bats are the most important vector species for human rabies, often transmitting the disease silently, by a bite of which the human is unaware. In recent years fruit-eating bats have also been recognized as important disease vectors (Halpin *et al.*, 2007). There are some 170 species of fruit-eating bats (*Megachiroptera*) in the tropical regions of Asia.

In 1994 a horse trainer and a stablehand who worked on a farm in Hendra, a suburb of Brisbane, Australia, both became ill while nursing a sick pregnant mare that had recently been brought on to the property. The disease spread to other horses on the property, and 14/21 infected horses died of pulmonary disease with haemorrhagic manifestations. Of the two infected humans, the trainer died, but the stablehand survived the infection after a lengthy illness. One year later, another horse farmer died 600 miles away in Mackay, from encephalitis caused by a similar virus. The virus, named Hendra virus, was found to be a new paramyxovirus with a large genome, about 19 kb in length, morphologically similar to other paramyxoviruses but with a very long nucleocapsid. Subsequently, this virus was recognized as causing disease again in 1997, when it caused the death of a horse in Cairns, in the far north of Australia, and in Queensland in 2007, when another veterinarian became ill after performing an autopsy on a thoroughbred horse that died of Hendra virus infection. However, in the meantime work carried out in the Australian Animal Health Laboratory in Geelong had identified the virus in fruit bats, and a survey revealed that a high proportion of fruit bats had antibodies against the virus.

Beginning in 1997, an outbreak of a new respiratory disease in pigs was noticed by farmers in Malaysia. In late 1998 and 1999 many farmers and other persons having close contact with pigs developed severe symptoms of encephalitis. In all there were 265 human cases, of whom 105 persons died. The disease did not appear to be transmissible between humans, and was stopped in May 1999 by the slaughter of more than a million pigs, causing great economic loss to the Malaysian pig industry. In March 1999 a virus was isolated in cell culture from the brain of a patient in Sg Nipah village, Bukit Pelandok, Malaysia. The virus caused syncytia during growth in Vero cells, and gave a positive test by immunofluorescence assay carried out at CDC using an antiserum made against Hendra virus. By thin-section electron microscopy of infected Vero cells, a paramyxovirus with a long nucleocapsid was found. Complete sequencing of the virus genome showed that it was a large negative-stranded RNA molecule, 18246 nucleotides in length, with about 80% homology to the genome of Hendra virus. The new paramyxovirus, called Nipah virus (Chua *et al.*, 2000), was subsequently found in large fruit-eating bats, and it was from these that the virus is presumed to have spread first to pigs, and then to humans in close contact with infected pigs. Curiously, the mortality rate in pigs was less than 5%, much less than was seen amongst the human cases. Pigs develop rapid, laboured breathing and an explosive nonproductive cough as the main symptoms, with occasional neurological changes, such as lethargy or aggressive behaviour. Humans develop a febrile encephalitis which rapidly progresses to multisystem involvement with vasculitis and syncytial giant cell formation at various sites. Spread to the brain is by the vascular route and leads to discrete small foci of necrosis and neuronal degeneration.

In 2001 an outbreak of Nipah virus infection occurred in Siliguri, West Bengal, involving eight human cases, and in nearby Bangladesh outbreaks involving humans who had contact with bats occurred in 2001 and 2004. These outbreaks were caused by a virus slightly different in genome sequence from the Malaysian Nipah virus (Harcourt *et al.*, 2005). Hendra and Nipah virus have now been classified as the members of a new genus of the *Paramyxoviridae* called the *Henipavirus* genus (Eaton *et al.*, 2006).

Nonhuman Primates as Virus Vectors

It is now recognized that HIV-1 and HIV-2 have their origins in chimpanzees and sooty mangabey monkeys, respectively (Holmes, 2001), which can both be infected with these viruses but do not themselves routinely develop AIDS. The transmission of these zoonotic infections has been ascribed to the practice of killing and eating the primates (as bushmeat), and it is clear that

other viruses can emerge in the same way. Viruses causing severe haemorrhagic fever, such as Ebola virus and Marburg virus, have certainly passed from nonhuman primates to man by this means on several occasions, but it is generally believed that another natural reservoir exists for these viruses, since, like man, nonhuman primates are highly susceptible to both these filoviruses. Because they cause extremely high mortality in man (up to 90% of infected persons), a great deal of concern is generated when an outbreak occurs. The original outbreak of Marburg virus was caused by direct transmission from infected monkeys by persons handling fresh monkey tissues, but in general filovirus outbreaks are largely amplified by person-to-person transmission, usually in a hospital setting, as occurred in the last major outbreaks caused by Ebola virus in Kikwit, Democratic Republic of the Congo, in 1995, and by Marburg virus in Angola in 2004–2005. Recent evidence suggests that the natural reservoir for Marburg and Ebola hemorrhagic fever viruses is a common African fruit bat (*Rousettus aegyptiacus*) (Towner *et al.*, 2007), and it is from this species that apes and humans become infected in the first instance.

Other viruses which have long been known to have their origin in nonhuman primates are human T-lymphotropic viruses (HTLVs) types 1 and 2, which originated independently and are related to distinct lineages of simian T-lymphotropic viruses (STLV-1 and STLV-2, respectively). These viruses belong to the genus *Deltaretrovirus*. It has been known for some time that HTLV-1 causes adult T-cell leukaemia and HTLV-associated myelopathy/tropical spastic paraparesis (HAM-TSP) in about 2–5% of those infected. HTLV has spread worldwide to more than 20 million people, sexually, from mother to child, and by exposure to contaminated blood through transfusion and injection drug use. HTLV-2 appears to be less pathogenic than HTLV-1. The butchering and eating of primates is a common occurrence in parts of Africa, and recently several new HTLVs have emerged from studies of persons in Africa involved in the preparation of 'bushmeat' from nonhuman primates (Switzer *et al.*, 2006; Wolfe *et al.*, 2005). These include HTLV-3, which appears to be related to STLV-3, a virus not previously seen in humans, and HTLV-4, which is not related phylogenetically to any previously isolated T-lymphotropic virus. It is not yet known whether these newly-discovered retroviruses are important causes of disease in humans.

Conclusions Regarding Contact with Vectors

It is clear from the experience gained over the past 20 years that animal, bird or arthropod reservoirs are extremely important sources for the emergence of new diseases. This has led to an assumption that most

newly-discovered virus diseases have their origin in another species. The outbreak of SARS coronavirus may be a case in point, and suspicion has been placed on various exotic animal species that are eaten by the Chinese and may have started the epidemic in Guangdong, although the reservoir species for the SARS coronavirus appears again to be a bat (Shi and Hu, 2008; Wang *et al.*, 2006). This remains to be proven, but it is widely believed that the next pandemic of human influenza will occur as a result of reassortment between an avian and a human influenza virus. Only by continued global surveillance and prompt reporting to the WHO can we hope to control the outcome of such an event.

FUTURE DIRECTIONS

It is clear that a large number of new viruses have emerged in recent years, and in many cases it is still unclear what role, if any, they play in human disease. This is in contrast to the original development of virology, when viruses were discovered by observing them or isolating them from diseased tissue. Recently a return to these classical observations has been the identification of a novel gammaretrovirus in human prostate tumours of patients homozygous for a reduced interferon response involving the activity of RNase L (Urisman *et al.*, 2006). The virus was isolated from human prostate tumours and found to be a novel gammaretrovirus, xenotropic murine leukaemia related virus (XMRV). XMRV provirus integration sites have been mapped in human prostate tumour tissue, and it is clear that this virus has infected at least a subset of human prostate cancer cases, though it is not yet clear whether the virus or its integration site have any influence on the aetiology or progression of prostate cancer (Dong *et al.*, 2007).

An ounce of prevention is worth a pound of cure
BENJAMIN FRANKLIN

INTRODUCTION

The science of vaccinology encompasses many disciplines and activities. They converge in making the best possible use of the discoveries of Edward Jenner, a country doctor in Gloucestershire, and his successors, who have shown that infectious diseases can be prevented by artificially inducing immunity through the administration of vaccines. Historically, a farmer from Yetminster in Dorset named Benjamin Jesty was the first known person to have experimentally tested, in 1774, the prevalent rumour that milkmaids had beautiful facial skin because they contracted cowpox during their work and were then spared the disfigurement caused by smallpox. However, Jesty only ‘vaccinated’ his wife and two of his children and did not pursue that bold experiment further. It was left to Jenner to provide convincing support for the hypothesis that cowpox protected against smallpox, get it generally accepted and popularize the practice of vaccination (Pead, 2006).

Around 1768, a milkmaid had told Jenner about cowpox, a rare bovine disease sometimes transmitted to humans which according to countryside folklore protected against smallpox. He thought about this over many years and discussed the hypothesis with many others before doing the crucial experiment. Finally, on 14 May 1796, Jenner scraped pus from a lesion caused by cowpox, from the hand of a milkmaid named Sarah Nelmes, and scratched it into the arm of an eight-year-old boy called James Phipps. This was done in the hope of protecting the boy against

smallpox, a contagious disease that had caused endless death and suffering among humans since antiquity. It is not known for certain whether Jenner had heard about Jesty before performing that experiment, although there are strong suspicions that he had (Pead, 2006). Much later, Jenner acknowledged the contribution of Jesty (Plotkin *et al.*, 2008). To prove that James had been rendered resistant to smallpox he underwent on 1 July of that year ‘variolation’, the then widely used, though risky, practice of inoculating dried material from smallpox lesions by various means in order to try to protect them against smallpox. James was found to be ‘secure’ (i.e. immune) to smallpox! Jenner and his followers then proceeded to generalize the inoculation of pus from cowpox lesions, from person to person, with great success, though also with some major disasters due to contamination of his inoculum with other pathogens. There was, however, no doubt that Jenner’s invention protected against smallpox. He even predicted that it would ‘annihilate’ (i.e. eradicate) the disease, something that was only achieved nearly 200 years later.

To honour the memory of Jenner, the word ‘vaccine’ (from ‘*vacca*’, ‘cow’ in Latin) was coined by Louis Pasteur many decades later. Pasteur, who established that ‘spontaneous generation’ did not occur and that transmissible diseases were caused by microorganisms, also developed the second vaccine against a human disease—rabies. This was subsequently shown to be caused by a virus, as was the case for smallpox. The past tense can now be used for smallpox because that bane of mankind (credited with being the natural main brake on population growth in Europe until the general use of vaccination) (Bonanni, 1998) has been eradicated (Fenner *et al.*, 1988). Smallpox eradication has been hailed, with good reason,

as Medicine's greatest triumph. However, since smallpox virus was not totally destroyed and has officially been kept in two laboratories (in the United States and Russia), and, unfortunately, may have been (unofficially) transferred to a small number of other countries, there remains the fear that bioterrorists may malevolently reintroduce it (Henderson, 1998).

The best weapon against viral diseases, in spite of the development of several efficacious antivirals, is still vaccination (Plotkin *et al.*, 2008). The purpose here is not to describe every viral vaccine that has been developed (they are, in any case, covered in the chapters on the individual viruses) but to describe the principles and practice of vaccinology. A non-exhaustive list of the disciplines and activities involved is:

1. Burden of viral diseases and their reproductive rates.
2. The immune system and its role in natural and artificially-induced immunity.
3. Discovery of protective antigens in pathogens.
4. Presentation of protective antigens through vaccines and types of vaccines.
5. Research and development on vaccines and their commercial introduction.
6. Social marketing of introduced vaccines.
7. Planning and implementation of vaccination programmes.
8. Surveillance of disease incidence and adverse events before and after implementation of vaccination.
9. Rectification of publicized falsehoods and maintenance of vaccination coverage.

The first nine sections of this chapter are therefore devoted to those aspects of vaccinology, while the final section, 'Viral Vaccines on the Horizon and Roadblocks to Future Vaccine Development', is a brief survey of the viral vaccines that may become available in the foreseeable future and of the hurdles to be cleared (Andre, 2003).

BURDEN OF VIRAL DISEASES AND THEIR REPRODUCTIVE RATES

Once the viral aetiology of a disease has been established, and before there is any discussion about the need to develop a vaccine, it is important to study its epidemiology and its burden on society in terms of its incidence, morbidity (range of severity and frequency of complications) and mortality. This is usually done by calculating the number of disability-adjusted life years (DALYs) that are lost as a result of the disease, at the local, country, regional and global levels (Murray and Lopez, 1996). In addition, the

financial cost of the disease (both direct medical and indirect societal costs) should be taken into consideration to get a total picture of the importance of an infection to human societies. The burden of the same disease on different societies may be different, greatly due to epidemiological and economic circumstances (Drummond *et al.*, 2001). The need for a vaccine will be determined by the DALYs lost and the economic burden inflicted worldwide by the disease it is meant to protect against.

The mode of transmission of the virus must be studied and it is also important to know whether the infection occurs in epidemic waves or is endemic. Seasonality of outbreaks will become obvious if precise diagnosis and recording of cases are in place. In order to design an optimal vaccination programme, the infectiousness and contagiousness of the virus should be known. This is expressed as the basic reproduction rate (R_0), defined as 'the average number of individuals infected by an infectious case during their infectious period, while in a totally susceptible population'. R_0 is a parameter that allows the calculation of the proportion of persons (P_c) that must be immune (either naturally or by vaccination) to reduce effective R_0 to below 1 (thus halting transmission in the population). The relation between P_c and R_0 is $P_c = 1 - 1/R_0$. When the actual P_c in a 'closed' population is high enough, herd immunity results. Attainment of herd immunity is the main reason, apart from the obvious one of protecting as many people as possible, for advocating high vaccine coverage rate, because when that is achieved, even the unvaccinated minority in a population is protected (Anderson and May, 1991). Table 5.1 shows the minimum vaccination coverage (taking into account vaccine efficacy) required to stop transmission of measles, mumps, rubella and poliomyelitis (Anderson and May, 1990; Nokes and Anderson, 1988). For varicella the required vaccination coverage is even higher, as >95% of susceptible close contacts of a case in the infectious phase will get infected.

What can be achieved by vaccination is illustrated in Table 5.2. The figures speak for themselves.

Table 5.1 Minimum vaccination coverage required to stop transmission of several viruses

Virus	Infectiousness (R_0)	Vaccination coverage needed (%)
Measles	15–17	92–95
Mumps	10–12	90–92
Rubella	7–8	85–87
Poliomyelitis	5–6	80–85

Adapted from Anderson and May, 1990.

Table 5.2 Vaccine-preventable diseases: reduction in annual prevalence in the United States after introduction of routine vaccination

Disease	Peak prevalence year	Number of cases	Cases in 1999	Percentage reduction
Diphtheria	1921	206 939	1	99.99
Measles	1941	894 134	86	99.99
Mumps	1968	152 209	352	99.76
Pertussis	1934	265 269	6031	97.63
Polio (wild)	1952	21 269	0	100.00
Rubella	1969	57 686	238	99.58
Congenital Rubella	1964–1965	20 000+	3	99.98
Tetanus+	1923	1 560	33	97.88
Invasive Hib Disease (>5 yr)	1984	20 000+	33	99.83

THE IMMUNE SYSTEM AND ITS ROLE IN NATURAL AND ARTIFICIALLY-INDUCED IMMUNITY

The immune system is a collection of organs, tissues, cells and molecules that work together to defend the body against attacks by pathogens and other foreign and potentially harmful substances. Its mission is to restrict entry of, neutralize and eliminate potentially harmful microorganisms and agents. It must recognize molecules as causing damage to tissues and take action to destroy or remove them, thus conferring protection. Damaged tissues liberate damage-associated molecular patterns (DAMPs), which are signals of danger. Danger signals are detected by the immune system through its recognition of pathogen-associated molecular patterns (PAMPs) on pathogens. DAMPs and PAMPs bind to pattern recognition receptors (PRRs) like toll-like receptors (TLRs) on dendritic cells and macrophages (Matzinger, 2007).

Two parts in the immune system, the innate and the adaptive, have been recognized.

The innate immune system provides the first line of defence against infectious or other attack; it is present from birth and is nonspecific. It does not generate a memory against the invading organism or other substance, since it is not more efficient in dealing with it on re-exposure. Innate immunity is, in the first instance, mediated by physical, chemical and biological barriers provided by the skin and mucous membranes of the gastro-intestinal, respiratory and genito-urinary tracts, and also by genetic attributes like the absence of a cellular receptor for a particular virus. For example, mice are genetically not susceptible to infection by polioviruses because they do not have a poliovirus receptor (PVR). However, if they are made transgenic for PVR, they can be infected and paralysed by virulent poliovirus (Levenbook and Nomura, 1997).

Unless the integrity of the skin and mucous membranes is breached by chemical or physical trauma, most microorganisms cannot cross them and invade the body. Protection by chemicals is conferred by acidic secretions (e.g. in the stomach and vagina) or enzymes like lysozyme secreted onto the surface of physical barriers. In addition, a biological protection is offered by the resident bacterial flora on these surfaces. The bacteria produce antimicrobial substances that attack potential invaders that land on them. Should the physical, chemical and biological barriers not suffice to prevent entry into the *milieu intérieur*, roaming cells (mainly macrophages and neutrophils) constitute a second line of defence. They phagocytose the invader and neutralize it by producing molecules like interferon that inhibit the replication of viruses. The innate system is also responsible for detecting DAMPs and PAMPs and presenting them through PRRs to antigen-presenting cells (APCs) in the adaptive system, in a way that will prompt it to respond most efficiently to the infection. The innate immune system is permanently present and acts on the pathogen immediately after invasion, while at the same time informing the adaptive immune system about the invasion (Medzhitov and Janeway, 1997; Trinchieri and Sher, 2007).

The adaptive immune system comes into play if innate immunity cannot stop the further spread of the infection. It is mediated by lymphocytes of two types: B lymphocytes (derived from the bone marrow), which secrete antibodies of various types (IgA, IgD, IgE, IgG, IgM) to antigens, and T lymphocytes (derived from the thymus), which react to the same antigens and inactivate the virus that carried them into the body. In cases where this does not occur (as for example in human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) or hepatitis C) a chronic infection is established. Sometimes the infection becomes 'latent', as

with herpes viruses. Nevertheless, infections sometimes result in death, either acute or delayed.

Immunity mediated by antibodies is called ‘humoral’, whereas that conferred through lymphocytes (such as killer T cells or specific cytotoxic lymphocytes) is said to be ‘cell-mediated’. Humoral and cell-mediated immunity (CMI) constitute the effector arm of the adaptive immune system.

In order to be brought into action, the effector arm needs information about the antigens that it must deal with and the microorganisms that carry them. This information is provided by the afferent arm of the system. That arm is mainly constituted by ‘professional’ APCs, such as ubiquitous macrophages and dendritic cells such as Langerhan’s cells in the skin. Some antigens—the T-independent ones like polysaccharides—can directly instruct B lymphocytes to synthesize specific antibodies that recognize them, but most antigens require the help of T cells to elicit an immune response. Antigens are molecules that stimulate the immune system to develop a specific response (either humoral, cell-mediated or both) to them. The adaptive immune system’s responses are ‘learned’ and antigen-specific; they rely on the ability of the system to recognize an antigen as ‘foreign’ or one (in the case of T-dependent antigens) that has been seen before (which implies the previous acquisition of a memory for that particular antigen). The memory for an antigen acquired by the adaptive system is manifested by an accelerated and enhanced humoral and/or cellular immune response when it again encounters the antigen. This response is called ‘secondary’ to differentiate it from the ‘primary’ response elicited on the first encounter. Figure 5.1 shows the serum antibody kinetics in the primary and secondary responses. The ability to mount a secondary response often

Figure 5.1 Kinetics of primary and secondary antibody responses and acquisition of immunological memory induction.

persists for life and in many cases ensures lifelong immunity to disease (although not necessarily to re-infection). T-independent antigens elicit only primary-type responses and therefore confer relatively short-lived protection.

In some diseases the incubation period is longer than the time required for the secondary response to reach protective levels. Detectable vaccine-induced serum antibody may be lost (e.g. following hepatitis B vaccination) but the infection that may result is subclinical and does not develop into a chronic one (the medically most important one).

Antibodies protect against viral infection and disease by at least two mechanisms:

1. Neutralization of the infectivity of viruses due to binding of a (or several) viral surface antigen(s) to a cellular receptor (steric hindrance). Antibodies can also hinder infection by preventing cell fusion and uncoating of viruses after they have entered a cell, thus conferring what has been called ‘sterilizing immunity’.
2. Destruction of infected cells by the mechanism of antibody-dependent cellular cytotoxicity (ADCC). Natural killer cells and macrophages carrying Fc receptors bind to the antibodies, reacting with the epitope of a viral antigen on the surface of the infected cells.

Also, specifically activated CD8 cells that liberate interferon-gamma and tumour necrosis factor-alpha destroy virus-infected (as well as cancer) cells, as well as having a direct cytolytic action. Perforins and granzymes mediate apoptosis of cells, which has been described as ‘pre-programmed cellular suicide’.

Until fairly recently, it was thought that the innate and adaptive immune systems were independent. But, with the discovery of TLRs (found on cells of both the innate and adaptive parts of the immune system), it is now known that they collaborate by secreting molecules like cytokines in order to ensure the best possible protective response (known as natural immunity) to a potentially dangerous invasion in nature. However, natural immunity sometimes fails against pathogens that have evolved escape mechanisms, for example, human papilloma virus (HPV). For such pathogens, vaccines that perform better than nature are needed.

TLRs recognize PAMPs and DAMPs and transfer information about them to professional APCs that have PRRs (Pattern Recognition Receptors). These APCs then present them to the effector arm of the adaptive system. Knowledge about TLRs is progressing fast and already contributes to a better understanding of natural and artificial immunity. Thus it is known that MPL (3-*O*-desacyl-4'-monophosphoryl lipid A), an adjuvant

used in some licensed vaccines, binds to toll-like receptor No 4 (TL-4) and so enhances the production of antibodies. Also, CpG motifs bind to the TL-9 that triggers CMI. Adjuvants are substances of various kinds that, alone or mixed, enhance an immune response.

A thorough understanding of the workings of both the innate and the adaptive immune systems and their interaction is very helpful in the development of new vaccines. Modern vaccine technology provides new means to modulate the magnitude and specificity of immune responses following vaccination. Matching the right adjuvant with the right antigen can improve immune responses in target populations and prevention of specific diseases. The use of novel adjuvant systems has shown encouraging preliminary results in preventing diseases such as malaria and (pre)pandemic influenza that had long been considered beyond the reach of conventional vaccines. Potential benefits from new adjuvants are:

- More appropriate direction of humoral and/or cellular immune responses.
- Induction of long-term protection through:
 - stronger immune responses
 - improved immunological memory
 - broader protection against related clones (cross-protection).
- Reduction of antigen dose.

‘Artificially-induced immunity’ is that resulting from vaccination (providing active immunity), or from the iatrogenic administration of protective antibodies or their transfer from a pregnant woman to her fetus via the placenta (conferring passive immunity). Passive immunity is short-lived as it will last only as long as the acquired antibodies, which are catabolized and not replenished, persist above the protective level, whereas active immunity is long-lived due to persistence of vaccine-induced antibodies at protective levels and immunological memory. The art of inducing artificial active immunity consists in matching the right adjuvant with a (some) protective antigen(s) to obtain a vaccine that will induce optimal protection in the target population (Aguilar and Rodriguez, 2007; Fraser *et al.*, 2007; Garçon *et al.*, 2007).

DISCOVERY OF PROTECTIVE ANTIGENS IN PATHOGENS

Before embarking upon the discovery of protective antigens, a crucial question that must be answered is: ‘do those who survive a viral disease develop immunity against further attacks of disease when exposed and infected with the same virus?’ In other words, does natural immunity occur after infection? If the answer is ‘yes’

then ‘protective antigen(s)’ exist(s) in the pathogen and it should therefore be possible to develop a vaccine against it. For viral diseases like AIDS and hepatitis C where natural immunity does not exist or is at best suboptimal, the problem of developing a vaccine becomes more complex, though hopefully not impossible.

The concept of protective antigens is fundamental to the development of modern vaccines. Historically, vaccines were developed by empirical hit-and-miss methods based on observation, hypothesis generation and confirmatory experimentation. The obvious example was the confirmation by Jenner that cowpox could protect against smallpox; a belief widespread among farmers at the time he undertook his experiment on James Phipps. A more recent example, in which the authors were personally involved, was the demonstration that a vaccine based on an attenuated bovine rotavirus could protect against human infantile rotavirus gastroenteritis. This was based on the hope that the Jennerian approach might again work—and it did (Vesikari *et al.*, 1983, 1984, 1985). Although the initial candidate vaccine derived from cattle was not further developed, that early proof of concept led to the commercial introduction of several rotavirus vaccines. Modern vaccines are being and will be developed by more rational scientific approaches but it must be recognized that traditional methods and serendipity may still sometimes yield valuable products.

A ‘protective antigen’ is one that can (but not necessarily will) stimulate an immune response, whether of the humoral or cellular type, and prevent or alleviate the clinically-important consequences of infection with a pathogen. The active principle(s) of future vaccines should only be the protective antigen(s), if necessary rendered more immunogenic by the addition of adjuvants. The art consists of choosing an adjuvant or mixture of adjuvants that will stimulate the relevant arm of the adaptive immune system through the help of the innate system and give optimal and long-lasting protection against the disease in question.

In the past, the discovery of protective antigens relied on the identification of presumed protective antibodies. Thus, the immunizing antigen elicited production of antibodies that would neutralize the infectivity of a virus in tissue culture or in an animal-challenge model. Nowadays, with our knowledge of the coding sequence of the genome of microorganisms it is possible to perform what has been called ‘reverse vaccinology’ (i.e. starting from the proteins that the genome can synthesize, finding those that are protective in an animal model (if it exists)). The putative protective (in man) antigen(s) can thus be identified and developed further (Mora *et al.*, 2006). Sometimes the protective antigen is not found on a particular molecule but is formed by the juxtaposition of several proteins on the

surface of the virus, as is the case for hepatitis A. An efficacious vaccine can then only be envisaged by presenting that epitope to the immune system through whole-virion vaccines (either inactivated or live) or nucleotide immunization (André, 1995).

However, the identification of a (some) protective antigen(s) is only the first step towards developing a vaccine. The following sections will make it clear that there is a very long road to follow before a vaccine is made commercially available and used efficiently for disease prevention, even after protective antigens have been identified and isolated from the pathogen, produced by genetic engineering or introduced into the body through nucleic acids that code for the antigen or protective epitope.

PRESENTATION OF PROTECTIVE ANTIGENS THROUGH VACCINES AND TYPES OF VACCINE

Once the protective antigen(s) is/are known, a decision must be made on how best to present them to the immune system.

In the field of viral vaccines, the classical methods of producing protective antigens were to either culture, harvest and then inactivate (chemically or physically), or to attenuate (by repeated passages in tissue culture) the virus. The resulting product was a 'killed' whole-virion vaccine or a live attenuated vaccine. Nowadays, more purified vaccines (like subunit influenza vaccine) and pure antigen vaccines produced by genetic engineering (like yeast-derived hepatitis B vaccine, produced in transformed *Saccharomyces cereviceae* cells that express the surface (protective) antigen of the virus) have been developed (André, 1990; Emini *et al.*, 1986; Stephenne, 1990). Attenuation of viral pathogens can now be obtained by genetic reassortment between wild and attenuated 'master viruses' for influenza (Maassab and Bryant, 1999) and rotavirus vaccines (Clark *et al.*, 1996), deletion of genes that code for virulence factors, or the directed mutagenesis of these genes to render them inoperative (Cohen, 2001).

There are many routes to developing vaccines that present the protective antigens they contain to the immune system in an appropriate way. The types of viral vaccine that can currently be envisioned are:

- Non-replicative (inactivated):
 - whole-virion, split, subunit, pure antigen(s) with or without adjuvant(s).
- Replicative:
 - live attenuated viruses
 - vectorized (gene of protective antigen introduced in a vector)
 - DNA-based (nucleotide or genetic vaccine).

The type of vaccine that will be considered for further development will depend upon considerations of feasibility and cost (not forgetting commercial viability), as the financial and human resources required for the research, development and introduction of a new vaccine in the current politico-economic world system are only likely to be available to large corporations (André, 2002).

The possible routes of administration of vaccines are multifarious. Traditionally, vaccines have been administered by scarification of the skin (e.g. smallpox), injection with needle and syringe (most vaccines), orally (e.g. oral polio vaccine (OPV)) or intranasally for the live influenza vaccine. There are many other possibilities, however, as listed in Table 5.3. These routes are being explored to achieve a more user-friendly administration of vaccines.

RESEARCH AND DEVELOPMENT ON VACCINES AND THEIR COMMERCIAL INTRODUCTION

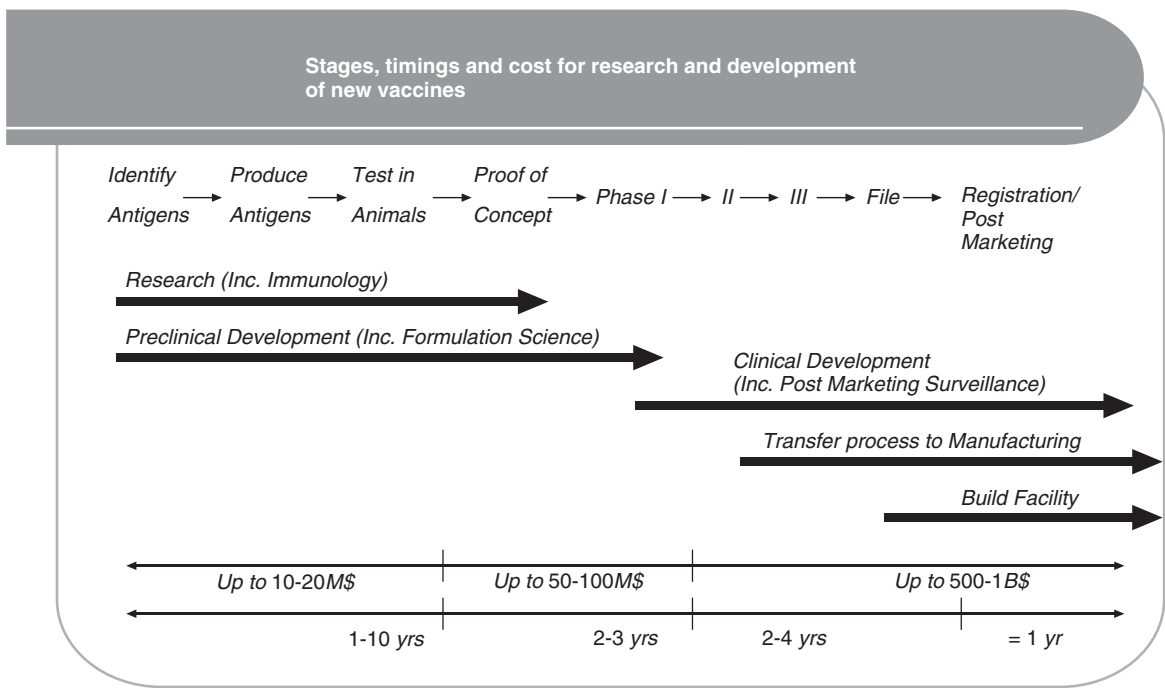

Whereas in the past single individuals or small research institutes could develop new vaccines, there are nowadays only a handful of vaccine manufacturers that have the resources and know-how to bring a new vaccine to market. More and more, the early research phases on new vaccines are done by biotechnology companies, research institutes and academia. Discoveries made in these institutions are then outlicensed to the few major manufacturers who can afford to bring them to market. Indeed, it now costs up to a billion pounds and 20 years of research and development to produce, register and launch a new vaccine. The phases of R&D and associated costs are shown in Figure 5.2.

The vaccine manufacturer, almost always a division of a major pharmaceutical company, must show to the satisfaction of regulatory authorities that the vaccine to be introduced is safe, efficacious and can be produced with consistent quality. This involves extensive characterization of the product to be tested, provision of a suitable antigen dose and administration schedule, and the application of good manufacturing practices to show it can be manufactured in a reproducible way. Antigen dose is based on relevant immune responses in preliminary (Phases I and II) clinical studies, which also monitor the reactogenicity and safety of the candidate vaccine. This stage of development may require the use of the vaccine in hundreds of volunteers of various ages (starting with healthy young volunteers) to determine an acceptable dose and administration schedule for the chosen vaccine formulation. In order to establish the safety, efficacy and consistency of the 'final' product (the commercial product may be produced by slightly different manufacturing

Table 5.3 Possible routes of administration of viral vaccines

Classical	New
By scarification (smallpox)	IM, SC, ID with needleless multidose jet-guns or unidose disposable devices
IM, SC, ID with needle and syringe	Transcutaneous, through antigen-loaded skin patches
Orally (OPV)	In sugar-glass needles
	With 'gene-guns'
	Mucosal (intranasal, respiratory, vaginal, rectal, sublingual)
	As combined vaccines

IM, intramuscular; SC, subcutaneous; ID, intradermal.

The Research & Development pipeline for new vaccines

Figure 5.2 Stages, timings and cost for research, development and introduction of new vaccines.

methods, in which case bridging studies are required), studies in greater numbers of subjects using at least three vaccine lots are carried out in Phase III. Up to 100 000 study participants may be needed to demonstrate that the vaccine is safe and efficacious. ‘Safety’, always a relative concept, is shown by the absence of unacceptable reactions attributable to the vaccine, while efficacy will be demonstrated in statistically valid controlled randomized prospective double-blind field trials. At this point the vaccine developer and manufacturer will have to collate

a voluminous dossier to submit to competent national and/or supranational regulatory authorities, which will describe, in great detail, the work that has been done to substantiate the claim that the candidate vaccine is safe and efficacious and can be produced at a consistent quality in required quantities for the vaccination of humans. To have any chance of getting marketing authorization, a candidate vaccine must have been developed according to the strict guidelines of regulatory authorities (European Medicines Agency, 2006).

SOCIAL MARKETING OF INTRODUCED VACCINES

It is illusory to think that every newly-introduced vaccine will be readily adopted by health authorities, governments and the general public (rarely, they are!), even if it has been shown to be safe and efficacious. It must be marketed just like any other new product in the national and international markets. The major client groups must be informed about the availability of the vaccine and the fact that the disease that it protects against is serious enough to cause a significant disease burden, and shown that it is 'safe' and efficacious. Furthermore, it must be marketed at a cost-effective price; in a growing number of countries this must be shown by pharmaco-economic studies. The best way to achieve acceptance will vary in different countries but usually consists of publishing scientific articles in medical journals and organizing symposia to inform the medical profession and the press.

Governments have to be persuaded that the vaccination is justified as they will need the support of the electorate

to spend taxpayers' money on any nationally-financed vaccination programme. The lay public must also be educated by the mass media through newspapers, magazine articles and radio and television programmes, not forgetting the powerful Internet. Getting vaccinated needs to be seen as being for personal benefit as well as for that of the whole community. It would be a waste of time and money to develop and introduce a new vaccine that is not used to best effect to prevent disease, disability and deaths. However, the successful introduction of a new vaccine requires meticulous planning and the coordinated deployment of the skills and efforts of many enthusiastic believers in it in order for it to gain acceptance by all stakeholders in both the public and private institutional sectors, as well as the general public. The studies and activities required to reach this goal, particularly in developing countries, are summarized in Figure 5.3. In developed countries, the goal can, in general, be achieved by a well-thought-out, well-prepared, widely-publicized, competently-implemented, closely-monitored and adequately-financed national vaccination programme led by dedicated individuals (Miller *et al.*, 2002).

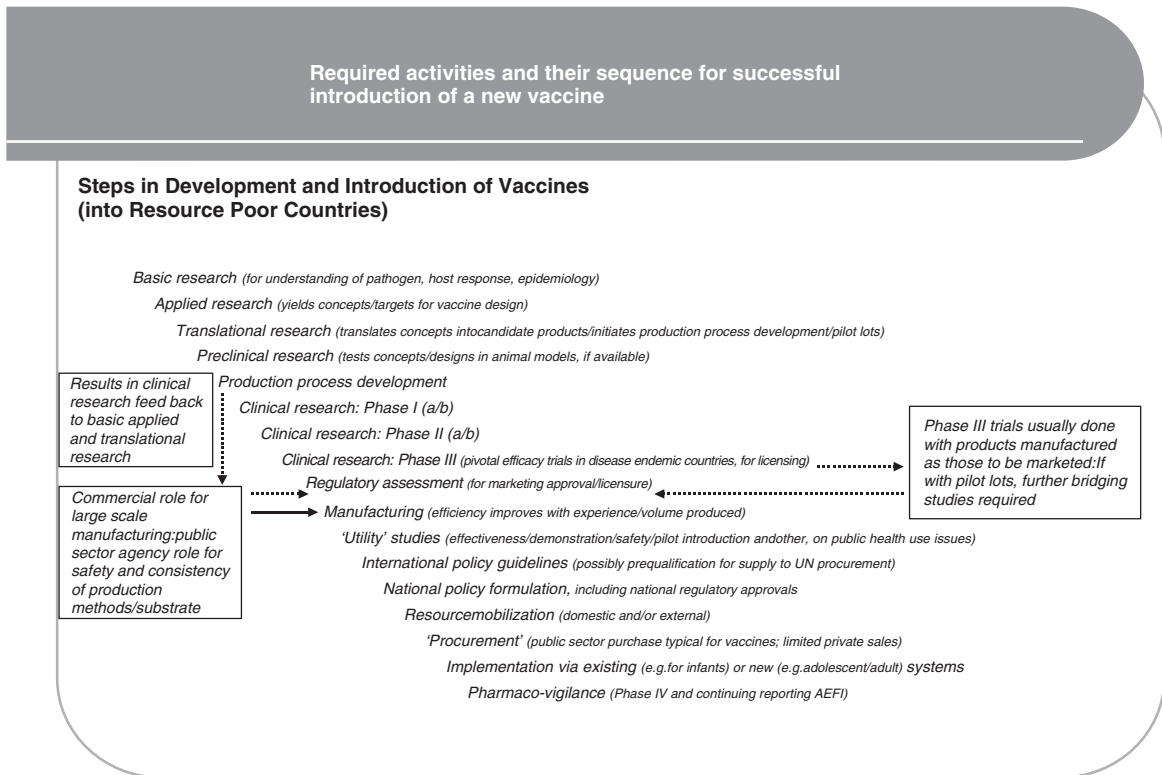

Figure 5.3 Required activities and their sequence for the successful introduction of a new vaccine. (Source: Amfo, K., May 2008 (personal communication).)

PLANNING AND IMPLEMENTATION OF VACCINATION PROGRAMMES

At the outset of the planning process for a vaccination programme, it is important to review thoroughly what is known about the epidemiology of the disease the vaccine is targeting. The strategy that is likely to have a maximum impact on its incidence can then be arrived at. Obviously, the vaccine should be administered before the age-related peak incidence of the disease, taking into account practical logistic considerations, such as ease of access to potential vaccinees, and whether the vaccine is efficacious in the age group being considered for vaccination. In the case of live vaccines, such as measles, maternally-acquired antibodies may prevent a 'take' of the vaccine and vaccination must be delayed until they have been catabolized. A fundamental issue is whether all at risk (potentially everybody except those known to be immune) will receive vaccine or only those at high risk of infection (because their environment, occupation or lifestyle might expose them to the pathogen). For relatively rare diseases that affect well-defined risk groups, it is conceivable that targeting these groups for vaccination (assuming they can be reached) might reduce disease incidence in the population to an acceptable level (i.e. control it). However, for prevalent diseases, targeted vaccination will almost certainly not have a significant impact on incidence and more widespread vaccination of the population will be required to achieve disease control. If the aim is to eliminate the infection, the effective reproduction factor will need to be reduced to <1 . Mathematical modelling of the levels of immunity in various age groups, obtained through serological surveys, can predict what would be the most efficient strategy to attain herd immunity (Nokes and Anderson, 1988). In most cases, systematic vaccination (at a coverage level determined by R_0 and the protective efficacy of the vaccine) of all future birth cohorts will be needed, augmented as required by a (periodic) catch-up campaign(s) in older age groups. Occasionally, the effectiveness of a vaccine in reducing disease incidence is much higher than could have been predicted from its protective efficacy and vaccine coverage. In Israel, for example, hepatitis A was controlled in the whole population within a few years by vaccinating only toddlers, since they were the spreaders of the virus in the community through their attendance at day-care centres (Dagan *et al.*, 2005). The capacity to protect the entire population by targeted vaccination of spreaders of the pathogen has recently been referred to as 'source drying' (André *et al.*, 2008).

Once a strategy has been decided upon and the budget to implement it has been made available, all those involved in the acquisition, storage, distribution, transport and administration of the vaccine must be adequately

trained to avoid mistakes. Nothing must be left to chance otherwise things will go wrong, discrediting all involved. The population will then continue to suffer unnecessarily the pain and misery of preventable diseases.

SURVEILLANCE OF DISEASE INCIDENCE AND ADVERSE EVENTS BEFORE AND AFTER IMPLEMENTATION OF VACCINATION

Good planning of a vaccination programme involves putting in place a surveillance system for disease incidence in order to monitor the impact of the programme on the outcome that matters, namely a reduction of the targeted disease following its implementation. Findings in surveillance systems that reveal changes in disease epidemiology (such as changing age-related disease incidence, immunity gaps detected in serological surveys and more precise information on duration of vaccine-induced protection) may require periodical adjustment of vaccination programmes.

Another surveillance system that must be available is one for adverse events following immunization (AEFI) so as to measure if some AEFIs occur more frequently after vaccination than could be expected from the background incidence of such events. This has become very important because there are many antivaccine lobbyists actively trying to discredit vaccines. The only rational way to deal with this issue (which is consuming much of the time of pro-vaccine scientists) is to have epidemiological studies that show whether AEFIs are causally linked or not, bearing in mind that science cannot prove for certain the absence of a link (Stratton *et al.*, 1994; Varricchio *et al.*, 2004).

RECTIFICATION OF PUBLICIZED FALSEHOODS AND MAINTENANCE OF VACCINATION COVERAGE

Currently the vaccination service in the United Kingdom is recognized worldwide as being one of the best since it incorporates the activities and skills that should guarantee success (Miller *et al.*, 2002). The British mass media have traditionally been fond of giving vaccines adverse publicity, thus encouraging the general public to refuse vaccination for nonscientific reasons, though more recently things have improved. The Internet, where unsubstantiated data can be posted by anybody and which is avidly read by the general public, is also not helpful in this regard. This is not a new phenomenon; vaccinologists have had to deal with antivaccination sentiment since the time of Jenner.

When Jenner's method of protecting against smallpox became generally known, critics predicted that inoculated

persons would develop bovine characteristics because the inoculum had been obtained (albeit indirectly) from a cow. The medical fraternity of the time was also against Jenner because he damaged their business by offering protection against smallpox free of charge; the technique of variolation (affordable only by the well-to-do) was a source of revenue for its practitioners. Laws were passed during the nineteenth century to make vaccination against smallpox mandatory, but sometimes this led to riots because it went against the political principle of free choice in democracies. In the twentieth century the undeniable effectiveness of vaccines to control infectious diseases like diphtheria, tetanus, whooping cough, poliomyelitis and measles led to a general acceptance that vaccines were desirable, but they became the victims of their own success; in the early seventies, for example, a Glasgow professor became convinced (erroneously as it turned out) that whooping cough vaccine was not only unnecessary—since the disease had almost disappeared because of vaccination—but also dangerous. According to him, it caused permanent neurological damage and he campaigned diligently to persuade families in the United Kingdom to refuse vaccination against whooping cough for their children. This had catastrophic consequences (Gangarosa *et al.*, 1998). The anti-whooping-cough-vaccine movement spread to other countries like Japan, Sweden, Italy and West Germany with the same effects. In the United Kingdom, vaccination against mumps, measles and rubella (MMR) has recently also been seriously damaged by a single doctor's unwarranted assertion that the MMR vaccine causes autism. For no good reason vaccines have a bad name in the mass media. However, to the credit of the general public, the great majority of children are still vaccinated; at least in developed countries. On the Internet, however, most comments about vaccines are negative (Wolfe *et al.*, 2002) and the general public invariably reads antivaccine Web sites. Furthermore, there is a general tendency to believe that decision makers and 'the authorities' seek to persecute the underdog, whereas the truth is that both those for and those against vaccination have their own reasons to believe that they are right. Objective facts support vaccination but personal decisions are often taken on subjective preferences.

How to deal with this dilemma? Clearly, scientific 'truth' can only be obtained through observation and experimentation. In Denmark it has been shown that allegations that childhood vaccines are responsible for autism (MMR vaccine and mercury in vaccines), type 1 diabetes and nonspecific infections due to 'overload of the immune system' are not supported by fact (Hvaid, 2008). The publicity in France about hepatitis B vaccine being causally responsible for multiple sclerosis has also been

scientifically demolished but lingers in the national psyche (Balinska, 2001; Mikaeloff *et al.*, 2007). In fact, scientific evidence supports the notion that vaccines are among the safest efficacious medical interventions. Experimentation to test the 'truth' of hypotheses about the safety of vaccines is made impossible by ethical considerations. It must not be forgotten that the scientific method can only disprove a hypothesis; it can never 'prove' anything.

It is now obvious that a major international campaign should be orchestrated to give vaccines the place that they deserve in the medical armamentarium (André, 2005). This has already begun but the process needs to be accelerated. The purpose is to make global opinion aware of the fact that vaccination is not the enemy of the populace but one of its best friends. Vaccinologists and other scientists have a duty to vigorously defend and propagate this undeniable truth in order to defend against the increasingly successful attacks of the antivaccine lobby (Cooper *et al.*, 2008).

VIRAL VACCINES ON THE HORIZON AND THE ROADBLOCKS TO FUTURE VACCINE DEVELOPMENT

Vaccines against practically all known human pathogenic viruses are in various stages of development. In the 2007 Jordan Report of the National Institute of Allergy and Infectious Diseases of the United States (US Department of Health and Human Services, 2007), 26 viruses are listed in an eight-page table as being targeted by vaccines in various stages of development. The many tens of projects for an AIDS vaccine were not even listed in that table. For many of the viruses there are several approaches towards developing a vaccine listed in the report. As an example, the projects for a cytomegalovirus (CMV) vaccine are shown in Table 5.4. For dengue there are no less than 15 different approaches. The 2007 Jordan Report lists 41 viral vaccine projects in basic R&D, 40 in preclinical development, and 19 in Phase I, 23 in Phase II and 3 in Phase III clinical studies. Among the 3 vaccines in Phase III clinical testing in 2006, 2 HPV vaccines (marketed by Merck and GlaxoSmithKline) have since been introduced. It is clear that only a few of the others will reach the market in the foreseeable future, not necessarily because their development is technically and scientifically unfeasible, but because the vast resources required are not available. Many of the projects have been in gestation for decades since they are not attractive enough for research-based vaccine manufacturers to work on them as a priority (André, 2002). Unfortunately, many potentially useful vaccines may not become available because of economic considerations.

Table 5.4 Status of cytomegalovirus vaccine research and development in 2006

Cytomegalovirus (CMV)	Basic R&D	Pre-clinical	Phase I	Phase II
Live attenuated strains (conventional)	+	+	+	+
Live attenuated strains (engineered)	+	+	+	
Glycoprotein subunit vaccine	+	+	+	+
Multiprotein subunit vaccine	+			
Nucleic acid (DNA) vaccines	+	+

CLOSING COMMENTS

It is abundantly clear to those who have taken the time to seriously examine the evidence that vaccination is, across the board, one of the best and most cost-effective tools in health care worldwide. This conclusion was reached by the World Bank in 1993 (World Bank, 1993) and acknowledged again at the end of the last century (Centers for Disease Control, 1999). In many cases vaccination is even cost-saving. In the United States, for example, vaccination against diphtheria, tetanus, whooping cough,

polio, measles, mumps, rubella, varicella, hepatitis B and *Haemophilus influenzae b* are all cost-saving, as illustrated in Figure 5.4.

In 1967, when the global eradication programme started, smallpox was still annually killing 1.5–2 million people in developing countries. The programme was completed in 10 years at a total cost of US\$100 million. It led to annual global savings of US\$1.35 billion (Barrett, 2004). In 1998, former US President Bill Clinton stated that the United States was, every 26 days, getting back (from not having to vaccinate against smallpox) what it

Figure 5.4 Some vaccines are not only cost-effective but also cost-saving: savings per unit of expenditure, medical and societal, in the United States.

spent on smallpox eradication. Other than for HIV, the contribution of antivirals towards alleviating the impact of viral diseases on human health pales into insignificance compared with what has been, is being and will be achieved with existing and future viral vaccines through prevention. Preventive medicine (as illustrated by the achievements of vaccinology) is far superior to curative medicine, though, unaccountably, the latter continues to get >98% of the health-care budget worldwide.

Herpes Simplex Virus Type 1 and Type 2

Marianne Forsgren¹ and Paul E. Klapper²

¹*Division of Clinical Microbiology, Department of Laboratory Medicine, Karolinska University Hospital, Huddinge, Sweden*

²*Clinical Virology, Manchester Medical Microbiology Partnership, Manchester Royal Infirmary, Manchester, United Kingdom*

Human herpesvirus 1 and human herpesvirus 2 are more commonly known as herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2). They are both members of the order *Herpesvirales*, a large group of enveloped double-stranded DNA viruses. More than 150 members of the *Herpesvirales* have been identified and the viruses have been found in almost every species in which they have been actively sought, including both warm- and cold-blooded species, vertebrate and invertebrate. There are presently nine members that are known to infect man (Table 6.1): eight whose natural host is man and one transmitted as a zoonotic infection from monkeys that can cause fatal encephalomyelitis in humans (Huff and Barry, 2003).

Viruses included in the order *Herpesvirales* have a double-stranded DNA genome of between 80 and 150 million Da molecular weight (Table 6.2). Following infection of their natural host the viruses establish a latent infection that persists for the life of the host. In the latent state only a small subset of the viral genes are expressed. Reactivation, with expression of viral proteins (VPs) and production of progeny virus, may occur at intervals to produce recurrent infection. This allows virus transmission to new, susceptible hosts. Individual members are well adapted to their natural host and exhibit little or no ability to cause cross-species infection.

The order *Herpesvirales* has three families:- the *Herpesviridae* containing mammalian, bird and reptile viruses (Davison et al., 2008); the *Alloherpesviridae* containing

fish and frog viruses; and the *Malacoherpesviridae* containing an oyster virus. The Herpesvirus Study Group of the International Committee on the Taxonomy of Viruses divided the *Herpesviridae* family into three subfamilies, the *Alpha-*, *Beta-* and *Gamma-herpesvirinae* (Fauquet et al., 2005), broadly on the basis of differences in the biological properties of the various viruses (Table 6.3). The subfamily *Alphaherpesvirinae* contains four genera—*Simplexvirus*, exemplified by human herpesvirus 1; *Varicellovirus*, exemplified by human herpesvirus 3; *Mardivirus*, exemplified by Gallid herpesvirus 2 - Marek's disease virus type 1; and *Iltovirus*, exemplified by Gallid herpesvirus 1 - infectious laryngotracheitis virus.

MORPHOLOGY

The morphology of the herpes simplex viruses (HSVs) as visualized by transmission electron microscopy (TEM) is the same as for all members of the *Herpesviridae* (Figure 6.1). With negative staining the virus particle often appears to be pleomorphic. However, the pseudoreplica electron microscopy (EM) technique reveals a spherical virus particle 150–200 nm in diameter with four structural elements:

- an electron opaque core;
- a protein capsid, surrounding the virus core, comprising 162 capsomeres;

Table 6.1 Classification of the human herpesviruses

Official name	Subfamily	Genus	Trivial name and abbreviation
Human herpesvirus 1	<i>Alphaherpesvirinae</i>	<i>Simplexvirus</i>	Herpes simplex virus type 1 (HSV-1)
Human herpesvirus 2	<i>Alphaherpesvirinae</i>	<i>Simplexvirus</i>	Herpes simplex virus type 2 (HSV-2)
Human herpesvirus 3	<i>Alphaherpesvirinae</i>	<i>Varicellovirus</i>	Herpes varicella-zoster virus (VZV)
Human herpesvirus 4	<i>Gammapherpesvirinae</i>	<i>Lymphocryptovirus</i>	Epstein-Barr virus (EBV)
Human herpesvirus 5	<i>Betaherpesvirinae</i>	<i>Cytomegalovirus</i>	Human cytomegalovirus (CMV)
Human herpesvirus 6	<i>Betaherpesvirinae</i>	<i>Roseolovirus</i>	HHV-6
Human herpesvirus 7	<i>Betaherpesvirinae</i>	<i>Roseolovirus</i>	HHV-7
Human herpesvirus 8	<i>Gammapherpesvirinae</i>	<i>Rhadinovirus</i>	Kaposi's sarcoma associated herpesvirus (KSHV)
<i>Macacine</i> herpesvirus 1	<i>Alphaherpesvirinae</i>	<i>Simplexvirus</i>	'B' virus

Table 6.2 Properties of the human herpesviruses

Virus	Site of latency	G + C (moles%)	Genome (kb pairs)	Sequence ^a
Human herpesvirus 1	Sensory nerve ganglia	68	152	X14112
Human herpesvirus 2	Sensory nerve ganglia	69	154	Z86099
Human herpesvirus 3	Sensory nerve ganglia	46	125	X04370
Human herpesvirus 4	Leukocytes, epithelial cells	60	172	V01555

- an amorphous tegument surrounding the capsid; and
- an outer envelope with spikes on its surface.

The core is composed of linear double-stranded DNA packaged in the form of a torus. Data derived from electron micrographs suggests that the DNA is physically stabilized within the capsid by a series of protein fibrils embedded on the inner surface of the capsid and passing through the central hole of the torus. The ends of the genome are probably held in close proximity within the capsid since the DNA rapidly circularizes in the absence of protein synthesis soon after it enters the host-cell nucleus. The complete sequence of HSV-1 and HSV-2 is known (Dolan *et al.*, 1998; McGeoch *et al.*, 1988). The genome of each virus can be viewed as consisting of two covalently-linked components, L (long) and S (short), each comprising unique sequences flanked by inverted repeat sequence. These components can invert relative to one another and equimolar concentrations of the four possible isomers of the DNA molecules formed by this inversion can be found in wild-type virus (Roizman *et al.*, 2004).

The viral capsid (100–110 nm in diameter) is a closed shell in the form of an icosahedron (T = 16) with

162 capsomers arranged as 12 pentamers (vertices) and 150 hexamers (face and edges). Using high-resolution cryo-EM and computer-image reconstruction techniques the three-dimensional structure of empty capsids of HSV-1 has been determined to a resolution of approximately 8.5 Å (Baker *et al.*, 2003; Zhou *et al.*, 2000). There appear to be four VPs (5, 19c, 23 and 26) aggregated as pentons and hexons that are associated with polypeptide triplexes to form the nucleocapsid. The interior of the capsid is accessible via transcapsomeric channels ('tubes') formed by the polypeptide arrangement of the pentons, hexons and holes at the base of each triplex. These openings are postulated to play a role in the transport of genomic DNA and scaffolding proteins during capsid morphogenesis.

Between the capsid and envelope is the tegument. Visualized in cryo-electron tomograms of isolated virions, the tegument appears to form an asymmetric cap: on one side, the capsid closely approaches the envelope; on the other side, it is separated by about 35 nm of tegument. The tegument substructure appears particulate, with some short actin-like filaments (Grünwald *et al.*, 2003). The tegument contains at least 20 proteins that are believed to

Table 6.3 Biological properties of *Herpesviridae***Common properties**

Large, linear, double-stranded DNA genome
 Synthesis of DNA and assembly of capsid within the nucleus, acquire envelope by budding through nuclear membrane
 Specify a large array of enzymes involved in nucleic acid metabolism and synthesis
 Production of progeny virus results in destruction of the host cell
 Establish latency in their natural host

Alphaherpesvirinae

Variable host range
 Short reproductive cycle
 Rapid spread in cell culture
 Efficient destruction of infected cells
 Establish latency primarily but not exclusively in sensory ganglia

Betaherpesvirinae

Restricted host range (a non-exclusive property of this subfamily)
 Long reproductive cycle
 Infection progresses slowly in culture, frequently forming enlarged (cytomegalia) cells
 Latency in secretory glands, lymphoreticular cells, kidneys and other tissues

Gammaherpesvirinae

Experimental host range limited to family or order of natural host
In vitro replication in lymphoblastoid cells
In vivo replication and latency in either T or B lymphocytes

have important functions in the early stages of virus replication following penetration of the host cell by the virion.

The virus envelope has a typical trilaminar appearance and is thought to be derived from patches of host-cell membrane modified by the insertion of virus glycoprotein spikes. Using cryo-electron tomograms of isolated virions the envelope can be seen to contain 600–750 glycoprotein spikes, which vary in length, spacing and the angles at which they emerge from the membrane. Their distribution appears to be nonrandom, suggesting functional clustering (Grünewald *et al.*, 2003).

REPLICATION

HSV-1 and HSV-2 are characterized by a short (18–24 hour) replicative cycle that is cytolytic. Initial attachment and penetration of the host cell is mediated via the 11

Figure 6.1 Enveloped herpesvirus particle. (a) Thin section. (b) Negative staining (Magnification $\times 140\,000$) (Courtesy of Hans Gelderblom, reproduced with permission from Van Loon *et al.*, (2004).

types of glycoprotein spike found on the virus envelope (Table 6.4). These spikes are responsible for the major antigenic differences between HSV-1 and HSV-2 and relate to the type-specific epitopes found on certain of the glycoproteins (Bergström and Trybala, 1996).

Initial attachment of HSV-1 appears to involve attachment to cell-surface glycosaminoglycans on heparan sulphate mediated via glycoprotein C and glycoprotein B, or, on cells devoid of heparan sulphate, equivalent glycosaminoglycan moieties of other cell-surface proteoglycans, such as chondroitin sulphate. Glycoprotein D then interacts with one of three alternative entry receptors: nectin 1, a member of a family of intracellular adhesion molecules; herpesvirus entry mediator (HVEM), a member of the tumour necrosis factor (TNF) receptor family; or 3-*O*-sulphated heparin sulphate (Campadelli-Fiume *et al.*, 2007; Reske *et al.*, 2007). The binding of glycoprotein D triggers a process of fusion of the virion envelope and the plasma membrane (or endosome membrane) through glycoprotein D working in concert with glycoprotein B and a heterodimer of glycoproteins H and L. The major pathway for virus entry is fusion of the envelope with the plasma membrane and transport of the released nucleocapsid to the nuclear pore. Alternative, ancillary, pathways have also been identified in cell culture, including fusion within an acidic endosome and fusion within a neutral endosome (Reske *et al.*, 2007).

Fusion results in the introduction of tegument proteins and viral nucleocapsid into the cell cytoplasm. Subsequently, host macromolecular metabolism is rapidly

Table 6.4 Herpes simplex virus glycoproteins

Glycoprotein nomenclature ¹	Gene ²	Essential for virus infectivity? ³	Function
gB	U _L 27	Yes	Essential for viral entry. Induces neutralizing antibody.
gC	U _L 44	No	Mediates cell attachment of virion to the cell. Modulates complement activation by binding C3 and blocking C5 and properidin binding to C3.
gD	U _S 6	Yes	Required after attachment to the cell. Interacts with the three cellular receptors for virus entry to the cell and thereby determines viral tropism. Enables fusion of the virion envelope with the plasma membrane through fusion mediated by gB, gH and gL.
gE	U _S 8	No	Forms a heterodimer with gI. The gE–gI complex constitutes an Fc receptor which is implicated in disruption of host immune defence. The gE–gI also facilitates basolateral spread of progeny viruses in polarized cells, suggesting a role for it in virion transport.
gG	U _S 4	No	Function not known. gG2 of HSV-2 is larger than gG1 of HSV-1 and the different antigenic determinants can be used to provide a means of differentiation of HSV-1 and HSV-2 immune responses.
gH	U _L 22	Yes	Essential for virion infectivity and for cell–cell fusion of infected cells. Transport of gH from the Golgi apparatus requires interaction with soluble gL. gH induces neutralizing antibodies.
gI	U _S 7	No	See gE.
gJ	U _S 5	No	Shown to block apoptosis.
gK	U _L 53	No	Found in low abundance. May have a role in preventing infected cells fusing with one another.
gL	U _L 1	Yes	Interacts with gH as detailed above. Probably acts to regulate the fusogenic activity of gH.
gM	U _L 10	No	Interacts with the product of U _L 49.5. May be required for the packaging of U _L 49.5 in virions.

¹Viral glycoproteins are named sequentially by letter as glycoprotein A, B etc. The missing sequence letters (e.g. glycoprotein A, glycoprotein F) reflect earlier misidentification of precursors of glycoprotein species as the actual virion glycoprotein. There are a further two (the products of genes U_L20 and U_L34), and possibly more, non-glycosylated viral proteins inserted in the virion envelope.

²Gene or transcriptional unit: U_S = unique short sequence of the genome; U_L = unique long sequence

³Information from *in vitro* experimentation with HSV-1. All glycoproteins are essential in wild-type virus. In cell culture only, some functionality can be dispensed with. Requirement for glycoprotein that is non-essential in routine cell culture can be demonstrated under specialised conditions, e.g. gC is essential for attachment to the apical surface of polarised MDCK cells; gI is essential for basolateral spread of virus in polarised cells.

and efficiently shut down. Host DNA synthesis ceases, protein synthesis declines rapidly, ribosomal RNA synthesis is reduced and host protein glycosylation ceases. There are at least 20 tegument proteins, and whilst the function of a number of these is not understood, they are all believed to act directly or indirectly to produce early shut-off of host macromolecular synthesis and to contribute to the early events of replication. The virion-associated host shut-off protein (vhs) appears to remain in the cytoplasm, where it causes the disaggregation of polyribosomes and degradation of cellular and viral RNA. Conversely, some tegument

proteins are believed to facilitate attachment of the nucleocapsid to nuclear pores and release of viral DNA.

The nucleocapsid is transported through the cytoplasm to a nuclear pore via microtubules of the cell cytoskeleton. On arrival at a nuclear pore, virus DNA is released from the capsid into the nucleus of the cell, where it immediately circularizes. To initiate transcription, the circularized DNA binds a host-cell protein Octamer binding protein 1 (OCT-1), the tegument protein α -trans-inducing factor (α -TIF), an additional host-cell factor designated C1, and other transcriptional factors to promote the expression of

α (or 'immediate-early') genes—the first set of viral genes to be transcribed (Roizman *et al.*, 2004). Viral-gene expression is regulated and sequentially ordered as a cascade ($\alpha \rightarrow \beta \rightarrow \gamma$). The five α -gene products are regulatory proteins; their expression is required for the production of all subsequent polypeptide groups. The proteins serve to *trans-activate* β and γ gene expression and to turn off both α - and early γ -gene expression (other domains of the viral genome are transcribed under ' α ' conditions, including the 'latency-associated transcript' LAT-1—see below). Viral DNA is transcribed throughout the replicative cycle by host RNA polymerase II.

The expression of the β genes results in the production of enzymes involved in nucleic acid metabolism (ribonucleotide reductase, thymidine kinase (TK), thymidilate synthetase, alkaline DNase, dUTPase, etc.) and in DNA synthesis (DNA polymerase, helicase, primase, etc.). Peak rates of synthesis of β -gene products are observed 5–7 hours post-infection and when sufficient levels of these proteins have accumulated within the infected cell, viral DNA replication commences. Early (α) gene expression is significantly reduced following the start of DNA replication, while late genes begin to be expressed at high levels. HSV DNA is believed to replicate by a rolling-circle mechanism, yielding a concatomer that must be subsequently cleaved to package genome lengths of DNA within the nucleocapsid.

The synthesis of nucleocapsid and all other structural proteins occurs when γ -gene expression is induced by β -gene products. HSV capsids are assembled around viral scaffolding proteins in the nucleus, and other VPs then interact with replicated viral DNA to allow DNA encapsidation. The tegument proteins also migrate to the cell nucleus and form patches underneath the modified nuclear membrane. The DNA-filled capsids proceed to associate with tegument (matrix) proteins near the nuclear membrane. Virus glycoproteins undergo extensive post-translational modification during transit through the golgi apparatus; they then become inserted in the nuclear and other cellular membranes. Three different models for the release of mature nucleocapsids from the cells have been proposed. In the first model capsids are enveloped at the inner nuclear membrane and transported within vesicles that fuse with the plasma membrane to release the enveloped capsids into the extracellular milieu; in the second model capsids are enveloped at the inner nuclear membrane and undergo de-envelopment at the outer nuclear membrane and re-envelopment at cytoplasmic membranes; and in the third model nuclear pores become enlarged sufficiently to allow egress of naked capsids and the capsids then become enveloped at cytoplasmic membranes. The evidence for and against each of the models is the subject of current debate. Whichever

method the virus uses for its release, productive infection of a cell results in the destruction of the host cell through the major structural and biochemical changes induced by virus replication.

Latency

Latency is central to the success of HSV as a human pathogen; it permits persistence of the virus in the presence of a fully-developed immune response and life-long infection of the host. As a result of periodic reactivation of latent virus and the production of recurrent infection, virus shedding and transmission of infection to susceptible individuals occurs at intervals throughout life, allowing the virus to persist in populations with high levels of herd immunity.

During the primary or initial infection, virus comes into contact with the cutaneous receptors of local sensory nerves. Virus attaches to and penetrates the nerve cell via these receptors (Figure 6.2). In oro-facial HSV infection this is predominantly the trigeminal nerve innervating the face, in genital HSV infection lumbro-sacral nerves innervating the genitalia. The unenveloped nucleocapsid and tegument proteins of the virus are transported within the nerve cell by retrograde transport along the microtubules of the axon (Diefenbach *et al.*, 2008). In animal experiments, viral-gene expression can be demonstrated within the nerve ganglion 24–72 post-infection. Several components of the innate immune response are then thought to interact to control early viral replication. Cytokine and chemokine expression increases within the infected ganglia and CD8⁺ T cells infiltrate the ganglion; the amount of virus decreases around day 7. CD8⁺ cells are thought to have a key role in controlling viral replication during the acute infection of the ganglia and within nervous tissue. At the level of virus replication a key factor in this initial phase of the establishment of latent infection appears to be the absence of expression of α (immediate-early) proteins. It has been shown that the cellular cofactor C1 that is required with Oct-1 and α -TIF for α gene expression is only found in the cell cytoplasm and is only transported to the nucleus when the virus reactivates. It is possible that the initial innate immune response within the ganglion is responsible for blocking the recruitment of C1 from the cytoplasm to its site of action within the cell nucleus. However, this is but one of several possible explanations of the process (Valyi-Nagy *et al.*, 2007).

A latent infection of the nerve cell is established. In the latent state the virus is believed to exist as extrachromosomal circularized DNA (analogous to plasmids). No virions can be detected and no viral antigens appear to be expressed on or within the latently-infected cell. The host immune response to infection rapidly eliminates virus and virus-infected cells from peripheral sites, but does not

Figure 6.2 The life-cycle of herpes simplex viruses.

recognize latently-infected nervous tissue as harbouring virus since no viral antigens are expressed.

The site of virus latency is related to the site of primary infection; for HSV-1 the trigeminal ganglia and for HSV-2 the sacral ganglia are the most common sites. Other dorsal root ganglia, including the superior cervical, vagal and geniculate ganglia may also harbour virus. Although primary HSV-1 infection of the genitalia and primary HSV-2 infection of the oropharynx are often reported, recurrent infection of the genitalia by HSV-1 and recurrent oro-facial infection by HSV-2 are uncommon. Infrequent reactivation is not thought to be due to a failure by HSV-1 to establish latent infection in cells of the sacral ganglia or of HSV-2 to fail to establish latent infection in cells of the trigeminal ganglion, since the respective genomes of the viruses have been detected at these sites. The inhibition seems to be at the level of effective viral-gene expression in relation to the particular environment of these sites.

A latently-infected neurone shows no evidence of viral-gene expression. A viral transcript—the LAT—is

expressed within the latently-infected ganglion but no VP expression is observed. Prolonged expression of cytokines and chemokines are observed in the latently-infected ganglion, and in murine experiments $CD8^+$ T-cell infiltration can be demonstrated. About 10% of the cells in a latently-infected ganglion are thought to contain at least one viral genome. Laser-capture microdissection of human trigeminal tissue latently infected with HSV suggests that there are an average of 11 genomes per cell of the HSV genome. This could be because multiple viruses infect an individual cell during primary infection, or because the viral DNA is replicated at a low level by viral or cellular mechanisms. The maintenance of the HSV genome in latently-infected neurones appears to be passive in that it does not require any other viral-gene expression or gene product. It is possible that low levels of replication of the viral genome occur since in animal experiments the numbers of copies per cell appears to increase with time. Such low-level replication may be important for the maintenance of latency and to allow

reactivation. A host-dependent origin of DNA replication has been identified within the viral genome (Sears and Roizman, 1990) and thus host-cell enzymes could effect VP-expression-independent replication of the viral DNA in latently-infected neurones.

The LAT intron is stable within the latently-infected cell nucleus and whilst viruses where the LAT gene is deleted are capable of establishing latency, viruses which lack LAT, a LAT promoter or a 348bp sequence in the 5' end of LAT exhibit reduced efficiency of reactivation. However, a full understanding of the role of LATs and of other molecular events involved in the latency remains elusive (Bloom, 2006). Among the many functions ascribed to the LAT introns are down-regulation of genes that are lytic, blocking of the transcription of the gene-encoding ICP0 (a potent gene transactivator), enabling of reactivation from the latent state, maintenance of virus in the latent state and protection of neurones from apoptosis.

Reactivation of latent virus produces recurrent infection. A variety of nonspecific 'triggers' for this process have been described, for example injury to tissue innervated by the latently-infected neurones, emotional or physical stress, menstruation, ultraviolet light and hormone imbalance. It is assumed that in reactivation the cascade of viral-gene expression ($\alpha \rightarrow \beta \rightarrow \gamma$) occurs in the ganglion and leads to the production of progeny virus that are released from the axonal tip after anterograde transport down the axonal microtubule system. The fate of the cell post viral reactivation is a subject of debate. If the usual process of virus replication were followed in nervous tissue then an individual experiencing frequent reactivation over a period of years might be expected to experience local loss of sensation through the progressive depletion of sensory nerves. The damage might also be compounded through the action of the immune system, because in a productive infection virus antigens are expressed on the infected cell surface, rendering the infected cell 'visible' to the immune system. Various models have been proposed to explain this process, though none are entirely satisfactory. It seems likely that upon reactivation, virus replication is so thoroughly controlled that only a few virions are produced, with no expression of virion glycoproteins on the cell surface (thereby permitting the cell to escape immune-mediated cytolysis). Viral genes interfere with apoptosis to prevent cell death and the cytopathology associated with normal productive infection is thereby prevented. In this way the neurone may be able to survive repeated episodes of reactivation.

The Immune Response to Infection

Data derived from human observation and animal experimentation suggests that the host genetic make-up has

an important role in determining immune responsiveness and disease pathogenesis. In man, numerous reports have (presumably because of population selection bias) alternately suggested or denied human leukocyte antigen (HLA) associations with HSV infection. In consequence there is no firm evidence to either confirm or refute HLA involvement in disease pathogenesis. Recovery from HSV infection and the control of reactivated virus infection involves all components of the immune system acting in concert. Macrophages, specific T-cell populations, complement, specific antibodies and lymphokine and cytokine responses all have important roles in the immune response to HSV infection.

Innate and Adaptive Immunity

The innate immune defence system acts to provide a formidable defence against infection and involves both intracellular and extracellular defence mechanisms (Pack and Rouse, 2006). Dendritic cells with natural killer cells, macrophages and neutrophils act with complement, natural antibody and interferons to provide an immediate defence against infection. HSV has evolved a number of strategies to overcome both intracellular and extracellular innate immunity to allow the virus to gain access to sensory nerve endings and establish a latent infection during a primary or initial infection.

The adaptive immune response then plays a crucial role in the resolution of primary or initial infection. T-cell-mediated immunity is of major importance. Host T-cell deficits result in prolonged and severe infections. Defence against HSV is believed to depend upon the development of cytotoxic CD8⁺ and CD4⁺ T cells and the products of Th1-dependent CD4⁺ cells (Jones and Cunningham, 2004; Koelle and Corey, 2003). Effector T-cell recognition of virus-infected cells or viral-antigen-expressing cells will result in both the destruction of the target cell and a local inflammatory reaction mediated by inflammatory cytokines that can cause ancillary tissue damage resulting in viral-mediated immunopathology.

Humoral Immunity

Western-blot and radio-immune-precipitation experiments show that serum from patients recovering from severe HSV infection may contain antibody to all the structural (virion) proteins of HSV. The actual range and the amount of antibodies detected correlate with the severity of infection; in mild infection only a restricted number of antibodies may be detectable.

The immune response is principally directed to the glycoprotein spikes (Table 6.4) found on the virion envelope and on the surface of virus-infected cells. Neutralizing

and cytolytic antibodies may be detected, glycoprotein D being the most potent inducer of neutralizing antibody. In a primary infection, an IgM subclass response is detected just before or at the same time as an IgG and IgA immune response. The response is relatively short-lived but IgM antibody may also be detected during recurrence, rendering serological differentiation of primary from recurrent infection difficult. Both IgG and IgA antibody persist, although the IgG antibody response is of greater magnitude. Repeated HSV recurrences lead to a gradual boosting of antibody levels but individual reactivation events or even re-infection may not result in a significant increase in circulating antibody. The presence of serum antibody may not protect from re-infection and neither the quantity nor the range of reactivity (i.e. the lack of antibody to a particular virus protein) appears directly to influence either the frequency or severity of reactivation events.

The early immune response to HSV is relatively type-specific but 'later' antibody is more broadly cross-reacting. Monoclonal antibody studies show that both type-common and type-specific epitopes may be found on virion glycoproteins. As a major part of the humoral immune response is directed to virion glycoproteins the change from type-specificity with time presumably reflects temporal changes in the relative preponderance of antibodies to type-specific and subsequently type-common epitopes on the virion glycoproteins.

Cell-mediated Immunity

The cellular immune response to infection involves a complex interaction of natural killer cells, macrophages, T lymphocytes and associated cytokines. During initial or primary infection the appearance of nonspecific inflammatory changes coincides with the peak of viral replication. Delayed type-hypersensitivity reactions that are followed by a cytotoxic T lymphocyte (CTL) response and the appearance of IgM- and IgG-specific antibodies may be detected. When virus reactivates from latency and produces lesions there is a swift infiltration of natural killer cells and CD4⁺ T cells, followed by CD8⁺ T cells. High levels of β chemokines and T-cell cytokines are also found. CTL activity peaks with CD4 activity and correlates with viral clearance (Koelle and Corey, 2003).

Although HSV-seropositive individuals are presumed to harbour latent virus, less than half the members of an HSV-seropositive population give a history of herpes labialis. Some may recall only one recurrence whilst others report frequent episodes. If seropositive persons with no history of herpes labialis are monitored, silent virus shedding may be shown to occur at intervals. Differences in humoral immune status fail to explain these observations. In a comparison of persons with infrequent recrudescence of oro-facial herpes and those with frequent

recurrence (10 or more episodes per year), differences in only HSV-specific T-cell proliferation, interferon- γ production and levels of HSV-specific IgE could be demonstrated between the two groups (McKenna *et al.*, 2001). In those suffering frequent recurrence the immune response is apparently both delayed and less effective than in those with infrequent recurrences, and is manifest as less effective control of HSV in the periphery following reactivation from latency. The reasons for the appearance or nonappearance of clinical symptoms and the severity of these symptoms are therefore probably explained in terms of an early and effective local cellular immune response. Support for this hypothesis is found in patients with known cellular immune deficiencies where herpes labialis occurs frequently and is a very much more severe and prolonged disease.

Immune Modulation

HSV infection triggers a complex series of cellular events to overcome the host innate immune response (Hook and Friedman, 2007; Roizman *et al.*, 2004). Infection leads to blockage of type 1 interferon effects and interferon-stimulated gene expression. Whilst infection activates toll-like receptors and toll-like receptor signalling with the production of pro-inflammatory cytokines and of type 1 interferon, both of these signalling pathways can be reduced by expression of the virus protein ICP0. Infection can also block dendritic cell maturation, thereby interfering with dendritic cell antigen presentation, and glycoprotein C has been shown to bind complement C3b and prevent complement activation.

Infection also blocks aspects of both the humoral- and the cell-mediated responses (Gewurz *et al.*, 2007). The product of HSV gene ICP47 binds to the transporter protein and blocks peptide transport in the endoplasmic reticulum for loading on to major histocompatibility complex (MHC) class I. This allows evasion of CD8⁺ T-cell effector mechanisms. HSV-infected cells can also inactivate cytotoxic T-cell function. The HSV gene product ICP22 inhibits the ability of B cells to present MHC class II epitopes to CD4⁺ T cells. Finally, the HSV gE and gI complex forms an Fc receptor of high affinity. The binding of the Fc portion of IgG-class antibodies prevents virus neutralization by these antibodies and also blocks antibody-dependent cytotoxicity.

Pathogenesis in Immunocompromised Patients

Congenital deficiencies in humoral immunity (hypogammaglobulinaemia or even agammaglobulinaemia) do not appear to be significant risk factors for serious primary or recurrent HSV disease. Congenital deficiencies in cell mediated immunity (CMI) may, however, be associated

with severe HSV disease. The risk of serious disease varies with the particular immune deficit; for example, patients with congenital athymic aplasia (Di George syndrome) do not appear to be at particular risk, whilst those with severe combined immune deficiency such as the Wiskott-Aldrich syndrome are. These differences emphasize the complex interplay of the immune network in controlling HSV infection. Severe HSV disease is also observed in infants, children and adults with deficiencies in CMI induced by 'therapy'. These include recipients of cytotoxic chemotherapy (e.g. for cancer) and recipients of major organ grafts. The severity of HSV disease in these patients is related to the type and degree of immunosuppression. Severe primary and recurrent HSV infections also occur in patients with acquired immune deficiency syndrome (AIDS).

EPIDEMIOLOGY

HSV has a worldwide distribution, and is endemic in all human population groups examined. There do not appear to be any animal reservoirs for the infection. The rate of infection and the timing of primary infection differ for HSV-1 and HSV-2, reflecting the differences in the major modes of transmission of the two viruses. Whilst both virus types may infect all bodily sites, and an increasing rate of primary HSV-1 genital herpes has been observed in certain populations, genital spread remains the principal route for transmission of HSV-2.

Primary HSV-1 Infection

Primary HSV-1 infection usually occurs when a susceptible individual comes into close and intimate contact with an individual who is actively shedding the virus in, for example, saliva. Thus infants become infected when their parents or relatives kiss them; adolescents who escape infection in infancy are usually infected later by kissing. Infection in an infant is likely to be missed, or dismissed as 'teething'. In adolescents, infection is more commonly symptomatic, but rarely severe. Because the majority of primary infections are asymptomatic, epidemiological data collected by observation of clinically apparent disease provide only a partial measure of its true incidence. For accurate data collection, serological studies must be employed.

The broad principles of the seroepidemiology of primary HSV-1 infection were established in the classic study of Burnet and Williams (1939) and have since been confirmed in numerous studies and, during the last decades, with type-specific serology. In Burnet and Williams' study, during the first six to nine months of

life infants were shown to escape infection by virtue of passively-transferred maternal immunity. Later, during the following five years, infants became infected and developed HSV IgG antibody, and those who escaped underwent seroconversion during adolescence or early adulthood; 90–95% infection rates were then observed by early adulthood and primary HSV-1 infection was a rare event in those of >30 years of age. A relationship between the age of acquisition of the virus and socio-economic status was also found. Populations associated with a low socio-economic environment collectively exhibited earlier acquisition of HSV infection than more affluent populations.

In recent years seroepidemiological studies have shown that, whilst there are large inter-country and intra-country differences, there has been a lowering in the prevalence of HSV-1 antibody in highly-hygienic young adult populations in Europe (e.g. in the United Kingdom; Pebody *et al.*, 2004), and in North America and Japan, where HSV-1 antibody prevalences of <40% have been recorded in young adults of <30 years (Smith and Robinson, 2002).

The major mediator of seroprevalence is the frequency of direct person-to-person contact. In crowded areas (e.g. disadvantaged inner-city areas with abundant opportunities for exposure in crowded households with high rate of family members with prior oro-labial infection) seroprevalence is and remains highest; in affluent and rural areas seroprevalence is lowest. Interestingly, despite the increased mixing which occurs as a result of increased day-care attendance of children in a country like Sweden, there has been no increase in the prevalence of HSV-1 infection in this age group (Svahn *et al.*, 2006). On a worldwide basis, however, overall rates of 90–95% seroprevalence are still commonplace in many adult populations, as judged by investigations of 20–40-year-old individuals in several cities in Asia, Central America and Africa (Nahmias *et al.*, 2006; Paz-Bailey *et al.*, 2007; Smith and Robinson, 2002).

Primary HSV-2 Infection

HSV-2 transmission is apparently less efficient than that observed for HSV-1. The principal route of transmission is sexual activity. Although a few infants acquire HSV-2 infection, in most cases primary infection is delayed until the onset of sexual activity in adolescence and early adulthood. At this time many persons will have already experienced primary infection with HSV-1 (i.e. infection with HSV-2 often causes an *initial* rather than a *primary* infection). A prior HSV-1 infection will not prevent a genital HSV-2 but will reduce the likelihood of HSV-2 acquisition. Because of the shared antigenicity of HSV-1 and HSV-2, HSV-1 immunity may be partially protective and the initial (first) HSV-2 infection is associated

with lesser clinical manifestations than are observed in primary HSV-2 infections. In contrast, a prior HSV-2 infection seems to provide some protection against HSV-1 acquisition.

The majority (80% or more) of those found to be HSV-2-antibody positive cannot recall signs of primary infection and are unaware of recurrent genital herpes, emphasizing that like HSV-1 the majority of HSV-2 infections are clinically 'silent'.

A major problem in determining the seroepidemiology of HSV-2 infections has been the lack of well-characterized methods to differentiate HSV-1 and HSV-2 antibody. Only during the last few years have relevant assays become available on a commercial basis. Not all those exposed to HSV-2 will necessarily become infected but women are generally more easily infected than men. The major influence on acquisition of HSV-2 infections is, as might be expected for a sexually-transmitted virus, the number of sexual partners (Smith and Robinson, 2002). Rates of up to 95% seroprevalence have been reported in some female commercial sex workers. In the general population there are wide differences in seroprevalence between different patient groups and even between apparently similar social groups in different cities. Women are generally infected at an earlier age than men and rates of infection in women are higher for all age groups up to and including those of 45 or more years of age. Studies among genito-urinary-medicine clinic attendees suggest that only in homosexual men do the rates of infection with HSV-2 match those found in women, although even in this context it is not until age 40–45 years that equivalent rates are observed.

HSV-2 and HSV-1 prevalence, overall and by age, varies markedly by country, region within country, and population subgroup, and in populations with higher-risk sexual behaviour (Pebody *et al.*, 2004). Available data (although incomplete) on HSV-2 prevalence in non-high-risk populations suggest that rates in general are highest in Africa and the Americas, lower in western and southern Europe than in northern Europe and North America, and lowest in Asia.

The Changing Seroepidemiology of HSV Infections

The changing seroepidemiology of HSV-1 infections in developed countries has meant that primary eye infections with HSV-1 are now infrequent in children but much more frequent in young adults. Young adults entering the world of work are also more frequently susceptible to primary herpes, as manifest by an increase in incidence of occupationally-acquired herpes simplex infection of the hand (see 'Herpetic Whitlows; Traumatic Herpes', below). In some populations followed over decades

(e.g. in the United States, Sweden, Hong Kong), HSV-2 seroprevalence rates showed an increase over time—with marked increases occurring during the 1970s, when oral contraceptives came into general use—and plateauing thereafter (see, for example, Forsgren *et al.*, 1994). In sub-Saharan Africa striking increases have been observed, especially among young women aged 15–24 years. In other populations the rates have remained stable or even decreased, although in most regions relevant data are lacking.

HSV-1 is now much more commonly seen in association with primary genital herpes. This trend was first noticed in Japan in the mid 1970s. During the last decade, 40 to more than 60% of isolates of HSV from first-episode genital herpes have been found to be due to HSV-1 in high socio-economic populations in studies from the United Kingdom, Scandinavia and the United States. A similar change has not been observed in populations of low socio-economic status.

Recurrent HSV-1 and HSV-2 Infection

Both silent and overt (i.e. symptomatic) recurrences of HSV-1 and HSV-2 infection occur, thus without continuous monitoring of a cohort for viral shedding, accurate data on rates of recurrence cannot be obtained. Only 38–45% of an adult population (in whom seroprevalence rates of 90–95% are reported) will give a history of recurrent herpes labialis.

The frequency of recurrence of genital HSV-2 infection (up to 60%) is higher than that observed in HSV-1 herpes labialis, although the number of lesions produced per episode and their duration are generally shorter. The rate of recurrence is believed to be slightly higher in men than in women, with rates of up to 2.7 and 1.9 episodes per 100 patient days, respectively.

Although primary HSV-1 genital herpes infection is now more commonly seen, this has not been accompanied by a corresponding shift in the type of virus involved in recurrent infection. This is because of the less common reactivation of genital HSV-1 and of oro-facial HSV-2. The majority of clinical and subclinical recurrences in the oro-facial region are HSV-1, whereas genital recurrences are still dominated by HSV-2.

Endogenous and Exogenous Re-infections

Re-infection, recognized by the appearance of lesions at another bodily site, for example infection of the finger (herpetic whitlow), can occur at any age. Exogenous re-infection of all types occurs more often in the immunocompromised than in the immunocompetent. Differentiation of endogenous and exogenous re-infection can only be accomplished by examination of viruses obtained from

distinct sites and demonstration of genetic polymorphism by restriction enzyme analysis or sequencing of a region of their respective DNAs.

VIRAL DIAGNOSIS

The ability of HSV to establish latent infection inevitably complicates diagnosis. A clinical role for the virus in causation of disease is not established simply because it is recovered from a patient. To achieve *meaningful* diagnosis a close collaboration between clinic and laboratory is always necessary, for interpretation of findings against clinical data. Moreover, in many clinical situations rapid diagnosis is a challenge for the viral laboratory as serious HSV disease may not be clinically distinguishable from other conditions and there is pressure for antiviral treatment to be started early (if possible within 24 hours after onset) to achieve maximal effect. Adequate preventive measures may also be dependent on the immediate aid of the laboratory.

Light and UV Microscopy

In diagnostic virology, direct-light microscopic examination of clinical material is now seldom used to provide a diagnosis of HSV infection, although histopathological examination remains an important technique in the differential diagnosis of infection. Staining of relevant tissue sections with specific antibodies tagged with enzymes provides rapid and specific localization of virus. Rapid detection of HSV in clinical material may be achieved by direct or indirect immunofluorescence (IF) microscopy. Scrapings from the bottom of vesicles before crusting, impression smears and cryostat sections of tissue biopsies all provide suitable specimens. Since virus localization within cells can be directly observed, the technique allows prompt diagnosis with 'in-built' specificity control, as opposed to the enzyme-linked immunosorbent assay (ELISA) techniques (see below). The drawbacks of these procedures are the requirement for experience in sampling and the special expertise in IF microscopy to achieve high test sensitivity and specificity.

Electron Microscopy

Transmission electron microscopic examination of negatively-stained vesicle fluid presents one of the most rapid methods for detection of HSV. Although now only available in few diagnostic laboratories, this procedure can be very helpful in establishing a rapid, early diagnosis. Collection of specimens for electron microscopy is a skilled procedure and several methods are available (Hazelton and Gelderblom, 2006). The

morphology of HSV is characteristic, although HSV-1, HSV-2 and herpes varicella-zoster virus (VZV) cannot be differentiated by such direct examination. The technique is relatively insensitive and a specimen must contain at least 10^6 or more particles per millilitre to allow detection of virus. In practice, vesicle fluid from primary infections will usually yield sufficient virus. Thin-section EM, sometimes combined with immunological staining using gold-labelled specific monoclonal antibody, has a role in examination of histological material.

Virus Culture

While the use of virus culture has declined in many diagnostic virus laboratories, virus culture remains an indispensable tool for the specialized laboratory when live virus is required for detailed analysis. HSV-1 and HSV-2 are among the easiest of viruses to cultivate and propagate in the laboratory. A wide range of both primary and continuous monolayer cell cultures can be infected with HSV. Cytopathic effect (CPE) develops as a rule within one to seven days of inoculation. Both ballooning degenerating cells and polykaryocytes may be observed. The CPE of HSV-1 and HSV-2 may be rapidly differentiated by IF staining of infected cells with type-specific monoclonal antibodies.

Virus isolation in cell culture provides a highly sensitive method for the detection of HSV but its efficiency depends on the method of specimen collection and the preservation of virus infectivity between the patient and the laboratory. Vesicle fluid from a 'fresh' vesicle is usually rich in virus. Virus is rarely isolated from crusted vesicles. A virus collection swab is used to swab ulcers or mucous membranes in order to detach virus-containing cells. To reduce loss of infectious virus between the patient and laboratory the swab is then placed in a suitable transport medium to stabilize HSV infectivity. If there is delay in transportation, the material should be maintained at $+4^{\circ}\text{C}$ or immersed in liquid nitrogen. Freeze-thawing should be avoided. Cerebrospinal fluid (CSF), biopsy or necropsy specimens are collected into dry sterile containers and require no special transport media. Such specimens should be transported and maintained at $+4^{\circ}\text{C}$; they should not be frozen. On arrival in the laboratory, specimens are inoculated on to at least two different cell types. Biopsy or necropsy specimens are homogenized in a small amount of transport medium prior to their inoculation on to cell cultures. As for human cytomegalovirus (CMV) (detection of early antigen fluorescent foci (DEAFF) test), detection of virus growth in tissue culture can be accelerated if specimens are centrifuged on to cells cultivated on small cover slips and the cells are stained after 24 hours with a monoclonal antibody directed to HSV early antigen. Isolates of virus may be readily typed as HSV-1

or HSV-2 by the use of specific monoclonal antibodies tagged with fluorescein isothiocyanate.

Enzyme-linked Immunosorbent Assay (ELISA)

A number of ELISA procedures are available for the rapid detection of HSV. Whilst the specificity of these procedures is high (about 98%), their sensitivity for the detection of virus in acute vesicular lesions is only about 80%, and with material from crusting lesions may reduce to less than 60%. In comparison to culture, immunoassays, which are not reliant upon the detection of infectious virus, may offer an advantage where suboptimal transportation of specimens to the laboratory has resulted in loss of virus infectivity.

Nucleic Acid Detection

Direct hybridization of clinical samples with radio- or enzyme-labelled oligonucleotides has been used for the direct detection of HSV but these techniques are now seldom utilized apart from in the examination of histopathological materials (see '*In Situ* Hybridization and *In Situ* PCR' below). A number of alternative nucleic-acid amplification or signal amplification techniques have been applied to the diagnosis of HSV infection but it is nucleic acid amplification, in particular the polymerase chain reaction (PCR), that is most widely applied. A wide variety of PCR techniques have been used, including single, semi-nested and nested PCR techniques, with product detection via gel electrophoresis, Southern blotting, ELISA-like hybridization, microarray or bead-based arrays such as the 'Luminex' procedure. The real-time PCR procedure is now most commonly used; this offers testing of high sensitivity, with reduced risk of intra-laboratory cross-contamination of samples from amplicon release and reduced test turnaround times, achieved by combining the detection of amplification with the thermal amplification process. The test allows direct detection of the products of amplification in real time, is quantitative and usually allows typing of HSV-1 and HSV-2 within the same test. Multi-target or 'multiplex' PCR procedures are also available in both real-time and conventional PCR formats. Careful optimization of these test procedures is necessary to ensure that the sensitivity of detection of each of the individual target viruses within the test is maintained when targets are combined. In special situations, for example the detection of HSV and VZV in vesicle fluids, preferential amplification of a target virus present in high concentration may prevent the detection of a second virus present in low concentration. Nevertheless, the advantage of multi-target detection is an immediate attraction for a diagnostic laboratory, and several successful procedures have been

described in the literature and are available as commercial assays.

Rigorous quality control and attention to detail to ensure adequate sensitivity and specificity are essential for routine application of any PCR technique. Many types of clinical sample contain substances that prove inhibitory to the PCR reaction, which, if not efficiently removed, will result in the production of false-negative test results. Internal control molecules within PCR tests are used to monitor for test failure through test-sample inhibition. Where internal molecules are not available the same check may be performed by 'spiking' a sample with a known amount of HSV or by checking for an alternative human gene expected always to be present within the clinical sample.

Extra- or intra-laboratory contamination of samples with virus or amplicons may give rise to false-positive PCR results. This represents a significant practical problem and requires careful consideration in the design of PCR protocols. A particular consideration in herpesvirus PCR is the possible detection of DNA from (asymptomatic) recurrent herpesvirus infections of no relevance for the current disease. This may create difficulties in defining the clinical significance of a test result.

Sequencing of products of PCR is a useful method for the comparison of strains of virus detected, for example, from different bodily sites or from different persons, and provides a more rapid method for epidemiological and population diversity investigation (Bowden *et al.*, 2006) than the technically demanding restriction-fragment polymorphic analyses previously applied in such studies.

PCR has been most widely applied in the diagnosis of herpes encephalitis and of herpes meningitis. While all types of PCR have been found to be capable of detecting HSV DNA in CSF, rigorous quality control and assay standardization are essential (Linde *et al.*, 1997). The application of real-time PCR for the diagnosis of herpes infection of the central nervous system (CNS) has shown that a sensitivity of between 10 and 25 genome equivalents (copies) per millilitre of CSF is necessary for adequate detection of HSV infection of the CSF. In HSV-1 infection of the CNS, initial CSF viral load has been found to vary between 2×10^2 and 2×10^7 ml⁻¹ for HSV-1 (Hjalmarsson *et al.*, 2007) and between 7×10^2 and 6×10^5 ml⁻¹ for HSV-2 (Franzen-Röhl *et al.*, 2007). The level of HSV DNA in the CSF should decline with treatment, and long-term persistence of HSV DNA in the CSF correlates with a bad prognosis. This further emphasizes the role of PCR in the diagnosis and management of HSV infection of the CNS.

The availability of simplified and automated methods for sample extraction and assay set-up and of improved assays employing internal control molecules to monitor possible sample-induced inhibition of PCR has

led to widespread uptake of PCR in diagnosis of other HSV infections. The use of automation coupled with real-time PCR procedures has allowed PCR to become price-competitive with virus culture. One of the major uses of viral isolation in cell culture was for confirmation of a diagnosis of genital HSV infection. Increasingly, PCR is being utilized to supplant culture, providing more rapid and more sensitive detection and typing of virus than can be achieved by cell culture.

***In Situ* Hybridization and *In Situ* PCR**

HSV nucleic acids may be detected in biopsy or necropsy material by *in situ* hybridization. Paraffin-embedded tissue sections are de-waxed, rehydrated and digested with proteinase-K. After a denaturing step, a labelled DNA fragment or 'probe' (an oligonucleotide produced synthetically or a cloned (plasmid-amplified) fragment of HSV DNA) is incubated with the tissue section. The section is then washed to remove unhybridized probe DNA. The probe may be detected by radiological, enzymatic or chemiluminescent methods appropriate to the label utilized. Where particularly small amounts of viral DNA are present in a clinical sample, *in situ* PCR methods are available to allow detection. The technical complexities of this procedure currently preclude its application except in research settings.

Assays for Antiviral Drug Resistance

Determination of phenotypic expression of antiviral drug resistance depends upon *in vitro* culture of the virus in cell culture. The increasing use of PCR for detection of virus in routine diagnostic laboratories therefore presents a problem if virus is no longer routinely cultured in cell culture. Genotypic analysis involving analysis of regions of the genome with known mutations leading to antiviral resistance is possible. The drawback is that the mutations resulting in resistance have not all been identified and that interpretation of the effects of other mutations that sequencing may identify may be difficult. Phenotypic tests are thus easier to interpret and may detect resistance that genotypic analysis cannot yet discriminate. Maintenance of the capability of cell culture in diagnostic laboratories is thus important.

Serology

Peripheral Blood

A large number of techniques are available to detect and quantify the humoral immune response to HSV infection, including complement fixation tests (CFTs), IF tests and tests for neutralizing antibody. Differences in specificity and in sensitivity are observed between the different

techniques and different assays. These tests have now been largely replaced by commercially-available ELISA tests. In most clinical situations assay of HSV-specific IgG antibody is sufficient. In primary infection seroconversion is readily detected in adequately-spaced samples (14 or more days). In a primary infection IgG production can be detected at or around the same time as an IgM response. Differentiation of primary and reactivated infection may be possible by measurement of HSV-specific IgG avidity. In recent infection IgG avidity will be low, while in reactivated infection IgG avidity will usually be high.

IgM antibody to HSV can be detected using a suitable enzyme-labelled antiglobulin in the standard indirect ELISA technique or, with superior specificity, by IgM 'capture' immunoassay. Detection of HSV IgM in HSV IgG-negative patients or in patients with very low levels of specific HSV IgG is suggestive of a primary infection. False-positive IgM reactions are known to occur, however, and follow-up serology to confirm a positive IgM antibody detection is therefore necessary. During reactivation and in initial infection an IgM response can often be detected. The detection of IgM antibody—especially low-level activity—does not always allow differentiation of a primary infection and a reactivation event. The magnitude of the response can vary from individual to individual. Thus the results of IgM immunoassays must be interpreted with caution.

The type-common epitopes of HSV-1 and HSV-2 ensure that most conventional ELISA techniques are adequate for the detection of seroconversion to either virus in a person without previous experience of HSV infection. Coincident seroconversions to herpes VZV are occasionally observed and may be due to an anamnestic immune response or possibly because of synchronous reactivation ('dual reactivation') or synchronous infection ('dual infection') of HSV and VZV.

ELISA procedures utilizing 'whole virus'- or membrane-associated glycoprotein preparations representative of the complete antigenic spectrum of HSV provide the most sensitive assays for HSV antibody. However, to differentiate HSV-1 and HSV-2 serological responses, ELISA procedures that utilize type-specific purified virion glycoprotein G, peptides and/or recombinant antigens to distinguish HSV-1 specific and HSV-2 specific antibodies are necessary. Such assays are commercially available and are useful in epidemiological studies and in specialized situations such as determination of the serostatus of the partner of a newly diagnosed case of genital herpes or characterization of the first episode of herpes in a pregnant woman. In low-risk populations their positive predictive value is not yet satisfactory. The sensitivity

and specificity of the commercial assays vary but in the best-performing assays are high. In general the sensitivity of these assays has been better for detection of HSV-2 antibodies and the specificity better for HSV-1, although this continues to improve. A prerequisite for the use of these assays is a knowledge of the performance and limitations of the test in use, and access to a reference test for equivocal results (e.g. western blot, Ashley *et al.*, 1988) as well as experience in validation and interpretation of the results (Ryan and Kinghorn, 2006).

Type-common serology remains the basis for the diagnosis of primary infections. Type-specific assays only provide a complement in this situation as the type-specific antibody response may be very late and take up to several months to appear.

Cerebrospinal Fluid

Demonstration of a peripheral blood HSV antibody response is not in itself diagnostic of CNS infection. Such a response may merely reflect reactivation of latent HSV secondary to neurological disease of unrelated aetiology. Serological diagnosis of CNS infection requires proof of intrathecal synthesis of specific antibody. To determine whether specific antibodies are produced intrathecally, and not passively transferred from serum, the integrity of the blood–CSF barrier (BCB) must be assessed. The most accepted methods in general use are those in which the ratio of antibody quantitated in both serum and CSF is compared to the distribution of a reference protein such as albumin (Cinque *et al.*, 1996). The use of total IgG as the reference protein or calculation of the herpes-specific fraction of the intrathecally-produced antibody however provides certain advantages in differentiation between polyclonal stimulation in neurological disease (Jacobi *et al.*, 2007). A technically simpler and rapid diagnostic procedure to attain this goal is λ -capture assays (for references see Aurelius *et al.*, 1989; Fomsgaard *et al.*, 1998). However, the requirement of labelled HSV antigen or specific antibody has hampered their general use due to a lack of commercial tests.

Quantitative and qualitative differences between CSF and serum antibody responses, for example in patterns after isoelectric focusing or western blot, provide additional information (Monteyne *et al.*, 1997). The antigen-mediated capillary-blot technique, performed after isoelectric focusing of serum and unconcentrated CSF, provides an alternative and sensitive method for the qualitative detection of specific intrathecal synthesis of antibody. The presence of two or more anti-HSV oligoclonal IgG bands present only in CSF is considered to provide a definite diagnosis.

ANTIVIRAL CHEMOTHERAPY

A large number of compounds with *in vitro* anti-HSV activity have been described. Few have progressed to clinical trial and fewer still have gained a place in clinical practice. The major ‘anti-herpetics’ in current use, aciclovir and penciclovir, are nucleoside analogues. Prodrugs of aciclovir and penciclovir, valaciclovir and famciclovir, are also available and offer better systemic bioavailability following oral administration (Waugh *et al.*, 2002). These antiviral drugs can suppress symptomatic disease and asymptomatic shedding, and prevent transmission and HSV infection, but they neither cure nor alter the natural history of HSV infections. The nucleoside analogues are virostatic and it is of crucial importance that therapy is initiated very early in HSV infection. Their efficacy in the very common mucocutaneous manifestations of HSV infection in immunocompetent individuals is moderate.

A second-generation nucleoside analogue, brivudin and derivatives, encountered serious, even fatal, drug–drug interaction with fluorouracil used for cancer therapy. Promising drugs in the pipeline (Biron, 2007) include compounds targeting the HSV helicase–primase and appear to be good candidates for combination therapy in the immunosuppressed. Resistance problems have been encountered with some HSV isolates but these were fortunately fully sensitive to aciclovir.

First-line or Standard Therapy

Aciclovir (Zovirax)

The structure of aciclovir is shown in Figure 6.3a and the mode of action of aciclovir is illustrated in Figure 6.4. The compound is an acyclic nucleoside analogue. Virus-infected cells appear to be slightly more permeable to aciclovir than noninfected cells but the compound is only entrapped and selectively concentrated within virus-infected cells. Within the infected cell, a virus-specified enzyme, thymidine kinase, TK, effects the monophosphorylation of aciclovir. The resulting aciclovir monophosphate cannot traverse cellular membranes and is consequently localized within the virus-infected cell. Host-cell kinases (including host-cell-derived TK) do not appear capable of catalyzing this reaction to any significant degree.

The active antiviral drug is aciclovir triphosphate and conversion of aciclovir monophosphate to the active triphosphate form is accomplished by host-cell kinases. The triphosphate form of aciclovir has much greater affinity for virus-specified, as opposed to host-cell-derived, DNA polymerase. Aciclovir triphosphate binds to virus-specified DNA polymerase, leading to the inactivation of this enzyme’s activity. Thus, viral

DNA replication is inhibited whilst normal host-cell DNA metabolism remains virtually unaffected. An additional antiviral action is via chain termination through incorporation into the growing viral DNA chain (absence of 2' and 3' carbons of guanosine).

Valaciclovir (Valtrex)

The oral bioavailability of aciclovir is relatively low and for this reason a prodrug—the L-valyl ester of aciclovir—valaciclovir—was developed (Figure 6.3b). Valaciclovir hydrochloride is rapidly adsorbed from the gastrointestinal tract and rapidly and almost completely

converted to aciclovir and L-valine by first-pass intestinal and/or hepatic metabolism. The mode of action, safety profile and clinical spectrum of activity of valaciclovir are believed to be identical to those of aciclovir. The plasma concentrations of aciclovir achieved after oral administration of valaciclovir are equivalent to those achieved by intravenous administration of aciclovir and are three to fivefold greater than are achieved with oral administration of aciclovir. Valaciclovir can therefore provide a much more convenient dosing regimen of once, twice or three times daily, in comparison to the five times daily for aciclovir.

First-line Antivirals

(a) **Aciclovir**

2-amino-9-((2-hydroxyethoxy)methyl)-1*H*-purin-6(9*H*)-one

(b) **Valaciclovir**

2-[(2-amino-6-oxo-6,9-dihydro-3*H*-purin-9-yl)methoxy]ethyl(2*R*)-2-amino-3-methylbutanoate

(c) **Penciclovir**

(2-amino-9-[4-hydroxy-3-(hydroxymethyl)butyl]-3*H*-purin-6-one)

**(d) Famciclovir**2-[(acetyloxy)methyl]-4-(2-amino-9*H*-purin-9-yl)-butyl acetate**Second-line Antivirals****(e) Ganciclovir**2-amino-9-[[[(1,3-dihydroxypropan-2-yl)oxy]methyl]-6,9-dihydro-3*H*-purin-6-one**(f) Foscarnet**

(phosphonomethanoic acid)

**(g) Cidofovir**(((2*S*)-1-(4-amino-2-oxo-1,2-dihydropyrimidin-1-yl)-3-hydroxypropan-2-yl]oxy)methyl)phosphonic acid**Figure 6.3** (continued)

Figure 6.4 Mode of action of aciclovir.

Penciclovir (Denavir)

Penciclovir is an acyclic nucleoside analogue (Figure 6.3c) whose mode of action and safety profile are essentially identical to those of aciclovir. However, the drugs differ in their rate of cellular uptake, phosphorylation rate, stability of the intracellular triphosphate and inhibitory concentration for HSV-DNA polymerase (100-fold higher for penciclovir triphosphate than for aciclovir triphosphate). The intracellular half-life of the active antiviral (penciclovir triphosphate) is substantially longer (7–20 hours) than that of aciclovir triphosphate (0.7–1 hour), which compensates for the slightly lower activity of the drug.

Famciclovir (Famvir)

Famciclovir (Figure 6.3d) is the diacetyl 6-deoxy pro-drug of penciclovir. Famciclovir achieves high levels of systemic bioavailability following oral administration, after which the drug is deacetylated and oxidized to form penciclovir. The mode of action and clinical spectrum of activity are thus identical to those of penciclovir.

Drug Toxicity

The safety profiles of aciclovir, valaciclovir and famciclovir are very favourable due to the selective monophosphorylation of the compounds by viral-specified TK. The risk of adverse reaction is very low; renal dysfunction and CNS neurotoxicity correlate with serum concentrations of

>100 μM (22.5 $\mu\text{g l}^{-1}$), which may be reached only in rapid infusion of large doses. Due to their low bioavailability there is no risk of toxicity with oral aciclovir or penciclovir administration, but toxicity may be seen if overdoses of valaciclovir or famciclovir are given. Safety and resistance data on patients on long-term therapy with aciclovir now extend to over 13 years of continuous surveillance. No long-term toxicity has been noted after suppressive oral aciclovir therapy.

Second-line Antivirals

Ganciclovir ([9-(1,3-dihydroxy-2-propoxy)methyl] guanine) (Figure 6.3e) has good activity against HSV-1 and HSV-2. It has higher toxicity than the aforementioned first-line anti-HSV drugs, its main side-effect being myelosuppression. The L-valyl ester valganciclovir allows oral administration of the drug (see also chapter 8 CMV page 181).

The pyrophosphate analogue foscarnet (trisodium phosphonoformate) (Figure 6.3f), an inhibitor of DNA polymerase, is utilized in severe HSV infections refractory to aciclovir therapy. Slow intravenous infusion of the drug is necessary because of its poor oral bioavailability and potential for nephrotoxicity. An alternative is the nucleotide analogue cidofovir (Figure 6.3g). This compound has, like foscarnet, dose-dependent nephrotoxicity and must be given with oral probenecid to reduce cidofovir accumulation in the renal tubules. The drug's extraordinary intracellular half-life means that only one intravenous infusion is required every one to two weeks.

Drug Resistance

Prolonged use of aciclovir can result in the development of drug-resistant strains of HSV. TK mutants have been reported, with either altered substrate specificity (i.e. aciclovir is no longer recognized as a substrate for virus-specified enzyme) or loss of TK activity. These mutants arise through non-sense, frame shift or missense mutations in the TK gene and are thus readily generated both *in vivo* and *in vitro*. A third type of mutant has altered DNA polymerase such that aciclovir triphosphate no longer binds, with high affinity, to the virus-encoded enzyme (altered substrate specificity). The consequence of alteration in TK is a failure of the virus-infected cell to phosphorylate and thereby selectively concentrate aciclovir. Alteration in DNA polymerase results in a much-reduced antiviral activity since the only antiviral action of the drug resides in the ability of aciclovir triphosphate to induce chain termination.

The emergence of drug resistance gives rise to concern but is currently limited to patients who are immunocompromised and on prolonged treatment; about 4% of HSV

isolates from patients with AIDS and up to 18% of isolates from recipients of bone-marrow transplants are resistant to aciclovir. Among immunocompetent individuals a very low rate (<0.5%) of resistance to aciclovir is observed. Most aciclovir-resistant strains of virus are also likely to be found to be resistant to penciclovir, valaciclovir and famciclovir. The majority of drug-resistant isolates have an altered or deleted TK and thus drugs which act directly upon the viral DNA polymerase, such as foscarnet or cidofovir, are effective as second-line treatments. Multiple drug resistance has, however, been documented. Drug susceptibility assays should be performed in immunocompromised patients with unresponsive herpes simplex infection in order to distinguish drug resistance from problems such as poor compliance or malabsorption of drug.

Transmission of drug-resistant HSV seems to date to be rare. This may be related to a requirement of TK for replication of virus within nervous tissue. Resistant virus shed in cold sores will revert back to wild type in subsequent reactivations.

Immunization

Active Immunization

The short time interval between loss of passively-acquired maternal immunity and acquisition of primary infection, together with the high level of HSV infection in the general population, means that effective prevention of HSV-1 infection by vaccination is problematic. However, the changing seroepidemiology of HSV-1 infections suggests that, at least in developed countries, application of a vaccine against HSV-1 is becoming a feasible possibility. Due to the psychosocial problems of HSV-2 infection and the increase in acquisition risk of human immunodeficiency virus (HIV) infection associated with HSV-2 infection, immunization against this virus has been much more actively sought. At the present time, two strategies are being investigated: classical immunization, which aims to produce so-called 'sterilizing immunity' (i.e. a broad and durable immune response which will be effective in preventing HSV entry via genital mucosa, facial mucosa or the eye) prior to virus exposure; and immunotherapy—modification of the immune response by vaccine administration designed to potentiate immunity and improve control of, or prevent or modify, recurrent infection.

Research on the production of effective vaccines against HSV has been actively pursued since the 1920s. A very wide range of vaccines have been explored, both as 'sterilizing' and immunotherapeutic vaccines. The evidence from the many studies performed suggests that cellular rather than humoral immune responses are important in protecting against both infection and

recurrence. Improved knowledge of the immune-evading mechanisms of HSV and viral determinants necessary to stimulate protective cellular immunity appears to be key to the future development of immunization against HSV (Koelle, 2006).

Two HSV-2 glycoprotein adjuvant vaccines (gB2 + gD2 and gD2) have reached phase III clinical evaluation. The overall protection rates were not significant. However, a gD2 vaccine formulated with an adjuvant alum and 3-deacylated monophosphoryl-lipid A showed a 73/74% protection from disease—but not infection—in women seronegative to HSV-1 and HSV-2. Gender differences and pre-existing HSV-1 serological status influence vaccine efficacy in these trials. Whilst the goal of an effective HSV-2 vaccine has not yet been achieved, the studies have helped define some of the complexity of HSV-1 and HSV-2 disease and shown some of the issues that will need to be addressed if an effective vaccine is to be developed (Kemble and Spaete, 2007).

Passive Immunization

Passive immunization using hyperimmune HSV-specific immunoglobulin has not been widely utilized; normal immune globulin is ineffective. In neonatal disease and possibly in immunocompromised patients, trials of therapy using human recombinant monoclonal antibodies are being contemplated as they may have a role in helping to prevent virus dissemination by viraemia.

CLINICAL FEATURES, DIAGNOSIS AND MANAGEMENT

Oropharyngeal and Oro-Facial Infection

Primary Infection

In a symptomatic, primary HSV infection of the oropharynx, gingivostomatitis is the most common symptom. The incubation period ranges from 2 to 12 days with a median of 4 days and the duration of clinical illness is 2–3 weeks. The spectrum of severity ranges from the trivial, involving the buccal and gingival mucosa, to severe, painful ulceration of the mouth, tongue, gingivae and fauces (Figure 6.5). In severe disease, shallow ulcers on an erythematous base evolve from vesicles and often coalesce, particularly on the mucosa of the cheeks and under the tongue. The ulcers are observed on the hard rather than the soft palate—a feature that may help differentiate herpetic ulcerations from those caused by the *Coxsackie* viruses ('herpangina'). In young children the skin around the mouth is frequently involved. Sub-mandibular lymphadenopathy and fever (39–40°C) are

Figure 6.5 Primary oro-facial herpes, severe ulceration of the mouth.

common and may produce febrile convulsions in children. A moderate lymphocytosis (up to 7000 mm^{-3}) and mild neutropenia are frequently observed. Elevated liver enzymes are noted in occasional cases. Acute gingivostomatitis is a self-limiting disease and resolution begins abruptly. The lesions become painless and inflammation subsides. Intraoral ulceration progresses to healing, although crusting of lesions is not usually observed. The patient becomes afebrile and symptoms regress rapidly, although lymphadenopathy may persist for several weeks.

Other symptoms that may be associated with primary infection include sore throat, mild conjunctivitis, nausea and vomiting, myalgia and abdominal discomfort. Dehydration and anorexia may result through the pain and oedema of the mucosal membrane infection, with its associated mouth discomfort and difficulty in swallowing. Older patients may experience a pharyngitis associated with a mononucleosis syndrome (up to 20% atypical lymphocytes) and submandibular lymphadenopathy. The tonsils are also frequently found to be ulcerated during this pharyngitis.

The oral disease can be associated with lesions elsewhere. Herpetic dermatitis, nasal herpes, ocular herpes, herpetic whitlows and even genital herpes are not infrequent complications of primary HSV infection of the mouth. These may represent viraemic spread of virus or endogenous re-infections caused by autoinoculation from the site of primary infection.

Diagnosis Clinical diagnosis is usually straightforward. The major differential diagnoses are herpangina and hand, foot and mouth disease, both usually caused by *Coxsackie* viruses. Oral vesicles in these conditions are found on the posterior part of the oropharynx and not outside the mouth. Demonstration of virus, viral antigen or viral DNA in saliva/lesions easily confirms clinical suspicion. If the

causative role of herpes is in doubt, seroconversion to HSV confirms the diagnosis of primary infection.

Management Primary or initial infection with HSV is, in the majority of cases, inapparent or only associated with mild symptoms. As the aetiological diagnosis may not be clear, antiviral therapy is not given and is usually not warranted. However, in severe cases and where the diagnosis is clear, oral antiviral therapy can be given. There is evidence of shortening of duration of pain and time to healing in children with gingivostomatitis with oral administration of aciclovir (children 15 mg kg^{-1} , max 200 mg; adults 200 mg doses five times daily (or valaciclovir (500 mg twice daily; not used in children) or famciclovir (250 mg, three times daily)). Intravenous therapy is indicated if the patient cannot swallow or is vomiting.

Secondary bacterial and fungal infection is common in severe symptomatic cases and may require appropriate antimicrobial therapy.

Steroid treatment in general increases the severity of disease and where patients are receiving high doses of steroids (e.g. in treatment of eczema) the appearance of HSV infection is an indication for temporary cessation or reduction of steroid dosage.

Recurrent Infection

Recurrent infection, triggered by a variety of apparently nonspecific stimuli (such as fever, stress, cold, menstruation or ultraviolet radiation), appears as a fresh vesicular eruption termed 'herpes labialis', 'herpes febrilis', 'fever blisters' or 'cold sores'. The most frequent site is at the border of the lips but lesions may appear elsewhere, for example on the chin or cheek and on or inside the nose. Their appearance is usually preceded by a prodrome of tingling or itching at the site where recurrence will occur. In the immunocompetent, the area of involvement is usually small and vesicles progress to the pustular and crusting stage within three to four days. The time for complete healing is variable (5–12 days, mean 7.5 days).

Asymptomatic oral shedding of HSV can occur and is occasionally preceded by a prodrome similar to that associated with overt herpes labialis. Recurrent intraoral ulcers are only rarely caused by HSV. In the few instances where reactivation of HSV is responsible, lesions are limited to the gingivae and the hard palate.

Diagnosis Herpes labialis is easy to diagnose clinically. Virus detection is helpful to confirm the herpes aetiology in minor ulcerative lesions, for example when misdiagnosed as sunburn or similar.

Management A number of household remedies, not subjected to controlled studies, are believed to have effect,

illustrating an apparent placebo effect in healing time. Episodic treatment with antivirals as well as frequent local applications of penciclovir 1% or aciclovir 5% cream have a very modest effect and require a very early start during the prodromal phase; that is, if and when there is an itching or slight burning sensation. The effect of antivirals in combination with topical steroids is under investigation.

Prevention No data are available to support the use of oral antiviral medication for the prevention of oral recurrences. As for recurrent genital herpes (see below), suppressive therapy may be used in frequent and severe recurrence (Gilbert *et al.*, 2007).

Genital Infection

Primary Infection

The clinical features of primary HSV-1 or HSV-2 genital infection are indistinguishable and without treatment primary genital disease may last for up to three weeks. Fever, dysuria associated with urethritis and cystitis (with urinary retention in a proportion of cases with or without apparent vesicles), localized inguinal adenopathy and malaise are common. Onset is usually four to seven days after sexual exposure. A prominent feature is pain, which, especially in women, may be severe. In women the lesions are typically bilateral and located principally on the vulva, but the vagina and cervix are almost always involved. The vesicles on the mucocutaneous surfaces soon ulcerate and coalesce and may extend to the perineum, upper thigh and buttocks. In men, vesicular lesions with an erythematous base are observed on the glans of the penis or on the penile shank. Perianal and anal infections producing proctitis are common in homosexual men. Secondary microbial infections often follow primary genital HSV infection and their occurrence necessitates appropriate antimicrobial therapy.

Complications of genital HSV infection include aseptic meningitis and sacral radiculomyelitis with urinary retention and attendant neuralgia; these may occur in the absence of apparent genital lesions. Primary (maternal) genital herpes occurring at or around the time of birth may produce severe neonatal infection (see below).

Diagnosis Detection and typing of HSV in material from fresh lesions or secretions in the genital tract by cultivation, antigen detection, ELISA, indirect immunofluorescence or molecular techniques provides diagnosis. PCR is the most sensitive procedure and allows typing, and may be considered the new gold standard for detection of HSV in genital secretions.

An analysis of the HSV-specific antibody response reveals the nature of the infection. In a primary infection no HSV IgG antibodies are demonstrable in acute

serum. Seroconversion to type-common HSV antigens confirms the diagnosis. In initial infection (prior infection with the heterologous, noninfecting, type of HSV), seroconversion is seen only to the type-specific antigen of the infecting virus type. It is, however, noteworthy that this type-specific antibody response may take up to 8–12 weeks to appear. If antibodies to the infecting virus are already in acute serum, the episode, which clinically may appear to be the first episode, is in fact a recurrence.

Treatment In practice, the large majority of primary/initial infections are undiagnosed (Figure 6.6), and in those that are, the peak of viral replication may already have passed before antiviral therapy can be commenced. If the diagnosis is apparent, as it often but not always is in severe cases, oral antiviral therapy can be given. There is evidence of shortening of duration of pain and time to healing provided patients are treated early—within five days of the start of disease (or later if lesions are still appearing). Aciclovir (200 mg doses, five times daily), valaciclovir (500–1000 mg twice daily), or famciclovir (250 mg, three times daily) are given for five days unless new lesions continue to appear, when extended therapy should be contemplated. In severe cases intravenous antiviral medication may be required, as well as procedures to control the pain and relieve any urinary retention.

Although severe primary or initial infections are associated with a higher frequency of symptomatic reactivation there is no clear evidence to suggest that treatment can alter the natural course of disease.

Figure 6.6 The majority of genital herpes infections produce either atypical or no symptoms. Only a minority of cases are recognized.

Prevention Effective preventive strategies are badly needed. Vaccines are not available to provide protection pre-exposure. Present strategies include education of the public to increase awareness about genital herpes; education concerning the substantial protection of consistent condom use in both sexes; education of health-care professionals and patients concerning recognition of vague clinical signs for increased detection; testing of asymptomatic partners; and counselling the seronegative. Abstaining from sex during clinically-overt outbreaks and episodic treatment may be of some protective value, although incomplete, as silent excretion of virus is the major transmission factor. Suppressive therapy of the infected partner (e.g. aciclovir or valaciclovir 500 mg once daily) reduces, but does not eliminate, transmission to the non-infected partner (Corey *et al.*, 2004). Consistent use of condoms significantly reduces transmission of HSV (Wald *et al.*, 2005).

The influence of HSV-2 infection on HIV acquisition and disease has resulted in increased efforts to find strategies appropriate to populations in the developing countries. HSV-2 is the most frequent cause of genital ulcers facilitating HIV transmission (Gupta *et al.*, 2007). Research on topical microbiocides is directed towards HIV prevention as well as to the feasibility of simultaneous prevention of HSV transmission.

Recurrent Infection

In recurrent genital herpes a limited number of localized vesicles are produced, often in unilateral sites anywhere in the anogenital region, the buttocks or the natal cleft (Figure 6.7). Their appearance is usually associated with irritation rather than with significant pain. Prodromes of pain and/or itching may precede the vesicles. New vesicles often appear during the course of a recurrence and delay healing. Complications (neurological or systemic) associated with recurrent infections are less common. Although HSV-1 is increasingly found as a cause of primary genital infection, recurrence of genital HSV-1 is infrequent, averaging about one episode per year in the first year and reducing thereafter (Gupta *et al.*, 2007). Asymptomatic shedding with HSV-1 is of short duration and occurs infrequently. This contrasts with HSV-2 genital herpes, where calculated rates of recurrence reach three to nine episodes per year, with frequent silent shedding in between (Gupta *et al.*, 2007).

Overall about 60% of patients known to have had primary infection will report recurrence, although many HSV-2 seropositives are not aware of their infection. Triggering factors for recurrence are nonspecific and may be menstruation, sexual intercourse or psychological stress, but in most instances the triggering factor is not known.

Figure 6.7 Genital herpes.

Diagnosis As for diagnosis of primary infection, the detection of virus or viral DNA from fresh vesicles provides the mainstay of diagnosis. Atypical recurrences are often misinterpreted by patients as well as by physicians; the recurrent infection may mimic a number of other conditions or appear as very discrete skin fissures or erosions. Demonstration of type-specific antibody to the infecting virus type confirms the recurrent nature of the episode.

In the absence of symptoms the finding of HSV-2-specific antibody is indicative of prior genital HSV-2 infection; in contrast recurrent genital HSV-1 can only be confirmed by virus detection.

Management Recurrent HSV infections inconvenience the host but are rarely serious in the immunocompetent individual. Frequent or severe recurrences may require oral or systemic antiviral chemotherapy. The most effective episodic treatment requires (self-) initiation of antiviral therapy as soon as portrayal symptoms are noticed or the debut of erythema/vesicles is observed. This reduces the severity and duration of the recurrent episode (by on

average two days). A five-day course of aciclovir, valaciclovir or famciclovir has been considered optimal. Data on the comparative efficacy of the drugs used in this way are not available. Recently, the same healing rates and reduced duration have been found with aciclovir (three day), aciclovir (two day) and famciclovir (one to two day). These short-term courses are well tolerated, with the added advantage of being more convenient and economical than standard regimens (Corey *et al.*, 2007).

Prevention Since the maintenance of latent virus infection appears to be independent of virus replication, present antiviral chemotherapy cannot ‘cure’ recurrent virus infection. Patients with frequent or severe recurrences (defined as more than six episodes per year) should be considered for continuous suppressive therapy. The decision has to be made on an individual basis. The optimal dose of aciclovir is 200 mg four times daily or 400 mg twice daily; of valaciclovir 500 mg daily or 250 mg twice daily; of famciclovir 250 mg twice daily. The treatments have been found to reduce (to about 20%) but not eliminate recurrent episodes. Silent episodes of virus excretion also occur. As the recurrence rate and severity may decrease with time after the acquisition of HSV-2, a six- to twelve-month period is usually chosen for continuous therapy and the necessity for therapy is then reassessed over a period of at least two episodes.

Herpesvirus Infections of the Skin

Herpes Simplex Dermatitis

Herpetic dermatitis is a complication of primary infection. Perioral or periorbital herpes simplex regularly accompanies more severe primary gingivostomatitis or primary/initial herpes keratitis. In babies, seeding of the virus can involve large areas of the face, and when transferred to the anogenital area by scratching may involve the whole napkin area. In primary HSV vulvovaginitis, vesicles readily appear on the perineum and thigh.

A distinct form of cutaneous infection ‘zosteriform herpes simplex’ is an infrequent presentation of herpes simplex, but is recognized when the distribution of HSV lesions accords with a dermatome and otherwise resembles zoster. Unlike zoster, recurrences are common and nerve root pain is not a feature.

Eczema Herpeticum, Thermal Burns and Other Conditions

In patients with atopic eczema the normal resistance of the skin to HSV infection is reduced. Primary, recurrent and possibly both endogenous and exogenous re-infection may all produce eczema herpeticum. Eczema herpeticum

as a primary infection carries a small but significant mortality through progression to severe generalized disease. In thermal burns, mycosis fungoides, pemphigus, or with follicular dermatosis (Darier’s disease) and other conditions where the defence of the skin is impaired, severe progression may also be seen.

Herpes Gladiatorum

Herpes gladiatorum, ‘scrum pox’ and ‘mat burns’ are conditions spread among wrestlers and rugby players through bites and facial scraping (Turbeville *et al.*, 2006). The appearance of herpetic vesicles at ‘unusual’ sites can sometimes be explained by an inquiry into the individual’s athletic pursuits!

Herpetic Whitlows; Traumatic Herpes

Under normal circumstances HSV does not readily penetrate healthy skin, but when the dermis is breached a portal of entry is created. Health-care personnel are at particular risk of perforation injuries. Direct inoculation of virus into the fingers of those who constantly manipulate in the oral cavity (dentists, dental nurses, intensive-care doctors, nurses and anaesthetists) may lead to herpetic whitlows, an inflammation of the nail folds (Figure 6.8). This treatable/preventable condition, which is often associated with painful recurrences, is frequently misdiagnosed as bacterial infection, especially if the clinical presentation is devoid of vesicles. A similar condition is seen in children and adolescents, who transfer their own oral virus through nail biting. In other situations, workers such as hairdressers, dressmakers and laboratory personnel can be infected by accidental stab injuries with contaminated needles or broken glassware (traumatic herpes).

Figure 6.8 Paronychia; ‘herpetic whitlow’.

Surgically-induced Reactivation

HSV-1 seropositive individuals undergoing surgery in the trigeminal nerve area (e.g. trigeminal nerve decompression, oral surgery or extensive facial cosmetic procedures) can suffer outbreaks of herpes, which may occur anywhere on the face, as a result of reactivation from the sensory branch of the nerve.

Reactivation of HSV-1 has been implicated in the pathogenesis of idiopathic peripheral facial palsy (Bell's palsy) (see Furuta, 2006 for a review). In a study from Japan (Murakami *et al.*, 1996) HSV-1 DNA was demonstrated in endoneural fluid from the facial nerve of 79% of facial palsy patients and also in 57% of tissues from the posterior auricular muscle innervated by the facial nerve. In a Scandinavian study (Stjernquist-Desatnik *et al.*, 2006) of 20 milder cases of idiopathic facial palsy, HSV DNA was, however, found only in 1 posterior auricular muscle biopsy.

Diagnosis Demonstration of virus/viral DNA in lesions easily confirms the clinical picture of cutaneous manifestations. The definition of a herpes aetiology in facial palsy is more difficult; serology is not useful (except in demonstration of seropositivity to herpes) and the demonstration of virus in, for example, saliva is not of diagnostic value. HSV DNA is not found in CSF (Kanerva *et al.*, 2007; Stjernquist-Desatnik *et al.*, 2006).

Management and Prevention Whilst many of these conditions are self-limiting, intravenous or oral antiviral therapy must be instituted as early as possible in vulnerable patients at risk of severe HSV (e.g. eczema herpeticum and/or similar conditions associated with impaired skin resistance). Steroid treatment in general increases the severity of disease and where patients are receiving high doses of steroids (e.g. in treatment of eczema) the appearance of HSV infection is an indication for temporary cessation or reduction of steroid dosage. Secondary bacterial and fungal infection is common in severe symptomatic primary and initial HSV infection and requires appropriate antimicrobial therapy.

Education on HSV and instruction in basic hygiene should be given to persons in close contact with individuals with known risk of severe herpes infection and also to risk groups such as wrestlers. In the health-care setting, the risk of herpetic whitlow is reduced by use of gloves and universal precautions to prevent penetrating injuries and contact with secretions. Preventative antiviral medication may be indicated before surgical intervention in the trigeminal nerve region and episodic or suppressive therapy may be required in some cases of frequent and painful recurrence of herpetic whitlow.

Prevention of facial palsy is not possible. Whereas there has been consensus on treatment with corticosteroids, the role of antiviral therapy has been less clear. Benefits of treatment with valciclovir plus prednisolone versus placebo have been demonstrated, but the role of valciclovir has been under debate and multicentre studies are ongoing. In a recent Japanese report (Hato *et al.*, 2007) a significantly better treatment effect in patients with facial palsy (excluding that caused by zoster *sine herpete*) was found with valciclovir (1000 mg day⁻¹ for five days) in combination with prednisolone than with prednisolone alone. Treatment was started within seven days. Recovery of complete or severe palsy was seen in 95.7% ($n = 92$) versus 86.6% ($n = 82$) and the recovery rate was more rapid in the valciclovir group.

Erythema Multiforme

Erythema multiforme is regarded as a hypersensitivity phenomenon precipitated by a variety of infectious agents, immunizations or drugs. The clinical lesions are characteristic: acraly distributed erythematous papules which evolve into concentric 'target' lesions; annular plaques and bullae may also be produced. Although usually mild and self-limiting the disease can be recurrent and progress to toxic epidermal necrolysis or to severe mucous membrane involvement (Stevens-Johnson syndrome). *Mycoplasma pneumoniae* and HSV are the infectious agents most commonly associated as precipitants. Up to 65% of patients with recurrent erythema multiforme give a preceding history of herpes labialis, on average 11 days before the lesions of the disease appear. Infectious virus cannot be cultured from the lesions but IF studies have shown HSV glycoprotein B located around keratinocytes in the viable epidermis, PCR studies have detected HSV DNA in cutaneous lesions and *in situ* hybridization has been used to demonstrate HSV nucleic acids within the epidermis.

Management and Prevention As HSV replication is apparently a precipitant of the disease but not a direct cause of the pathology, erythema multiforme does not respond directly to antiviral chemotherapy. However, cases of recurrent HSV-associated erythema multiforme can be prevented by prophylactic use of antivirals. Some cases of idiopathic-recurrent erythema multiforme (i.e. where antecedent herpes labialis is not suspected) also respond to prophylactic use of antivirals. This is perhaps consistent with a preceding 'silent' recurrence of HSV.

Ocular Infection

The early symptoms of herpes keratitis are of a unilateral or bilateral conjunctivitis, with pre-auricular lymphadenopathy. The most common first presentation is,

Figure 6.9 Herpes simplex keratoconjunctivitis.

however, of a unilateral, characteristic, dendritic (branching) ulcer (Figure 6.9). The normal course of the disease is three weeks but if ulcers are large, healing can be slow. Mild systemic disturbances, blepharitis and circumocular herpetic dermatitis are commonly present during the primary infection. Infection may occur as a part of a primary infection or by autoinoculation from the site of a recurrent infection. Most cases are due to HSV-1.

New HSV infections of the eye are estimated to occur at a rate of 8.4 per 100 000 person years in the United States (Mayo Clinic data) and the overall incidence of new and recurrent ocular HSV is calculated to be 20.7 per 100 000 person years. Lower rates are reported from Europe, with a rate of 4 per 100 000 population in Croatia and 6–12 per 100 000 population in Denmark (for references see Liesegang, 2006).

A single recurrence of ophthalmic infection is observed in between 20 and 30% of patients within two years of the first infection. Subsequent recurrences are less common but if a second recurrence does occur then further recurrences will be observed in 40–45% of these cases. There are several forms of recurrent ophthalmic infection and these may occur in combination. Dendritic or larger ‘geographic’ ulcers are usually the first manifestation of recurrence, with the patient complaining of ocular irritation, lacrimation, photophobia and sometimes blurring of vision. Infection is usually confined to the superficial layers of the cornea and stromal involvement is absent or only relatively mild.

In some cases days or weeks after the recurrent infection a new disease manifestation may appear where the corneal epithelium ulcerates, to form a nondescript ovoid ulcer known as the post-infectious or metaherpetic keratitis. Virus replication does not appear to be directly responsible for the production of this ulcer. If the ulceration is prolonged (weeks and months) collagenolytic activity may appear, leading to stromal melting and perforation.

Repeated and severe epithelial disease recurrence or chronic epithelial keratitis leads to involvement of the deeper layers of the cornea, producing interstitial or disciform keratitis. Neovascularization and scarring may ultimately lead to loss of vision. In developed countries ocular HSV disease is a major cause of corneal blindness (Liesegang, 2006).

The observation of recurrent infection of the cornea raises questions as to extraneuronal sites of latency of HSV within cornea. Using PCR, HSV DNA has been demonstrated within corneal cells of both normal and diseased corneal tissues obtained at keratoplasty. The incidence of HSV epithelial keratitis is six times higher in patients who have undergone corneal transplantation for nonherpetic corneal disease than in nontransplanted individuals. Moreover, infectious virus has been isolated using cocultivation techniques from corneas obtained from patients with stromal herpes keratitis. However, these observations do not prove that corneal latency of HSV occurs, as it remains difficult to distinguish this from low-grade virus persistence and low-level subclinical reactivation within the trigeminal ganglion.

The influence of the immune response in control of ocular infection is an additional area of interest in the pathogenesis of ocular HSV infection. Whereas superficial corneal epithelial disease is primarily a viral infection, recurrent disease keratitis and the other forms of ocular HSV are more complex, with viral infection, immune and inflammatory responses combining to attack ocular structures. Because of the unique anatomy and physiology of the eye, the local immune response to infection may differ from that occurring at, for example, cutaneous sites. The lack of, and/or relative overproduction of, individual components of the immune response undoubtedly influences disease pathogenesis at this site. Whether viral-strain specificity and genetic susceptibility, as has been demonstrated in animal experimentation, is of importance in human ocular disease is not yet clear.

Recurrent iridocyclitis and occasionally panuveitis may be caused by HSV. Iridocyclitis, produced by intraocular inflammation, is often observed in association with active herpes keratitis. It may be due to direct involvement of the virus or may be secondary to the irritative effects of keratitis. Also, structures behind the lens may be involved. Acute retinal necrosis is a rare, severe ocular inflammatory syndrome which if untreated is associated with a poor visual prognosis. The condition is caused by infection with VZV, HSV-1 (in older patients) or HSV-2 (in younger patients). An association with a history of prior or concomitant HSV encephalitis and meningitis has been reported (Ganatra *et al.*, 2000; Lau *et al.*, 2007). The presentation is usually unilateral but may progress to involve the fellow eye even after extended periods of time.

Ophthalmic disease, associated with intrauterine and neonatal infection with HSV, can present as keratoconjunctivitis or later as chorioretinitis. However, cataract, corneal ulceration, anterior uveitis, vitritis, optic atrophy, nystagmus, strabismus, microphthalmia and retinal dysplasia have all been reported in association with such infection.

Diagnosis HSV keratitis can usually be recognized by its appearance in the ophthalmoscope (Figure 6.9), and specific laboratory tests are as a rule not performed. However, in doubtful cases specific tests are highly recommended. Demonstration of HSV DNA by PCR is more sensitive than virus isolation or antigen detection. Intraocular HSV disease is demonstrable by the detection of HSV DNA in anterior chamber or vitreous fluids and/or locally produced antibody production (Ganatra *et al.*, 2000; Lau *et al.*, 2007). Simultaneously-taken serum is required for parallel analyses, including albumin or total IgG, to demonstrate intraorbital antibody production. HSV DNA and/or herpes-specific antibody production may be found in CSF (El Azazi *et al.*, 1991).

Management In conjunctivitis and corneal epithelial disease conservative treatment is warranted with application of specific antiviral chemotherapy (aciclovir ophthalmic ointment) and possibly debridement of the cornea (Wilhelmus, 2007). Misdiagnosis of the condition has frequently led to the administration of corticosteroids to the eye. As the innate immune response limits the spread of virus and hastens resolution, such treatment may exacerbate and prolong the infection. Steroids should not be given. Oral or systemic antiviral therapy should be given in severe disease. Secondary bacterial infection may occur, necessitating appropriate antimicrobial therapy.

Recurrent ocular HSV infections are managed in a similar fashion, except that the indication for antiviral chemotherapy is more pronounced.

In stromal herpes keratitis, and possibly also in iridocyclitis, steroid therapy is almost certainly indicated, since most damage is believed to result from an inflammatory reaction rather than the direct action of virus replication in corneal tissues. Severe stromal scarring necessitates corneal transplantation.

Prompt antiviral therapy should be given in posterior ocular infections, along with preventive and reparative measures for retinal detachment (Lau *et al.*, 2007).

Prevention As ocular HSV infection may result from an endogenous re-infection (i.e. transfer of virus from the site of a recurrent infection to the eye), education on the need for hand hygiene when overt recurrent herpes lesions are present may be of value in prevention of transmission.

Long-term suppressive oral aciclovir therapy (400 mg twice daily) has been shown to be of benefit in patients with prior HSV stromal keratitis (Herpetic Eye Study Group, 2000) but of lower benefit in preventing recurrence of epithelial keratitis. Antiviral prophylaxis should follow corneal surgery in patients with a history of ocular HSV. Suppressant antiviral therapy is warranted for patients with acute retinal necrosis infection of one eye, to prevent progression of the disease to involve the fellow eye.

Herpes Simplex Encephalitis

The most well-known presentation of herpes simplex encephalitis (HSE) is of a focal encephalopathic process with signs and symptoms that localize to the fronto-temporal and parietal areas of the brain. As the disease progresses, symptoms increase in severity and there is progressive decrease in consciousness, leading in severe cases to coma and death. Herpes encephalitis occurs in all age groups, with one half of cases occurring in individuals older than 50 years and one third in those of less than 20 years of age. The same frequency is found in both men and women; among children there is a slight preponderance of boys affected by the condition (De Tiège *et al.*, 2008). There is no seasonal variation in incidence and cases occur sporadically. An estimate of the nationwide incidence 1990–2001 in Sweden was 2.2 cases of HSV-1 per million population per year; there was a median age of 62 years in male patients and 66 in female patients (Hjalmarsson *et al.*, 2007). Most cases are caused by HSV-1, with HSV-2 causing between 2 and 6.5% of cases. In about two thirds of cases the illness appears to be due to reactivation of the patient's own virus or to re-infection (Studahl and Sköldenberg, 2006; Whitley, 2006). In paediatric HSE patients, especially in infants, HSE is more often (but not always) the consequence of primary HSV infection (De Tiège *et al.*, 2008). In the mildly-to-moderately immunocompromised, 'classical' herpes encephalitis appears to occur at the same rate as in the immunocompetent, although in AIDS patients an atypical, subacute encephalitis associated with either HSV-1 or 2 has been identified in 2% of cases studied at autopsy, usually in association with a concurrent CMV infection of the CNS (Cinque *et al.*, 1998).

The onset of disease may be either abrupt, with altered consciousness and focal neurologic symptoms, or insidious, especially in children. Early signs and symptoms of the infection may not be distinctive. In about half of patients there is a history of a 'flu-like' illness occurring less than a week before the appearance of neurological symptoms. In children seizures are more common than in adults.

Electroencephalographic (EEG) examination is a relatively sensitive indicator of disease process but is of

low aetiologic specificity. EEG will usually reveal focal or diffuse nonspecific slow-wave activity during the first five to seven days of illness. Later, more characteristic paroxysmal sharp waves or triphasic complexes with a temporal predominance may be found. Low-density lesions are demonstrable by X-ray computed axial tomography (CT) within five days of the onset of neurological illness in about 70% of cases. Single photon emission computed tomography (SPECT) may demonstrate hyperperfusion at an early stage in the temporal lobes in HSE, a feature not observed in other encephalitides. Proton magnetic resonance imaging (MRI) has the potential to detect abnormalities that may not be revealed by routine CT. MRI may show fronto-basal and temporal lesions as hypointense lesions on T1-weighted images and hyperintense lesions on proton-density- and T2-weighted images at an earlier stage than changes can be detected by CT. In children, involvement of particularly the parietal lobe and opercular region is seen; thalamic lesions are also much more common than in adults (De Tiège *et al.*, 2008).

The histopathological changes associated with severe HSE consist of acute inflammation that evolves to produce haemorrhagic and necrotising lesions. The lesions are characteristically located in the temporal lobes and the orbital surface of the frontal lobes, but adjacent frontal, parietal and occipital lobes and the cingulate gyri may also be involved. In children the cortical and subcortical regions may be affected. Clinically, herpes encephalitis ranges in severity from a mild encephalitis of low mortality and morbidity to severe necrotizing encephalitis. In the period before specific antiviral chemotherapy and expert neurological care were available, HSE was associated with both high mortality (70–90%) and high morbidity (with <10% of survivors returning to normal neurological function). Prompt initiation of chemotherapy using the antiviral drug aciclovir, combined with intensive neurological nursing care, has resulted in a reduction of mortality to less than 20%, with up to 40% of survivors returning to apparently normal neurological function. However, there may be residual neurological deficit in a considerable proportion. This may be severe, with impairment or complete loss of short-term memory being the most commonly observed sequelae.

In contrast to several other enveloped viruses (including varicella-zoster, Epstein–Barr virus (EBV) and CMV), HSV does not seem to be a significant cause of perivascular leukoencephalopathy ('post-infectious encephalitis'). However, a similar picture has been reported to occur in relapse in patients recovering from acute herpes encephalitis. Five days to many years after apparent recovery from acute encephalitis the patient suddenly develops a 'relapse' and a further bout of encephalitic illness. In some cases HSV may again be demonstrated in CSF,

especially in children, but in other cases a secondary immune-mediated process is more likely as viral DNA is not detected in the CSF or brain biopsy when performed. Most patients survive but neurological deterioration is seen in children (De Tiège *et al.*, 2008), whereas adults may recover to at least their level of disability following acute herpes encephalitis (Sköldenberg *et al.*, 2006; Whitley, 2006).

The pathogenesis of herpes encephalitis remains incompletely understood. The structure of the vasculature within the brain together with the meninges surrounding the brain represents, in the physiologically-normal host, a significant barrier to virus entry to brain parenchyma. Haematogenous spread of virus to the brain is usually prevented by these blood–brain and blood–CSF barriers. To gain access to the brain the virus must circumvent the physiological/anatomic barriers. It may achieve this by transiting from the periphery within nerve cells. Another possibility is reactivation of virus within the brain, as HSV genomes—but not infectious virus—have been demonstrated in normal brain (medulla, pons and olfactory bulb) from apparently normal individuals (Baringer and Pisani, 1994). Various pathways have been proposed, although in all probability no one route explains all cases of herpes encephalitis.

During the early stages, infection is principally of neurones, with only occasional involvement of astrocyte and glial cells. The frontal and temporal lobes, together with the associated limbic structures of the brain, appear to be the primary targets of the infectious process (Esiri, 1982) and this has led to the suggestion that this localization reflects the particular neurochemical and perhaps local neuroimmunological environment of the limbic region (Damasio and van Hoesen, 1985). However, such localization is not observed in all cases and virus may spread to involve other regions of the brain. Host immunity plays an essential role, and genetic susceptibility due to monogenic mutation resulting in impairment of the production of α/β and λ interferon was recently described in children (Sancho-Shimizu *et al.*, 2007).

Diagnosis In retrospective studies conducted using stored samples of CSF from proven cases of herpes encephalitis, with samples taken during the acute stages of illness (less than 10 days after onset of neurological illness), PCR was found to have a sensitivity of between 95 and 100% and a similarly high specificity of between 98 and 100% (Studahl and Sköldenberg 2006, Whitley 2006). In extended prospective studies it is recognized that PCR is not infallible, and especially in children (De Tiège *et al.*, 2003) negative results may be obtained with samples taken early in the disease course (days 1–3 after onset of neurological illness) or where aciclovir therapy

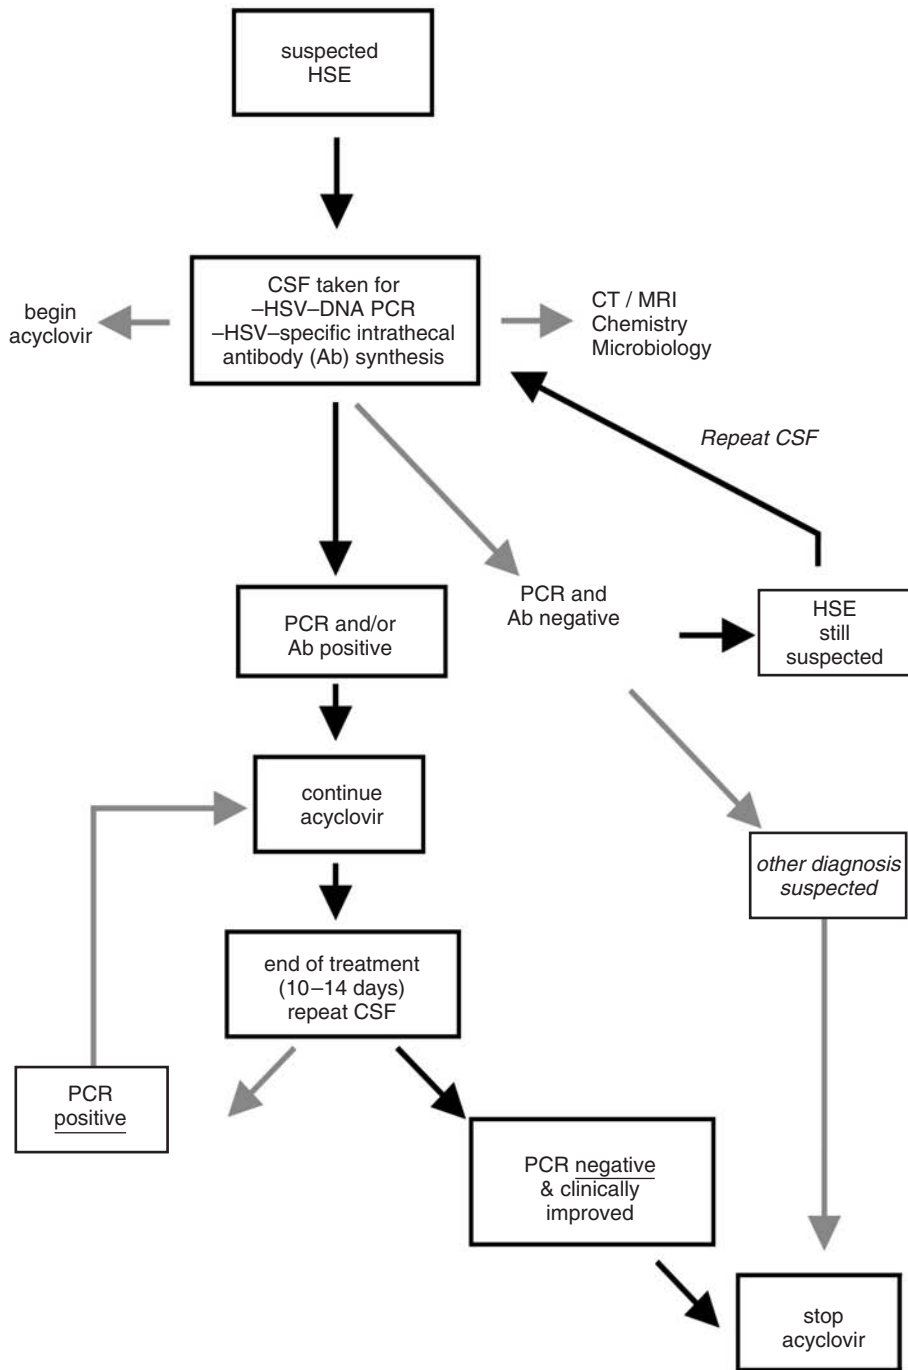

Figure 6.10 Diagnostic algorithm for the management of patients with suspected HSE. (Reproduced, with permission, from Cinque *et al.*, 1996) As patients may present with raised intracranial pressure, immediate lumbar puncture may not be possible. In these circumstances commencement of aciclovir therapy prior to lumbar puncture is warranted.

has been instituted very early in acute infection. Caution is therefore warranted in the interpretation of results, and an algorithm (Cinque *et al.*, 1996; reproduced as Figure 6.10) emphasizes the necessity of repeating the lumbar puncture wherever negative test results are obtained and the diagnosis is still in doubt. It has been reported that initial CSF viral load has prognostic value (Domingues *et al.*, 1998), a finding not confirmed by all investigators (De Tiège *et al.*, 2008; Hjalmarsson *et al.*, personal communication, 2007; Muñoz-Almagro *et al.*, 2008). Quantification is, however, beneficial for follow-up of treatment effect in the individual patient.

The consensus algorithm (Cinque *et al.*, 1996) further mentions the necessity of repeating the lumbar puncture at the end of therapy to ensure full clearance of viral nucleic acid from the CSF. It is important to emphasize that antiviral chemotherapy and/or an intrathecal immune response may clear viral DNA from CSF, and the reliability of PCR in diagnosis of herpes encephalitis declines rapidly in the second week of diagnosis (Figure 6.11). PCR is thus a valuable method during the acute stages of illness but its usefulness reduces 10–12 days after onset, when measurement of specific intrathecal antibody responsiveness is a more appropriate diagnostic procedure, which also—in the majority of cases—allows retrospective diagnosis years to decades later (Aurelius *et al.*, 1991). At the same time, it is a

means of quality control of the routine performance of PCR and antibody techniques. In primary infections, seroconversion and an HSV-specific IgM response are demonstrable in serum/CSF.

Treatment Treatment of herpes encephalitis requires the prompt administration of antiviral chemotherapy. Initiation of treatment should not await firm diagnosis as herpes viral DNA may not be present in the first CSF sample (Cinque *et al.*, 1996; Studahl and Sköldenberg, 2006; Whitley, 2006). Previous trials of antiviral treatment for herpes encephalitis used a 10-day intravenous course of aciclovir at 10 mg kg⁻¹ given every 8 hours. However, due to the high rate of neurologic sequelae and relapses, treatment with 10–15 mg every 8 hours for 14–21 days, and in neonates 15–20 mg every 8 hours for 21 days, are recommended and used in clinical practice (De Tiège *et al.*, 2008; Studahl and Sköldenberg, 2006). The value of at least a further three months of suppression with oral valaciclovir is being addressed in ongoing trials. Aciclovir therapy should be approached with caution in patients with impaired renal function, and the dose of aciclovir should be adjusted appropriately since build-up of excessive serum concentrations of aciclovir has been associated with (reversible) neurotoxicity.

Figure 6.11 HSV-DNA and HSV-specific intrathecal antibody production in relation to time after onset of neurological symptoms in CSF samples from 43 consecutive patients with confirmed herpes simplex encephalitis. None of 36 additional CSF samples taken at 30 days or more of illness were HSV-DNA positive; all 36 had intrathecal antibody production. For details see Aurelius *et al.*, 1991.

Specific antiviral chemotherapy is not the only important factor in treatment of CNS infection. Careful management in close collaboration with several clinical disciplines and the clinical virology laboratory is essential (Cinque *et al.*, 1996; Studahl and Sköldenberg, 2006). Brain oedema is believed to represent the major cause of mortality in herpes encephalitis, hence reduction in intracranial pressure is an important consideration in the overall treatment regime. There is certainly a need for a better understanding of the different pathophysiology and immunological effects of HSV infections in the brains of children and adults, to form more adequate therapeutic strategies in HSE.

Herpes Simplex Meningitis and Other Neurological Disease Caused by Herpes Simplex Virus Type 2

Symptoms of herpes meningitis include headache, stiff neck, vomiting and photophobia and are largely the same as in aseptic meningitis caused by other viruses. Fever is a frequent but not obligatory finding. Mild, mainly monocytic, pleocytosis is found in the CSF. The meningitis often resolves without complications within two to seven days. However, not infrequently, symptoms are protracted, with neurasthenic symptoms persisting for several weeks (Aurelius, 2006). Neurological symptoms due to sacral myeloradiculitis, such as urinary retention, radiating pain in the lumbosacral area, are recorded in about half of the cases of herpes meningitis. Herpes simplex meningitis is a complication of primary genital infection and occurs whether apparent mucocutaneous symptoms are present or not, or have preceded the meningitis by one to two weeks. Herpes meningitis often follows subclinical acquisition of genital herpes HSV-2. Apparent genital or lumbosacral lesions may occur later. Although occasional cases of HSV-1 are reported in association with primary genital HSV-1 infection the increase of genital HSV-1 primary infections has not been accompanied by higher incidence of HSV-1 meningitis.

The prognosis of HSV meningitis is generally good, although in about 20–30% of cases 1, 2 or up to more than 20 new episodes of meningitis may occur after an interval of months to years or even decades—often without mucocutaneous signs of herpes. Improvement in diagnosis through the use of PCR has shown that HSV-2 is the major cause of benign recurrent meningitis, including most cases of so-called Mollaret's meningitis (benign recurrent aseptic meningitis of previously unknown aetiology characterized by 3–10 episodes of fever and meningeal irritation occurring over a period of years). In addition to this well-recognized complication of HSV meningitis, it is becoming clear that HSV-2 may cause a wider

spectrum of neurologic disease (Aurelius, 2006). In patients presenting with episodes of acute headache and malaise interfering with everyday life but without clear-cut symptoms of meningitis, an HSV-2 aetiology should be kept in mind. Urinary retention and other signs of sacral radiculomyopathy or neuritis may occur without obvious signs of genital herpes, and in rare cases HSV-2 has been found as the aetiology to serious or even fatal ascending myelitis or transverse myelitis. Classical HSE localized to the brainstem may also be caused by HSV-2.

The age of acquisition and geographical distribution of herpes meningitis follow those of primary genital infection, with a peak incidence in early adulthood. Herpes meningitis is more common in women than in men. Risk factors other than female gender and a lack of prior HSV-1 antibodies have not been identified. Meningitis has been calculated to occur in at least 4–8% of cases of primary genital herpes; in United States studies this translates into about 20–30% of patients seeking medical assistance for primary genital infection. A study from Denmark suggests an annual crude incidence rate of HSV-2 CNS disease of 0.26 per 100 000 population, of whom 88% have meningitis, 19% of which results in recurring lymphocytic meningitis (Omland *et al.*, 2008). The proportion of aseptic meningitis caused by HSV-2 is dependent on the local epidemiology of both HSV types as well as other causative agents. In a recent Swedish study an HSV-2 aetiology was confirmed in 16% and suspected in another 3% of aseptic meningitis (Franzen-Röhl *et al.*, 2007) in an area with a young adult seropositivity of 20–30% seropositive to HSV-2 and about 70% to HSV-1.

Diagnosis Virus isolation from CSF has a low sensitivity for diagnosis of HSV meningitis. HSV-DNA PCR analysis (of well-controlled sensitivity) of CSF sampled during the first week of illness has a high diagnostic sensitivity (87%) in primary herpes meningitis and a somewhat lower sensitivity (75%) in recurrent meningitis (due to the lower viral load; Franzen-Röhl *et al.*, 2007). Recovery of HSV-2 from peripheral lesions preceding or at the same time as an attack of meningitis may support an HSV-2 diagnosis, although caution is warranted as the peripheral appearance may merely indicate concomitant reactivation of HSV and be of no causative relevance.

Demonstration of seroconversion of HSV-2-specific activity may add diagnostic evidence. Intrathecal antibody production has not been studied to the same extent as in encephalitis. Immunoblotting of oligoclonal bands has been found to be of value in the diagnosis of recurrent meningitis and may motivate repeat lumbar puncture in the diagnosis of HSV-2-seropositive but HSV-DNA-negative cases where the aetiology of the meningitis remains unclear.

Whilst neuroradiological imaging is not often helpful in cases of meningitis, MRI is an important procedure in the diagnosis of serious cases of myelitis.

Management In immunocompetent individuals HSV-2 meningitis is a self-limiting disease. The role of antiviral therapy is less well-defined than in genital infection and controlled studies are in progress. Until more data are available intravenous antiviral therapy should be promptly instituted in a confirmed or suspected case of meningitis with serious neurological complications, such as myelitis and/or encephalitis. Antiviral medication may be justified in cases of meningitis where symptoms are still progressing, in order to shorten the period of convalescence. In patients with nausea and vomiting intravenous aciclovir will have to be given until oral medication can be tolerated. Valaciclovir 1000 mg tid has been found to yield the CSF concentrations required for HSV treatment. In infrequent attacks of recurrent meningitis, prompt episodic treatment may be beneficial.

Prevention Prevention of genital herpes is the major means of preventing meningitis. The value of short- or long-term antiviral therapy to prevent an attack of meningitis after first-episode genital herpes is presently not known. In patients with frequent recurrences of herpes meningitis, long-term prophylaxis with aciclovir, valaciclovir or famciclovir in a dosage at a minimum level to prevent clinical breakthrough is beneficial. The medication should be stopped at intervals to test if the need still persists. In cases of debilitating recurrent attacks of neurologic symptoms of suspected HSV-2 origin (HSV-2 antibodies demonstrable but no firm aetiological diagnosis) a trial of the effect of HSV antiviral treatment or prophylaxis may be worthwhile.

Neonatal Herpes

A child with neonatal herpes may be born with overt disease due to primary maternal infection in pregnancy, or may be infected through premature rupture of membranes and ascending infection from an infected birth canal. Most commonly, infection is acquired during passage through an infected birth canal, causing disease presenting at age three days up to six weeks. Primary oral herpes in the mother or ongoing herpes among relatives or hospital staff in close contact may also infect a baby not protected by maternal antibody.

HSV-1 and HSV-2 can both cause devastating neonatal infection, with symptoms ranging from the very severe to the relatively mild. Even mild disease can, however, be a cause of significant residual morbidity. Three major presentations are seen: lesions of the skin, eye and mouth (SEM, evident age 7–12 days); neurological symptoms

Figure 6.12 Neonatal herpes. Left picture: CT of the brain 8 days after first neurologic symptoms (seizures) in a 20-day-old girl. Increased attenuation is seen in the whole of the left hemisphere. Right picture: 3.5 months of age, widespread destruction of brain parenchyma.

with/without SEM (appearing by age 2–6 weeks); and disseminated disease with/without vesicles, often with involvement of the brain (apparent age 4–11 days). There is an overlap between the types, for example the CNS may be involved in presentations seemingly limited to skin manifestations or may become disseminated. The disseminated disease carries the highest mortality, sometimes presenting as a picture of fulminant liver failure or as multiorgan failure. If untreated, mortality in disseminated disease exceeds 80%, and is >50% in those with CNS symptoms alone. Severe neurological and ocular morbidity is seen in survivors of CNS disease (Figure 6.12). Babies exhibiting only SEM may suffer permanent ocular damage and/or sign(s) of neurological impairment may appear later.

The incidence of neonatal herpes varies with the epidemiology of HSV and may differ in subpopulations from the same area. The magnitude of the problem is reflected in reports of extremes of 1 case in 2500 live births (Alabama, USA) to 1.65 per 100 000 live births (United Kingdom) but the incidence is not known in many areas of the world. Genital herpes and neonatal herpes have in many populations been predominantly caused by HSV-2. In the largest US systematic study of neonatal herpes (over a 17 year period to 1999; Brown *et al.*, 2003), 10/18 were due to HSV-2. In Sweden (Stockholm area; Forsgren and Malm, unpublished data) 29/36 cases were due to HSV-2 over a 23 year period to 1996. However, in Japan and parts of Europe, and associated with a shift in the cause of primary genital herpes to HSV-1, 70% or more of neonatal cases have been reported to be caused by HSV-1. The frequency of neonatal herpes—as reported from the Stockholm area and the Netherlands (van Everdingen *et al.*,

1993)—did not increase over an observation period of 17 years when rates of genital herpes simplex infection were increasing. Under-reporting of cases was thought an unlikely explanation as clinical awareness has increased and the diagnostic tools improved over the period. Factors such as improving hygiene standards, changing sexual behaviour and women postponing childbearing to a higher age come into play.

Clinical awareness and prompt initiation of antiviral treatment are the most important factors for a favourable outcome. The difficulty in early recognition of infection has been identified as a major problem. Obvious skin lesions, facilitating the diagnosis, may be lacking in half of the cases. A history of herpes in the mother and father may give some hint but most mothers transmitting herpes are not aware of herpes-like symptoms. The diagnosis of neonatal herpes must be considered along with other pathogens in septicaemia in the first weeks of life. If there are seizures with no obvious cause starting two to six weeks after birth, or signs of encephalitis, a herpes aetiology must be actively excluded before a clinical suspicion is abandoned. In encephalitis pleocytosis, erythrocytes and increase in protein content are regular findings in the CSF. Abnormal EEG patterns appear two to three days after the first CNS symptoms; lesions are evident on MRI on day 2–3 and on CT scan at days 4–6 (see Forsgren and Malm, 2000).

Diagnosis Appropriate investigation of a potential case of neonatal herpes entails the examination of blood, urine, nasopharyngeal specimens, skin vesicle swabs and scrapings, as well as CSF for viral culture, DNA detection and (if available) detection of antigen by IF in vesicle material. Samples should be taken on wide indications and contact between the clinician and a colleague in a specialized laboratory is highly recommended.

PCR examination of CSF is essential and should be performed in all cases and also when infection is seemingly localized to the skin. However, diagnosis must not rely solely upon examination of CSF and a negative finding does not exclude the diagnosis. In SEM, HSV DNA is found in the CSF in only 24% of cases and even in overt CNS disease only in 76–78% of cases, although a higher diagnostic yield (about 90%) may be achieved if PCR analyses include blood (Kimberlin, 2007; Malm and Forsgren, 1999). HSV findings in blood and CSF are diagnostic of active herpes infection, as is recovery of virus from any other bodily location, provided that sampling is undertaken more than 48 hours after birth. The nonspecific ‘colonization’ of a baby from a mother with herpes virus in the birth canal may then no longer be detectable. Determination of the infecting herpes virus is useful for assessing the prognosis and quantitation, and

follow-up of HSV viral load in serum and CSF provides additional information for the management and prognosis of the herpes-infected child (Kimura *et al.*, 2002).

Serological investigation in the child and mother has a limited place in the acute phase of diagnosis. However, higher levels of HSV type-common and/or specific antibody in the mother compared to simultaneously-taken serum from the child may give a first hint of a possible diagnosis. The demonstration of an HSV-specific IgM in serum and/or CSF from the child may be of value, especially in environmentally-acquired infections.

Retrospective diagnosis of HSV-2 infection may be achieved by the demonstration of HSV-2 recurrences in an older child (which appear in the majority of children with neonatal herpes), or the demonstration of HSV-2-specific antibodies when maternal antibodies no longer persist (>12–18 months after birth). A finding of HSV-1 recurrence or of HSV-1-specific antibody is less conclusive as postnatally-acquired HSV-1 infections are not uncommon in early childhood. If dried blood spots, taken from the child for metabolic testing in the neonatal period, have been stored and are available, the demonstration of HSV DNA in blood extraction may contribute to diagnosis in some—although not all—cases (Lewensohn-Fuchs *et al.*, 2003).

Management Initiation of antiviral therapy should not await a confirmed diagnosis if there is a significant clinical suspicion of infection. If vesicles are present, the suspicion of herpes disease may rapidly be verified in the laboratory. Much more difficult are cases without vesicles, those that mimic septicaemia or those starting with a fit without other obvious cause (often with onset in week 2–6). In such cases therapy must be started as soon as there is reasonable suspicion of a herpes diagnosis—when sampling for herpes and other pathogens has been secured—and not abandoned until an alternative diagnosis is obtained or the clinical course and several laboratory results contradict herpes disease.

Studies have demonstrated the benefit of high-dose aciclovir therapy. Current recommendations (Buckley *et al.*, 2006; Kimberlin, 2007) are to administer 60 mg kg day⁻¹ intravenously in 3 divided doses for a period of 14 days in SEM disease (no HSV DNA demonstrable in CSF) and for at least 21 days in disseminated and CNS forms (defined as positive HSV DNA finding in CSF or CNS symptoms). Lumbar puncture should be repeated near the end of therapy. Those who remain positive should be given intravenous antiviral therapy until the PCR becomes negative. Infants with ocular disease are also given antiviral topical treatment. The prognosis in SEM disease after treatment is very favourable, although neurological sequelae appear in 5–10% of cases. In the disseminated form of

the disease high mortality still occurs despite high-dose aciclovir therapy. The mortality is lower in CNS disease, but unacceptably high morbidity rates remain. Only one third of babies with CNS disease have normal development and more than half of the children are left with severe to moderate neurologic and ocular sequelae. Infections with HSV-2 have a worse prognosis than for HSV-1. Virus is probably already spread via neuronal pathways to the brain at the onset of symptoms. Progressive disease can occur with recurrence of herpetic lesions and relapse of neurological or retinal disease. Acute retinal necrosis 20 years after infection has been observed (El Azazi *et al.*, 1991). Long-term suppressive oral antiviral therapy is often arbitrarily given pending the results of two phase III placebo-controlled trials to examine whether oral suppressive therapy (six months) is of benefit in prevention of the long-term neurologic sequelae in children treated for SEM disease or CNS disease (Collaborative Antiviral Study Group, www.casg.uab.edu).

A child with neonatal herpes should be carefully followed up to assess their special needs for early intervention programmes.

Prevention Primary/initial maternal genital or oral herpes at delivery or in the weeks before and after delivery poses the greatest threat of the baby being unprotected by maternal antibody from the infecting HSV type (Brown *et al.*, 2003, 2007). In recurrent maternal HSV infections maternal antibodies seem to protect a child in the post-natal period but may be insufficient to prevent transmission of the virus to the neonate if exposure to virus in the birth canal is intense. Invasive obstetrical procedures, prolonged rupture of the membranes and low levels of neutralizing antibodies are risk factors for transmission.

The main obstacle to the prevention of neonatal herpes is the frequent lack of clinically-recognizable signs of herpes in the mother in primary as well as recurrent infection. Silent excretion is frequent in pregnant women with genital herpes. The patient's history of previous attacks is also unreliable: a supposed first episode of genital herpes may more often be a secondary infection than a primary infection.

Regular antenatal cultures have no predictive value; not even culture at term is an absolute predictor of risk of neonatal herpes. Current options for prevention of vertical transmission are therefore based on clinical recognition of herpes in pregnant women and a growing insight into the course of HSV infections. However, evidence for the efficacy of intervention practices is still insufficient. Preventive measures include antiviral treatment of overt maternal disease, suppression therapy to decrease the risk of shedding and Caesarean section to decrease apparent exposure of the child. No side effects on the neonate

occasioned by aciclovir treatment in early pregnancy have been reported, and there have been no reports of maternal or fetal toxicity caused by suppressive therapy before delivery. Suppressive therapy before delivery reduces but does not eliminate recurrence episodes and shedding, and there are some reports of neonatal herpes in spite of maternal suppressive therapy or Caesarean section.

Most guidelines agree that primary oral or primary or initial genital herpes acquired at any time in pregnancy should be treated with oral or intravenous aciclovir as appropriate to the clinical condition. Treatment is imperative in infection occurring in the weeks just before and after delivery. Where overt genital lesions are present at term, Caesarean section should be considered. Suppressive therapy before birth should be given after a primary or initial genital infection occurring at any time in pregnancy due to the increased risk of viral shedding and the likelihood of a low level of protective (neutralizing) antibodies. It is recommended that whenever possible, specific diagnostic tools including HSV type-specific antibody tests are used to optimize the management of first-episode herpes. It is important to verify the diagnosis by virus detection if the clinical picture is unclear because of the need to follow up an exposed child.

In mothers suffering recurrent genital herpes the transmission risk is very limited, even in those with active lesions at birth (<1–2%). If noncrusted recurrent maternal lesions within the birth canal are evident at the time of delivery the current guidelines in many countries recommend Caesarean section, provided that the membranes have not been ruptured for more than four to six hours. This recommendation is under debate (for references see Forsgren and Malm, 2000) since protection afforded by Caesarean section is not absolute and Caesarean section is associated with some risk to the mother and, to a lesser extent, to the baby. Also, antiviral suppression with aciclovir or valciclovir before birth, widely applied in pregnant women with frequent or late recurrences in pregnancy, has been questioned in populations with low rates of neonatal herpes (e.g. van Everdingen *et al.*, 1993). It is clear that antiviral suppression may reduce the rate of Caesarean section, but given the low rate of neonatal herpes there have not been randomized controlled trials large enough to demonstrate a reduction in the risk of this disease. Scalp electrodes and instrumental delivery should only be used when strictly necessary. In a high-risk area it has been suggested that type-specific serological assays for HSV-1 and HSV-2 could be used to identify mothers who are seronegative for HSV-1, HSV-2 or both, as well as their discordant partners. Appropriate counselling could then be given to avoid risk during the third trimester. Such a strategy may, however, be difficult to implement and would not prevent all cases of neonatal

herpes. Improved sexual-health counselling with respect to the risk of acquiring genital herpes infection during pregnancy, coupled with heightening of clinical awareness about the condition, remains the current mainstay for prevention of this infection.

Disease in the Immunocompromised

Patients who are immunocompromised through deficits in cell-mediated immunity (for example transplant and oncology patients, patients with congenital or acquired immunodeficiency) are at risk of severe HSV infection with the possibility of life-threatening, disseminated infection (Crippa and Cinque, 2006). Primary, recurrent and exogenous reinfections all pose a significant threat to such patients, the severity of disease observed in them being linked with the degree of immunosuppression. Oral HSV infection can progress to extensive necrotic mouth ulceration and involve the pharynx and oesophagus, with bacterial superinfection or haemorrhage in those with thrombocytopenia. Equally severe, progressive genital HSV infections may occur. Autoinoculation may result in initial infection at sites distant from the original focus. Cutaneous dissemination can take place and may be clinically indistinguishable from varicella (Figure 6.13). Visceral dissemination is also possible in haematopoietic stem cell and organ transplant recipients; this can involve the oesophagus, respiratory tract, liver and even the gastrointestinal tract. In HIV patients with moderate CD4⁺ counts (above 200/ μ l), both typical and atypical mucocutaneous oral, genital or perianal manifestations are frequent. In more advanced HIV infections, severe recurrent HSV infection may occur with high frequency at multiple sites; there may be widespread cutaneous distribution and markedly prolonged times to healing of lesions. Prolonged viraemia leads to multiorgan distribution with extensive

Figure 6.13 Cutaneous dissemination of herpes simplex in an organ transplant recipient (Kaposi's varicelliform eruption).

visceral involvement, also affecting the eye (severe keratitis, progressive or acute necrotic retinitis) and CNS (sub-acute diffuse periventricular encephalitis, and concomitant CMV infection is common).

Diagnosis Demonstration and quantitation of virus by isolation, immunochemistry or molecular methods are the main tools. In cases where the diagnosis is unclear a search for viraemia may be of value. Where there is a suspicion of treatment failure, susceptibility testing of a viral isolate is beneficial. Serological tests are of very limited value. To confirm a causal role for HSV, for example in oesophagitis or colitis, a tissue biopsy for histopathological examination/viral demonstration *in situ* is often required. The diagnosis of disease affecting the eye requires corneal scrapings, biopsy and aqueous or vitreous fluid for virus culture/HSV DNA detection. In CNS infections examination of CSF is an essential diagnostic tool.

Treatment HSV infection in the immunocompromised host always gives cause for concern because of the possibility of the development of generalized multiorgan infection. In cases of iatrogenic immunosuppression, HSV infection is an indicator for temporary reassessment of the dosage of the immunosuppressive therapy. Oral medication with aciclovir, valaciclovir, famciclovir or intravenously with aciclovir has documented effect. As antiviral drug resistance has emerged as a significant difficulty, more often in haematopoietic stem cell recipients (10–18%; 2% in autologous and 19% in allogenic transplant patients) than in solid organ recipients (2–3%) and most frequently in HIV patients with low CD4⁺ counts, therapy may have to be switched to intravenous foscarnet (or cidofovir, although cross-resistance with aciclovir may occur). Serious HSV infections require not only the prompt initiation of aggressive specific antiviral chemotherapy but also full medical and nursing intervention. Generalized infection in the immunocompromised patient produces osmotic imbalances, endocrine dysfunction, and circulatory and respiratory failure, which necessitate an aggressive approach to intensive care.

Prevention HSV has effectively ceased to be a major problem in transplant patients since prophylactic antiviral regimens have become routine. Antiviral prophylaxis is given to those HSV-seropositive recipients receiving haematopoietic stem cells over the aplastic phase (or longer in the case of graft-versus-host reaction) and to organ transplant recipients for four to eight weeks. HSV-seronegative recipients and HIV-positive patients should be counselled on prevention of HSV exposure. In patients with HIV, combination anti-HIV therapy has

significantly reduced the prevalence of active herpes. For those patients with HIV suffering frequent recurrence of infection, suppressive antiviral therapy is used selectively as there is some evidence that active HSV infection, in common with other herpes viruses, can act as a cofactor in AIDS, activating HIV and making it easier for HIV to infect certain cells. Herpes infections remain a frequent complication where antiviral therapy is not available.

CONCLUDING REMARKS

Whereas most HSV-1 and HSV-2 infections are silent or harmless, knowledge of serious disease caused by the two viruses has widened through the application of modern molecular diagnostics. Rapid diagnosis enables early therapy, but the presently available antiviral agents are not in themselves adequate. The crucial viral and host-factor determinants of HSV pathogenicity in man remain largely unknown and cannot be targeted. Devastating sequelae and chronic infection frequently remain after, for example, HSV disease of the CNS. Prevention of disease through vaccination, urgently needed in the face of the worldwide problems of the growing number of immunocompromised patients and of the role of HSV in the HIV epidemic, is not yet attainable. It is to be hoped that research into the genomics and proteomics of HSV and the immunopathology of serious HSV disease will result in steps forward in the field.

Varicella Zoster

Judith Breuer

St Bartholomew's and the Royal London School of Medicine and Dentistry, London, UK

INTRODUCTION

Two common diseases are caused by human herpesvirus 3, often called varicella zoster virus (VZV): chickenpox (varicella) and shingles (herpes zoster). Nobody appears to know for sure what the word 'chicken' has to do with chickenpox but one possible derivation is from the Old English 'gican' (itch), designating it the 'itchy' pox to differentiate it from diseases such as smallpox. The words 'zoster' and 'shingles' are derived from Greek and Latin words, respectively, both meaning a belt or girdle, and are obviously descriptive of the characteristic distribution of the rash.

Chickenpox is the manifestation of primary infection with VZV and is one of the commonest communicable diseases worldwide. Its characteristic presentation in the majority of cases is as familiar to laymen as it is to doctors and is usually of little concern to either. However, it has also been long recognized that chickenpox can have serious consequences in adults and in immunosuppressed individuals. Shingles is the manifestation of VZV reactivation and although rarely a life-threatening disease, it is perhaps of more concern community-wide because of the pain, not only of the acute lesion but also of the frequent post-herpetic neuralgia (PHN), which can be very debilitating and is notoriously difficult to treat.

The common aetiology of varicella and herpes zoster was first recognized at the beginning of the twentieth century by clinicians who noticed that a case of zoster in a household was often followed by an outbreak of varicella in younger members of the family. Furthermore, it was shown that vesicle fluid taken from lesions of herpes zoster could induce chickenpox when inoculated into young volunteers. Virus particles were first observed in vesicle fluids by electron microscopy (EM) in 1943 and

definitive evidence that the two diseases are due to the same virus came with the isolation of the virus in cell culture by Weller in 1953 (Weller *et al.*, 1958). Edgar Hope Simpson, a GP in Cirencester, first hypothesized that VZV persisted latently following chickenpox and reactivated to cause shingles (Hope Simpson, 1965). Analysis of viral DNA from lesions of a patient with chickenpox who later developed zoster confirmed that the virus was the same in both cases (Straus *et al.*, 1984).

VZV is the first human herpesvirus for which successful vaccines have been licensed. Thus, the increasing number of patients at risk of severe varicella and zoster, as a result of the growth in the size of the elderly population, the success of treatment regimens that are immunosuppressive in the fields of oncology and transplantation surgery, and the increasing number of individuals who are infected with human immunodeficiency virus (HIV), has been matched by the introduction of VZV vaccines for prevention of chickenpox and zoster.

THE VIRUS

Structure

VZV has the characteristic morphological appearance of a herpesvirus (Figure 7.1), which has been described in detail in Chapter 6. However, because VZV is quite difficult to grow and particularly difficult to purify, less is known about its proteins and genome organization than is known about those of herpes simplex virus (HSV). In fact, much of the knowledge about VZV has been obtained by parallels with HSV. The complete DNA sequence of VZV was published in 1986 by Davison and Scott. A general review of the molecular biology of VZV is given

Capsid Three forms exist: A (empty), B (intermediate) and C (mature). Assembly proteins present in the B form are lost during DNA insertion to produce the C form

Tegument A complex mass of proteins surrounding the capsid. Contains enzymes controlling virus replication and regulating cell function

Glycoprotein 'spikes'
Glycoproteins gE, gB, gH, gI, gC and gL project through the lipid envelope, allowing the virus to interact with its environment. gE/gI and gH/gL are present as complexes

Envelope A complex membranous structure derived from cellular membranes of the trans-Golgi network

Figure 7.1 Structure of the VZV particle (virion). When intact, the particle is spherical and approximately 200 nm in diameter. Amorphous forms may be seen using traditional transmission electron microscopy. (Source: *The Sourcebook of Medical Illustration*, Parthenon Press.)

by Davison 1991. The genome is a linear double-stranded DNA molecule with a molecular weight of 80×10^6 (approximately 125 kilobase pairs (bp)) and is thus among the smallest of all herpesviruses studied. Buoyant density estimations, as well as the sequence data, show a (G + C) content of 46%, which is much lower than in most herpesviruses, for example 67% in HSV-1 and 58% in cytomegalovirus (CMV) DNA. Within the genome there are, however, (G + C)-rich regions, notably the repeat regions. The organization of the VZV genome (summarized in Figure 7.2) shows distinct similarities with HSV

DNA and the two viruses have sufficient sequence homology to permit hybridization under nonstringent conditions. However, there is substantial local variation in the extent of this homology, most notably in the almost complete loss of the repeats around the long unique sequence in VZV, which accounts for much of the size difference between the genomes of these two viruses. The similarities between the HSV and VZV genomes would be compatible with a common ancestry, and a model for this has been proposed (Davison and McGeoch, 1986). The VZV genome is divided into two main coding regions:

Figure 7.2 Organization of the VZV genome.

a unique long region (U_L) (about 105 000 bp), which is flanked by inverted repeat (IRs) elements (at 88 bp far shorter than those of HSV), and a unique short region (U_S) (about 5200 bp), also flanked by inverted repeat sequences (7300 bp). The short region can be found in either of two orientations relative to the long region, producing two isomeric forms of the genome, which occur in equal proportion. Inversion of the long region is rare. By contrast, in HSV and CMV both regions invert at equal frequency, resulting in four isomeric forms. An inherent size variation of the genome of approximately 2% (2500 bp) has been demonstrated in clinical isolates, concentrated in five variable regions. Restriction endonuclease cleavage patterns show some DNA polymorphism between clinical isolates, and strain differences in circulating viruses are

now becoming apparent, which may make such analyses a useful tool in epidemiological studies (see below).

Seventy unique open reading frames (ORFs) have been identified on the VZV genome, of which three are repeated, two are spliced and two are located entirely within other genes. Over seventy RNA transcripts have been demonstrated in VZV-infected cells but the majority of these appear to contain more than one ORF. The genes that have been identified to date account for virtually the whole genome, although the presence of overlapping genes does allow for further ORFs to be identified. The list of genes that have been identified, mostly by analogy with HSV, is given in Table 7.1. Five of the VZV genes, including a gene for a thymidylate synthetase, are not found in HSV, while three HSV genes have no VZV

Table 7.1 VZV genes for which functional products have been identified

Gene	HSV homologue	Protein identity (%)	Translation product (kDa)	Function
1	No homologue	—	12.1	Membrane protein
4	U _L 54	29	51.5	Transcriptional activator (IE protein)

68	U _s 8	22	70.0	Membrane glycoprotein gE (gpI)

equivalent. In common with other herpesviruses, the synthesis of VZV proteins broadly involves three phases, designated immediate-early (IE) (α), early (E) (β) and late (L) (δ). More than 30 virus-coded polypeptides can normally be detected in VZV-infected cells, ranging in molecular weight from 7 kDa to over 200 kDa. Among these, at least six groups of glycoproteins can be identified, with molecular weights ranging from 3.8 to 118 kDa, which correspond to the gene products of VZV glycoproteins E, B, H, I, C and L. VZV gE is the major glycoprotein expressed on VZV-infected cells and mediates IgG Fc-binding in a complex with VZV gL. Two signal sequences within the gE cytoplasmic domain interact with cellular proteins to transport gE complexed with gL to the *trans*-Golgi network (TGN), where post-translational processing occurs before expression on the cell surface. The cellular receptor for gE has recently been found to be insulin-degrading enzyme (Li *et al.*, 2006). Reduction in IDE leads to reduced cell-to-cell spread of virus. The other glycoproteins, including gB, which is present in virions as a disulfide-linked complex of 140 kDa molecular weight, and gH, which is chaperoned by gL, are also directed to the TGN of membranes to be processed before expression at the cell surface. Glycoproteins C and I have been shown in the SCID-hu mouse animal model (see below) to be important for infection of skin cells (Mortal *et al.*, 2002). In addition to the glycoproteins, a range of nonglycosylated proteins have been identified in the virion. These include the main protein component of the nucleocapsid (major capsid antigen (MCA), 155 kDa), an assembling proteinase/assembly protein complex produced from gene 33 and the IE62 protein (175 kDa), an IE translational activator analogous to the HSV ICP4 protein, which is present in the virions. Many of the other proteins of VZV are involved in virus replication. These include the thymidine kinase and thymidylate synthetase enzymes, several virus-specified protein kinases, a range of DNA-binding proteins, including the viral DNA polymerase, and five transcriptional regulators produced from ORFs 4, 10 and 61–63 (see Table 7.1).

Replication

VZV attaches to the outer membrane of the cell, and this is followed by membrane fusion and entry of the viral core into the cell. This process is mediated primarily by the glycoproteins projecting from the virus particles, although some tegument proteins may also play a role in viral penetration. Attachment involves binding, predominantly of gB to heparan sulphate proteoglycan on the cell surface. This binding is followed by attachment of mannose-6-phosphate (M-6-P) oligosaccharides, present on the surface of VZV particles, to M-6-P-specific receptors on the host cell (Zhu *et al.*, 1995). Glycoprotein

E attachment to insulin-degrading enzyme also mediates virus entry and is important for cell-to-cell spread.

The tegument proteins prepare the cell to produce virus and separate from the nucleocapsid during transportation of virus particles to the nucleus. Once within the nucleus, the linear DNA genome circularises.

In common with other herpesviruses, the replication cycle is coordinately regulated. There are three basic stages of gene expression and protein synthesis: IE, E and L. The first viral proteins (IE) can be detected 4–6 hours post-infection. Structural proteins (E) such as the major capsid protein and viral glycoproteins are not detected until 18 hours post-infection. Viral protein synthesis appears to reach maximum levels at 46–48 hours post-infection in some cell culture systems.

IE transcripts are translated in the cytoplasm and the IE (regulatory) proteins are then transported back into the nucleus, where they induce the early gene expression and downregulate further IE gene transcription. The E proteins include those that are required for VZV DNA replication, such as viral DNA polymerase, viral thymidine kinase and protein kinases. Among the late gene products are the nucleocapsid structural and glycoproteins. DNA synthesis occurs following synthesis of E proteins and involves seven viral gene products, including the DNA polymerase (encoded by ORFs 28 and 16), the origin-binding protein (OBP) (ORF51) and the helicase primase complex (ORFs 6, 55 and 52). DNA synthesis is initiated when the OBP binds to the viral origin of replication, OriS, two copies of which are located in inverted Us repeat (Stow and Davison, 1986). This is followed by the movement of the DNA polymerase around the circularized genomic DNA, producing head-to-tail polymers of the viral genome (concatamers). This is referred to as a 'rolling circle' mechanism. After translation of late mRNA, the structural proteins that will form the viral capsid are transported back to the nucleus and assembled around a core of the viral assembly protein. The newly transcribed DNA genome is inserted into the assembled capsid, concurrent with the loss of at least some of the assembly proteins (Harper *et al.*, 1995). Capsids acquire a 'temporary envelope' from the inner nuclear membrane and move to the TGN, where the final stages of assembly take place. The nucleocapsid acquires an envelope containing the viral glycoproteins, to which the tegument proteins are bound. In the normal course of events it appears that a second membrane derived from TGN forms a transport vesicle around the mature virions, which then leave the infected cell by a process of exocytosis. In some cells, however, the virions appear to be aberrantly processed and are transported to digestive lysosomes, which possibly accounts for the very low level of cell-free infectious virus found in VZV-infected cell cultures (see below).

Growth in Cell Culture

VZV replicates, with varying degrees of success, in cultures of many cells of human and several of simian origin. Cells from non-primates are generally resistant to infection but the virus has been adapted to embryonic guinea-pig cells, and passage in these cells was an early stage of the attenuation of the virus used in the current live vaccine. The behaviour of VZV in cell culture can be regarded as being intermediate between that of HSV, which will grow in nearly all cell cultures, and CMV, which will grow only in a few cell types of human origin. In other respects, VZV behaves more like CMV, for example it grows slowly even in the most sensitive cell systems, with the cytopathic effect (Figure 7.3) taking from three days to over two weeks to appear. This process may be mediated by apoptosis rather than direct cell killing. VZV remains even more strongly cell-associated than CMV, and with most systems passage can be achieved only by transfer of infected cells. Cell-free virus can be obtained by a number of procedures, which typically include sonication of the infected cells. Additionally, protective storage media may be used to increase the yield of infectious virus. Higher yields of infectious cell-free virus can be obtained from the media of infected cultures of human thyroid or malignant melanoma cells, which may reflect the release of a high proportion of defective virus particles in other cell culture systems, as noted above. An M-6-P knockdown MeWo cell line is also reputed to yield higher titres of cell-free virus (Chen *et al.*, 2004).

The cytopathic effect in most cell systems is so characteristic that no further means of identification may be

Figure 7.3 The typical early ovoid cytopathic effect of VZV seen in unstained human embryo lung cells.

required. Because of the strong cell association of the virus, the lesion it produces is typically focal and slowly extends into the surrounding cell sheet, due to the spread of virus between contiguous cells. Viral antigen can be detected much more rapidly than cytopathic effect. Typically, antigens can be detected in the cytoplasm and nuclei of infected cells within two to four hours after infection and in neighbouring cells after eight to eighteen hours, depending on cell type and the type of antigen targeted. The shape of the lesion is dependent on the architecture of the cell sheet. The typical elongated ovoid shape of the lesion in human embryo lung fibroblasts is shown in Figure 7.3. Enlarged cells can frequently be seen in the lesion and staining reveals that these are multinucleated, resulting from virus-induced cell fusion. Staining of the affected cell sheet reveals another feature of VZV cytopathology, namely that many of both the mononuclear and the multinucleated cells have irregularly-shaped intranuclear inclusions (Figure 7.4). With time, the infection ultimately spreads to involve the whole cell sheet.

Strain Variation and Antigenic Properties

The nucleotide diversity of the VZV genome as a whole has been estimated at 0.063%, which is comparable to that of human DNA but may be less than that of HSV (0.2–0.5%). As with all herpesviruses, the VZV genome contains blocks of repeated nucleotide sequences, in this case five (R1–5). R1, R2 and R3 are GC-rich and are located in the coding sequences of genes 11, 44 and 22 respectively. R4 (which is present in both of the inverted repeat regions (TRL and IRL) flanking the unique long region) and R5 are noncoding. Variation in the number of repeat elements within these regions has been used to distinguish one strain of virus from another, either by means of restriction endonuclease sites generated or lost, or by variations in the length of the cleaved fragments (Hawrami *et al.*, 1996). Other restriction sites and single nucleotide polymorphisms (SNPs) throughout the genome have also proved useful for typing of clinical isolates and this has led recently to the identification of at least five main genotypes (Muir *et al.*, 2002; Peters, 2006; Norberg, 2006; Loparev, 2007) which are to some extent geographically segregated. There is evidence that the many genotypes have arisen as a result of recombination events occurring in the distant past (Norberg, 2006). Even today, recombinant genotypes are described particularly in areas where migration has occurred, for example in London and Rio de Janeiro. SNPs have been used to distinguish the Oka vaccine virus from wild-type strains. A Pst-1 restriction site in gene 38 and a Bgl-1 restriction site in gene 54 have been used to distinguish most UK and US wild-type viruses from the Oka vaccine strain, but in 30% of cases were unable to discriminate between

Figure 7.4 (a) Stained VZV-infected human embryo lung fibroblasts. Note the rounded and multinucleated cells (arrow) (H&E stain). (b) High-power view with many affected cells showing typical intranuclear inclusions.

wild-type Japanese strain and Oka. More recently, three fixed mutations in the vaccine strain, each of which generate restriction sites, have been used to distinguish vaccine virus from wild type in cases of chickenpox and zoster occurring in Oka vaccinees (Loparev, 2000; Quinlivan, 2005). One of these hitherto unique vaccine mutations has now been described in a US strain, although whether it is a recombinant between wild type and vaccine remains to be seen.

Worldwide, experience suggests that antibody produced against any strain of VZV is protective against clinical disease and this is the basis for immunization with the live attenuated Oka vaccine. However, well-documented clinical re-infection has been described in up to 13% of children (Hall *et al.*, 2002) and rarely among pregnant women with low antibodies (Martin *et al.*, 1994). A case of recurrent zoster in the same, immunocompetent, person due to different genotypes provides further evidence for

re-infection (Taha *et al.*, 2006). A number of wild-type strains of VZV in which mutations in IgE abrogate binding of the 3B3 monoclonal antibody, which is commonly used for diagnostic immunofluorescence, have been isolated. One of these MSP-VZVs has been shown to replicate and spread more aggressively in tissue culture and animal models, such as the SCID-hu epithelial mouse (Santos *et al.*, 2000).

Some serological cross-reaction with HSV does occur, indicating that these two viruses share common antigens. It has not been shown conclusively on which of the viral proteins the responsible epitope (or epitopes) is situated. The gB glycoproteins of VZV and HSV have cross-reading epitopes but it has been difficult to demonstrate any significant cross-reactivity with other proteins, in spite of the sequence homologies between the two viruses. More likely is that infection with one virus boosts the levels of antibody to any different but antigenically-related virus strains previously encountered—so-called ‘original antigenic sin’. This theory cannot entirely explain the heterologous reactions between VZV and HSV, since it is known that a small number of children with no previous exposure to VZV but who are experiencing primary HSV infection go on to develop low levels of antibody transiently which react with VZV. The converse has also occasionally been observed with patients experiencing primary VZV infection. It is not known whether this cross-reactivity extends to cellular immune responses or whether it confers any cross-protection between the two viruses.

Host Response to Infection

Following infection with VZV, antibodies are produced to the various structural and nonstructural proteins of VZV. Up to 30 protein bands can be detected with convalescent sera by radioimmunoprecipitation or immunoblotting. The predominant immunogenic components of the virus appear to be the glycoproteins, the major capsid protein and the assembly protein complex (Harper *et al.*, 1988). Both IgG and IgM antibodies react with these proteins (Figure 7.5). Typically, sera from cases of zoster react more strongly and reveal a wider range of proteins compared to varicella. gE, gH and the tegument protein IE62 are the major targets for the cell-mediated immune response against VZV, although T-lymphocyte responses are also measured against epitopes in gL, gB and gC, as well as the transcriptional regulator IE63, and the products of ORF4, ORF10 and ORF29 genes (Arvin *et al.*, 1991). Although specific antibody against VZV may protect against or attenuate infection, control of primary infection and clearance of virus appears to depend on cellular immunity. The incidences of complications and

Figure 7.5 Typical immunoblot patterns for IgG and IgM antibodies obtained with early convalescent sera from varicella and zoster cases. The viral proteins were separated on a 9% polyacrylamide gel, electroblotted on to nitrocellulose and reacted with the sera. IgG and IgM antibodies were detected with ^{125}I -labelled sheep anti-human IgG or IgM. The bands revealed by zoster sera are more numerous and more intense.

death from primary infection are higher if there is underlying impairment of cell-mediated immunity.

Pathogenicity for Animals

Animals other than man are reputed not to be susceptible to VZV but there are reports of successful infection

of primates, such as gorillas and chimpanzees, as well as marmosets. It has also been shown that guinea pigs can be infected with virus which has been passaged in embryonic tissue obtained from these animals, leading to virus replication in the nasopharynx, viraemia and an immune response, but without a rash. Hairless guinea pigs have been reported to frequently develop a papular rash after inoculation but this model remains challenging to use. Inoculation of the rat hind limb produces infection of the dorsal root ganglia, and similarities in the pattern of gene expression with that seen in latent VZV in humans has led to its use as a model of latent infection (Sadzot Delvaux, 1995). However, no *in vivo* reactivation is observed in this model. Moreover, unlike VZV latent infection in humans, the rats experience neuropathic symptoms. As a result this is also useful as a model for the persistent pain, known as PHN, which can occur following zoster (Fleetwood Walker, 1999). In the past 10 years, the use of SCID-hu mice with thymus/liver and epithelial implants has greatly facilitated studies of virus tropism for and replication in T cells and skin, respectively (Moffat, 1995). Studies of simian varicella virus continue to identify similarities to human VZV (Pumphrey and Gray, 1995) but the applicability of data obtained from such a model directly to man remains to be seen.

Pathogenesis

Knowledge about the pathogenesis of VZV-induced diseases, particularly the primary infection, is still limited due to the difficulty in growing the virus and the paucity of suitable animal models.

Surprisingly little is known about the source and route of transmission of the virus. The skin lesions are certainly teeming with infectious virus, even at the maculopapular stage. Airborne transmission from skin lesions is therefore highly likely, especially since VZV DNA is readily detected by polymerase chain reaction (PCR) in the air surrounding patients with VZV infection. It is virtually impossible to isolate infectious virus at any stage from the upper respiratory tract of cases of varicella, although viral DNA may be detectable by PCR. Nevertheless, it is widely believed that transmission occurs from this site, probably from asymptomatic oral lesions which are present before the skin eruption appears. Whatever the case, VZV undoubtedly is transmissible via an airborne route and does not require close personal contact. The clinical attack rate of varicella in outbreaks is typically around 70% in susceptible individuals, which is slightly less than for other viruses transmitted via the respiratory route, for example 90% for measles.

For many years the model for the pathogenesis of varicella was extrapolated from the Fenner and Grose mousepox model (Figure 7.6). Virus was hypothesized to enter

Figure 7.6 Proposed models for the pathogenesis of varicella. (Reproduced from Grose 1981.)

the respiratory tract and replicate in the nasopharyngeal lymphoid tissue. After two to three days the virus spread in lymphocytes to reticuloendothelial tissue, hence after a further period of replication a second viraemic phase resulted in the virus reacting with the end organs, including the skin, lungs, gut and sometimes brain.

Using data from the SCID-hu mouse model, an alternative model of pathogenesis is gaining acceptance. Following replication in the respiratory lymphoid tissue, the virus infects specialized skin-homing CD4-positive T lymphocytes, which are abundant in tonsillar tissue. Virus may be carried directly to the skin within two to three days of infection. The fact that lesions do not form for another 10 days is thought to be due to interferon α production by surrounding uninfected epithelial cells, resulting in barriers to cell-to-cell spread of the virus (Ku *et al.*, 2004). Eventually, the virus is able to downregulate MHC and other cell-signalling molecules, overcoming innate defences and leading to the development of virus-filled vesicular lesions. Further spread occurs by infected T cells trafficking through infected skin. In healthy individuals, primed T

lymphocytes act to limit the severity of infection (Zerboni *et al.*, 2005).

Histological examination of the skin lesions of both varicella and zoster shows focal degenerative changes in the epidermis. In both cases, virus seems to infect the cells in the isthmus of the hair follicle, an area rich in stem cells. From there the virus spreads to infect the epithelium. Affected cells are swollen and many of these contain well-defined eosinophilic intranuclear inclusions. Multinucleated cells, also with intranuclear inclusions, are characteristically seen at the base of the lesion (Figure 7.7). The histology of the skin lesions is thus essentially similar to the cytopathology seen in cell culture. The lesion extends and its centre fills at first with clear fluid, which then becomes cloudy due to the influx of inflammatory cells.

Termination of the infection at this site is indicated by the drying up of the pustules, which is followed by separation of the scabs and regeneration of the epithelium. Termination must be brought about mainly by cell-mediated immunity. The presence of large amounts

(a)

(b)

Figure 7.7 Multinucleated cells.

of free and cell-associated virus in the lesion, as well as degenerating cells showing all the characteristic features of VZV infection, strongly suggests that the damage results from a lytic effect of the virus. The lesions in the immunocompromised are not modified in any way other than being more extensive and this makes it unlikely that immunopathology is playing an important part in their genesis.

Recovery from the primary infection results, in most people, in lifelong immunity to exogenous infection, although clinical re-infection has been described in up to 13% of children and in some pregnant women with low antibody titres (Hall *et al.*, 2002; Martin *et al.*, 1994). Subclinical re-infection may be even more common, since it has been demonstrated that seropositive individuals who are in contact with varicella can occasionally show significant rises in the level of specific antibodies and boosting of cell-mediated responses (Arvin *et al.*, 1983; Gershon *et al.*, 1996). Furthermore, viral DNA can be detected by PCR in nasopharyngeal secretions of immune individuals

who are in close contact with chickenpox, suggesting that localized re-infections may occur (Connelly *et al.*, 1993). Asymptomatic systemic spread of virus is also suggested by reactivation of UK viral strains in patients whose primary infections occurred in Africa (Quinlivan *et al.*, 2002). More recently, a case where two episodes of zoster were caused by different strains of VZV re-inforced the likelihood that, as with other herpesviruses, re-infection can occur (Taha *et al.*, 2006). Hope Simpson in 1965 hypothesized that reexposures to VZV throughout life help to maintain effective immunity to varicella, and this has been substantiated by more recent epidemiological data (Brisson *et al.*, 2002; Thomas *et al.*, 2002).

Latency

Following the primary infection, the virus remains latent in one or more posterior root ganglia. The predominant route for infection of nerve ganglia is thought to be by retrograde spread from the skin. Only cell-free virus, which is abundant in vesicular fluid, is able to infect the ganglia and establish latency. Infection with cell-associated virus results in lytic destruction of the ganglion, and this is thought to be because it contains ORF61 protein, which is absent in cell-free virions (Chen, 2003). Production of cell-free virions in vesicle fluid is possible because differentiated keratinocytes lose the M-6-P receptor which normally binds M-6-P present in virion envelope and sequesters the virus into cell-associated endosomes (Chen, 2004).

The trigeminal and thoracic ganglia are most frequently infected, but ganglia at multiple sites may contain VZV DNA, including ganglia not directly connected with the skin (Furuta *et al.*, 1997). VZV can also infect T lymphocytes and this is likely to be the route of infection in cases of asymptomatic re-infection. In up to 25% of individuals, a single reactivation of the virus, known as herpes zoster, occurs usually several decades after the primary infection. The virus reactivates in the ganglion and then progresses peripherally down the sensory nerve to produce the typical skin lesions of herpes zoster, which are restricted to the dermatome supplied by the nerve.

Less is known about how VZV maintains latency and what triggers reactivation than about the corresponding processes with HSV. During latency the viral DNA appears to exist in episomal form, with fused genome termini. Latent virus is located predominantly in the neurons within the ganglia (2 – 5%), with a much smaller proportion (less than 0.1%) of nonneuronal satellite cells being infected. Unlike HSV, there is no evidence that VZV encodes latency-associated transcripts. There is evidence that, unlike HSV, protein products of ORFs 4, 21, 29, 62 and 63 are produced during latency (Mahalingam *et al.*, 1996; Lungu *et al.*, 1995) and are present in the cytoplasm

Figure 7.8 Destructive inflammatory changes in a ganglion.

as well as the nucleus, as expected, of both neuronal and nonneuronal cells (Lungu *et al.*, 1995).

Reactivation of virus is associated with intense destructive inflammatory changes in the involved ganglion (Figure 7.8) and this may be reflected in the severe pain which is frequently experienced in association with zoster. The failure of the host defence mechanisms to contain the virus in the ganglia after such prolonged periods of time is not understood. In immunocompetent individuals it is probably due to the decline of the effectiveness of previously acquired 'cell-mediated' immunity to VZV. In particular, T-cell responses to IE63 have been proposed to protect against reactivation. Inadequacy of cell-mediated immunity is likely to be of critical importance, since not only the elderly but patients with Hodgkin's lymphoma, HIV and similar diseases are more likely to experience zoster. These patients are also more likely to experience more than one attack of the disease, or they may develop the 'disseminated' form of the disease. The term 'disseminated' implies that the virus spreads through viraemia from the affected dermatome to infect the skin or other organ at some distal site, producing lesions that are similar to those of varicella in their appearance and distribution. Most cases of zoster occur spontaneously but trauma and stress have also been proposed as triggers of reactivation.

EPIDEMIOLOGY

Cases of varicella are seen throughout the year but in temperate climates they occur more frequently in the spring months. Annual variation in incidence also occurs, with higher than average incidence in three-to-four-year cycles. Herpes zoster, in contrast, occurs sporadically and evenly throughout the year.

In tropical climates, varicella occurs during the dry seasons and outbreaks are curtailed by the advent of the rains. Different parts of the world can show significant variations in the age distribution of infection. In 'temperate areas' it is one of the classic diseases of childhood. In the past the highest incidence of varicella occurred in the age group 4–10 years (Figure 7.9). Recent serological surveys and data from surveillance general practices (Royal College of General Practitioners) have shown that the peak age of primary infection in Western countries occurs in children aged under five years, which is presumably related to an increased use of day-care and playgroup facilities, leading to greater exposure at a younger age. In general, varicella is highly communicable in temperate countries, with a reported attack rate of up to 96% in close contacts (i.e. household or playfriend), and therefore most people become infected before adulthood. Seroprevalence studies generally show that fewer than 10% of young adults are still susceptible to varicella (Figure 7.9) and despite a temporary increase in the incidence and overall proportion of cases in adults (aged over 15 years) (Fairley and Miller, 1996), this remains the case today.

In many tropical countries, varicella is predominantly a disease of adults, with a mean age of 20–25 years, or even as high as 38 years reported from St Lucia. Studies from the Indian subcontinent, South East Asia and the Caribbean have shown that 25–60% of adults aged over 15 years are susceptible to varicella. It appears that less transmission occurs amongst the young children in these areas and this may reflect patterns of social mixing between infected cases and susceptible contacts. The effects of temperature and humidity at these latitudes on a naturally labile virus have also been proposed to explain lower rates of infection, but are partially discounted by evidence of a childhood pattern of infection in countries with similar climatic conditions, such as Hong Kong and northern Australia. The effect of low population density in a rural setting leading to lower rates of transmission is supported by the lower rates of VZV seropositivity for subjects living in rural Bengal and rural Brazil, as compared with their age-matched urban counterparts (Mandal *et al.*, 1998; Yu *et al.*, 2001). Other theories include competition with other viruses infecting the respiratory tract. A study in Thailand showed the interaction of both mixing and temperature, with urban areas which experience cooler temperatures showing earlier infection (Lohlekha *et al.*, 2001). However, little or no evidence for ethnic differences influencing age of infection have been found (Talukder *et al.*, 2007). Asymptomatic infection occurring in infants protected by maternally-transferred antibodies is also possible, with the virus failing to establish latency and some individuals thus remaining susceptible later in life.

Figure 7.9 Age prevalence of antibodies to VZV. The antibodies were detected by both RIA and indirect immunofluorescence procedures. The numbers of each age group tested are given at the end of the columns. These results were obtained in a collaborative study with Dr J. Cradock-Watson, Withington Hospital, Manchester.

It is important in hospital practice in temperate climates to be aware of the fact that staff who were born in tropical countries are more likely to be susceptible to varicella.

Molecular Epidemiology

The VZV genome is 124 000–125 000 bases long and different viruses have been found to vary by 40–200 bases (Peters *et al.*, 2006). Phylogenetic analysis has shown five distinct genotypes, the nomenclatures of which still have to be agreed. At least three of these strains have arisen by recombination in the past (Norberg *et al.*, 2006). Geographical segregation of strains occurs. Two strains are endemic in countries with populations of European origin and one is endemic in Japan (Muir *et al.*, 2002; Sengupta *et al.*, 2007). There is also evidence that recombination is occurring in areas of population mixing (Barrett-Muir *et al.*, 2002). Genetic typing has been used to prove that the virus causing chickenpox in an individual is the same as that reactivating as zoster some years later, and more recently that re-infection with different strains may occur (Adams *et al.*, 1989; Taha *et al.*, 2006). Genotyping of the Oka vaccine strain has identified changes which distinguish the virus from all wild-type strains. As yet there has not been any evidence for recombination between the vaccine and wild-type strains.

CLINICAL FEATURES

Varicella, the Primary Infection

The incubation period of varicella is approximately 2 weeks but a range of 7–23 days has been quoted. A shortened incubation period occurs particularly in immunocompromised patients. The illness usually commences with the appearance of the rash but occasionally there are prodromal symptoms that resemble an influenza-like illness. These symptoms appear a few days before the rash and are seen more frequently in adults than in children.

The rash is characteristically centripetal in distribution and is seen mainly in areas that are not exposed to pressure, such as the flanks, between the shoulder blades and in the axillae. It is generally sparse in the antecubital and popliteal fossae and is rarely seen on the palms or the soles. This distribution is markedly different from the more centrifugal distribution of the smallpox rash, a distinction which used to be of considerable diagnostic importance. Other differentiating features are that the lesions of smallpox are rounder and deeper than the more superficial and irregular-shaped lesions of varicella.

The skin lesions progress fairly rapidly through the stages of macules and papules to vesicles, which rapidly break down with crust formation. The vesicle with its surrounding area of erythema is the most characteristic

feature of the rash. The lesions appear in a series of crops, so that all stages in their genesis can be seen at any one time. This is very different from smallpox, where the lesions are always at the same stage. Patients with varicella are generally considered to be infectious from a couple of days before the rash until new vesicle formation has ceased and existing vesicles have crusted. This usually occurs five to seven days after onset but may be longer in the immunocompromised. The crusts separate usually within 10 days, revealing healthy skin, but a minor degree of scarring is common. The general constitutional symptoms of the illness are typically mild, particularly in children.

Complications of Varicella

Sepsis Secondary bacterial infection is by far the most common complication of varicella, especially in children, and causes increased scarring of the skin. Streptococci group A and staphylococci are most frequently involved and may be life-threatening in the immunocompromised. Of those children requiring hospitalization for pneumonia associated with VZV, over 30% may have bacterial pathogens.

Viral Pneumonia Symptomatic varicella pneumonia occurs in 1 in 200 000 cases of varicella in children, rising to 1 in 200 in immunocompetent adults, although radiological changes may be found in 10 times this number. In pregnant women the incidence of pneumonitis is increased to 9%, whilst 10% of smokers develop this complication (Mohsen *et al.*, 2001; Parayni *et al.*, 1986). Those most at risk are the immunocompromised, including children with leukaemia, in whom up to 32% develop pneumonitis, with a mortality of up to 25% (Feldmann and Lott, 1987). Adults with malignant disease of the lymphoreticular system who have received organ transplants and patients taking systemic steroids are also at increased risk.

Pneumonia complicating varicella begins one to three (range 1–6) days after the onset of rash and the clinical features include dry cough, dyspnoea and tachypnoea, with chest pain, haemoptysis and cyanosis occurring less frequently. Over 90% of patients with chest symptoms will develop pneumonitis and all such patients should be admitted to hospital for antiviral therapy. Histological examination of an area of lung affected by VZV shows alveoli filled with oedema fluid, a few foamy macrophages and other round cells. The absence of an extensive outpouring of polymorphonuclear leucocytes is a feature that distinguishes this disease from bacterial pneumonia. The presence of multinucleated giant cells with intranuclear inclusions (Figure 7.10) is pathognomonic, although somewhat similar cells are seen in measles pneumonia. It is important to realize that these multinucleated cells are not

Figure 7.10 Varicella pneumonia. Area of consolidated lung with typical multinucleated cells (H&E stain).

always seen, but large swollen mononuclear cells, similar to cytomegalic cells but without the dominant intranuclear inclusion, are always present. Clinical diagnosis is confirmed by chest X-ray changes and direct immunofluorescence (IF) of vesicle fluid and nasopharyngeal secretions, using a fluorescein-conjugated monoclonal antibody. PCR of vesicle fluid and respiratory secretions and specific IgM antibodies in the serum are also useful.

The illness runs a fulminating course if not treated early with high-dose intravenous aciclovir and is the single most common cause of varicella-associated death in the immunocompromised. Surviving patients may recover completely but others develop fibrosis of the lungs, with permanent respiratory impairment.

Haemorrhagic Chickenpox Haemorrhagic symptoms sometimes occur during the course of varicella and usually make their appearance on the second or third day of the rash. Haemorrhage typically occurs into the skin, but epistaxis, malaena or haematuria may be additional presenting features. The haemorrhage may be so severe as to be life-threatening. This complication is more commonly seen in immunocompromised patients such as renal transplant recipients, in whom a thrombocytopenia and/or consumptive coagulopathy may also develop. Other clinical features in these cases often include hepatitis and gastrointestinal bleeding or distention. Treatment of all serious cases of chickenpox is with high-dose intravenous antivirals (aciclovir or foscarnet, if resistance occurs) and intensive care. Intravenous immunoglobulin, although it has not been formally evaluated, is also commonly used. Steroids may be added in cases of respiratory distress and some benefit may be seen with extracorporeal membrane oxygenation (ECMO).

Encephalitis Varicella meningoencephalitis necessitating admission to hospital occurs in 3–4 cases per 100 000

children and more commonly in adults. Cerebral symptoms are more common in adults, whilst cerebellar ataxia occurs in children. In the majority of cases symptoms begin four to eight days after onset of rash. CSF examination may be normal or reveal a lymphocytosis, with a high cell count and protein level being more likely in encephalitis than in cerebellar disease. Typical cases of encephalitis presenting with headache and vomiting and proceeding to coma are rarely seen but carry a high mortality. By contrast, most patients with cerebellar disease recover fully, although it may take some months. Other neurological disorders, including meningitis, transverse myelitis and Guillain–Barre syndrome, have also been associated with the disease.

As with varicella pneumonia, central nervous system (CNS) involvement occurs much more frequently in immunocompromised patients and is another important factor contributing to the increased mortality of the disease in these patients.

Other Unusual Manifestations and Complications of Varicella As mentioned in the Section “Pathogenesis” above, VZV infection may involve virtually any organ of the body but it is unusual for infection at sites other than the skin and occasionally the lung and brain to manifest clinically. Nevertheless, myocarditis, arthritis, hepatitis and both renal and ureteric damage associated with varicella have been reported.

Reye’s syndrome is a serious and frequently fatal form of encephalopathy which is secondary to liver damage occurring in children with varicella or influenza and is associated with ingestion of aspirin. The incidence of this has fallen with strictures on the use of salicylates in children.

Varicella in Pregnancy

From Figure 7.9 it can be seen that approximately 10% of women of childbearing age are still susceptible to varicella, but this figure may be as high as 20% in communities with a high proportion of immigrants from India, the West Indies, the Far East and Africa. The incidence of varicella in adults aged 15–44 years has been estimated at 3 cases per 1000, which would result in about 2000 cases per year in pregnant women in England and Wales. In areas with immigrant populations from India and Africa, the incidence may be over twice as high. Varicella in pregnancy can present two quite distinct problems, depending on whether the infection is contracted in the early or in the very late stages of the pregnancy. For a review of varicella in pregnancy, see Hanshaw *et al.* (1985).

Varicella in the Early Stages of Pregnancy Congenital varicella syndrome occurs in fewer than 1% of fetuses

Table 7.2 Clinical features of the congenital varicella syndrome

Scarring of the skin
Hypoplasia of the limbs, muscular atrophy, rudimentary digits
Cortical atrophy, psychomotor retardation, choreoretinitis, cataracts

where maternal infection occurs before 13 weeks of gestation, but this rises to 2% if maternal infection occurs between weeks 13 and 20 (Enders *et al.*, 1994; Pastusak *et al.*, 1994). The main features of this syndrome are shown in Table 7.2. Certain defects, such as those involving the brain and eye, are similar to those seen in congenital infections caused by rubella virus and CMV, but other features are quite different. Scarring of the skin, which can be extensive, is a unique feature of the varicella syndrome and indicates that VZV is dermatotropic even *in utero*. Other unique features are hypoplasia of the limbs and rudimentary or even missing digits, indicating that VZV intrauterine infection has a marked propensity for the musculoskeletal system. Gastrointestinal abnormalities are also described. The pathogenesis of the unique lesions of the congenital varicella syndrome is not fully understood but it is probable that they result from fetal zoster following the initial VZV infection. The very short latency period is explained by poorly-developed cell-mediated immunity in the fetus.

All of the reported cases in the literature were seriously affected and less than half of them survived beyond 20 months. In addition, a few cases have been reported in the literature of babies born with severe disseminated varicella acquired as late as the twenty-fifth week of gestation. One case report of congenital varicella following maternal herpes zoster did not exclude the possibility of damage arising as a result of asymptomatic primary maternal infection early in pregnancy.

Varicella in the Late Stages of Pregnancy In common with other viruses (e.g. poliovirus), varicella is known to cross the placenta in the late stages of pregnancy, causing congenital infection of the fetus, and infection acquired in this way can result in the child developing varicella. Varicella occurring within 10 days of delivery is evidence of intrauterine infection. The risk of a child acquiring varicella in this way is dependent on the rapidity with which the mother develops and transfers humoral immunity across the placenta and also the time interval between the date of onset of the rash in the mother and the date of delivery. This period is important because it affects the management of these cases. From numerous clinical observations it has now become consistently apparent that

if the onset of the rash in the mother occurs seven days or more before delivery, sufficient immunity will have been transferred so that, even if infection has occurred *in utero*, it will subsequently be mild or even inapparent. In contrast, if the onset of the mother's rash is six days or less before delivery, the child will be exposed to infection without the protection of maternally-transferred antibody. Young children infected in this way may experience severe fatal disseminated forms of the disease. Case fatality rates of approximately 30% have been reported for untreated neonatal varicella. Also at risk of severe infection are babies born to seronegative mothers who contract varicella in the neonatal period, as no passive immunity will have been transferred from the mother. The administration of varicella zoster immune globulin (VZIG) to attenuate infection (see below) is therefore recommended for all children in contact with varicella within the first 28 days of birth where the mother is seronegative. Infected children born to seropositive mothers are usually protected, although it is worth noting that this protection is not complete, since cases of mild varicella have been reported in babies born to seropositive mothers. The protective efficacy of the maternal antibodies is maximal during the first two months of life. Children born before 32 weeks gestation may not have acquired maternal immunity, even if the mother has antibodies to VZV. In such cases, and indeed in all cases where a prematurely-born infant is exposed to varicella whilst in hospital, it is advisable to test the infant for varicella antibody and administer prophylactic VZIG if it is absent. As stated above, the pathogenesis of varicella is not fully understood. The behaviour of VZV in pregnancy does, however, shed some light on this. First, the fact that intrauterine infection occurs at all provides further evidence that primary infection must have a viraemic phase. Of greater significance is the observation that serious neonatal varicella will occur only if the onset of the maternal rash is within seven days of delivery. This clearly indicates that humoral immunity can affect the course of infection.

Herpes Zoster, the Reactivation Infection

Herpes zoster results from reactivation of latent VZV, which typically affects a single dermatome of the skin. The average annual incidence is 0.2% and it can occur at any age. Over 50% of cases occur in individuals aged over 50 years but the incidence rises sharply from far fewer than 1 per 1000 in the under-50s to 3 per 1000 patient years in those aged over 50 and 8–10 per 1000 in those aged 65 years and above. Zoster is rare in children, although maternal varicella and varicella acquired during infancy have been identified as predisposing factors.

The disease is a result of the virus reactivating in a single sensory ganglion and then proceeding peripherally

down the associated sensory nerve to infect the skin supplied by that nerve. The location of the skin lesions is therefore dependent on the ganglion involved. The ophthalmic branch of the trigeminal nerve, as well as the lower cervical (in children especially), thoracic and lumbar (T5–L2) posterior root ganglia are those that are most frequently involved. The eruption is usually preceded by abnormal sensations and, perhaps, by burning or shooting pains in the involved segment, and the skin may be exquisitely tender to the touch (hyperaesthesia). This is followed by the familiar unilateral 'strap' of vesicles on the trunk. This can be accompanied by muscle weakness in the affected or adjoining limb. The density of the vesicles is very variable, being often sparse in children but densely packed in adults. Definitive involvement of the eye in ophthalmic shingles is signalled by vesicles appearing at the tip of the nose, which is supplied by the nasopharyngeal branch of the nerve (Hutchinson's sign). Where the sacral ganglia may be involved, the skin lesions might be associated with retention of urine or symptoms suggestive of urinary-tract infection, and sometimes there is frank haemorrhagic cystitis. Facial palsy associated with vesicles in the external auditory meatus is known as the Ramsay–Hunt syndrome and is thought to be a form of zoster involving the geniculate ganglion of the seventh nerve. It is often accompanied by hearing loss and vertigo. However, the pathology of this form of zoster is disputed and it is preferable to refer to this disease as 'aural zoster' rather than by its eponymous title or even 'geniculate herpes'. Although VZV reactivation has also been implicated as a cause of facial Bell's-type palsy without vesicles or other symptoms, this association is difficult to prove. A double-blind randomized controlled clinical trial failed to show benefit from aciclovir treatment added to prednisolone (Sullivan *et al.*, 2007), although a study of valaciclovir and prednisolone did improve outcome (Hato *et al.*, 2007). A form-fruste of herpes zoster (*zoster sine herpette*), in which dermatomal pain is present without lesions, has been shown to be associated with high IgG antibody titres to VZV, and VZV DNA is detectable by PCR in circulating lymphocytes (Gilden *et al.*, 1994) and in the nasopharyngeal secretions (Furuta *et al.*, 2001).

As with primary VZV infection, herpes zoster is a far greater problem in immunocompromised patients. In these individuals it frequently occurs earlier in life, and second attacks, which are virtually unknown in the immunocompetent, are seen in up to 30% of HIV-positive patients. Moreover, the disease process is frequently prolonged in immunocompromised patients and they are most likely to experience the 'disseminated' form of zoster. If any patient with zoster is examined carefully it is not uncommon to find isolated vesicles in areas of the skin far away from the main lesion. This means that a minor

degree of dissemination must occur quite frequently. In one study, asymptomatic VZV viraemia was detected in 19% of bone-marrow transplant recipients, using PCR (Wilson *et al.*, 1992). In the immunocompromised patient, however, extensive di-semination of the virus can occur. In some cases visceral involvement without lesions may present as fever with abdominal pain and distention. Diagnosis requires a high index of suspicion and PCR of blood (de Jong *et al.*, 2001). Mortality can be high because treatment with intravenous aciclovir is delayed.

Herpes zoster, unlike varicella, does not usually present a problem during pregnancy. The disease is typically mild in pregnant women. One case of transmission to the fetus has been described; however, from the details, it is not possible to exclude asymptomatic primary infection in the mother earlier on in her pregnancy, with reactivation of virus in both mother and child later on in the pregnancy (West *et al.*, 2006). Herpes zoster near term is not associated with serious neonatal infection, presumably because of the protection afforded by maternal antibodies.

Complications of Herpes Zoster

Infection As with varicella, secondary bacterial infection of the skin can occur and occasionally can lead to impetigo or cellulitis, but with appropriate antibiotic therapy this is rarely a serious problem.

Neuralgia Pain lasting more than four weeks after the onset of the rash has been termed PHN. Since the pain is usually a continuum of the pain occurring during the acute phase, a more modern terminology is zoster-associated pain (ZAP). Prolonged ZAP is the most common complication of zoster, occurring in 15% of cases overall and up to 40% of those aged 60 years and over. Nearly all patients experience severe acute pain at the site of the lesion, although the severity and duration increase with age. The pain may be present before the onset of the rash but in just over 85% of cases it remits within two to three weeks. It may consist of a constant pain, an intermittent stabbing pain or paraesthesia. Worsening of the pain on touch, allodynia, is also characteristic. In some patients severe disabling chronic pain occurs. The cause of the pain is not clear but is associated with ganglionic destruction and scarring with perturbation of type C nociceptor function (Rowbotham and Fields, 1996). Symptoms may be precipitated by temperature change and are often worse at night. Age and, when that is controlled for, severity of pain at the onset of zoster are the factors which most strongly predict severe ZAP. Female gender and ophthalmic location of the rash are also associated with more severe and prolonged pain. Treatment with antiviral drugs will reduce the incidence, duration and severity of ZAP if started within 72 hours of the onset of rash, especially in

those aged over 50 years. The level of active drug, both peak values and total dose (area under the curve), have also been shown to be inversely correlated with severity and duration of ZAP (Beutner *et al.*, 1995) and more recently the presence of virus in the blood at presentation was found to correlate with prolonged ZAP (Quinlivan *et al.*, 2007). PHN is rarely seen in children.

Meningitis Encephalitis and Myelitis Neurological complications due to VZV may be more common than hitherto thought. PCR of CSF has determined that VZV is amongst the most frequently detected viruses in patients with aseptic meningitis. VZV may also cause encephalitis, usually in the presence of lesions but sometimes, in immunosuppressed patients, in the absence of visible rash. Typically the rash, if present, involves the cranial or upper cervical nerves. It is fortunately very rare and little is known about its pathogenesis.

A number of clinical observations have strongly suggested that motor as well as sensory neurons may be involved in cases of herpes zoster. Ptosis associated with ophthalmic zoster and paralysis of the intrinsic muscles of the hand associated with skin lesions of the deltoid region are examples of this. The phenomenon is thought to be due to centripetal spread of the virus from a ganglion into the CNS and thence into a motor neuron. It is possible that facial palsy with aural herpes, referred to above, may be mediated in this way rather than through involvement of the geniculate ganglion. Most of the motor neuropathies are fortunately transient and serious sequelae are rarely seen. Guillain-Barre syndrome and transverse myelitis with ascending paralysis have been reported in small numbers of cases and appear to be more common in HIV-positive patients. A rare but serious complication, particularly associated with ophthalmic zoster, is contralateral hemiparesis. This is caused by a granulomatous inflammatory process in the brain, with infarction of the cerebral arteries.

Ocular The presentation of ophthalmic zoster is complex because of the many structures of the eye and its surrounds which can be involved, such as the eyelid, conjunctiva, sclera, cornea and iris. Consequently the risk of complications is high, even in immunocompetent individuals. The risk of complications is particularly high if the nasociliary branch of the fifth cranial nerve is involved. Iritis and keratitis are the most common complications. Blindness following ophthalmic zoster is, however, rare.

Varicella Retinitis Acute retinal necrosis due to reactivation of VZV has been described, and is characterized by focal, well-demarcated necrotizing retinitis occurring predominantly unilaterally. Treatment with intravenous

aciclovir produces improvement within 48–72 hours and prevents the development of ragged retinal holes and retinal detachment. A similar picture can be produced by HSV, usually in association with encephalitis. The clinical complexities of ophthalmic zoster have been reviewed by Marsh (1976) and Culbertson *et al.*, (1986).

In patients with acquired immunodeficiency syndrome (AIDS), rapidly progressive herpetic retinal necrosis due to VZV infection has been recognized. First described as progressive outer retinal necrosis (PORN), the condition is characterized by outer retinal opacification and absence of inflammatory changes in the eye, bilaterality and multifocality. The signs are rapidly progressive and are distinct from the retinal infiltration and haemorrhages seen in CMV retinitis. Untreated, PORN quickly progresses to bilateral total blindness. VZV is the most common cause of this condition and is diagnosed by PCR of fluid from the anterior chamber. Treatment with intravenous aciclovir or ganciclovir may halt the progression of the lesions but will not usually affect the loss of visual acuity. Foscarnet has also been used, both alone and in combination with a nucleoside analogue, either aciclovir or ganciclovir. Foscarnet and ganciclovir have been given as intravitreal injections.

Zoster and HIV Zoster occurs in up to 30% of patients with HIV infection, and in parts of Africa 85% of patients with zoster aged less than 45 years are HIV-1 positive. Most episodes of zoster occur early in the HIV disease process, before the CD4 cell count has fallen, and tend to be unidermatomal. Zoster occurring after the onset of AIDS is associated with disseminated and multidermatomal zoster. Recurrent zoster is common as the CD4 cell count falls, occurring in up to 30% of patients. Up to 10% of patients will also experience an episode of zoster following the start of antiretroviral therapy. This reactivation can be triggered by immune reconstitution. Some HIV-positive patients may develop a chronic form of zoster with atypical verrucous-like skin lesions, which have been associated with decreased expression of VZV gE and gB (Nikkels *et al.*, 1997).

DIAGNOSIS OF VZV INFECTION

The clinical presentations of both varicella and herpes zoster are usually so typical that laboratory confirmation is rarely required. That notwithstanding, in one series of shingles diagnosed clinically in the community 15% turned out to be due to HSV infection or nonherpetic (Breuer *et al.*, 2001). Where the distinction between HSV infection and herpes zoster is difficult, such as in a generalized vesicular rash occurring in an immunocompromised

patient or where atypical lesions occur, laboratory confirmation should be sought. Similarly, laboratory diagnosis may also be useful for some of the less common CNS and ocular complications affecting immunocompromised patients. The VZV antibody status of an individual is also commonly required, now that treatment and prophylactic measures are readily available and also because of the increasing problem of nosocomial varicella outbreaks which require prompt intervention.

Direct Demonstration Techniques

The main advantage of these techniques is that they are rapid, usually giving results on the same day that the specimen is received.

Electron Microscopy (EM)

Typical herpesvirus particles can be seen in profusion in fluid taken from early vesicles of either varicella or zoster. The particles can also be seen in emulsions of material scraped from the base of lesions. The particles are more difficult to see when the specimens are taken late in the disease. EM unfortunately will not distinguish between VZV and HSV infection unless combined with immunological techniques.

Cytology

Smears or scrapings of the base of the lesions, stained by Papanicolaou's method or, for quickness, methylene blue, will reveal characteristic multinucleated giant cells (Figure 7.11), also known as Tzanck cells. Although not a routine procedure, microscopic examination of biopsies of the lesion will also reveal these giant cells, as well as the other characteristics of the histology which have been described above. Again, neither cytology nor histology will distinguish between HSV- and VZV-induced lesions.

Immunofluorescence Cytology

A more specific diagnosis can be made if IF or immunoperoxidase examination of the smears is carried out. Even cells from crusted lesions contain viral antigen in abundance, allowing easy detection. This method is therefore particularly useful at a time when EM or virus isolation (see below) may not be reliable. Direct detection of VZV in cells scraped from the base of a vesicle is now easily achieved using the FJTC-conjugated monoclonal 3B3 antibody, which is directed against an epitope in gE. This simple method has replaced indirect immunofluorescence.

Detection of Viral DNA

The PCR is more sensitive than IF, EM and culture for the detection of VZV in vesicle fluid. For this reason it is the

Figure 7.11 Scraping of the base of a lesion of herpes zoster. Note the typical multinucleated cells (Papanicolaou stain).

method of choice where the vesicular viral load is low and a diagnosis is required, for example where the rash is old, following antiviral treatment or where recurrent varicella infection is suspected. PCR of vesicle fluid is also used to confirm verruciform zoster occurring in HIV-positive patients, and has been shown to detect VZV in up to 10% of simplex-like rashes. PCR is most extensively used for the diagnosis of VZV CNS and ocular disease. Using PCR, VZV was the commonest virus (29%) detected in 3231 Finnish patients with suspected meningoencephalitis. This result is borne out by other studies, confirming that VZV is a significant cause of viral meningitis and encephalitis in both immunocompetent and immunocompromised patients. VZV viral load in the blood may be useful for the detection of visceral zoster infection, which may present in immunocompromised patients as abdominal pain in the absence of rash. PCR of vitreous fluid is also used to confirm the diagnosis of ARN and PORN.

More recently, PCR has been used to demonstrate the presence of viral DNA in throat swabs from patients with zoster and zoster *sine herpette* as well as asymptomatic astronauts (Mehta *et al.*, 2004). PCR of vesicle fluid is also the method of choice for differentiating the Oka vaccine virus from wild-type strains in rashes occurring in subjects who have been immunized (Loparev, 2000; Quinlivan, 2005).

Virus Isolation

This remains the gold standard for diagnosing VZV infections; however, isolation of virus is difficult and recovery

rates in most laboratories are generally less than 50%. Human fibroblast cultures are used in most laboratories as they can be maintained for the 21 days required for some isolation.

Vesicle fluids or material swabbed from the base of fresh lesions are the most suitable for isolation attempts. Virus has also been isolated from the respiratory tract of patients with herpes zoster and of asymptomatic astronauts. The most likely explanation for this is that VZV, in common with other herpesviruses, is shed asymptomatically, although whether it is infectious remains to be seen.

With virus-containing specimens, the characteristic cytopathic effect of VZV will ultimately be produced (see Figure 7.3). Occasionally, clinical isolates only show a reduced CPE on primary isolation and require 'blind passage' on to fresh fibroblast cultures before the classical CPE develops.

It is possible to increase the speed of isolation by centrifugation-enhanced infection ('shell vial' culture). In addition, immunological staining techniques utilizing monoclonal antibodies can be used to detect viral antigens in cell cultures within 24–48 hours after inoculation, before a cytopathic effect becomes apparent (Figure 7.12).

Identification of Isolates

VZV in tissue culture can be identified by its characteristic CPE and by staining with VZV monoclonal antibodies, which recognize the 3B3 epitope in glycoprotein E (Figure 7.12). There are at least four reports of VZV isolates in which the 3B3 epitope has mutated, abrogating binding of the monoclonal antibody. In each case, the change in the epitope appears to have arisen as an antibody escape mutation. Detection of DNA by PCR can also be used to confirm the identity of VZV.

Serological Diagnosis

A number of different methods are currently available for the serological diagnosis of VZV infection, but perhaps the most important use of this technology is the determination of the immune status of patients prior to the administration of prophylaxis.

The serological diagnosis of varicella using acute and convalescent sera is easily accomplished but is less reliable for herpes zoster. Sera obtained in the early stages of varicella are either devoid of or contain only low levels of specific antibody, whereas these antibodies are present in high titre in sera taken in the convalescent period. Whilst significant rises in antibody titre in paired sera can be demonstrated in cases of zoster, this is generally only possible if the first serum is taken soon after the onset of the rash, for the reason that pre-eruption sera will always contain some specific antibodies and the titres rise very

Figure 7.12 Immunological staining technique showing viral antigens in a cell culture.

rapidly after onset. In cases of zoster it is not uncommon to see a drop in the pre-eruption antibody level around the time of onset, so that the antibodies may barely be detectable in sera taken within the first two days after appearance of the rash. Testing for avidity of IgG antibodies provides a means of distinguishing between primary and secondary antibody responses.

The sharing of antigens between VZV and HSV (discussed above) sometimes makes the interpretation of serological results difficult. It is quite frequently found that levels of antibodies to both VZV and HSV will have shown significant rises in association with a particular illness; however, without additional information, such as virus isolation data, it may be impossible to determine which of these viruses was responsible for the infection.

Complement Fixation (CF)

This test is now all but obsolete for the diagnosis of VZV as it is too slow, not sensitive enough for the determination of immune status and more susceptible to cross-reaction between VZV and HSV than other tests.

Immunofluorescence (IF)

This method provides a sensitive determination of serological status to VZV but has now been superseded by enzyme immunoassay (EIA) in most diagnostic laboratories. In IF tests, serial dilutions of sera are reacted with VZV-infected culture cells, and any specific antibodies attaching to these cells are detected with a fluorescein-conjugated anti-human IgG serum. There are

two variants of this basic test. One is the standard IF procedure, in which sera react with acetone-treated culture cells, which is therefore capable, at least theoretically, of detecting antibodies to all virus-induced proteins. This method is no more sensitive than most commercially-produced EIAs. The other is the fluorescent antibody-to-membrane antigen (FAMA) technique, which uses unfixed or glutaraldehyde-fixed cells and is designed to detect only antibodies to viral antigens that appear on the surface of infected cells. FAMA results correlate with the presence of neutralizing antibodies. Moreover, a FAMA titre of >2 has been shown to correlate with both natural and vaccine-induced protection against varicella.

Enzyme Immunoassays (EIAs)

In general, the commercially-available assays for varicella zoster antibodies are less sensitive than FAMA. Currently, commercial tests may fail to detect protective vaccine-induced antibodies in up to 30% of 'immunized' individuals. The gpELISA, developed by Merck, which uses VZV glycoproteins as antigen, is highly sensitive. A level of 5 units or above in the gpELISA at 6 weeks was correlated in one study with protection against breakthrough infection following vaccination. Over 95% of children in this study achieved 5 gpELISA units. In contrast, FAMA testing of vaccinees shows only 78% with levels of >2 . Since post-immunization re-infection occurs in up to 25% of children in the 5 years following immunization, it is likely that FAMA is a better test of protective antibody than a gpELISA reading of 5.

Latex agglutination is more sensitive than most commercially-available EIAs but can be difficult to interpret. Although assays of the indirect solid-phase kind are used most frequently, a competitive-type assay has also been described, which should not, theoretically, be affected by cross-reacting antibodies to HSV.

Neutralization

Theoretically, this should be the method of choice for determining VZV immune status, since it measures antibodies concerned with protection. However, current procedures are technically very difficult to carry out, due mainly to the difficulty of obtaining a consistent supply of challenge virus, since virus infectivity is so highly cell-associated. It is also an insensitive test. For these reasons, it has no role in routine diagnosis. Antibody detected by FAMA correlates well with neutralizing antibody (Grose *et al.*, 1979).

Detection of VZV-specific IgM-class Antibodies

This class of antibody can be detected using the indirect IF or immunoassay procedures, in which the labelled antibody used in the system is directed against human-IgM-class antibodies. Procedures in which the IgM antibodies are captured on to the solid phase (or MACEIA) can also be used. VZV IgM may not initially be detectable in sera from patients with varicella but is present in 100% of convalescent sera, and it can be detected for about three months from the onset of the illness.

Unfortunately it is not possible to use these tests to distinguish reliably between primary and recurrent VZV infection, since specific IgM antibodies are also induced in most cases of herpes zoster. In these patients, however, the amount of IgM antibody is generally lower than that found in varicella cases and is also of shorter duration.

VZV IgM can also be detected in some congenital varicella infections, whereas in others only IgG is detected.

TREATMENT

Varicella

Varicella in healthy individuals is generally mild and complications are rare. Where treatment is indicated, the drug of choice is aciclovir, a nucleoside analogue that blocks viral replication. VZV is less susceptible to aciclovir than is HSV and requires approximately a 10-fold higher concentration of the drug for effective inhibition. The inhibitory concentration (ID50) of aciclovir for VZV in cell

culture is usually in the range of 2–20 μ m, depending on the cell type and virus strain used. It is possible to obtain adequate inhibitory concentrations in the blood if a dose of 10 mg kg⁻¹ (or 500 mg mg⁻² for children aged < 12 years) is given intravenously over a 1 hour period every 8 hours. This dosage maintains plasma levels in the range 10–90 mM. Duration of treatment is normally 5–10 days, depending on the severity and progression of the disease, but a minimum of 7 days is recommended for immunocompromised patients and adults with visceral complications. Oral aciclovir is poorly absorbed and the recommended dose of 800 mg, 5 times a day, will give blood levels of 4 μ m, which are only just at the ID50 concentration for VZV. Studies in children (Dunkle *et al.*, 1991) and adults (Wallace *et al.*, 1992) have shown that antiviral treatment must be started within 24 hours of the onset of rash to be effective. In immunocompetent patients, the duration of rash and fever was reduced by treatment with aciclovir but none of the studies have had the power to show whether treatment reduces the risk of complications. Although in the United Kingdom it is not the practice to treat all healthy adults, this is different from the United States where treatment is advised for adults and adolescents.

The nucleoside analogues famciclovir (Famvir) and valaciclovir (Valtrex) are both better absorbed orally (50–70%) than aciclovir (20%) and are metabolized to produce blood levels of active drug equivalent to intravenous aciclovir. Although not licensed for the treatment of varicella, both are in widespread use for this indication.

A detailed review and recommendations for the management of varicella in different patient groups have recently been prepared by the UK Advisory Group on Chickenpox for the British Society for the Study of Infection (Carrington and McKendrick, 1998).

Varicella in Children

For the typical childhood case no treatment is required apart, perhaps, from soothing lotions for itching and antibiotics if there is any question of secondary infection. A study in Guinea Bissau confirmed anecdotal evidence for more severe infection occurring in second cases (Poulsen *et al.*, 2006) and treatment of such cases, particularly adolescents, is advocated by some, although the current UK consensus is not to use oral aciclovir routinely in healthy children. Children on inhaled or intranasal steroids are not considered to be at special risk but such cases should be considered individually. No great pressure is usually exerted on parents even to quarantine affected children and, indeed, there are some who advocate that it is preferable for children to contract the disease to ensure that immunity is acquired at an early age.

Varicella in Adults

One in 200 adults will develop clinical pneumonitis and approximately 1 in 2000 will require intensive care. Those most at risk include smokers, patients with severe chronic lung conditions and those with more dense rashes. Aciclovir commenced within 24 hours of the onset of symptoms does reduce viral shedding and new lesion formation by 0.5 days, and accelerates rash healing by 1–2 days (Wallace *et al.*, 1992). Pregnant women are also at increased risk of pneumonitis but aciclovir is currently not licensed for use in pregnancy. However, it has been used successfully in numerous pregnant women to treat serious VZV disease without ill effect and there is no evidence to date that it is teratogenic, although it is known to cross the placenta and it can be detected in the urine from infants of mothers who have been treated. It is not known at present whether treatment with aciclovir has any beneficial effect on fetal varicella syndrome. Current UK recommendations are therefore to treat varicella presenting within 24 hours in otherwise healthy adult smokers, patients with chronic lung conditions (including adults on inhaled steroids) and pregnant women, particularly in the second half of pregnancy (Carrington and McKendrick, 1998). Adults presenting more than 24 hours after the onset of the rash should have their clinical progress assessed. Those who appear to be deteriorating, for example with recurrent fever or progressive rash, or who develop chest symptoms or signs, should be admitted for chest X-ray, gases and assessment as to whether they need intravenous aciclovir and antibiotics. For detailed algorithms for the management of varicella in adults, see Wilkins *et al.*, (1998).

Varicella in the Immunocompromised

Varicella in the immunocompromised can be a serious, even fatal, illness and consequently its management in these patients is different from that in a previously healthy individual. Immunocompromised patients, including those on systemic steroids (including for up to three months previously), should be aware of their immune status, and seronegative patients, where possible (that is, in all except those with lymphoreticular malignancies) should be immunized with live attenuated Oka vaccine. Where this is not possible, seronegative patients should be counselled against contact with patients with varicella or zoster as well as being advised to seek medical help immediately if contact occurs. Where the patient has no immunity and significant exposure has occurred, measures should be taken to prevent or attenuate the infection (see below). Significant exposure has been defined arbitrarily by the American Academy of Paediatrics and by the UK Joint Committee on Vaccination and Immunization. Broadly,

there is consensus that ‘significant contact’ constitutes living in the same house as a case of zoster or chickenpox, indoor contact with a case of zoster or chickenpox for a period of time (15 minutes or more in the United Kingdom) and face-to-face contact with a case of chickenpox.

Aciclovir has been shown to be effective in preventing varicella in the immunocompetent if given between seven and nine days post-exposure. Post-exposure aciclovir prophylaxis is not effective if given earlier than seven days, presumably because it interferes with the primary viraemic phase, which primes the specific T-cell responses.

Herpes Zoster

The main aims of therapy in acute herpes zoster occurring in a previously healthy individual are to heal the rash rapidly, alleviate acute pain, prevent PHN and reduce the risks of ophthalmic and neurological complications.

Antiviral Drugs

Several drugs are currently licensed for use in the United Kingdom for treatment of acute shingles, including topical idoxuridine (which is no longer used), aciclovir, famciclovir, valaciclovir and foscarnet. Patients given high-dose aciclovir (800 mg orally, five times day) for acute shingles have been shown, in placebo-controlled studies, to have faster resolution of the rash (by up to two days), less acute pain, reduced viral shedding (by one to three days) and fewer ophthalmic complications. Several studies have also shown a reduction in the incidence, severity and duration of persistent ZAP in those most at risk, that is those over the age of 50 years, when aciclovir is given within 72 hours of the onset of rash. Valaciclovir (a prodrug of aciclovir) and famciclovir (a prodrug of penciclovir) give higher blood levels of the active drug and thus allow easier treatment regimens on account of their improved oral bioavailability. In addition, penciclovir and its derivative, famciclovir, have a significantly longer intracellular half-life compared to aciclovir. A dosing schedule of famciclovir of 250 mg three times per day or valaciclovir 1000 mg t.d.s. are as effective as high-dose aciclovir for treatment of zoster. The newer prodrugs also have the potential to prove more effective than aciclovir in reducing the severity and duration of ZAP (Beutner *et al.*, 1995; Cirelli *et al.*, 1996). Valaciclovir has also been shown to have an effect if given later than 72 hours after the onset of rash.

Other new drugs that have been developed for the treatment of zoster include sorivudine (BVaraU) and brivudin (BVDU). Both these agents are particularly active against VZV when taken orally, and result in accelerated rash healing. BVDU has been licensed in Germany. However,

when administered in combination with 5-fluorouracil, BVaraU has caused the deaths of a number of patients. BVDU is also contraindicated in this situation.

Adjunctive Treatment

Oral prednisolone in addition to aciclovir slightly reduces acute symptoms but does not protect against prolonged ZAP more than aciclovir alone. Oral steroids are generally not used, as the risks are felt to outweigh the benefits. A retrospective case-control study showed that amitriptyline acutely reduced the severity and duration of pain. Other treatments, such as sympathetic nerve blocks, have been reported anecdotally to reduce pain, and require proper trials to assess adequately.

Treatment of Established ZAP

During the acute attack of zoster, paracetamol, with or without mild opiate analgesics, is recommended. Nonsteroidal analgesics are less effective. Low-dose tricyclic antidepressants such as amitriptyline, the dose of which is titrated against side effects and pain relief, can also be given for four to eight weeks, particularly if sleep loss is a problem. The anticonvulsants gabapentin and pregabalin have also been shown to be effective in patients with pain of three months duration or more. Other recommendations for pain relief include ice packs, topical local anaesthetic (e.g. lidocaine patches), capsaicin and, if necessary, stronger opiates. Patients with intractable pain should be referred for specialist pain-management advice.

Ophthalmic Zoster

Management of patients with ophthalmic zoster should include topical aciclovir applied to the eye and oral aciclovir (800 mg five times per day) or valaciclovir (1 g t.d.s.), whatever the patient's age. Treatment should, however, be started as soon as possible to be effective and preferably within 72 hours of onset. Early referral of patients with ophthalmic zoster to an ophthalmologist is desirable and topical steroids should in no case be administered without specialist consultation.

Herpes Zoster in Immunocompromised Patients

The more severe, and particularly the disseminated, forms of herpes zoster are seen in those who are immunocompromised, and may be life- or sight-threatening. Patients at high risk should be educated to recognize shingles and to seek medical advice early. Highly immunocompromised patients should initially receive intravenous aciclovir followed by oral valaciclovir or famciclovir if necessary. Treatment should be continued until the lesions crust,

approximately five to seven days later. Less severely immunocompromised patients with localized shingles can be given oral valaciclovir or famciclovir. Serial measurement of viral load in the blood has proved useful in monitoring response to treatment, although anecdotal evidence suggests that even after clinical response, a low-level viraemia can persist.

Antiviral Drug Resistance

VZV resistance to aciclovir has been described in immunocompromised patients, particularly those infected with HIV. There is currently no evidence that such resistant virus strains are transmissible but they can present a considerable challenge to treatment and are therefore of much concern. Almost all the resistant strains that have been characterized to date have had reduced TK function as a result of mutations in the thymidine kinase gene (Talarico *et al.*, 1993), although some DNA-polymerase mutants have also been found (Kamiyama *et al.*, 2001). Mutations in the TK gene have been identified as either (i) deletions or point mutations leading to a truncated protein, or (ii) single point mutations leading to amino acid substitutions. Mutations involved in resistance to aciclovir have been demonstrated in different positions in the gene and are not restricted to the ABP or nucleotide binding sites on the protein. Some aciclovir-resistant strains have also been shown to be cross-resistant to other TK-dependent drugs, including penciclovir and BVaraU. However, such resistant strains are generally found to be sensitive to foscarnet, a broad-spectrum antiviral drug which directly inhibits viral DNA polymerase and thus provides an alternative treatment. AIDS patients with aciclovir-resistant VZV infections have been successfully treated with foscarnet (40 mg kg⁻¹ every 8 hours in a 1-hour infusion over 10 days) in an open study (Safrin *et al.*, 1991). The nucleotide analogue, cidofovir, is also effective against varicella zoster.

PREVENTION

Prevention of VZV is important in those who are at risk of contracting the severe forms of the disease. An increase in adult susceptibility to varicella (see Section 7.0 above) also has serious implications for hospital infection control, since medical staff without immunity may become infected following contact with zoster patients and can, sometimes with disastrous consequences, transmit the infection to patients who are immunocompromised.

Many immunocompromised patients without pre-existing immunity to VZV are at risk of severe infection

and should be offered prophylactic treatment if in contact with VZV.

Antiviral Drugs

Prophylactic acyclovir or valaciclovir has been shown to reduce the risk of herpes zoster by over 90% in both recipients of solid organ transplant and haemopoietic stem-cell transplants. Oral acyclovir has been shown to prevent or modify varicella in young immunocompetent household contacts given a seven-day course (40 mg kg⁻¹ in divided doses), beginning seven to nine days after the contact with the index case; that is, during the presumed phase of secondary viraemia. Administration within seven days following contact—that is, during primary viraemia—was not as effective, possibly because early priming of T cells is reduced.

Passive Immunization

Human immunoglobulin preparations with high titres of antibody to VZV are an established means of preventing or ameliorating varicella. Such preparations were originally made by cold ethanol precipitation from the blood of patients recovering from shingles and were consequently designated 'zoster immunoglobulin' (ZIG). Current preparations are obtained by processing preselected sera from blood donors with high titres of antibody to VZV. These preparations are referred to as 'varicella zoster immune globulin' (VZIG) or 'human antiviral zoster immunoglobulin'. VZIG preparations are frequently in short supply but antibody concentrations in the blood as high as those with VZIG have been obtained with intravenous normal human immunoglobulin (iv-NHIG) preparations and these may be used empirically as an alternative when VZIG is not available. NHIG given intramuscularly has been shown not to be effective and plays no role in the prevention of varicella.

VZIG is recommended for any susceptible 'at-risk' individual (Table 7.3) who has 'significant' exposure to varicella or herpes zoster. It should be administered as soon as possible after contact, preferably within 96 hours, although some studies have shown VZIG to have a beneficial effect when given up to 10 days after contact. The immune status of the patient should be assessed by testing for specific antibodies in the serum before administration of VZIG whenever possible. Since tests with the appropriate sensitivity (see Section "Diagnosis of VZV Infection" above) are generally only available in specialist laboratories, the administration of VZIG should not be delayed past seven days after the initial contact while waiting for the test result. A convincing history of varicella or zoster is a reasonably reliable indicator of immunity and usually obviates the need to administer prophylactic agents.

Table 7.3 Underlying or associated conditions which place patients at risk of contracting the severe forms of varicella

Leukaemias, Hodgkin's disease and other neoplasms of the lymphoreticular system, whether or not treatment is being given
Other cancers that are being treated with cytotoxic drugs or other regimes that are immunosuppressive
Primary immunodeficiency syndromes
Bone-marrow transplant recipients, irrespective of their own or the donor's VZV status
Diseases requiring systemic steroids at a dosage equivalent to at least 2 mg prednisone/kg/day
Susceptible pregnant women in close contact with VZV
Newborn infants of women who contracted varicella less than seven days before or after delivery
Premature infants whose mothers have no history of varicella or any infant whose birth weight was <1000 g

Nevertheless, it is recommended that an antibody test is performed to confirm the immune status in immunocompromised patients, even if a past history of VZV infection is given. The true efficacy of VZIG has not been established in well-controlled trials and differences in the results of different studies may reflect different potencies of the preparations used. It is known that VZIG gives incomplete protection against infection. In a study carried out in the United Kingdom it was shown that of 27 seronegative children who were in contact at home, 18 (67%) became infected—14 (52%) with symptoms—in spite of receiving VZIG. Therefore, the rationale for administering VZIG to those at risk is not so much to prevent infection but to prevent the serious forms of the disease with visceral involvement. There are numerous studies, based on case series, showing the beneficial effects of VZIG in reducing morbidity and mortality compared to historic controls or untreated patients. Unfortunately, there are also reports of correctly administered VZIG failing to prevent fatal varicella in immunocompromised patients. Feldmann and Lott (1987) reviewed the impact of varicella in 280 children with cancer and the effectiveness of various forms of management. In their study group, passive immunization significantly reduced both the incidence and mortality of pneumonitis compared to untreated children. Even so, pneumonitis developed in 11% of children who received VZIG, requiring intensive additional antiviral chemotherapy.

It is important, particularly in a hospital environment, to be aware of the shortcomings of VZIG and to be alert to the possibility that an inoculated patient might develop varicella and become a source of infection for others.

It is also recommended that VZIG be given to susceptible pregnant women in close contact with VZV infection at any stage of the pregnancy, in the hope that it will reduce the risk of transmission of infection to the fetus and also in order to ameliorate any potentially serious VZV disease which can occur in pregnant women. Maternal varicella can still occur despite VZIG prophylaxis but a large prospective study has shown that even in such cases, the risk of fetal infection during the first 20 weeks of pregnancy, and of subsequent fetal damage, may be reduced (Enders *et al.*, 1994). Should a woman contract varicella perinatally, it is important to administer VZIG to the newborn baby (Table 7.3).

The recommended dosages for VZIG preparations available in the United Kingdom are as follows: 0–5 years, 250 mg; 6–10 years, 500 mg; 11–14 years, 750 mg; and 15 years or more, 1000 mg. A second dose can be given after three weeks if necessary.

Active Immunization

Although individual cases of varicella may be prevented or modified by VZIG or with antiviral drugs, control of varicella in the community can only be achieved by widespread vaccination. Active immunization also has the advantage in individual ‘at-risk’ patients by offering long-term protection. Varicella vaccines based on the attenuated Oka strain of VZV have been available since 1974, when it was first developed in Japan (Takahashi *et al.*, 1974). The original vaccine was derived from VZV isolated from vesicles of a three-year-old child with typical varicella and was attenuated by serial passage in guinea-pig cells and human embryo lung cells. Biologically, vOka grows less well than wild-type virus at 37 °C and better at 33 °C. The Oka vaccine strain has been shown to replicate to lower titres in models of differentiated epithelial tissue (SCID-hu epithelial implants and explant skin cultures) whereas replication in lymphocytes and neuronal tissues appears to be less impaired compared to the parental strain (Moffat *et al.*, 1995). Comparison of the sequence of the vaccine Oka strain and wild-type strains, including parental Oka, has identified approximately 20 amino acid changes unique to vOka. Eight of these are located in the IE62 protein and reduce its ability to transactivate the expression of early VZV proteins (Gomi *et al.*, 2002). Only three mutations, all in ORF62, are fixed in the vaccine strain; the rest are present as mixtures of wild-type and vaccine SNPs. As a result, the Oka vaccine contains a mixture of strains, none of which are genetically identical except at the three fixed SNPs. These in turn allow identification of the vaccine strain which accounts for 60% of the small number of rashes following immunization.

The vaccine is clinically attenuated. The infrequent occurrence of rash is thought to reduce the opportunity for cell-free virus to infect skin sensory nerve endings, which in turn reduces latent infection and zoster due to the vaccine. Where vaccine virus rashes do occur, they appear to be due to selection by the host of a subset of strains within the original vaccine mixture.

Clinical studies in Japan, the United States and Europe have shown the vaccine to be effective; 95% of healthy children seroconvert after one dose of the vaccine, while leukaemic children immunized during maintenance therapy, and healthy adults, require two doses to achieve 90% seroconversion. Clinical protection against subsequent (breakthrough) varicella appears to be about 75%, although protection against severe varicella is 96%. Vaccine failure correlates with length of time since vaccination and with younger age at vaccination. The original estimates, based on gpELISA antibody titres measured at six weeks, of 95% protection are not supported by FAMA, which shows nearer to 75% seroconversion following vaccine. Over 25% of children immunized against VZV become re-infected. Whether this is because of primary vaccine failure rather than waning immunity is still not clear. Fewer than 5% of recipients develop a mild varicella-like rash after vaccination and fever is rare. Genotyping of virus shows that vaccine-related rashes occurring within the first two weeks of immunization are more likely to be wild-type in origin, while those occurring after two weeks are more likely to be vaccine-related. No data are available for the GSK vaccine. In vaccinated leukaemic children, the incidence of adverse events in the first six weeks after immunization is higher than in healthy children, and this, coupled with a reluctance to interrupt chemotherapy for immunization, has led to other approaches to preventing serious varicella in immunosuppressed children. To this end, the vaccine has been licensed for the immunization of seronegative household contacts of children suffering with leukaemia and cancer.

Since 1995 the Oka vaccine has been given to all children in the United States at age 12–15 months. This has resulted in a fall in circulating varicella and a reduction in associated hospitalizations and mortality in both vaccinated and, by herd immunity, unvaccinated individuals (Seward *et al.*, 2002). Other countries, including Germany, Greece Australia and Canada, have since introduced childhood vaccination programmes. In the United Kingdom, considerable doubts about the economic benefits of preventing varicella in healthy children remain, especially if the costs of time lost from work by parents caring for sick children are not included in the analysis (reviewed in Breuer, 2002b). Moreover, modelling of the consequences of vaccination against VZV have shown that a reduction of circulating wild-type chickenpox would

be likely to lead to a reduced boosting of immunity in adults latently infected with VZV and an increase in the incidence of zoster due to wild-type virus. These data are supported by two studies showing that contact with children, a surrogate for contact with varicella, is inversely related to the incidence of zoster (Brisson *et al.*, 2002; Thomas *et al.*, 2002). Such data, when included in economic models, severely prejudice the likelihood of mass vaccination against varicella alone being medically or economically beneficial. As a result, some countries, including the UK, have limited vaccine programmes to vulnerable groups including seronegative health-care workers and seronegative household contacts of immunosuppressed children. Immunization of adolescents and women (post-partum) without a history of chickenpox have also been shown to be cost-effective (Pinot de Moira *et al.*, 2006).

One formulation of the vaccine (Merck) is licensed for post-exposure prophylaxis, however it is not 100% effective.

Vaccines Against Herpes Zoster

A large randomized double-blind case-controlled study of 36 000 adults over 60 years who received the Oka vaccine strain at a higher titre (18 000 pfu) than is present in the varicella vaccine (3000 pfu) showed a 51% reduction in the incidence of herpes zoster and a 66% reduction in PHN in those who received the vaccine. Overall, the burden of disease calculated from the severity of pain and its duration was reduced by 61% in vaccinees. Protection appears to persist, although follow-up has only been for four years so far. Cost-benefit analyses show economic and medical benefit from immunization of subjects aged over 60 years.

Cytomegalovirus

Paul D. Griffiths

Royal Free and University College Medical School, London, UK

INTRODUCTION

Cytomegalovirus (CMV) infections were first described in the early years of the twentieth century, when the typical ‘owl’s eye’ intranuclear inclusions were found by histopathologists in tissues from fetuses stillborn following cytomegalic inclusion disease. These strange inclusions were thought to result from a protozoan infection and, in 1910, one group of workers even proposed the name *Entamoeba mortinatalium* for the supposed agent. In the 1920s, the similarity of the inclusions to those produced by varicella was noted and the guinea-pig form of CMV was transmitted by salivary gland extracts passed through a Berkefeld N filter. Despite these two pieces of evidence suggesting a viral aetiology, reports were still occurring in the late 1940s attributing the disease to a strange protozoan infection. In 1956, three laboratories simultaneously isolated CMV, having successfully developed cell-culture technology, so that the true nature of the infectious agent was apparent. One of these three investigators, Weller, gave the virus its name from the effects produced in cell culture (cytomegaly), so CMV is named after its cytopathic effect (CPE).

THE VIRUS

Morphology

Electron micrographs of CMV reveal a typical herpesvirus appearance (Figure 8.1). The central DNA-containing core is surrounded by a capsid composed of 162 capsomeres, each of which is a hollow hexagon in cross-section. The capsid is in turn surrounded by a poorly-demarcated

area, the tegument, which is itself surrounded by a loosely-applied envelope.

When CMV is propagated in cell cultures, two additional morphological forms are produced from the virus-specific proteins and envelope. The first is termed a dense body and appears as a large amorphous structure without nucleocapsid or DNA. The second has been termed a noninfectious enveloped particle and consists of an empty capsid surrounded by a lipid envelope.

Nucleic Acid

CMV strain AD169 contains 235 kb of double-stranded DNA. The structure of the DNA is similar to that of herpes simplex virus (HSV) in that long and short unique sequences are bounded by terminally repetitive segments. Each long and short sequence can be orientated in one of two directions, so that four DNA isomers are produced by cells in culture. The whole genome of strain AD169 has been sequenced (Chee *et al.*, 1990). The genes are numbered according to their relative positions on one of these four isomers, termed the prototype configuration. Nonpassaged strains contain an additional 22 kb of DNA. By international agreement, the proteins they encode are designated by p (for protein), gp (glycoprotein) or pp (phosphoprotein), followed by the gene number. This formal terminology may then be followed by a trivial name, for example gpUL75 (gH) is glycoprotein H, the product of gene number 75 in the unique long region.

Productively-infected cells produce linear genomes from concatameric precursors. Cleavage is accomplished by an endonuclease (terminase) coincident with packaging. pUL89 is part of this complex, and there are thus similarities between the cleavage/packaging of herpesvirus

Figure 8.1 The typical electron microscope appearance of cytomegalovirus. (Photograph kindly prepared by Mr J.A. Bishop.)

DNA and that of bacteriophage T4, supported by sequence conservation of the terminase genes. The physical state of the CMV genome during latency in myeloid precursors is episomal.

Some areas of the genome are homologous with regions of human chromosomal DNA, which has practical importance for the selection of CMV DNA probes. Distinct transforming regions of DNA have been identified. One maps to a previously unrecognized open reading frame (ORF), UL111A, which is expressed in transformed cells (reviewed in Doniger *et al.*, 1999). The UL111A protein binds p53 and is spliced to two other exons within UL111A to form another protein, which binds to the cellular IL-10 receptor. It is not known whether the transformation is linked to the expression of the IL-10 homologue (Kotenko *et al.*, 2000). In addition, CMV induces specific breaks in chromosome 1 when infection occurs during the S phase of the cell cycle (reviewed by Fortunato and Spector, 2003). While such experiments are interesting, it must be emphasized that, at present, there is no confirmed evidence that CMV is naturally oncogenic.

The DNA can be digested with restriction endonucleases so that, following gel electrophoresis, oligonucleotide patterns characteristic of distinct CMV strains are produced. This technique cannot prove that two strains are identical, but if strains fail to show different patterns after digestion with at least two restriction endonucleases then it is very likely that they are identical (Huang *et al.*, 1980). Use of restriction enzyme analysis can provide useful epidemiological information, but there is no confirmed evidence to suggest that any one strain is associated with any particular type of clinical presentation (Pignatelli *et al.*, 2004).

Genetic changes also occur in the genome without acquisition of new cleavage sites for commonly used restriction enzymes. The polymerase chain reaction (PCR) followed by sequencing can be used to explore genetic variation at the fine molecular level for particular regions of interest, for example where viral variants acquire resistance to antiviral drugs.

Control of Genome Expression

Expression of the CMV genome is controlled by a cascade synthesis of proteins. The first proteins to be synthesized (α or immediate-early) are required for the transcription of the messenger ribonucleic acid (mRNA) for the second group of proteins (β or early). The early proteins allow DNA replication to proceed and this is followed by the appearance of the last proteins (γ or late). This cascade sequence is depicted in Figure 8.2, which also shows the stages at which metabolic inhibitors can be employed to manipulate the cascade. If cell cultures are prepared and infected with CMV in the presence of an inhibitor of protein synthesis then relatively large concentrations of α -mRNA build up behind the metabolic block. When this block is released by refeeding the cultures, synthesis of α -proteins will occur within minutes. To prevent α -proteins inducing β -mRNA and then β -proteins, inhibitors of transcription should be incorporated into the refeeding medium. To allow β -protein expression without inducing γ -proteins, the cultures can be refed with an inhibitor of DNA synthesis. Finally, fresh medium without added inhibitors can be used to induce the cells to produce γ -proteins. It should be emphasized that this cascade synthesis dictates that at each time after infection the appropriate proteins, together with their preceding proteins, are present in the infected cells. It is therefore not possible to produce cells containing only β -proteins or only γ -proteins by means of infection; to achieve this, individual genes must be cloned and expressed separately.

Note that some γ -genes are transcribed at early times but are only translated after DNA replication has occurred. These are sometimes termed leaky-late genes to differentiate them from true late genes, which are only transcribed after DNA replication. Some latency-associated transcripts which map in both sense and antisense orientation to the major immediate-early (MIE) region of CMV have been described (Kondo *et al.*, 1994). Some of these have unique expression at immediate-early and late times and so have been classified as λ -genes. The term virion RNAs refers to transcripts packaged within the virus which are delivered to an uninfected cell (Bresnahan and Shenk, 2000). It remains to be proven that such RNAs are specifically packaged and play the postulated role of producing viral proteins before the onset of genomic transcription.

Figure 8.2 Cascade genome expression of herpesviruses. Genes labelled α (immediate-early), β (early) or (γ) (late) are transcribed into messenger RNA and then translated into proteins. Inhibitors of protein synthesis (cycloheximide), transcription (actinomycin-D) or DNA replication (cytosine arabinoside (ara-C) or ganciclovir (GCV)) can be used to interrupt genome expression, as discussed in the text.

The mechanism(s) which control genome expression are not fully understood. Certainly, there is no evidence for a canonical sequence upstream of β -genes which could be activated directly by α -proteins. This suggests that α -proteins mediate their effects through activation of endogenous transcriptional factors. Cellular transcription factors such as SP1 and NF- κ B have been implicated so far.

Some control of expression is also exerted at the translational level. The DNA polymerase (pUL54) has an untranslated leader region which suppresses translation. Furthermore, the presence of upstream AUG codons, which, according to the ribosome scanning hypothesis, allow production of short peptides in preference to the authentic proteins, appears to restrict early expression of some transcribed leaky-late mRNA.

Proteins

The CMV genome is sufficiently large to encode over 200 proteins of average size, and sequencing of one strain has identified 204 predicted ORFs (Chee *et al.*, 1990). A revision of the total coding capacity suggests that wild-type CMV contains 165 genes (see Dolan *et al.*, 2004 for colour gene map).

One expression unit has been studied in great detail: that encoding the MIE proteins of CMV. As shown in Figure 8.3, this genetic unit is expressed via differential splicing to produce four α -proteins of distinct M_r . The protein of M_r 86 000 (IE86) interacts with the basal transcriptional machinery, especially the TATA binding protein, to enhance formation of pre-initiation complexes. It also cooperates with the M_r 72 000 protein to synergistically increase expression of its own, and heterologous, promoters, probably through activation of endogenous transcription factors and/or by bridging between their binding sites and the TATA binding protein. The IE72

protein (together with pp71) inactivates cellular restriction factors termed Daax and promyelocytic leukaemia (PML) which would otherwise degrade incoming CMV DNA.

The M_r 55 000 protein has minor stimulatory effects, either alone or in combination with either of the other two larger proteins. The smallest protein (M_r 18 000) is expressed during replication in differentiated monocytes.

The largest of these proteins downregulates its own synthesis and so is autoregulated (Stenberg and Stinski, 1985). This downregulation is mediated by a distinct region in the carboxy terminus, which is shown stippled in Figure 8.3. This region is also present in a late protein of M_r 40 000 embedded within this region, and it is likely that activation of its promoter at late times leads to downregulation of the MIE region. IE86 also binds cellular p53, which may decrease p53-induced apoptosis, and interacts with the protein product of UL84, which is a transdominant inhibitor of IE86. Some of the latency-associated transcripts found in the bone marrow of normal donors code for proteins which are recognized by infected humans (Kondo *et al.*, 1994). Their function is obscure but, by analogy with HSV, they may play important roles in the establishment or regulation of the latent state. Expression of the MIE region was found in multiple tissues of transgenic mice containing a *lacZ* gene which correlated well with the cell types in which CMV replication is found *in vivo* (Baskar *et al.*, 1996). Thus, in summary, expression and regulation of the MIE region are remarkably complex, with the potential for exquisite control of virus replication.

Other immediate-early genes are of interest. Genes UL36–37 encode transactivators which are essential for DNA replication. The first exon of UL37 acts as a mitochondrial inhibitor of apoptosis. The UL36 protein is an inhibitor of caspase activation, preventing apoptosis driven by extrinsic death signals. The UL38 protein also

Figure 8.3 Proteins encoded within the major immediate-early region of CMV. Exons are numbered 1–7. TA, transcriptional activation; PA, polyadenylation; ie, immediate-early; l, late.

blocks apoptosis, although the mechanism remains undefined. TRS1 is required for DNA replication. pUL69 is present in the tegument of the virion, as is ppUL83. Although the latter is a late protein, in combination these two proteins appear to play a similar role to the α -transinducing factor of HSV, which is released into the cell during the process of uncoating and is then able to interact with a cellular transcription factor to upregulate the MIE promoter.

Early proteins mainly provide essential enzymic functions within the cell, for example pUL54, DNA polymerase and pUL97, a protein kinase which phosphorylates antiviral nucleosides such as ganciclovir (GCV) and aciclovir (ACV), so starting their anabolism to the functional nucleoside triphosphate inhibitors of pUL54.

Late proteins generally play a structural role in virion formation, for example surface glycoproteins are potentially important because of their interaction with the immune system. Neutralizing epitopes have been described on gB, gH, and gM/gN. gH requires gpUL115 (glycoprotein L) to facilitate surface expression. Much of the neutralizing activity of serum samples can be absorbed by recombinant gB, suggesting that this protein contains dominant neutralizing sites (Britt *et al.*, 1990). gB forms the active component of some vaccine preparations which have reached the stage of Phase II clinical testing.

Note that an alternative nomenclature system terms gB 'glycoprotein complex I' (gCI) and gH 'glycoprotein complex III' (gCIII) (Gretch *et al.*, 1988). The protein products of individual genes which combine to form these complex glycoproteins are summarized in Table 8.1.

A variety of other proteins have been identified and mapped to the genome, important examples of which will

be mentioned briefly. A total of 11 proteins are required in *trans* to effect replication (see Table 8.2). Many of these perform similar functions to HSV proteins, except that CMV does not have an identified origin-binding protein and requires transactivators. pUL80A and pUL80.5 encode the protease and assembly protein, respectively. Protease, which is not packaged into the virion, is responsible for cleaving the original polyprotein at four distinct sites. The assembly protein facilitates formation of B-capsids and entry of DNA, being lost from the capsid in the process. Four genes (US27, US28, UL33 and UL78) are homologous to G-protein-coupled receptors and so may be involved in signal transduction. The US28 gene facilitates entry of HIV into CD4⁺ cells, which are otherwise not susceptible to HIV infection (Pleskoff *et al.*, 1997), and also confers chemotactic mobility on arterial smooth muscle cells, which may be relevant to the pathogenesis of atherosclerosis (Streblov *et al.*, 1999).

Note also that 22 extra genes are not present in AD169 but are found in other strains of CMV with a lower

passage history (Cha *et al.*, 1996). Presumably, they were lost during the process of adapting CMV to grow in fibroblast cell lines which led to the strain termed AD169. This strain is popular with researchers because it grows rapidly to relatively high titre and releases many extracellular virions. Recent results suggest that one of the missing genes (UL138) normally maintains the state of latency, so explaining why AD169 grows relatively well.

Wild strains of CMV lack these properties and so are difficult to work with in the laboratory. As a result, one has to question whether AD169 is fully representative of CMV strains *in vivo*, and the presumed loss of these 22 genes illustrates this issue. None of the 22 genes has homology with known herpesvirus proteins. Many appear to encode glycoproteins, and their potential roles in evading host immune responses will be discussed later.

Growth *In Vitro*

The only cells which replicate CMV to high titre *in vitro* are human fibroblasts, although wild strains can also be propagated in endothelial cells, macrophages and smooth muscle cells. This finding is in complete contrast to that *in vivo*, where, at post mortem, cells infected with CMV are found in organs of epithelial origin (kidney, liver, bile ducts, salivary gland, gut epithelium, lung parenchyma, pancreas) as well as in endothelial cells. This observation again suggests that the virus propagated in the laboratory should not be assumed to be an authentic model of the wild-type virus. The genetic changes which confer tropism for endothelial cells and for polymorphonuclear leukocytes map to UL128, UL130 and UL131A. The cell surface proteins which act as receptors for CMV have not been confirmed, although several candidates have been proposed.

In fibroblast cell cultures, encapsidation occurs in the nucleus. The products of genes UL50 and UL53 combine

to digest the structural lamins which form the inner nuclear membrane (Muranyi *et al.*, 2002) and the virus envelope is then acquired by budding through this membrane. Enveloped virions are found within vesicles in the cytoplasm and these appear to fuse with cellular membranes to allow egress of the mature virus particles. Dense bodies also mature and are released from the infected cell in the same way as virions, so that they contain virus-specific glycoproteins.

At late times after infection, CMV induces the appearance in infected fibroblasts of an Fc receptor which has high affinity for human IgG but not other human immunoglobulin isotypes, and has low affinity for rabbit or mouse IgG (Keller *et al.*, 1976). One Fc receptor is encoded by gene TRL11 and its duplicate ILR11, while a second is formed by a UL119–UL118 fusion protein. The Fc receptor is found in the Golgi apparatus, which enlarges to form a perinuclear inclusion body in the concavity of the reniform nucleus. It has been suggested that HSV produces an Fc receptor so that antibody attached by its Fab portion to a virus protein can be bound by its Fc portion back on to the virion. This would have the effect of preventing immune effector mechanisms, which require an intact Fc portion after opsonization. Whether such a mechanism is operative for CMV remains to be defined. However, the production by CMV of Fc receptors *in vivo* might allow opsonized bacteria or fungi to gain access to cells which they cannot normally infect; this might explain why CMV infection is often associated with secondary bacterial and fungal infections. A similar process might operate for HIV coated in nonneutralizing antibody.

Unlike HSV, CMV does not switch off host macromolecular synthesis but actually stimulates cellular DNA, RNA and protein synthesis. The overall effect is to push the cell towards the S phase of the cell cycle without allowing cell division to occur. One cellular function which is stimulated as a result is thymidine kinase activity. It is tempting to suggest that CMV has learned to increase cellular uptake of thymidine by switching on the host enzyme responsible, whilst HSV has used a different tactic, the production of a novel thymidine kinase, to achieve the same objective. Likewise, CMV induces cellular topoisomerase II and may package this enzyme into the extracellular virions. Recent results have also shown that human complement is bound to the virion but not activated. Host-cell-complement regulatory proteins were detected in virions and might explain this phenomenon (Spiller *et al.*, 1997). Thus, like HIV, the mature virion may contain host proteins of potential importance for understanding pathogenesis, and proteomic experiments support this (Vamum *et al.*, 2004).

EPIDEMIOLOGY

CMV must be acknowledged as one of the most successful human parasites. It has learned to survive in its human host by infecting both vertically and horizontally; the virus can be transmitted by either route during primary infection, re-infection or reactivation; at all times the virus causes minimal disability, allowing infected individuals to remain active and so maintain the maximum opportunity of encountering susceptible contacts; the virus is excreted from multiple sites, so contact of varying degrees of intimacy can lead to transmission.

Infection may be acquired during delivery, following ingestion of infected maternal genital secretions, or soon afterwards by ingestion of breast milk containing CMV (Schleiss, 2006). These two means of prenatal transmission combine to infect 2–10% of infants by the age of six months in all parts of the world.

Throughout the rest of childhood, close contact is known to be required for transmission, although the precise route of infection is not known. As a result, CMV may transmit readily within family groups. The possibilities for infection must be increased where individuals are crowded together in unhygienic circumstances, and this probably explains why CMV infection is most common

in societies which are socially disadvantaged. Infection is transmitted less well in the general community, apart from child-to-child transmission, which has been documented in playgroups (Pass *et al.*, 1986). Once infected, such children can transmit CMV to their parents (Pass *et al.*, 1986) and so represent a potential threat to a future sibling should the mother be pregnant.

In populations of poor socio-economic background, the vast majority of children have experienced primary CMV infection by the onset of puberty. In countries with good social circumstances, roughly 40% of adolescents have been infected, and, as shown in Figure 8.4, seroprevalence increases by approximately 1% per year thereafter (Griffiths and Baboonian, 1984). Such primary infection can lead to vertical transmission if an individual is pregnant when she becomes infected.

The prevalence of CMV IgG antibodies in organ transplant recipients reflects their socio-economic grouping. The same applies to individuals who acquired HIV infection via blood (or blood products), heterosexually or through contaminated needles used for intravenous drug use. In contrast, HIV-positive male homosexuals have a very high prevalence of CMV IgG antibodies (typically 95%).

At whatever age primary infection occurs, the virus is not eradicated from the host but persists for the rest of the

Figure 8.4 The age-specific prevalence of complement-fixing serum antibodies against cytomegalovirus. The number of women in each group is shown above each column of the histogram. (Reproduced by permission from Griffiths and Baboonian (1984).)

life of the individual. Occasionally, however, CMV reactivates from its latent state and infectious virions appear in the saliva and/or urine. These reactivations of CMV are entirely asymptomatic but form an important means by which CMV can spread horizontally. Immune hosts can also be re-infected with another or, possibly, the same strain of CMV. Epidemiologically, it is important to distinguish between re-infection and reactivation of latent infection, but in clinical practice the term 'recurrent infection' is often used to cover both possibilities. Recurrent infections can also lead to vertical transmission of CMV. This finding came as something of a surprise, since it was assumed that a woman who possessed antibody against CMV before becoming pregnant would be immune to intrauterine transmission. A recent population-based study reports that natural maternal immunity present prior to conception provides 69% protection against delivering a subsequent neonate with congenital CMV infection (Fowler *et al.*, 2003). While this protection is substantial, the high prevalence of seropositive women means that more fetuses are infected worldwide by this route than are infected as a result of primary maternal infection. Congenital CMV infection thus has its highest incidence in the poorest communities of the world, since most women in poor societies are infected before reaching childbearing age. Note, however, that primary CMV infection in the mother represents a greater risk to the fetus than recurrent maternal infection (Fowler *et al.*, 1992), so the burden of congenital disease is greatest in developed countries.

ROUTES OF INFECTION

Intrauterine Infection

As is the case with rubella, intrauterine infection is assumed to follow maternal viraemia and subsequent placental infection, although this has not been proved formally. Due to the lack of maternal illness it has not been possible to identify a series of pregnant women with primary CMV infection and show that viraemia is a risk factor for congenital infection. If viraemia is responsible for transmission then it must be determined whether cell-free virus or leukocyte-associated virus is required for placental infection. Intrauterine transmission of CMV occurs in only one third of pregnant women with primary infection but we remain ignorant of how the majority prevent the virus from infecting the fetus. It may be that the placenta acts as a form of barrier, but representation of this organ as a sieve which might or might not trap CMV must surely be simplistic. Ultrastructural studies of the placenta emphasize the importance of macrophage-mediated defence against potential virus infections. There is also the

possibility that the placental Fc receptor may be able to bind CMV coated in nonneutralizing antibody and facilitate its transfer to the fetus (Maidji *et al.*, 2006).

Perinatal Infection

Perinatal infection is acquired predominantly from one of two sites: infected maternal genital secretions or breast milk. During delivery, the fetus is surrounded by copious quantities of genital secretions, which may contain high titres of CMV as a result of recurrent maternal infection. Under these conditions, infection has been described as occurring 'during passage through the sea of cytomegalovirus'.

Breast milk, especially colostrum, has also been shown to be a good source of CMV. Although virus titres are relatively low, large quantities of milk are imbibed, so a heavy viral inoculum can be ingested. Clinical studies have demonstrated that it is not just the presence of CMV in breast milk which is required but that this milk must also be fed. Women whose only site of CMV excretion was from the breast were studied and perinatal infection occurred only when breast-feeding took place, not when such women gave formula feeds (Stagno *et al.*, 1980). Having ingested CMV, infection might be established in the neonate by infection of buccal, pharyngeal, respiratory, salivary gland or oesophageal mucosa.

Postnatal Infection

The absence of symptoms associated with postnatal CMV infection makes it impossible to implicate with certainty the routes of transmission, although evidence exists to support salivary transmission.

Saliva containing CMV has been recovered from toys at day-care centres and this would seem to be an ideal means by which the virus could be transmitted among young children unable to conform to basic standards of hygiene (Pass *et al.*, 1986). Likewise, occasional cases of CMV mononucleosis are seen in young adults and, by analogy with Epstein-Barr virus (EBV), the infection has been dubbed a 'kissing disease' (see Chapter 9).

The prevalence of CMV IgG antibodies in developed countries increases at 1% per year from puberty to middle age (see Figure 8.4). It is often stated that these infections result from sexual exposure but this remains unproven. Certainly they result from contact with an infected individual, but whether this contact takes place at the level of oral or genital mucosa is a matter of speculation. Evidence can be found to support the concept of venereal transmission, since CMV is found in semen and on the cervix. However, this is only circumstantial evidence; we do not talk of brain-to-brain transmission of poliomyelitis or urinary transmission of mumps just because these viruses

may be found at particular sites. Sexual contact is almost invariably preceded by oral-to-oral contact. Thus, even if CMV is shown to be transmitted by intimate contact, it may have resulted from salivary rather than from venereal exposure. This issue is important because we may need in the future to target CMV vaccines to particular mucosal sites in order to prevent infection, and parents may be less reluctant to vaccinate their adolescent children against a 'kissing disease' than against a perceived 'sexually transmitted' infection.

One setting in which sexual transmission of CMV does occur, however, is between male homosexuals, who have a high prevalence of CMV infection, and those who are initially seronegative run a high risk of primary infection during follow-up. At least one study has implicated rectal intercourse as an independent risk factor for CMV seroconversion, implying that the rectal mucosa provides less of a barrier to the high titres of virus found in semen than is provided by the stratified squamous epithelium of the vagina.

Blood Transfusion

In the early 1960s, when extracorporeal blood perfusion was introduced to facilitate open-heart surgery, a syndrome of leukopenia, pyrexia and atypical leukocytosis was recognized which was termed the post-perfusion syndrome. In the mid-1960s, Finnish workers showed that the syndrome was attributable to primary CMV infection acquired by fresh blood transfusion.

Although it has been established that CMV can be transmitted by blood transfusion, it is clear that this is an uncommon event, since only 1–5% of blood units taken from seropositive donors lead to infection of seronegative recipients. To date, it has not been possible to determine which donors have a high risk of transmitting the virus. It is presumed that the virus exists in the blood of healthy donors in a latent state within monocytes (Soderberg-Naucler *et al.*, 1997) and that CMV is reactivated following transfusion when these cells encounter an allogeneic stimulus (reviewed in Roback, 2002). In contrast, CMV can be grown from the peripheral blood of immunocompromised patients and pp65 antigen is found in polymorphonuclear leukocytes and macrophages. However, this is clearly a different pathogenetic situation from that found in healthy blood donors and could be the result of the phagocytic scavenging activity of these cells.

Transmission via blood products has been virtually eliminated by the routine use of filters to remove leukocytes during transfusion.

Organ Transplantation

Several studies have shown that seronegative patients undergoing renal transplantation can be divided into two

risk groups according to the serological status of the donor. Those receiving a kidney from a seronegative donor have a virtually zero risk of acquiring primary infection, whereas a seropositive kidney may transmit the virus in 60–80% of cases. Molecular typing of CMV strains excreted by multiple recipients of organs from a single donor proved that the donor organ was the source of CMV (Wertheim *et al.*, 1983). Since both organs from a single donor are usually concordant for transmission, the infectivity must be bilateral; either parenchymal cells or infiltrating leukocytes are prime suspects. Interestingly, the same techniques showed that donor virus could also infect seropositive individuals and cause CMV disease (Grundy *et al.*, 1988). Thus, recipient natural immunity acquired prior to immunosuppression cannot prevent but may alleviate CMV infection, a finding which has implications for the development and evaluation of CMV vaccines. Several studies have shown the same results following all types of solid organ transplant, so all organs from seropositive donors should be regarded as potentially infectious.

In contrast, typing of virus strains showed that the virus causing disease after bone marrow transplant is derived from the recipient and not from the donor (Winston *et al.*, 1985). Seropositive donors have been reported to adoptively transfer immunity to recipients (Grob *et al.*, 1987). This has only been reported in recipients of T-cell-depleted marrow, so it is tempting to speculate that this process removes the cells containing CMV while leaving intact immunocommitted non-T cells, which can function in the recipient.

PATHOGENESIS

Risk Factors for CMV Disease

Comparison of the results from pregnancy, from recipients of solid organ transplants, from bone marrow transplants and from patients with HIV infection reveal some interesting parallels, despite the different organs involved in CMV disease (Table 8.3). Thus, primary infection is a

Table 8.3 Risk factors for CMV disease

major risk factor during pregnancy and for recipients of solid organ transplants but not for bone marrow transplant or AIDS patients. Viraemia has been repeatedly shown to be a risk factor following solid organ or bone marrow transplantation (Meyers *et al.*, 1990) and the same is true for AIDS patients (Bowen *et al.*, 1997). A high CMV virus load was initially shown to be important in neonates with congenital infection (Stagno *et al.*, 1975b) and more recently in renal transplant (Cope *et al.*, 1997b), liver transplant (Cope *et al.*, 1997a), bone marrow transplant (Gor *et al.*, 1998) and AIDS patients (Bowen *et al.*, 1996). Furthermore, multivariate statistical analyses show that, for renal transplant patients, once virus load in urine has been controlled for as a marker of poor prognosis, the other recognized risk factors of viraemia and donor/recipient serostatus are no longer statistically associated with CMV disease (Table 8.4). This demonstrates that high CMV load is the determinant of CMV disease and that viraemia and donor/recipient serostatus are markers of CMV disease, simply because of their statistical association with a high virus load. Similar multivariate studies in liver transplant and bone marrow patients confirm that high CMV load in blood explains the association with donor/recipient serostatus (Cope *et al.*, 1997a; Gor *et al.*, 1998). Furthermore, in all groups of transplant patients, a threshold association with CMV disease is apparent (see Figure 8.5) showing that low viral loads are tolerated by the host.

All of these results provide insight into the pathogenic stages leading to CMV disease. Figure 8.6 illustrates the concepts, using the flow of water from a tap into a bath with an open drain. This is analogous to virus-infected cells at a peripheral tissue (such as kidney or salivary gland) producing CMV virions. Their number may be controlled by local immune responses (drain), but if these are inadequate the number of virions will increase. If they overwhelm the local immune responses, virions will overflow into the systemic circulation, causing viraemia. The same process is then repeated in the target tissue (e.g. liver, retina), whose local immune responses may be able to prevent virus load reaching the critical levels required to cause disease. This explains why viraemia is a strong predictor of CMV disease, but does not guarantee that

Figure 8.5 The threshold concept: non-linear relationship between increasing viral load in urine and the risk of CMV disease. (Reproduced by permission from Cope *et al.* (1997b).)

Figure 8.6 Cartoon illustrating the kinetics of CMV production leading to disease in a target organ. The tap represents production of virions by virus-infected cells. The drain represents the ability of local immune responses to control CMV accumulation.

it will occur. Finally, the model suggests that different cellular mechanisms of pathogenesis may be activated at different virus loads. Thus, immunopathology may be triggered by low virus loads, while high virus loads

may be required to damage sufficient cells by lysis to cause clinically recognized disease. Speculatively, some disease may be produced when cells are bombarded with very high virus loads without requiring replication, for example, binding of gB and gH can activate release of transcription factors (Yurochko *et al.*, 1997).

Based on the model in Figure 8.6, it has been possible to conduct clinicopathological studies to define the dynamics of CMV replication (Emery *et al.*, 1999). Remarkably, serial measures of viral load in blood show that CMV replicates with rapid dynamics, giving a doubling time (viral load on the increase) or half-life (viral load on the decrease) of approximately one day. This information has been used to predict the emergence of resistant strains of CMV during prolonged GCV treatment and explain why conventional cell culture assays frequently fail to detect this (Emery and Griffiths, 2000). The perspective of CMV replication and pathogenesis given by this application of modern molecular biology highlights the misleading impressions given about CMV when studied by fibroblast cell cultures (see Table 8.5).

Incubation Periods

Examination of three settings in which the date of infection and date of onset of virus excretion can be reliably predicted gives an estimate of four to eight weeks for the 'incubation period' of primary infection. The three informative clinical settings are where infection is acquired perinatally, where it is transmitted by organ allograft and where it is transmitted by blood transfusion.

In contrast, it is not clear whether congenital infection involves a fetal incubation period as well as a maternal one. Maternal seroconversion at different stages of pregnancy has been documented in several studies, with gestational stage recorded as the duration of pregnancy at which maternal seroconversion occurred. However, even if it is assumed that the placenta is infected following maternal viraemia at the time of seroconversion, it is not known whether the fetus can be infected immediately or whether replication in the placenta provides an

intrauterine incubation period before viral dissemination to the fetus can occur. This point is important, as the damage to the fetus should be described according to its developmental maturity when infected rather than the length of the mother's amenorrhoea; this has implications for the timing of diagnostic amniocentesis (see later).

Allograft recipients typically have recurrent CMV infections in the second month following transplantation. Studies of pregnant and nonpregnant women as well as male homosexuals have shown that up to 10% of seropositive individuals may be excreting CMV from saliva or urine, or from the cervix in females. Excretion rates are, however, very low after the age of 30 years, suggesting that a host response required for suppression may 'mature' at about this age.

Earlier reports showed that virus excretion from the cervix increased as pregnancy progressed and this was interpreted as being a response to some 'immunosuppressive' effect of pregnancy. A single later study, however, showed that CMV excretion was actually suppressed during early pregnancy, so the increase seen in virus isolation towards the end of pregnancy only brought the rate up to the level seen in nonpregnant women (Stagno *et al.*, 1975a). All studies to date have been cross-sectional rather than longitudinal, so person-to-person differences in CMV excretion could account for these results and confirmation is required before definitive conclusions can be reached.

Host Defences

The defences mounted by the host against different types of CMV infection will be outlined. In combination, these responses in people with normal immunity keep CMV suppressed into a latent state in most individuals for most of the time. Abrogation of these responses permits CMV replication, with full expression of its potential pathogenicity in some cases. Since severe CMV disease is restricted to individuals with impaired cell-mediated immunity (CMI), it can be concluded that this arm of the immune response provides most protection against

Table 8.5 Misleading impressions about CMV

Impression	Fact
<i>In vitro</i> strains represent those found <i>in vivo</i>	AD169 strain has 22 missing ORFs; Towne strain has 19
Live attenuated vaccine can be prepared in fibroblasts	No protection against CMV infection from Towne, but decreased severity of disease
<i>In vitro</i> assays correctly identify susceptibility of CMV to antivirals	Failed to detect clinically-important susceptibility to ACV
CMV is a slowly-replicating virus	CMV replicates rapidly
GCV-resistant strains occur infrequently in immunocompromised patients	Resistance is more common. Cell cultures select against detection of resistant strains

disease. Nevertheless, several lines of evidence suggest that humoral immunity may contribute towards control of CMV: (i) randomized trials of prophylactic CMV immunoglobulin report that CMV disease was reduced compared to patients receiving placebo; (ii) neonates who acquire CMV from blood products have reduced disease if they are born to seropositive women, showing that transplacental antibody from their mothers protects against disease (but not infection); (iii) results with rituximab, a humanized mouse monoclonal reactive against CD20, report severe CMV disease secondary to profound B-cell immunodeficiency.

Humoral Immunity

Antibodies of IgG class are produced promptly at the time of primary infection and persist for life. IgM-class antibodies are produced on primary but not recurrent infection of immunocompetent individuals and persist for three to four months. Some immunocompetent individuals may have IgM antibodies detectable by sensitive assays during recurrent infections. Immunocompromised patients may fail to produce IgM antibodies with primary infection and one third of them have IgM detectable with recurrent infections. With intrauterine infection, IgM antibodies are produced by the fetus, together with an IgG-class response, which only becomes detectable as passively-acquired maternal IgG antibody is catabolized.

Intrauterine CMV infection represents less of a risk to a fetus if it has been transmitted by means of recurrent maternal rather than primary maternal infection (Fowler *et al.*, 1992). Women with primary CMV infection who transmit the virus *in utero* have higher levels of total IgG but lower levels of neutralizing antibodies and lower avidity than women who do not transmit (Boppana and Britt, 1995). While all of this information is compatible with the concept that immune responsiveness can be protective, it does not prove that antibody is the beneficial component. For example, cytotoxic T cells may be protective and the ability to mount this response promptly may correlate with the ability to mount a humoral immune response. Likewise, the postulated humoral defect in women experiencing primary infection during pregnancy may be a relative failure of T helper responses rather than of B cells.

There is evidence to show that enhanced humoral immune responsiveness in the fetus correlates with poor prognosis. Cord blood levels of specific IgM, total IgM and rheumatoid factor are positively correlated with symptomatic rather than asymptomatic congenital infection. This effect has been shown to be independent of virus titre at birth and so is not simply secondary to a high virus load in symptomatic infants. Although this suggests that fetal antibody is responsible for immunopathology, it

could equally well be that there is another response of the fetus which is damaging and which indirectly correlates with the humoral immune response.

The beneficial or adverse effects of humoral immunity could be discerned better if reactivity against a particular virus-coded protein could be shown to correlate with prognosis. Many CMV proteins are recognized by the humoral immune system and work to date has not been able to identify such a pattern in congenitally- and perinatally-infected infants. The ability of serial sera to immunoprecipitate radiolabelled virus-coded proteins has simply shown that symptomatic infants are more likely to have reacted to multiple virus proteins and that their sera will precipitate more of any given virus protein than will asymptomatic infants. These results are therefore compatible with heightened immune responsiveness leading to disease production.

Cell-mediated Immunity

For studies of CMI, the lymphocyte blastogenic response to CMV antigen has mainly been used, supplemented recently with tetramer assays. Most seropositive adults have a positive test result, with a surprisingly high proportion of total CD8 cells (e.g. 1%) recognizing tetramers containing epitopes from ppUL83 (pp65). This proportion is suppressed for at least six months in transplant recipients, in direct correlation with the dose of immunosuppressive drugs received (Hassan-Walker *et al.*, 2001).

The lymphocyte blastogenic response is suppressed in congenitally- or perinatally-infected infants. This failure recovers with time and there is a direct correlation between cessation of viraemia and acquisition of immune responsiveness at three to five years of age (Pass *et al.*, 1983). The defect is known not to be one of generalized T-cell immunosuppression, for three reasons. First, CMV-infected infants who also acquire HSV infections generally mount good responses against HSV but not against CMV. Second, these infants respond normally to both killed and live vaccines. Third, the suppressor and helper T-cell lymphocyte counts remain normal.

Recent work, summarized in Figure 8.7, has identified complex but plausible mechanisms which, in combination, allow the CMV-infected cell to evade lysis by T cytotoxic, macrophage and natural killer (NK) cells. Immediately after uncoating, the tegument protein ppUL83 (pp65) is available in the cell to phosphorylate the IE72 isoform of the MIE protein and so prevent its presentation as a target epitope. At immediate-early times, pUS3 retains Class I human leukocyte antigen (HLA) molecules within the endoplasmic reticulum (ER). Once the virus-infected cell has moved into the early phase of CMV gene expression, pUS2 and pUS11 act to re-export Class I HLA molecules back from the lumen of the ER into the cytoplasm, where

Figure 8.7 CMV gene products which interfere with the ability of cytotoxic T-cells or NK cells to recognise cells infected with this virus.

they are degraded in the proteasome. At both early and late times, pUS6 blocks the activity of the transporter associated with antigen presentation so that epitopes derived from CMV proteins cannot be presented as targets. All of these functions might, in combination, decrease surface HLA display to such an extent that the cell becomes a target for NK cells or macrophages which recognize the absence of these normally ubiquitous molecules. To prevent this, CMV has evolved a series of distinct strategies. The leader peptide of HLA-E is normally presented at the plasma membrane to indicate a healthy immunological flux of Class I molecules. Gene UL40 contains the same peptide as this leader, which is displayed to provide a negative signal to NK cells via their CD94 molecule. CMV also encodes another protein, pUL18, which is structurally strongly homologous to Class I HLA molecules and acts as a decoy to prevent macrophages attacking the CMV-infected cells. The pUL18 ligand on macrophages is leukocyte immunoglobulin-like receptor 1. Another protein, pUL16, is not membrane-bound but interferes with the ability of cellular proteins (termed UL16-binding proteins) to activate NK cells via their NKG2D receptors. Two additional CMV proteins interfere with the normal recognition of stressed cells by NK cells (Figure 8.7).

From the description above, it will be apparent that CMV has evolved a series of genes which act in a coordinated way to abrogate immune responses specific for the virus. There is much to be learned about the mechanistic aspects of how this objective is achieved. For

example, the expression of UL18 is not blocked by the action of the set of US genes which normally reduce Class I expression and, remarkably, US2 is able to block Class II expression as well as Class I. Thus, many responses may be initiated but are unable to detect their cellular targets during the initial round of replication. However, when the virus leaves the first cell to initiate infection in a second cell, it is vulnerable to display of epitopes before downregulation of HLA can be effected in that cell. Accordingly, the dominant effector CMI is directed against ppUL83 (pp65), revealed when the input virion is uncoated, thus explaining why CMI is focused on this late protein rather than those formed earlier in the viral cascade. However, it is possible that epitopes from other proteins may make contributions as well, with the MIE proteins being prime contenders.

Possible Interactions with HIV

The multiple mechanisms by which HIV may interact with herpesviruses are reviewed elsewhere (Griffiths, 1998). Many studies have shown *in vitro* that CMV infection (or transfection of particular genes) can transactivate HIV (reviewed in Ghazel and Nelson, 1993). Under some circumstances, CMV can also downregulate HIV replication, but CMV is more likely to stimulate HIV when the latter has an integrated provirus and when CMV is not actively replicating (Moreno *et al.*, 1997).

All of the postulated mechanisms of interaction would require close contact between HIV and CMV, either in

the same cell or in neighbouring cells. Studies of human autopsies have shown that CMV and HIV frequently co-infect the same organs and that individual cells can be found infected with both viruses.

Epidemiological studies report that the presence of active CMV infection or high quantities of CMV are associated with more rapid progression of HIV infection to AIDS or AIDS to death. It is therefore possible that CMV (and other herpesviruses) may act as cofactors to accelerate HIV disease. Indeed, multivariable analyses in the era of highly active antiretroviral therapy (HAART) show that the detection of CMV viraemia and a low CD4 count still correlate with death and that measurement of HIV viral load does not add further statistical predictive value (Deayton *et al.*, 2004). However, the cofactor hypothesis remains unfashionable and the reader is referred elsewhere for more details (Griffiths, 1998).

CLINICAL FEATURES

Congenital Infection

12.7% of congenitally-infected babies are born with symptoms. They are said to have ‘cytomegalic inclusion disease’ and their prognosis is poor. The remaining 87.3% appear to be normal at birth but about 13.5% develop sequelae on follow-up (Figure 8.8).

Those Symptomatic at Birth

The classic presentation is one of intrauterine growth retardation, jaundice, hepatosplenomegaly, chorioretinitis, thrombocytopenia and encephalitis, with or without microcephaly. It is often difficult, even for experienced paediatricians, to differentiate solely on clinical grounds between the several agents causing chronic intrauterine infection; laboratory tests for CMV, rubella, syphilis and toxoplasmosis are therefore invaluable. Most of the pathology outside the central nervous system (CNS) is self-limiting, although severe thrombocytopenic purpura, hepatitis, pneumonitis and myocarditis are occasionally protracted and life-threatening. The CNS involvement may present as microcephaly, hearing loss, encephalitis, seizures, apnoea or focal neurological signs. As regards congenital malformations, inguinal hernia in males, first branchial arch abnormalities, anophthalmia, diaphragmatic eventration and cerebellar hypoplasia have all been reported. However, these occur sporadically and so may be merely coincidental. There is therefore no evidence that CMV acts as a teratogen to impair normal organogenesis. Most of the clinically-apparent sequelae can be attributed to destruction of target organ cells once they have been formed.

Figure 8.8 Outcomes for 1000 children born with congenital CMV infection. 12.7% are born with symptoms. They are said to have ‘cytomegalic inclusion disease’ and their prognosis is poor. The remaining 87.3% appear to be normal at birth but about 13.5% develop sequelae on follow-up.

In 0.5% of these cases the damage caused by the virus is so severe that they die during infancy. If a neonate survives, it is almost certain to have serious abnormalities for life, especially if there is microcephaly or if abnormalities are seen by computerized axial tomography (Noyola *et al.*, 2001). On follow-up, clinically-apparent extraneural damage is rare but brain damage may manifest as microcephaly, mental retardation, spastic diplegia or seizures and perceptual organ damage such as optic atrophy, blindness or deafness. Any of these abnormalities may occur alone or in combination. These defects may appear in children who do not have signs of CNS involvement at birth (including cerebrospinal fluid (CSF) examination). Milder forms of CNS damage, such as defects in perceptual skills, learning disability, minor motor incoordination or emotional lability, may be noticed as the child becomes older.

Those Asymptomatic at Birth

Long-term follow-up of such children has revealed that approximately 13.5% are likely to have hearing defects or impaired intellectual performances when compared

Figure 8.9 Histological preparation of an inner-ear structure from a fatal case of congenital CMV infection showing cell extension of CMV accompanied by an inflammatory response. (Courtesy of Dr S. Stagno, Alabama.)

to control children (Dollard *et al.*, 2007). The mean intelligence quotient of infected children has been reported to be significantly lower than controls. Other investigators have not noted these defects but their studies have often failed to follow the children for a sufficient length of time or have failed to use matched controls. There is now sufficient evidence to prove that the hearing loss can occur in a child born with normal hearing. In addition, a plausible pathogenesis for progressive hearing loss is apparent. Figure 8.9 shows a histological preparation of inner-ear structures from a fatal case of congenital CMV infection, demonstrating virus spread by the cell-to-cell route to produce a focus of infection surrounded by inflammation. It is tempting to suggest that this represents the infectious process in the inner ear causing progressive damage to the organ of Corti and decreased ability to perceive sound.

Perinatal Infection

Despite the continued excretion of virus for many months, the vast majority of perinatally-infected infants appear not to develop acute symptoms. The initial titres of CMV in the urine are significantly lower than those found in neonates with congenital CMV infection or disease (Stagno *et al.*, 1975b), which is compatible with the virus load hypothesis of CMV disease induction. Occasional cases of infantile pneumonitis have been attributed to perinatal CMV infection. This would appear to be an uncommon event, although CMV is a frequent pathogen in those few infants who do develop pneumonitis in the first three months of life. Disease may occur in preterm neonates (<1500 g birth weight). One study reported transmission of CMV in 17% of cases (Yeager *et al.*, 1983), while a more recent publication reported transmission in 37% (Hamprecht *et al.*, 2001). In both papers, individual cases

of neutropenia were temporally associated with CMV acquisition, sometimes accompanied by a clinical picture of sepsis with negative bacterial cultures.

Postnatal Infection

The commonest clinical outcome of primary or recurrent postnatal infection is a mild course without the production of symptoms. Most individuals identified by prospective serological studies as having seroconversions express surprise when told that they have experienced a virus infection.

Occasionally, however, primary infections are accompanied by the syndrome of infectious mononucleosis. This is similar to the syndrome produced by EBV except that lymphadenopathy is uncommon and that the Paul–Bunnell test is invariably negative. Sometimes, the hepatic component of CMV mononucleosis is prominent, so a diagnosis of viral hepatitis is considered initially. Within a few days, however, the full clinical picture becomes clear, with persisting pyrexia and atypical lymphocytosis. The post-perfusion syndrome, described earlier, is essentially CMV mononucleosis acquired by blood transfusion.

CMV is such a common virus infection that primary infection tends to occur by co-incidence with a variety of medical conditions. In addition, since CMV is an opportunist, it will tend to reactivate when a patient becomes debilitated as a result of some underlying condition. If the underlying disease is esoteric and has an unknown aetiology, a case report tends to appear describing the association. By scanning through PubMed (www.ncbi.nlm.nih.gov/pubmed), Internet surfers will be able to find literally dozens of such spurious associations, but they should be reassured: CMV is not the cause of all known diseases.

Immunocompromised Patients

Immunocompromised patients may respond to primary or recurrent CMV infections by remaining asymptomatic. More frequently, they will develop a spiking pyrexia which resolves after a few days. Some may develop viraemia with fever and leukopenia, which is sometimes termed CMV syndrome. This may progress to pneumonitis, or pneumonitis may supervene directly. In either case, once pneumonitis has become established, the prognosis is poor (mortality 80–90%). Some patients present with virus dissemination to the retina without other signs. Any part of the gut may be the site of CMV replication, which may be asymptomatic or may be associated with ulceration, which can, in extreme circumstances, cause erosion of neighbouring blood vessels, with catastrophic haemorrhage. Patients with AIDS may develop an encephalopathy of either a subacute progressive dementia or

an acute presentation with cranial nerve palsies caused by necrotizing ventriculitis. Alternatively, AIDS patients may present with a syndrome of weakness of the lower limbs, bladder paralysis and a polymorphonuclear CSF response which is termed polyradiculopathy. At post-mortem examination, AIDS patients often have CMV adrenalitis. Finally, CMV may induce an immunosuppressive syndrome in which the patient becomes unable to deal with superinfecting bacteria or fungi. In this instance, and in some of the other clinical presentations (pneumonia, hepatitis, gut ulceration, septicaemia), the underlying nature of the CMV infection is often not recognized by the clinical staff, who are understandably distracted by the more easily recognized superinfecting organisms.

The major clinical diseases associated with CMV are summarized in Table 8.6, according to the type of immunocompromised patient. Some complications, such as gastrointestinal involvement, are found in all patient groups. Some predominate in one group; for example, 85% of CMV disease presents as retinitis in AIDS patients compared to less than 5% in transplanted patients. While this observation remains unexplained, it is hypothesized that CMV pneumonitis in allograft patients is an immunopathological condition caused by an aggressive cell-mediated response against a lung target antigen coded by, or revealed by, CMV infection. Accordingly, AIDS patients may be relatively spared pneumonitis because, by the time they are sufficiently immunocompromised to permit CMV dissemination to the lung, they have insufficient T-cell responsiveness to mount the postulated immunopathological response. Likewise, the myelosuppressive CMV disease results when CMV replicates in stromal supporting cells,

releasing cytokines and producing a milieu unfavourable for haematopoiesis.

These observations concerning the different CMV diseases found in distinct patient groups, combined with the increasing knowledge about the importance of CMV viraemia and viral load, lead to a potential explanation for the diversity of CMV diseases. CMV viraemia may be a prerequisite for CMV disease at any target site. Increasing viral load may increase the chance that CMV can penetrate tissues to cause disease. Other organ-specific changes, distinct for each patient group, may then dictate in which organ CMV localizes; for example the marrow suppression is presumably found only after bone marrow transplant because these new cells are receptive to CMV replication.

Indirect Effects

Many studies consistently associate CMV with allograft rejection, secondary fungal or bacterial infections and accelerated atherosclerosis after heart transplant. The results (discussed later) from double-blind placebo-controlled trials of antiviral agents demonstrate that each of these is significantly reduced by preventing CMV disease, so supporting the hypothesis that CMV causes these conditions in some patients. There are no clinical features to distinguish CMV-associated graft rejection/secondary infection/atherosclerosis from the cases that are not prevented by anti-CMV drugs.

CMV is also clearly a contributor to immunosenescence. The CD8 response to CMV is prominent (discussed earlier) and may cause disease in two ways. First, it may divert immunological resources such as cytokines away from their intended function of mounting *de novo* immune responses. Second, the activated CD8 cells may trigger inflammatory diseases such as atherosclerosis. There is evidence for both of these phenomena; CMV-seropositive individuals mount an impaired response to influenza vaccine and have a significantly increased risk of death compared to age-matured CMV seronegatives in longitudinal studies (Strindhall *et al.*, 2007; Trzonkowski *et al.*, 2003).

DIAGNOSIS

As with all viruses, there are two potential strategies for providing a diagnosis: the detection of virus or the demonstration of a specific immune response.

Detection of Virus

Collection of Specimens

Urine can be obtained by mid-stream collection, by urine bags in neonates or by urinary catheter. Samples can be

collected at any time of day and should be sent to the laboratory without additives, since CMV is stable in urine.

Saliva should be allowed to soak onto a plain cotton-tipped swab, which is then shaken in virus transport medium and broken off. For PCR, from blood acid-citrate-dextrose or EDTA is preferred to heparin.

Tissue biopsies should be placed into plain sterile containers with no additives. Fluid and cells obtained by bronchoalveolar lavage should similarly be placed in a plain sterile container.

Amniotic fluid should be collected into a plain sterile container without any additives.

All specimens should be sent to the laboratory without delay. If delay of more than a few hours is anticipated then all samples should be sent refrigerated or on wet ice. Whole blood for PCR can be frozen at -20°C .

Selection of Sites for Examination

To diagnose congenital or perinatal infection, urine or saliva samples are usually collected. More invasive procedures, such as lumbar puncture or liver biopsy, are sometimes performed, but identification of CMV at these sites has not been shown to have any prognostic value.

If adults with mononucleosis or hepatitis are being investigated then urine and blood are the best samples. It should be possible to detect CMV from all urine samples collected within a few weeks of onset, whilst viraemia is often detected in the first few days of illness. The identification of urinary CMV excretion in a patient with such symptoms might be coincidental but the detection of viraemia strongly supports the diagnosis of CMV mononucleosis or hepatitis.

If pregnant women have symptoms, they should be investigated for viraemia. Amniotic fluid can be tested by PCR and culture but amniocentesis should not be performed before 21 weeks because fetal renal function must be established to allow CMV to appear in fetal urine and then amniotic fluid. In addition, amniocentesis performed within six weeks of primary infection may give false-negative results for CMV because of the postulated placental incubation period, which delays the transfer of CMV from the maternal to the fetal compartment. However, there is no advantage in actively screening asymptomatic women. Investigations involving the culture of urine, genital secretions, saliva and breast milk have been carried out but the results are not predictive of which women will have babies with congenital or perinatal infection. Since the 'patient' in these examples is the neonate, not the woman herself, samples should not routinely be collected from any maternal site.

Immunocompromised patients should be investigated by means of surveillance samples, taken preferably twice weekly, of blood and possibly also urine or saliva. This

must be done as routine on all patients, rather than waiting for symptoms to develop. CMV excretion from urine and saliva is very common in allograft recipients so the relative risk for future disease is typically 3. In contrast, PCR viraemia is detected less frequently in allograft patients but, when it does occur, is indicative of a relatively poor prognosis, with a relative risk of about 10. However, even the detection of viraemia does not guarantee that CMV is the cause of, say, the patient's hepatitis or pneumonitis. Ideally, samples should be collected from these target organs whenever possible.

An alternative way of detecting viraemia is through detection of antigenaemia in preparations of peripheral blood mononuclear cells as targets (van den Berg *et al.*, 1991). These are reacted with monoclonal antibodies against ppUL83 (pp65), followed by immunoperoxidase staining (see Figure 8.10). Note that the monoclonal antibody required for this assay does not recognize the immediate-early proteins as originally described. Presumably, the phagocytic activity of the leukocytes shown in Figure 8.10 has led them to ingest virus-infected material, among which ppUL83 is prominent. It is tempting to speculate that this may derive from dense bodies, since ppUL83 is a major component of these aberrant forms. In practice, antigenaemia is useful where samples can be processed by the laboratory within a few hours and where the leukocyte count is relatively normal, for example in recipients of solid organs.

Figure 8.10 Direct detection of cytomegalovirus in peripheral blood leukocytes. M, monocyte; P, polymorphonuclear leukocyte. (Kindly provided by Professor H. Thé.)

Histopathology

CMV can be recognized in histological preparations by its characteristic 'owl's eye' inclusions. These Cowdry type-A intranuclear inclusions have a surrounding halo and margined chromatin. They can be found in kidney tubules, bile ducts, lung and liver parenchyma, gut, inner ear and salivary gland but are less prominent in brain tissue (see Figures 8.9 and 8.13 for examples).

Although histopathology provides a specific diagnosis, it is known to be insensitive. One study showed that CMV can be cultured from tissue six times more frequently than typical inclusions can be seen, while a later study showed that organs with inclusions have a median viral load two logs higher than those in which inclusions could not be seen (Mattes *et al.*, 2000).

Tissue Immunofluorescence

Some biopsy samples (e.g. liver, lung) may contain cells infected with CMV, which can be visualized by staining frozen sections with antisera to CMV. Alternatively, the tissue can be disrupted and the cells fixed to glass slides before staining. Bronchoalveolar lavage fluid contains a suspension of cells exfoliated from the respiratory tract, which can be centrifuged, washed to remove adherent mucus and then air-dried and fixed to microscope slides before staining.

Cell Cultures

For conventional cell cultures, human fibroblasts are used. Foreskins or embryo lungs may be employed as a source of fibroblasts and must be used only at low passage (<25).

To detect wild strains of CMV reliably, the cultures must be cared for obsessively. The medium must be drained and 0.2 ml of each clinical specimen inoculated and incubated at 37°C for 1 hour to permit virus adsorption. The cultures should then be refed with maintenance medium to reduce the toxic effects of the inoculum. This is especially important in the case of particulate samples, such as blood and tissue homogenates. For the detection of viraemia, buffy coat or unseparated heparinized blood can be inoculated into cell cultures. If toxicity is observed, denuded areas of the monolayer can be repaired by the addition of fresh fibroblasts.

All cultures should be observed at least twice weekly for the typical focal CPE of CMV (Figure 8.11). Occasionally, urine samples from cases of congenital infection produce widespread CPE within 24 – 28 hours, which resembles that of HSV. Usually, however, the CPE evolves only slowly, so the cultures must be maintained for a minimum of 21 days before being reported as negative. This delay in obtaining an answer

Figure 8.11 The local cytopathic effect typical of cytomegalovirus seen in monolayer cultures of human embryo lung fibroblasts. (Photograph kindly prepared by Ms A. Grzywacz.)

has stimulated research into more rapid ways of detecting CMV, which are discussed below.

Electron Microscopy

Samples of urine from infants infected congenitally or perinatally contain high titres ($10^3 - 10^6$ TCID₅₀/ml) of CMV. Using the pseudoreplica electron microscopy technique, it has been possible to demonstrate this viraemia. Several authors have reported that approximately 80% of infected infants can be detected, with the false negative results being clearly attributable to low-titre urine samples (<10³ TCID₅₀/ml). The viral specificity of the technique has been reported at 100%, simply because it would be most unusual for any other herpesvirus to be found at such high titre in urine from infants.

Electron microscopy cannot be used in immunocompromised patients for several reasons. First, the titre of CMV found in clinical samples from adults is generally lower than that found in infants. Second, all human herpesviruses frequently infect immunocompromised patients and cannot be distinguished from each other by electron microscopy. Since different antiviral therapy may be required for each herpesvirus, the results of electron microscopy would not be specific enough to influence patient management.

Detection of Early Antigen Fluorescent Foci (DEAFF)

The technique of detection of early antigen fluorescent foci (DEAFF) was developed as a means of retaining the specificity and sensitivity of cell culture without having to wait for the production of CPE as a diagnostic end point (Griffiths *et al.*, 1984).

Following inoculation on to cell cultures, CMV is absorbed into the cell within minutes. CMV rapidly starts to produce α - and β -proteins but CMV DNA synthesis is

Figure 8.12 Cytomegalovirus infection diagnosed by detection of early antigen fluorescent foci (DEAFF).

delayed and protracted until several days after infection. This explains the long delay seen in conventional cell cultures, since CMV needs to replicate, produce daughter virions and infect neighbouring cells in order to produce the CPE shown in Figure 8.11

To speed up the diagnostic process, cells are inoculated with clinical specimens and stained after only 18 hours incubation, using monoclonal antibodies directed against some of the α - and β -proteins of CMV (Figure 8.12). This technique is termed shell vial assay in the United States because of the vessels used for the sample processing (Gleaves *et al.*, 1984).

Enzyme Immunoassay (EIA)

Some workers established EIA detection systems using polyclonal hyperimmune sera or monoclonal antibodies. The results indicated that EIA could detect small amounts of CMV complement-fixing (CF) antigen or of virus when added artificially to buffer systems. However, when clinical samples containing CMV were assayed, results of low sensitivity and/or specificity were obtained.

Detection of Viral DNA

Earlier reports of the detection of CMV by dot-blot methods have been completely superseded by PCR. Different parts of the CMV genome have been chosen as targets by various authors, but there is no obvious advantage in any particular one. Ideally, one would wish to amplify a conserved region, but the degree of genetic variability found in clinical strains is only beginning to be defined. Potentially, PCR methods could be so sensitive that they detect low quantities, even latent virus, which would not necessarily be clinically relevant; accordingly, some authors have concluded that their nested PCR procedures do not provide prognostic information. We deliberately chose a non-nested procedure to avoid this problem, and found

that PCR produces good prognostic information in both transplant patients (Kidd *et al.*, 1993) and HIV-positive individuals (Bowen *et al.*, 1997). Clearly, 'PCR' is not a single procedure and each laboratory should measure the clinical significance of its results through formal assessment (Bowen *et al.*, 1997; Einsele *et al.*, 1995; Kidd *et al.*, 1993; Shinkai *et al.*, 1997). The availability of fully quantitative PCR assays for CMV, especially in a real-time format, offers another approach for further refining prognostic values, as well as for understanding pathogenesis, as discussed previously.

Amniotic fluid should be tested in multiple replicates by PCR to avoid false-negative results (Revello *et al.*, 1998).

As described later, dried blood spots can be tested by PCR to provide a retrospective diagnosis of congenital CMV infection. The testing algorithm described by Barbi *et al.* (2006) should be followed.

Characteristics of the Various Assays Described

These are summarized in Table 8.7. In the first three editions of this book, I described conventional cell culture as the gold standard against which newer assays should be compared. In the fourth edition I proposed that this process is complete for PCR, so that it can be recommended as the new gold standard for providing diagnostic information in a timely manner able to influence the management of individual patients. This conclusion is supported by a series of subsequent reports, so that any PCR assay which has had a published validation showing correlation with clinical end points can be employed (Einsele *et al.*, 1995; Kidd *et al.*, 1993; Shinkai *et al.*, 1997). Note that the samples required, the sample extraction method and the assay-specific details all differ among these validated assays, so colleagues should choose one system and follow the whole procedure exactly as described. We have always used whole blood because fractionation offers additional opportunities for sample contamination and mislabelling and so should only be performed if clear benefits can be shown. This choice is vindicated by a recent study which directly compared the utility of testing whole blood versus blood fractions (Razonable *et al.*, 2002).

Advantages and Disadvantages of Virus Detection

1. The anatomical site of the infection can be documented (e.g. lung involvement in a patient with pneumonitis).
2. The patient's immune response is not required for diagnosis, so all infected immunocompromised patients, not just those able to mount an immune response, can be identified.
3. Rapid diagnostic methods have enabled infected patients to be recruited into therapeutic trials of potential

Table 8.7 CMV detection in body fluids

Method	Sensitivity	Specificity	Reliability	Rapidity	Proven prognostic value

Detection of early antigen fluorescent foci	+	+++	++	++	+
Antigenaemia	++	+++	++	+++	+
Polymerase chain reaction	+++	+++	++	++	+

antiviral agents so that patient management may be influenced.

4. PCR methods can quantify the amount of virus in clinical samples and allow quantitative virological assessment of antiviral agents.
5. If resistant virus emerges during a course of treatment, this may be detected by the assay and so provide an opportunity for prescription of an alternative drug.
6. A potential disadvantage is that the monoclonal antibodies or DNA probes used to detect CMV may be too specific and identify only some strains of the virus, although this has not proved to be a problem to date.

Detection of Immune Response

IgG Antibody as a Marker of Past Infection

The detection of IgG antibodies against CMV is clearly indicative of infection sometime in the past. The individual is said to be seropositive and is liable to experience reactivations of their latent infection. The presence of IgG antibodies against CMV is thus a marker of potential infectivity; although a seropositive individual is 'immune' in the immunological sense, this term should not be used to imply protection from endogenous or exogenous infection.

Many assays have been described for the detection of CMV IgG antibodies. Those most frequently used

are listed in Table 8.8, together with estimates of their performance. In patients with intact immunity, the CF test is perfectly adequate, provided that an efficient antigen is employed and optimal incubation temperatures are used. Other tests (marked '+' in Table 8.8) are more sensitive in that they produce higher antibody titres, but they do not detect substantially more seropositive individuals in a population.

With immunocompromised patients, the CF test often gives false-negative results by failing to detect low levels of IgG antibody. Thus, a more sensitive technique is required, and any of those marked '++' in Table 8.8 are satisfactory, with EIA being used most frequently. If an immunofluorescence (IF) method is chosen, the IF assay-late antigen (IFALA) assay should be avoided because all human sera bind to the IgG Fc receptor induced by CMV and this perinuclear fluorescence can be difficult to distinguish from the virus-specific nuclear fluorescence found with seropositive samples. Anticomplement IF (ACIF) is the IF method preferred, since it is unaffected by IgG binding to the Fc receptor.

IgG Antibody as a Marker of Acute Infection

Rising levels of IgG antibody were employed in the past but this approach has been completely superseded by assays for detecting virus itself. However, the detection of IgG antibodies of low avidity provides evidence of

Table 8.8 Performance characteristics of several assays used to measure IgG antibodies against CMV

Method	Performance characteristics			
	Sensitivity	Specificity	Objectivity	Rapidity

primary infection in the recent past, for example 16–20 weeks (Guerra *et al.*, 2000).

Detection of IgM Antibodies

Attempts to detect CMV-specific IgM antibodies have been plagued by the use of methods of poor sensitivity and specificity and by interference from rheumatoid factor. Testing for IgM antibodies may be helpful in cases of suspected CMV mononucleosis or in pregnant women. In all other cases of suspected active CMV replication, investigations using virus detection methods are recommended.

Problems Associated with Serological Diagnosis

1. Some immunocompromised patients fail to mount a typical immune response and die from disseminated CMV infection. If diagnoses are made solely by serology, these cases will not be identified.
2. The passive transfer of CMV IgG antibodies with blood products may produce 'seroconversions' if sensitive IgG assays are employed.
3. The major objection to detecting CMV infection serologically is that the diagnosis is delayed.

MANAGEMENT

Congenital Infection

The most important part of the management of these cases is to make an unequivocal diagnosis. This is usually accomplished in the case of those symptomatic at birth but is more difficult in those who are initially asymptomatic.

Babies born with symptoms are usually investigated using the appropriate tests: culture or PCR of urine or saliva for CMV. The presence of CMV in a neonate aged less than three weeks is clearly indicative of congenital infection.

Those born without symptoms are unlikely to have tests performed and typically present from the age of six months onwards with sequelae such as hearing loss or mental retardation. These cases should be tested for CMV but if the virus is present this does not guarantee that the infection was acquired congenitally rather than perinatally.

Testing for specific IgM antibodies is of no help in this situation, since they should be present following congenital infection and will presumably be produced acutely in cases of perinatal infection, although this remains to be proven rigorously.

Instead, a request should be made for retrieval of a stored dried blood spot taken in the first few days of life as part

of a screening programme for phenylketonuria, where the child was born in a country which performs such screening. Testing such dried blot spots by PCR has excellent sensitivity and specificity for detecting CMV DNA even when the card has been stored at room temperature for years (Barbi *et al.*, 2006). Provided that the sample was collected within the first three weeks of life, a positive PCR result is diagnostic of congenital CMV infection.

If CMV is found in a child who develops symptoms during infancy, it is worthwhile bleeding the mother and contacting the laboratory servicing her antenatal clinic to see if sera have been retained. Occasionally, a laboratory has kept a serum used to test for rubella status. If this serum has CMV IgG but not IgM antibodies then it is unhelpful, since the mother may have had recurrent infection during pregnancy or, if she presented later than 16 weeks, primary infection early in pregnancy. If, however, the serum has low-avidity antibodies or is IgM positive, it will confirm that she had primary infection during pregnancy, which makes it more likely that her child's CMV was acquired congenitally. Similarly, if the mother seroconverts between early pregnancy and paediatric presentation, this supports a congenital transmission. Finally, the mother may remain seronegative, in which case the child cannot have had intrauterine infection and so the diagnosis of congenital infection can be excluded.

It will be evident from this discussion that the management of these cases would be greatly facilitated if it were possible to screen all new-borns for evidence of congenital infection, in a similar fashion to the established phenylketonuria screening programme. At present, cell culture is too cumbersome and expensive a technique to be used widely but testing of dried blood spots could fulfil this role reliably if there was the political will and funding to start such screening.

Once the diagnosis of congenital infection has been established, an assessment should be made of the prognosis for the child and for a future pregnancy. An estimate of the child's prognosis can be given from the magnitude of neonatal viraemia and the presence of viraemia detected by PCR because this correlates with a poor prognosis (Bradford *et al.*, 2005).

The prognosis for a future pregnancy is clear if the diagnosis has been definitely proven and the child was symptomatic at birth; since only one example of cytomegalic inclusion disease has been reported in consecutive siblings, the risk of an identical recurrence must be very low. If, however, the child developed symptoms during infancy then the position is not so clear. No sibling cases have been reported but this might be because the correct diagnosis has not been made in the past. It remains possible, therefore, that a woman could have a future pregnancy damaged in a similar way. To be scientifically and legally

correct, the risk cannot be given as zero, but, on humanitarian grounds, the author usually emphasizes that it must be very low. Before a definitive virological diagnosis is available, the differential diagnosis often includes a recessive gene for presentations with hearing loss, which has a recurrence risk of 25%. If the parents are prepared to gamble with their genes then the virologist must not dissuade them from taking what must be a far lower risk with CMV. It is conventional to advise such women to wait one year between the estimated date of infection and trying to conceive, which approximates to two years between births, for which there is supporting evidence of low risk from a cohort study (Fowler *et al.*, 2004). However, there are no laboratory tests to determine whether it is 'safe' for an individual to proceed.

Having established the diagnosis and prognosis, treatment must be considered, including remedial therapy to compensate for hearing, speech or developmental defects. GCV has been studied in a dose-comparative trial (Whitley *et al.*, 1997), which showed that the drug was relatively well tolerated over the six weeks duration of therapy, with no excess toxicity from the higher dose of 6 mg kg⁻¹ b.i.d. intravenously. As a result, this dose was compared against no treatment in a randomized controlled trial and significantly worse hearing was reported at six months among those who were not treated (Kimberlin *et al.*, 2003). Thus, despite the toxicity of GCV, which caused neutropenia and thrombocytopenia in substantial numbers of the neonates, this drug has become the standard of care for those born with CNS symptoms. The same investigators have shown that the valganciclovir (VGCV) prodrug is bioavailable in infants and so can be used to deliver GCV orally. Further controlled trials are required to determine the optimal duration of therapy and a randomized comparison of six weeks versus six months of GCV therapy has just begun. Additional studies are required in infants born without symptoms of congenital CMV infection to determine whether the toxicity of GCV can be justified in them.

Until such trials are conducted, this author concurs with the opinions of the investigators, that GCV should not be used outside the setting of a controlled clinical trial (Kimberlin *et al.*, 2003; Whitley *et al.*, 1997). The toxicity profile of GCV includes carcinogenesis in rodents and so possible therapeutic advantages must be balanced carefully against potential adverse consequences.

Finally, the parents should be informed about the nature of the child's illness and advised on its infectivity (see below).

Perinatal Infection

These cases produce few medical management difficulties. Most remain asymptomatic and undiagnosed. Cases

of infantile pneumonitis should have samples of urine, saliva and nasopharyngeal aspirate cultured for CMV but, apart from bronchoscopy and/or lung biopsy, there is no way of proving that the pneumonitis is due to CMV in an individual case. The main medical importance of perinatal infection is the difficulty it produces for the diagnosis of congenital infection (see above) and the fear of contagion that it stimulates.

It is clear that children less than 18 months of age with perinatal infection can transmit CMV to their parents (Pass *et al.*, 1986). This presumably results from close contact with infected saliva during normal family life and so would be difficult to control completely. Control should be considered, however, if the mother is contemplating pregnancy (Adler *et al.*, 2004), although care must be taken not to induce feelings of social isolation or rejection in the older sibling. There is no evidence that these children are contagious to adults outside the family or day-care centre but it seems prudent to advise the parents that the infants should avoid intimate contact with women who may be pregnant or with immunocompromised patients. Unfortunately, this advice, when ultimately passed to school teachers, can lead to the children being treated as lepers. The teaching staff may have to be reassured strongly to ensure that the children are not treated differently from any others. It usually suffices to emphasize that 10–20% of the children in the classroom are asymptotically excreting CMV as a result of perinatal infection, so that routine hygienic precautions should be used by all staff for all children. The same advice should be given when the child has congenital CMV infection, irrespective of whether or not the virus has induced disease. It would be absurd to ostracize the occasional case of symptomatic congenital infection knowing that literally hundreds of other children of the same age are excreting similar amounts of the same virus.

Postnatal Infection

Most cases of postnatal infection are asymptomatic and so do not require management. Exceptions are CMV mononucleosis and hepatitis, which may well be treated once a safe orally bioavailable anti-CMV drug becomes available.

When postnatal infection occurs in a pregnant woman, however, the possibility of termination of pregnancy requires consideration. Recurrent maternal infections are invariably asymptomatic and there is no laboratory test currently available that can detect which immune women are transmitting the virus *in utero*. For these practical reasons, it is not possible to contemplate therapeutic intervention in these cases, even though some produce childhood damage (Fowler *et al.*, 1992), so discussion must be limited to primary maternal infections.

By analogy with rubella infection during pregnancy, it has been assumed that primary CMV infection will be most severe when it occurs during the first trimester, so therapeutic termination of such pregnancies would be justified if the diagnosis could be made sufficiently early. Studies have shown that asymptomatic primary CMV infection can be reliably diagnosed early in pregnancy by testing for IgG avidity and specific IgM antibodies (Guerra *et al.*, 2007). It has also been clearly shown that the vast majority of women in developed countries present early enough in pregnancy to allow the infection to be detected and for termination of pregnancy to be performed safely. Studies have confirmed the assumption that primary CMV infection is more severe at this stage of pregnancy—so severe that it produces a statistical excess of fetal losses. These results clearly suggest that some pregnancies involving the potentially most severely affected fetuses are terminated naturally, so that medical intervention directed towards the survivors may not be as beneficial as has been assumed.

Currently available data indicate that the risk that an individual fetus may survive to be born with cytomegalic inclusion disease following primary maternal infection before 28 weeks gestation is about 4% (Griffiths and Baboonian, 1984; Stagno *et al.*, 1986). Antenatal screening has been performed in Italy and the results of specialized reference tests show that women with positive IgM screening tests can be divided into one group with a low (1%) background risk of disease and another with a substantial (30%) risk. When given these results, most women can be supported to continue with their pregnancies (Guerra *et al.*, 2007).

When counselling women, it must be remembered that the presence of intrauterine infection does not necessarily indicate that clinically-evident disease would have presented itself in childhood, since the majority of congenitally-infected infants develop normally. There is also no evidence to suggest that a symptomatic woman is more likely to deliver an affected baby than is an asymptomatic woman; therefore, whilst the final decision rests with the parents and their obstetrician, the same virological advice should be given to all. Amniocentesis with culture and PCR of the amniotic fluid has been performed in case series. Overall, these results show that, after 21 weeks gestation, CMV can be detected in amniotic fluid in most cases. (Revello 98; Guerra *et al.*, 2000). Amniocentesis frequently gives false-negative results if performed before 21 weeks because fetal kidney function is required to excrete CMV into the amniotic fluid. Given the need to make the diagnosis rapidly at this late stage of pregnancy, PCR has a distinct advantage over culture, but the parents must be counselled about the possibility of false-negative results. In addition, quantitative PCR of amniotic fluid

shows that high viral loads correlate with a high risk of disease, but the range of values found in practice means that precise risks cannot be given to individual women.

Coupled with the results of ultrasound scanning to assess fetal growth, amniotic fluid testing for CMV aids detection of some of the potentially most severely damaged cases, but the techniques are still restricted to specialized reference laboratories. Furthermore, a randomized controlled trial of administering valaciclovir to pregnant women with PCR-positive amniotic fluid is about to start, coordinated from Paris (Ville, Y., personal communication).

In two published independent cases, female members of paediatric medical or nursing staff requested termination after discovering that they had acquired asymptomatic primary CMV infection during pregnancy. Serological tests had been performed because they were caring for infants known to have congenital CMV infection. Virus isolates were obtained in each instance from the index case, the mother and the aborted fetus. In both cases, the maternal and fetal isolates were shown to be indistinguishable from each other by restriction enzyme analysis but were quite different from their respective index case. The conclusion is clear: primary CMV infection occurs commonly during pregnancy and will be found if women of childbearing age are investigated. Typing of strains in the published cases showed that the infections were not acquired from recognized occupational exposures, a finding which has important medical implications. There is little evidence that staff exposed professionally to infectious cases have an increased risk of contracting CMV infection, but it seems prudent to advise pregnant staff to avoid such contacts if possible by practising good hygiene precautions, such as hand washing after patient contact. This cautious approach is applied to female technical staff working with CMV in the laboratory, although we have never had a case of seroconversion among our predominantly seronegative staff. It should be emphasized that the same advice is given to female staff irrespective of their serological status; clearly preconceptional humoral immunity in these women cannot be equated with a guarantee of protection for the fetus.

Immunocompromised Patients

The most important part of the management of these patients is to make the diagnosis of CMV infection rapidly. Once extensive damage to target tissues has occurred, as is shown in Figure 8.13, no antiviral therapy can reasonably be expected to have a successful outcome. To provide advance warning of CMV disease, blood should be collected twice weekly from all allograft recipients and processed by one of the rapid diagnostic methods described in the previous section.

Figure 8.13 The post-mortem histological appearance of cytomegalovirus pneumonitis in a bone marrow allograft recipient. (Reproduced by permission from Griffiths (1984).)

If CMV is found in an allograft recipient then the patient's condition should be reviewed with the clinicians. Many are asymptomatic but some may subsequently become unwell and the availability of rapid virological results may allow the clinicians to reduce immunosuppressive therapy before extensive dissemination of CMV has occurred. The importance of rapid diagnosis in the clinical management cannot be overemphasized, since the differential diagnosis of some illnesses requires an increase in immunosuppressive therapy (e.g. renal allograft rejection episodes). Strategies for the use of antiviral drugs in asymptomatic patients found to have active infection with CMV will be discussed in the next section.

PREVENTION

Is Prevention Needed?

Prevention of an infection can be justified only if it leads to a reduction in ill health; in other words, the infection itself need not necessarily be the target as long as the infectious process can be modified to prevent disease. Potential strategies by which this objective may be accomplished will be detailed, but first it is necessary to consider the magnitude of the problem in the two major populations: congenital and immunocompromised patients.

Congenital Infection

While it is well recognized that babies symptomatic at birth have a poor prognosis, the full effects on those babies who appear to be normal at birth are only now becoming apparent (Fowler *et al.*, 1992). However, the figures outlined in Figure 8.8 translate into approximately 5000 children per year in the United States and 870 per

year in the United Kingdom suffering overtly as a result of congenital CMV infection. These figures confirm congenital CMV infection as the second commonest known cause of mental retardation after Down syndrome. Prevention of such a relatively common condition would be justifiable if this could be achieved safely and at low cost. A recent Institute of Medicine report estimates that \$3 billion is spent annually in the United States providing care for these unfortunate children (Stratton *et al.*, 2000).

Immunocompromised Patients

Infections form the commonest single cause of death in allograft patients. In bone marrow recipients, the single most important infection is CMV, responsible for approximately 15% of mortality before antiviral treatment became available. In recipients of solid organ transplants, several investigators report this virus to be a major cause of morbidity and mortality, with an annual cost of \$1 billion in the United States (Stratton *et al.*, 2000). In an analysis of hospital charges, CMV disease significantly increased costs, showing that if the expense of extra days spent in hospital is taken into account then prevention of CMV disease should potentially be cost-effective (Kim *et al.*, 2000). Philosophically also, it would seem sensible for health services to want to prevent CMV disease if this can be done at reasonable cost, since their investments in high technology transplantation are wasted if the procedures are effective but patients die from complications.

Prevention of Transmission

Knowledge of the potential routes of CMV transmission raises the possibility of prevention by interruption of infection. For example, seronegative renal allograft recipients could be matched to receive only kidneys from seronegative donors. Retrospective analysis by means of life-table survival curves has shown that CMV matching has a greater effect on the survival of cadaver kidney recipients than does matching the same patients for HLA Class I status. However, CMV re-infection from the donor kidney has also been shown to cause disease, albeit at a rate lower than that found after primary infection (Grundy *et al.*, 1988). If seronegative kidneys were reserved for seronegative recipients then more infected kidneys would be given to seropositive recipients and matching for other characteristics, such as HLA, might be prejudiced. Clearly, a controlled trial of the potential benefits of matching would be required before it could be justified as a clinical routine. While there is no doubt that matching could reduce morbidity and mortality due to CMV, there is equal concern that even greater morbidity and mortality due to graft rejection could result from a policy of matching for CMV. Put bluntly, patients and

their relatives would not thank us for merely substituting one specific cause for another on the death certificate.

A counsel of perfection is to give only CMV-seronegative blood or blood products to all pregnant women, all neonates and all immunocompromised patients, including those with AIDS. Alternatively, in-line filters should be used to remove leukocytes during blood transfusion, since this has been shown to reduce CMV transmission in a special-care baby unit (Gilbert *et al.*, 1989).

Transmission could theoretically be reduced in the general population by advising women of childbearing age to avoid salivary or sexual contact with seropositive consorts and children, but this clearly would be unpopular. There is no evidence that testing individuals serologically would add to the general advice given about avoiding exposure.

Pre-exposure Immunization

This strategy allows CMV exposure to occur but immunizes the recipients beforehand, in the hope of preventing disease. Several vaccine candidates have undergone Phase I clinical testing (reviewed in Schleiss and Heineman, 2005). These include recombinant soluble glycoprotein B, canarypox or alphavirus vectors expressing gB or pp65, as well as recombinant live attenuated Towne strains incorporating the novel genes from the Toledo strain. The recombinant soluble gB (with MF59 adjuvant) induced neutralizing antibodies in seronegatives and boosted the neutralizing titre in seropositives. The canarypox-gB did not induce neutralizing antibodies, although it primed volunteers to respond to subsequent challenge with the Towne strain. The canarypox-pp65 induced CMI in seronegatives. It thus appears that we have several candidate vaccines which are immunogenic and safe and so we should consider how they could be evaluated for efficacy.

In the past, vaccinologists assumed that efficacy would have to be proved by reducing the rate at which neonates

were born with symptomatic congenital CMV to mothers given vaccine or placebo many years earlier. The practicalities, logistics and expense of conducting such studies are prohibitive. However, modern virology can now be employed in distinct patient populations to determine whether a vaccine protects against primary infection and can provide immunological control against high viral loads (see Table 8.9). In the author's view, a vaccine which could protect one population of women and/or one population of transplant patients should be licensed for routine immunization (e.g. of teenagers) with post-marketing active surveillance used to document the anticipated reduction in symptomatic congenital CMV infection. As shown in Figure 8.14, herd immunity works by reducing the number of infectious individuals in a population and so should reduce both primary infections and re-infections. Since the basic reproductive number (i.e. the number of people who become infected from one infectious individual) for CMV is only 2.5, a vaccine with only 60% protective efficacy against primary CMV infection could be used to eradicate this infection from communities (Griffiths *et al.*, 2001). Certainly, there are no fears that widespread introduction of such a vaccine could affect herd immunity and so shift the incidence of primary infection into the childbearing years, because the average age at which CMV is acquired in developed countries is already greater than the average age at pregnancy (Griffiths *et al.*, 2001). Furthermore, the USA Institute of Medicine report should provide a strong financial incentive for the necessary studies to be performed, because their economic analysis shows a cost saving of \$50 000 for each quality-adjusted life year gained by a hypothetical vaccine which costs \$360 million to develop (Stratton *et al.*, 2000). At the time of writing, Dr Pass's study of gB vaccine with MF59 has shown protection against primary infection. Publication of the full report of this landmark study will undoubtedly provide support for the concept of universal immunization against CMV.

Table 8.9 Populations in whom efficacy of CMV vaccines could be evaluated using virological end points

Populations given vaccine/placebo	Outcome
Seronegative workers at day-care centres	Reduced primary CMV infection
Seronegative women with children at day-care centres	
Seronegative pregnant women immunized post-partum ^a	
Seronegative teenagers ^a	
Seronegative or seropositive patients on waiting list for receipt of solid organs ^a	Reduced CMV viraemia/need for pre-emptive therapy
Seronegative or seropositive donors of bone marrow to seropositive recipients	

^aindicates clinical trials currently underway.

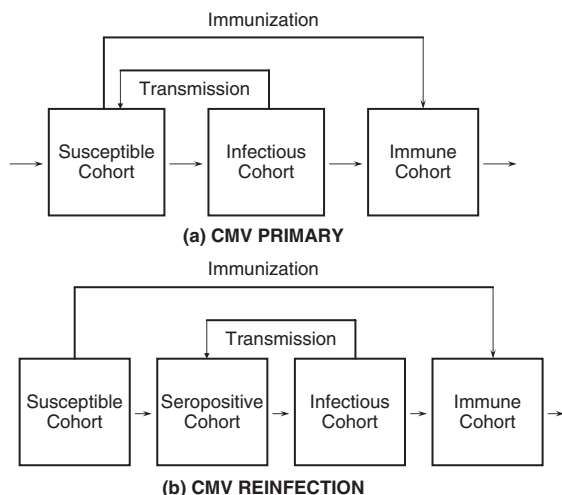

Figure 8.14 How vaccines should protect populations from (a) primary CMV infection; (b) CMV re-infection.

The live attenuated Towne strain of CMV vaccine reduced the severity of disease in seronegative recipients given seropositive kidneys (Plotkin *et al.*, 1991). Nowadays we would interpret this as evidence that the vaccine reduced the peak viral load. It could not prevent re-infection of the recipients with a different strain of CMV but no evidence was found of reactivation of Towne vaccine virus when the patients were immunosuppressed.

Homosexual men are at greater risk of acquiring CMV infection than are heterosexual men and could be considered as candidates for the assessment of the efficacy of CMV vaccines. However, most are already seropositive and so studies would have to address the question of whether vaccination could prevent recurrent infection in this group (immunotherapy). Vaccines could also be investigated for immunotherapy in patients receiving allografts. Clearly, attempting to present T-cell epitopes may be difficult because the patients would receive drugs such as cyclosporin in order to suppress these responses. However, one could aim to present B-cell epitopes with the hope of boosting the humoral immune response to keep the CMV load below that required to cause disease. In the case of bone marrow transplantation, immunization of the donor prior to marrow harvest may potentially lead to adoptive transfer of immunity to the recipient.

Passive T-cell immunotherapy has also been evaluated after bone marrow transplantation. Donor cells are expanded *in vitro* and passively administered to recipients. The clinical results show that the cells persist in recipients, and controlled trials to evaluate protective efficacy are required.

TREATMENT

The drugs GCV, foscarnet, cidofovir and fomivirsen (intravitreal only) have been licensed for serious or life-threatening CMV infections in immunocompromised patients, while valaciclovir is licensed only for prophylaxis. Note that fomivirsen and oral GCV are no longer marketed. GCV is phosphorylated by the product of the UL97 gene of CMV (Sullivan *et al.*, 1992) and then the triphosphate acts to inhibit virion DNA polymerase (UL54). Cidofovir is a phosphonate compound which is structurally analogous to a nucleoside monophosphate. It does not require activation by UL97 but is converted to the diphosphate (structurally analogous to a nucleoside triphosphate) by cellular enzymes, and then inhibits UL54. Foscarnet is a low-molecular-weight analogue of the inorganic pyrophosphate product of DNA polymerase activity and so acts at a different site and does not require prior anabolism. Foscarnet and cidofovir must be administered by intravenous infusion; GCV can now be given orally by means of the valganciclovir prodrug, which is absorbed and cleaved in gastrointestinal cells to release GCV. This prodrug offers the potential of administering GCV without the need for intravenous infusion (which is clinically important for a drug which causes neutropenia). However, clinical studies are required in each patient population to show that the drug is bioavailable. This has been done for liver transplant patients (Pescovitz *et al.*, 2000) and bone marrow transplant patients (including those with gastrointestinal graft-versus-host disease). GCV produces neutropenia, which may be dose-limiting. In animal toxicology studies, GCV has a cytostatic effect on the testis; the clinical significance of this for humans is unknown. Foscarnet is nephrotoxic, although this effect can be reduced by large volumes of normal saline. Foscarnet also affects ionized calcium levels and produces a fixed drug eruption on the skin of the genital area. Cidofovir is nephrotoxic and it is important that patients are hydrated and receive probenecid to decrease renal concentrations of drug.

Maribavir is a drug in Phase III development which directly inhibits UL97. To date, mutations in CMV UL97 selected with this drug do not give cross-resistance to GCV, but this is a subject which must be kept under review (Chou *et al.*, 2007).

Strategies for Deploying Antiviral Drugs

Based on the different stages of pathogenesis shown in Figure 8.6, four distinct treatment strategies can be envisaged for CMV (see Table 8.10). While these strategies have been evaluated formally in transplant patients, it is disappointing that they have only recently been applied to the design of studies in AIDS patients.

Table 8.10 Strategies for deploying chemotherapy against CMV

Term used	When drug given	Risk of disease	Acceptable toxicity
Prophylaxis	Before active infection	Low	None
Suppression	After peripheral detection	Medium	Low
Pre-emptive therapy	After systemic detection	High	Medium
Treatment	Once disease apparent	Established	High

Prophylaxis

This approach is to give a drug active against CMV from the time of transplant, and Table 8.11 lists the double-blind, randomized, placebo-controlled trials which have been conducted to date of such prophylaxis. GCV, the most potent drug *in vitro*, has been subjected to the rigours of several such trials but the other two licensed drugs, foscarnet and cidofovir, have not. In addition, Table 8.11 shows that interferon- α (IFN α), ACV, valaciclovir and immunoglobulin have also been studied, although many physicians do not associate these therapies with anti-CMV activity.

The results summarized in Table 8.11 show that GCV has consistently demonstrated activity against CMV infection in all patient groups. It also reduced CMV disease in most groups, with some discrepancies which require discussion. After bone marrow transplant, GCV had a strong trend towards protection, which was significant in one study (Goodrich *et al.*, 1993) but failed to reach statistical significance in a second (Winston *et al.*, 1993). After heart transplant, GCV had a significant effect in seropositive recipients (Merigan *et al.*, 1992) but not primary infections in one study, while the opposite was seen in another (Macdonald *et al.*, 1995). Note that GCV prophylaxis after bone marrow transplantation had no significant effect or even a trend in favour of survival; presumably, the drug-induced neutropenia facilitated bacterial and fungal infections, to which the patients succumbed (Goodrich *et al.*, 1993; Winston *et al.*, 1993). This illustrates the principle in Table 8.10, that prophylaxis exposes all patients to the risk of side effects and so should only be contemplated when a drug has no serious toxicity. In patients with AIDS, a trial of oral ganciclovir (oGVC), 1 g t.d.s., versus placebo was termed prophylaxis because patients did not have CMV disease at trial entry (Spector *et al.*, 1996). Note that this is not virological prophylaxis as defined in Table 8.10. Nevertheless, PCR data show that the greatest effect of GCV was seen when it was given prophylactically, because the drug had less effect in those who were already PCR-positive at trial entry.

The results in Table 8.11 also show that IFN α , ACV and valaciclovir each had anti-CMV effects *in vivo*, whereas there was no evidence of anti-CMV activity

of immunoglobulin. This suggests that, if immunoglobulin does have clinical benefit against CMV disease, this is provided by interference with secondary phenomena rather than CMV itself. Note that the anti-CMV effect of ACV is clinically important; indeed, ACV is the only antiviral drug shown to improve survival when used for prophylaxis after bone marrow transplantation, presumably because its modest antiviral activity is not offset by bone marrow toxicity, as is the case with GCV. A randomized comparison of prophylaxis with ACV or GCV after liver transplant (not included in Table 8.11) shows GCV to be superior in controlling CMV disease (Winston *et al.*, 1995), illustrating that the toxicity of GCV is less prominent if bone marrow is not the organ being transplanted.

Early Treatment of Active Infection

Where allograft recipients are monitored closely to detect active CMV infection at the earliest possibility, trials have been conducted to determine whether early intervention with antiviral drugs can provide clinical benefit. There are two main approaches: *suppression*, where the drug is given after CMV has been detected at a peripheral site, such as in urine or in saliva; and *pre-emptive therapy*, where CMV is detected systemically, either from blood or the lung sampled by bronchoalveolar lavage. The collection of the latter sample is predicated on the immunopathological nature of CMV pneumonitis, so that therapy is directed at early virus replication before disease has become established. Both approaches have produced clinical benefit (see Table 8.12). In particular, the study of GCV in bone marrow transplants by Goodrich *et al.* 1991 showed this drug was literally life-saving when used in pre-emptive mode, in contrast to its lack of effect on mortality when used prophylactically (Goodrich *et al.*, 1993; Winston *et al.*, 1993). Again, the principles summarized in Table 8.10 are prescient, showing that the toxicity of drugs for particular organs is as relevant as their antiviral potency, and that survival benefit can be achieved when the number of patients exposed to a toxic drug can be kept low by using laboratory markers to target therapy to individuals. The results in Table 8.12 also show that where GCV was compared to placebo or observation it

Neonates	Urine	Culture	100	Observation	GCV	NG	Reduced	Same	Kimberlin <i>et al.</i> (2003)
					6 mg kg ⁻¹ b.d 6 wk				

BMT_x, bone marrow (or stem cell) transplant; BrW, bronchial washings; LT_x, liver transplant; GCV, ganciclovir; oGCV, oral ganciclovir; d, days; w, weeks; NG, not given; CCC, conventional cell culture; DEAFF, detection of early antigen fluorescent foci; PCR, polymerase chain reaction; Ag, antigenaemia; Fos, foscaet.

Table 8.13 Comparison of the proposed advantages of prophylaxis and pre-emptive therapy

Proposed advantages of prophylaxis	Proposed advantages of pre-emptive therapy
Proven benefit of controlled clinical trials	Target resources on patients most at need (financial, skill)
<ul style="list-style-type: none"> • CMV disease • Indirect effects 	
Avoids complicated logistical problems	Treat when viral load lower
<ul style="list-style-type: none"> • Real-time laboratory assays • Organization of sample collection • Geographical location 	<ul style="list-style-type: none"> • Shorter treatment • Reduced recurrences? • Reduced resistance?
Protects against HSV, VZV	Allows low-level stimulation of immunity—reduces late-onset disease?
Overall, may be more cost-effective	Protects patients noncompliant with prophylaxis
<ul style="list-style-type: none"> • Cost of laboratory tests • Indirect effects of CMV • Other herpesviruses 	
	May also reduce indirect effects

usually produced less CMV disease, often accompanied by a survival benefit. In contrast, where GCV was compared to another effective management, such as foscarnet or prophylaxis with GCV, no significant benefit was seen. The results in Table 8.12 thus provide the evidence that GCV and foscarnet are each effective anti-CMV compounds, that they can be given in combination (each at half dose) to minimize toxicity but do not show synergy *in vivo*, and that pre-emptive therapy and prophylaxis are each effective for preventing CMV disease. Each of these strategies has its advantages and disadvantages (see Table 8.13) and decisions about which to choose should be made locally and supported by continuing audit of what should now be a low incidence of CMV disease in transplant patients, for example 1–2% compared to approximately 15% before treatment became available (Singh, 2006; Snyderman, 2006).

This conclusion, that prophylaxis and pre-emptive therapy are both effective ways of controlling CMV disease, is supported by the results of a recent, randomized trial which compared both strategies directly in renal allograft recipients (Khoury *et al.*, 2006). Late-onset CMV disease developed once valganciclovir prophylaxis was stopped, but such late-onset disease was not seen with pre-emptive therapy. Importantly, there were no significant differences in the incidence of CMV disease or in indirect effects such as bacterial infections or graft rejections between the two strategies.

In contrast, although pre-emptive therapy should be an effective strategy in AIDS patients, there is no evidence for this because controlled trials were not conducted

to address the possibility. However, the PCR data at trial entry from a ‘prophylaxis’ trial in AIDS patients (Feinberg *et al.*, 1998) of valaciclovir versus doses of ACV shown in two previous randomized, double-blind, placebo-controlled trials to be ineffective against CMV disease, can be interpreted to show that this drug worked best for pre-emptive therapy (Griffiths *et al.*, 1998). This interpretation was initially controversial but is now supported by natural history studies from three separate research groups, showing that PCR viraemia identifies AIDS patients at high risk of imminent CMV disease. Although HAART has revolutionized the prognosis of AIDS patients, cases of CMV disease still occur in developed countries, for two reasons. First, many individuals are unaware that they are infected with HIV and present with AIDS-defining conditions including CMV. Second, some patients have progressive HIV disease despite having tried all available antiretroviral compounds. In this latter group, a randomized placebo-controlled trial of pre-emptive therapy with valganciclovir has been conducted by the AIDS Clinical Trial Group (Protocol 5030), triggered by the detection on a single occasion of CMV DNA in plasma (Wohl *et al.*, unpublished). This is the first trial to apply the concepts of CMV pathogenesis learned from transplant patients to the parallel group of patients immunocompromised by HIV, but recruitment was difficult because of the availability of new HAART options. This underpowered study did not provide any evidence to support the use of pre-emptive therapy in AIDS patients. In addition, it is known that the institution of HAART in a patient with asymptomatic CMV

viraemia leads to prompt resolution of viraemia (Deayton *et al.*, 1999), so that HAART can be thought of as a form of pre-emptive therapy, analogous to reducing the dose of immunosuppressive drugs in a transplant patient with CMV infection.

Treatment of Established Disease

The treatment of an established disease is the most difficult strategy to pursue successfully, since the virus may trigger pathological phenomena unresponsive to antiviral drugs and because extensive tissue damage is often followed by target organ failure and secondary opportunistic agents, which present their own management problems. It is thus salutary to note that, in contrast to the proven benefits of prophylaxis and pre-emptive therapy, no double-blind randomized placebo-controlled trial of anti-CMV therapy in established CMV disease has demonstrated that treatment at this late stage can provide a clinical benefit (see Table 8.14).

One trial reported that GCV and foscarnet are equipotent for the treatment of CMV retinitis in AIDS patients, but that foscarnet is associated with a significant survival benefit (Studies of Ocular Complications of AIDS Research Group, in collaboration with the AIDS Clinical Trials Group, 1992). Although foscarnet should thus be considered the treatment of choice under these circumstances, the difficulties with intravenous administration, toxicity and cost of foscarnet usually lead clinicians to prescribe GCV instead. This illustrates that the drugs available at present for the treatment of CMV are far from ideal, so the development of safe, orally bioavailable drugs is eagerly awaited. Note also that a randomized trial in AIDS patients showed that the combination of GCV plus foscarnet was superior to either drug given alone (Studies of Ocular Complications of AIDS Research Group ACTG, 1996). In the absence of evidence for synergy between these two drugs *in vivo* against CMV (Mattes *et al.*, 2003), this outcome is best interpreted as the earliest example of combination antiretroviral therapy providing a transient clinical benefit against an opportunistic infection (because foscarnet also inhibits HIV).

The management of established CMV retinitis is complex, with multiple therapeutic options, including intravitreal injections of antiviral compounds as well as intraocular implantation of a device which slowly releases GCV into the vitreous fluid.

These therapeutic options have frequently been evaluated by recruiting patients with peripheral retinitis which is not immediately sight-threatening and randomizing them to immediate therapy versus therapy with the same drug delayed until progression of retinitis has been observed (reviewed in Thorne *et al.*, 2007).

Note that CMV lung infection in AIDS patients is not routinely treated because of the theory that they do not mount the cell-mediated response required for immunopathology, and because cohort studies in the pre-HAART era showed no excess mortality among patients with *Pneumocystis carinii* pneumonia who were co-infected with CMV. CMV pneumonitis in allograft patients is treated with immunoglobulin in addition to GCV because components of the preparation may possibly block the hypothesized immunopathological response to target antigens in the lung.

CMV strains resistant to GCV, to GCV plus foscarnet, or to GCV plus foscarnet plus cidofovir, have been described in AIDS and transplant patients (Chou *et al.*, 2005). Genetic changes in UL97 usually confer low-level resistance to GCV. Continued selective pressure may select for UL54 mutants, some of which are cross-resistant to cidofovir. Rare mutations in UL54 can confer resistance to both GCV and foscarnet (Chou *et al.*, 2005). Based on knowledge of the replication dynamics of CMV, it was predicted that CMV resistance was a greater problem than had been appreciated in the past and would be found in individuals with high-level replication receiving partially-effective antiviral prophylaxis for a long time, for example more than 100 days (Emery and Griffiths, 2000).

Clinical studies in transplant patients confirm this prediction and suggest that approximately 15–25% of patients with CMV disease in transplant (Limaye *et al.*, 2000) and AIDS patients in the pre-HAART era (Bowen *et al.*, 1996; Hu *et al.*, 2002) have ganciclovir-resistant strains.

When HAART is introduced in a patient with established CMV retinitis, an inflammatory reaction may occur, leading to vitritis, which often impairs vision more than the underlying retinitis. This pathological interaction between CMV and the immune system might be avoided if CMV retinitis were prevented by using pre-emptive therapy. Interestingly, no exacerbation or reduction of any other CMV disease has been observed with HAART, whereas an increase in CMV pneumonitis should be expected if the condition is immunopathologically mediated. In patients receiving GCV maintenance therapy for CMV retinitis, this can be stopped once the CD4 count and HIV viral load have responded to HAART for more than three months.

To summarize the main evidence base for treatment, different strategies have been described, with advantages and disadvantages for different groups of patients. For transplant patients, several strategies are available, and which is chosen by a particular unit will depend upon clinical preference and the laboratory support available (Bowen *et al.*, 1996; Emery, 2001; Hart and Paya, 2001)

Table 8.14 Randomized controlled trials of therapy for established CMV disease

Patient group affected	Drug 1	Drug 2	Planned duration of therapy (d)	No. of patients		Significant markers of efficacy reported				References	
				Drug 1	Drug 2	Reduced viraemia	Reduced excretion	Reduced disease	Reduced dissemination		Increased survival
BMT _x Upper gastrointestinal tract (GIT)	GCV 2.5 mg kg ⁻¹ t.d.s.	Placebo	14	18	19	No	Yes	No	No	No	Reed <i>et al.</i> (1990)
AIDS Retina	GCV 5 mg kg ⁻¹ b.d. 14 d then o.d.	Foscarnet 60 mg kg ⁻¹ t.d.s. 14 d then 90 mg kg ⁻¹ o.d.	14; induction then maintenance	127	107	ND	ND	No	No	Yes	Studies of Ocular Complications of AIDS Research Group Dieterich <i>et al.</i> (1993)
AIDS Lower GIT	GCV 5 mg kg ⁻¹ b.d. 14 d then o.d.	Placebo	14	32	30	No	Yes	No ^d	Yes	No	Studies of Ocular Complications of AIDS Research Group ACTG (1996)
AIDS Retina (relapsed or active retinitis despite maintenance)	GCV 5 mg kg ⁻¹ b.d. 14 d then 10 mg kg ⁻¹ o.d. or foscarnet 90 mg kg ⁻¹ b.d. 14 d then 120 mg kg ⁻¹ o.d.	GCV plus foscarnet: continue existing maintenance dose, add induction dose of second drug for 14 d. For maintenance: GCV 5 mg kg ⁻¹ o.d. foscarnet 90 mg kg ⁻¹ o.d.	Life	183	96	ND	ND	Yes	ND	No	Studies of Ocular Complications of AIDS Research Group ACTG (1996)

BMT_x, bone marrow transplant; GCV, ganciclovir; GIT, gastrointestinal tract; ND, not determined; ^dintention to treat analysis, but Yes in subsidiary analysis.

(Table 8.13). However, such patients should clearly be managed by one of the proactive strategies (prophylaxis or pre-emptive therapy), since it would be unethical to continue to allow the natural history of CMV disease in these patients to proceed unchecked in the face of overwhelming benefit demonstrated in controlled clinical trials. Similar principles can be applied to AIDS patients and congenitally-infected infants, but much less evidence is available to date.

Epstein–Barr Virus

Tanzina Haque¹ and Dorothy H. Crawford²

²*School of Biomedical and Clinical Laboratory Sciences, The University of Edinburgh, Summerhall, Edinburgh, UK*

INTRODUCTION

The discovery of Epstein–Barr virus (EBV) in 1964 resulted from the description by Denis Burkitt of a geographically-restricted tumour occurring in African children (Burkitt, 1958). The tumour, which characteristically arises in the jaw, is now known to be of B-lymphocyte origin and is called Burkitt's lymphoma (BL). Burkitt noticed that the geographical distribution of the tumour in Africa corresponded to that of holoendemic malaria, and was determined by the climatic conditions (high temperature and high rainfall) in which the malaria-carrying mosquito can breed. Because of this observation, Burkitt suggested that the tumour had an infectious aetiological agent for which the mosquito was the vector. This hypothesis led to electron microscopic studies on fresh tumour biopsy material, but this technique was unrewarding. Later, cell lines were grown in suspension culture from BL tumour material (Epstein and Barr, 1964) and in these cells virus particles were seen (Epstein *et al.*, 1964). Further studies showed this to be a new and distinct member of the herpesvirus group. Thus Burkitt's initial postulate of an infectious agent being involved in the aetiology of the tumour proved to be correct, and, although the mosquito does not play the role of vector for the virus, the association with hyperendemic malaria remains an important and constant finding.

Seroepidemiological studies have since shown that the virus is a ubiquitous agent; seropositivity increases with age in all communities studied, so that over 90% of adults worldwide are seropositive. When carrying out these studies, Henle and Henle (1966) made the observation that

a member of their staff seroconverted while undergoing an attack of acute infectious mononucleosis (IM). Further studies on college students in collaboration with Yale University proved that EBV is the sole aetiological agent in IM (Niederman *et al.*, 1970).

Since its discovery, EBV has been associated with a variety of other lymphoid and epithelial tumours. Early seroepidemiological and molecular studies pinpointed an association between EBV infection and anaplastic nasopharyngeal carcinoma (NPC) (Old *et al.*, 1966; Wolf *et al.*, 1973), a geographically- and genetically-restricted tumour which is very common in southern China. Other EBV-associated tumours include the lymphoproliferative lesions and lymphoma which develop in immunocompromised individuals (Crawford *et al.*, 1980), certain types of T-cell lymphoma (Jones *et al.*, 1988), a subset of Hodgkin's lymphoma (Anagnostopoulos *et al.*, 1989), as well as a minority of gastric carcinomas (Tokunaga *et al.*, 1993). The benign epithelial lesion of oral hairy leukoplakia (OHL) also contains replicating EBV (Greenspan *et al.*, 1985).

THE VIRUS

Structure

EBV is a DNA virus, which is a member of the *Herpesviridae* family, subfamily *Gammaherpesvirinae*, genus *Lymphocryptovirus*, showing a structure indistinguishable from other human herpesviruses by electron microscopy. It is a large virus with a buoyant density in

Figure 9.1 Electron micrograph of the thin section of cells from an EB virus-immortalized lymphoblastoid cell line (M-ABA). Arrows indicate (a) immature virus particles and (b) enveloped virus particles (x 39 000).

caesium chloride of 1.2–1.3 and a molecular weight of 100×10^6 Da. The central nucleic acid of the virion is surrounded by an icosahedral capsid consisting of 162 triangular capsomeres and measuring 100 nm in diameter (Figure 9.1). This, in turn, is surrounded by an outer, irregularly-shaped, lipid-containing envelope giving the mature particle a diameter of 150–200 nm. The viral envelope is derived from cellular membranes of infected cells and, like other herpesviruses, is believed to be acquired at the final envelopment sites in the *trans*-Golgi network (Mettenleiter *et al.*, 2006). The envelope is essential for infectivity, and the sensitivity of the virus to ether and other lipid solvents results from its destruction.

The Viral Genome

In the virion the EBV genome is a linear double-stranded DNA molecule 172 kb in length (De Jesus *et al.*, 2003). Structurally, the genome consists of alternating unique and internal tandem repeat regions flanked by terminal

repeat (TR) sequences (Figure 9.2). The genome sequence shows around 85 predicted open reading frames (ORFs), which are designed by a four-letter and one-number acronym; for example, BZLF1 refers to the first leftward ORF of the Bam H Z fragment of the genome (Baer *et al.*, 1984). Two strains of EBV have been defined—type 1 and type 2 (alternatively named A and B), which differ at the domains which code for the Epstein–Barr viral latent proteins. Although these types show no specific geographical restriction, in Western countries type 1 virus is more commonly isolated than type 2. *In vitro* type 1 viruses are more efficient at transforming B lymphocytes than type 2; however, neither type has a specific disease association. Variation within types occurs in the number of repeat sequences in each internal repeat, making it possible to define specific isolates by the size of their latent genes and/or their products. Analysis of these genes can therefore be used in epidemiological studies to monitor virus transmission within families or populations.

Following infection of B lymphocytes *in vitro*, EBV establishes a latent type of infection with blast transformation of the cell and a restricted (latent) viral gene expression compatible with continued cell proliferation. The viral genome does not usually integrate into cellular DNA but forms a closed circular episome by covalent linkage of the TR elements. The episome replicates to give multiple copies shortly after infection and thereafter resides in the nucleus and replicates with cellular DNA, with equal partitioning to daughter cells allowing the copy number per clone to remain constant. These episomal forms can be activated to a lytic infection with the release of multiple viral progeny and cell death.

Viral-coded Proteins and Transcripts

The viral genome is large enough to code for around 85 average-sized proteins, but not all of these have been identified and assigned to ORFs on the viral genome. Nine viral-coded proteins are expressed in latently-infected cells (Table 9.1; Figure 9.2) in addition to the classical herpesvirus immediate-early, early and late proteins associated with the lytic infection. The EBV genome also codes for two small RNAs (EBV-encoded RNAs, EBERs) which form abundant transcripts but are untranslated. EBERs may play a role in tumorigenesis as they confer resistance to interferon α -induced apoptosis in BL cells by inhibiting phosphorylation of RNA-activated protein kinase (Nanbo *et al.*, 2002). They also induce expression of interleukin (IL)-10 in BL cells (Kitagawa *et al.*, 2000). In addition, a complex series of highly-spliced transcripts from the Bam A region (BART transcripts) of the genome are found in latently-infected cells, but their function remains unclear. Recently, several microRNAs have been identified in the Bam A region of the genome and it is

Table 9.1 EBV-coded latent proteins and latent transcripts in different diseases

Antigens/transcripts	Expressed in

EBNAs 3A, 3B, 3C are also termed EBNAs 3, 4 and 6, respectively. Leader protein (LP) is also termed EBNA5. LMPs 2A and B are also termed terminal protein 1 and 2.

IM, infectious mononucleosis; BL, Burkitt's lymphoma; NPC, nasopharyngeal carcinoma; HD, Hodgkin's disease; PTLD, post-transplant lymphoproliferative disease; NK, natural killer; EBERs, EBV-encoded RNAs; BARTs, Bam H1 A transcripts.

Figure 9.2 Linear map of the EBV genome, showing the open reading frames for the major latent proteins.

postulated that these may have roles in the regulation of host and viral gene expression (Pfeffer *et al.*, 2004).

Latent Proteins

(Reviewed by Young and Murray 2003.)

EB Viral Nuclear Antigens (EBNAs)

EBNAs were first detected by anticomplementary immunofluorescence in the nuclei of latently-infected EBV transformed B cells (Reedman and Klein, 1973), and subsequently identified as six separate proteins (EBNA1, 2, 3A, 3B, 3C and leader protein (LP) (also called

EBNA1–6)) which are translated from a long polycystronic mRNA by alternative splicing (Table 9.1).

EBNA1 is coded by the Bam K ORF and characterized by a 20–45 kDa glycine–alanine (gly-ala) repeat sequence which varies in length, causing the molecular weight of the protein to vary between viral isolates (65–85 kDa). The protein binds to the viral origin of replication and to metaphase chromosomes, thereby accounting for EBV episomal maintenance within the infected cell and equal partitioning into daughter cells at cell division. EBNA1 is essential for *in vitro* transformation of B cells, and mice expressing EBNA1 as a transgene in B cells have been reported to develop lymphoma (Wilson *et al.*, 1996). It has been postulated that EBNA1 may have anti-apoptotic

Figure 9.3 A photomicrograph of cells from an EB virus transformed adherent lymphoblastoid cell line (MABA) stained for EBNA. Bright nuclear fluorescence is seen in all cells. The cells are counterstained with Evans Blue ($\times 70$).

function in normal and tumour cells (Kennedy *et al.*, 2003).

EBNA2 is an 86-kDa protein which is coded for by the Bam WYH ORFs. Expression of *EBNA2* is essential for B-cell transformation and the protein plays a pivotal role in this event by transactivating all the other latent viral genes. In addition, *EBNA2* activates cellular genes including the B-cell activation and proliferation antigens CD21 and CD23, and the proto-oncogenes *c-myc* and *c-fgr*. *EBNA2* also upregulates BLR2/*EB11*, a G-protein-coupled receptor gene that plays a role in lymphocyte trafficking. *EBNA2* does not directly bind DNA and provides transcriptional regulation by interacting with cellular DNA-binding proteins such as retinoblastoma protein- κ and PU.1 (Johannsen *et al.*, 1995).

EBNA3A, *EBNA3B* and *EBNA3C* are a family of related proteins coded for by the BERF ORF, with molecular weights of 140–180 kDa. All three proteins inhibit transcriptional activation of *EBNA2*-responsive genes, thereby counterbalancing the action of *EBNA2*. However, only *EBNA3A* and *EBNA3C* are essential for transformation of B cells.

EBNA-LP is coded for by the BWRFL1 ORF, which also forms the leader sequence of the *EBNA* RNAs. Because of multiple repeat regions in the DNA, *EBNA-LP* varies in size from 20 to 130 kDa. The protein is not absolutely essential for transformation but enhances the *in vitro* growth of infected B cells by complementing the growth-promoting effects of *EBNA2*.

Latent Membrane Proteins (LMPs)

LMP1 is coded for by the BNLFL1 gene, and its expression is induced by *EBNA2*. BNLFL1 is the most abundantly transcribed region of the genome in latently-infected cells. The protein is mainly located in the plasma membrane of infected cells, where it associates with the cytoskeleton. Structurally, *LMP1* has six membrane-spanning domains, with both the amino and carboxy termini in the cytoplasm. *LMP1* is essential for the transformation and continued proliferation of B cells and induces a tumorigenic phenotype on transfection into rodent fibroblasts (Wang *et al.*, 1985). When transfected in B cells, *LMP1* upregulates expression of the cell-adhesion molecules, CD23 and CD40, inducing B-cell activation and DNA synthesis (Wang *et al.*, 1990). These changes mimic those seen following CD40-mediated B-cell activation, many of which, in both cases, are mediated by tumour necrosis factor receptor-associated factor (TRAF)-signalling molecules and the transcription factor NF κ B. The amino terminus is essential for these effects, and a truncated form of *LMP1* lacking this region, which is expressed in lytic infection and located in the viral envelope, lacks these properties. When transfected into squamous epithelial cell lines, *LMP1* induces the membrane receptor molecules CD40 and the epidermal growth factor receptor and inhibits terminal differentiation processes.

Sequence analysis of the *LMP1* gene in EBV isolates from different tumours and geographical locations has

identified a common 30-bp deletion in the C terminus as well as several point mutations when compared to the prototype genome. However, these have not been associated with increased oncogenicity.

LMP2A and LMP2B (previously called terminal proteins 1 and 2) are formed by alternative splicing from an ORF which spans the TR sequences, and thus the intact gene is only formed and transcribed after the genome has circularized. Both are membrane proteins with 12-membrane spanning segments, but whereas LMP2A has an amino terminus of 119 amino acids, this is truncated in LMP2B. The amino terminus of LMP2A contains eight tyrosine residues, two of which form immunoreceptor-tyrosine-based activation motifs (ITAMs). These ITAMs interact with protein tyrosine kinases, leading to their degradation. This leads to blockade of B-cell-receptor (BCR) signal transduction and inhibits activation of lytic viral replication cascades. LMP2A thereby promotes cell survival and maintenance of viral latency (Miller *et al.*, 1995). LMP2B on the other hand is believed to exhibit a negative regulatory effect on LMP2A (Rechsteiner *et al.*, 2007).

Lytic Cycle Proteins

EBV lytic genes show extensive homology to those of other herpesviruses, and their expression similarly follows an orderly cascade, with the expression of each set being activated by the previous and inhibited by the following set. They are divided into immediate-early, early and late, according to whether they are transcribed before (immediate-early and early) or after (late) viral DNA synthesis.

Immediate-early genes. EBV possesses two genes that can be classified as immediate-early genes, BZLF1 (Z protein) and BRLF1 (R protein), which are activated in a latently-infected cell following BCR stimulation through cross-linking of surface immunoglobulin (Ig). Z and R proteins in turn transactivate the early genes, thereby leading to the switch from latent to lytic infection in B cells. R protein also activates viral DNA polymerase. Z protein can activate cell-cycle genes such as c-fos and human immunosuppressive cytokines such as IL-10 and tumour growth factor- β .

Early genes. First identified by the staining pattern of sera-containing antibodies to EBV when applied to the Raji cell line which lacks expression of the late genes, the early gene products (early antigens, EAs) were characterized as diffuse (D) (nuclear and cytoplasmic staining) and restricted (R) (nuclear staining) (Henle *et al.*, 1971). It is now known that there are around 30 early proteins,

most of which have enzyme functions required for viral DNA replication, including viral DNA polymerase and viral thymidine kinase. Some early gene products are involved in regulation of RNA transport and stability. BHRF1, an early lytic gene, is a homologue of the cellular anti-apoptotic gene, BCL-2, and the protein has a role in inhibition of apoptosis in EBV-infected cells.

Late genes encode viral structural proteins such as viral capsid antigen complex (VCA), tegument proteins and membrane proteins. These genes are transcribed and translated following lytic replication, thus allowing the linear viral genome to be packaged. The major capsid protein is coded for by the BcLF1 ORF. VCA can be detected by indirect immunofluorescence in around 10% of cells in a permissive cell line such as P3HR1 using an EBV-positive human serum. BCRF1, an EBV-late gene, codes for a homologue of human IL-10 which is important in immune evasion.

EBV Glycoproteins

The EBV-coded glycoproteins are involved in viral infectivity and spread. Ten have been identified, most of which are inserted into membranes in an infected cell, and several of these become components of the viral envelope (membrane antigens, MAs).

The major envelope glycoprotein gp340/220 is coded for by the BLLF1 ORF. The protein mediates virus attachment to the B-cell surface by binding to the EBV receptor CR2 (also called CD21). Antibodies to gp340/220 prevent infection by blocking attachment, and the protein has therefore been developed as a vaccine candidate.

gp85 is coded for by the BXLF2 ORF. It has homology to herpes simplex virus (HSV) glycoprotein gH and induces fusion between viral and cellular membranes. gp85 requires another glycoprotein, gp25 (homologous to HSV gL), for its transport to the cell surface. Here it forms a trimolecular complex with gp42 and gp25 which is also present in the viral envelope. The complex mediates B-cell infection by inducing fusion between viral and cellular membranes (gp85 and gp25) and viral penetration by binding to HLA class II molecules in the B-cell surface (gp42). gp42 is not required for infection of epithelial cells which are HLA class II negative (Borza and Hutt-Fletcher, 2002).

gp110 is coded for by the BALF4 ORF and has homology with the HSV glycoprotein gB. It is localized in nuclear and cytoplasmic membranes of infected cells but is not detected in the viral envelope.

Host Range and Growth *In Vitro*

The host range of EBV is limited to man, its natural host, and some subhuman primates, including the gibbon, owl monkey, squirrel monkey and some species of tamarin, all of which can be infected experimentally.

In humans only B lymphocytes are regularly infected by the virus and this restriction of infection is probably accounted for by their expression of CR2 (the receptor for the C3d component of complement, also called CD21), the cell-surface receptor used by EBV. A similar molecule found on a subpopulation of squamous epithelial cells may result in infection of these cells in the oropharyngeal cavity, although the extent and role of this infection in normal individuals is a controversial issue. Activated T cells and dendritic cells also express CR2 and may on rare occasions support EBV infection. A recent study suggests that monocytes/macrophages may become infected by EBV from B lymphocytes, migrate into the epithelium and spread virus to oral epithelial cells (Tugizov *et al.*, 2007).

EBV-induced B Cell Transformation and Immortalization

When EBV is used to infect B lymphocytes *in vitro*, cell activation occurs within 24 hours. Initially, small resting B cells undergo blastogenesis with an increase in HLA-DR expression, nuclear size and cytoplasmic volume, and the expression of B-cell-activation antigens on the cell surface. In particular, CD23 expression is reported to be essential for this so-called cellular transformation. DNA synthesis is initiated, followed by cell division, and around this time Ig can be detected in the cytoplasm of many infected B cells and is subsequently secreted into the culture medium; IgM always predominates. This latter finding indicates that EBV is a potent polyclonal activator of Ig production by B cells. These early changes seen in B cells after infection with EBV are similar to those seen after stimulation with other B-cell activators such as CD40 ligand. However, the polyclonal activation of B cells by EBV leads to transformation, which is a permanent rather than a transient event. Thus, once DNA synthesis is initiated, the cells will continue to proliferate in culture as EBV-positive B lymphoblastoid cell line (LCL). This phenomenon is also known as 'immortalization'.

EBNAs 2 and LP are the first viral antigens to be detected in infected B cells, followed by the expression of all the other EBNA. LMPs 1, 2A, 2B are expressed last, after the genome circularizes. This pattern of viral gene expression (EBNAs 1, 2, 3A, 3B, 3C, LP; LMPs 1, 2A and 2B) is seen in virtually all cells in an LCL and is termed full latent gene expression or latency type

3 (Table 9.1). Other forms of EBV latency include: EBNA1 only (latency 1), seen in BL cells; and EBNA1, LMP1, LMP2A (latency 2), seen in NPC and Hodgkin's disease (HD). EBERs and BART transcripts are present in all forms of latency (Table 9.1). Recently, a state referred to as latency 0 has been detected in peripheral memory B cells from seropositive individuals where only EBER transcripts are present without expression of latent proteins (Hochberg *et al.*, 2004).

Only a minority (<1–10%) of cells in an LCL at any one time enter a productive phase resulting in viral progeny and cell death. LCL derived from different sources show varying degrees of permissiveness for viral replication. Tamarin-derived cell lines are the most permissive with around 10% of lytically-infected cells, and the tamarin B cell line B95–8, which was originally transformed with IM-derived EBV, is used in most laboratories to obtain infectious virus for experimental purposes (Miller *et al.*, 1972). Virus production into the culture supernatant medium can be induced by the addition of tetradecanoylphorbol-13-acetate (TPA) and sodium butyrate (Luka *et al.*, 1979; zur-Hausen *et al.*, 1978, 1979). Another cell line which can be induced to produce high levels of EBV by the addition of antibodies to surface Ig is BL-derived Akata (Takada, 1984).

Handling of EBV in the Laboratory

EBV is used as a tool for transforming B lymphocytes *in vitro*, and EBV-positive cell lines, most of which produce small quantities of infectious virus, are grown in many laboratories for research purposes. The virus is of low infectivity, and no authenticated cases of primary infection contracted in the laboratory have been reported. EBV is classified as a hazard group 2 pathogen and therefore EBV-positive cell lines should be handled according to routine microbiological laboratory practice for this group.

EPIDEMIOLOGY

In seroepidemiological studies the presence or absence of IgG antibodies to VCA is generally used to determine past infection, since these antibodies arise early in primary infection and thereafter persist for life. UK results show that seropositivity increases with age, reaching a level of around 90% in adults. Two peaks of seroconversion occur, one between the ages of 1 and 6 years and the other at 14–20 years (Figure 9.4), with infection occurring later in high compared to low socio-economic groups. These findings are very similar to those from other countries in the Western world. In developing countries

Figure 9.4 Histogram analysis of IgG anti-VCA antibodies in sera from 1469 individuals. The percentage of seropositivity increases with age to a plateau of 92%.

seroconversion occurs early in life, with more than 90% of children over the age of two years being seropositive. Most seroconversions occur subclinically but if primary infection is delayed until adolescence or early adult life acute IM may result.

EBV Infection in the Normal Seropositive Individual

In most individuals primary infection occurs subclinically during childhood, and thereafter a lifelong carrier state exists in which a balance is maintained between the level of virus infection and the cellular and humoral immune mechanisms which keep the infection controlled. Continued low-grade virus shedding in the oropharynx can be found in most seropositive individuals and can be detected by the presence of viral DNA from saliva and throat washings. Furthermore, EBV DNA is present in around 1 in 10^6 circulating long-lived memory B cells, which evade immune surveillance mechanisms by expressing no or a very restricted number of latent genes. However, details of the exact gene expression in these cells have not been elucidated. Periodic reactivation of this latent B-cell infection into lytic replication in lymphoepithelial sites such as the tonsil, perhaps in association with B-cell activation/maturation processes, allows new virus production and replenishment of latently-infected cells, and egress from the body.

EBV-specific, HLA class I-restricted, CD4- and CD8-positive cytotoxic T cells (CTLs) are present in the circulation of all normal seropositive individuals and many latent and lytic T-cell epitopes have been identified. Thus a lifelong balance between virus infection and immune mechanisms is established which successfully controls the infection at subclinical levels in the healthy

host. However, if this balance is altered by intercurrent disease or iatrogenic means which cause a decrease in the specific immune response, EBV-associated disease may occur.

EBV-ASSOCIATED DISEASES

EBV is associated with several disease states, in some of which it is the direct aetiological agent whilst in others it acts as an essential cofactor in a complex series of events which lead to the disease. The EBV-associated tumours are shown in Table 9.2. IM is the result of primary infection, whereas BL and NPC occur in seropositive individuals as a result of a series of alterations in a cell type infected by EBV. OHL and lymphoproliferative lesions occur in seropositive individuals in whom immunosuppression has allowed the cell populations naturally harbouring the virus to expand.

EBV is also associated with a variety of other tumours, including subsets of T-cell lymphomas (Jones *et al.*, 1988), Hodgkin's lymphoma (Anagnostopoulos *et al.*, 1989) and carcinoma of the stomach (Imai *et al.*, 1994). Here the tumour cells harbour clonal viral DNA and express viral antigens, suggesting an aetiological association, whereas links with salivary-gland tumours (Raab-Traub *et al.*, 1991), thymomas (Leyvraz *et al.*, 1985) and leiomyosarcomas in immunodeficient children (Lee *et al.*, 1995) are more tenuous.

Infectious Mononucleosis

IM or glandular fever is an acute, self-limiting lymphoproliferative disease resulting from primary infection with EBV. It classically occurs in adolescents and young adults (aged 15–25 years) in Western societies where a susceptible seronegative population is present in this age group. A recent study among UK university students showed that 25% were EBV seronegative at the time of entering university, that 50% of these seroconverted while at university and that clinical disease occurred in 25% of these individuals while undergoing a primary infection. The remainder (in common with most individuals before adolescence) seroconverted without overt clinical illness (Crawford *et al.*, 2006). The disease is more common in upper socio-economic classes and in the Western world because these individuals have been relatively protected from infection during childhood. The incidence of the disease varies with differing demography and lifestyles, but since in both developing and industrialized countries the majority of those reaching the susceptible age for IM are already seropositive, classical outbreaks of the disease are uncommon.

Table 9.2 EBV-associated tumours.

Tumour	At-risk population	EBV association
Lymphoid origin		
B lymphoproliferative disease (BLPD)	Post-transplant—PTLD ^a	90%
	HIV ^b infection	
	Primary central nervous system lymphoma	<100%
	Peripheral lymphoma	50%
Burkitt's lymphoma (BL)	African children—endemic BL	97–100%
	HIV infection—sporadic BL	25%
Hodgkin's disease (HD)	Children—developing countries	Overall 65%, mixed cellularity type 80%, childhood 80%
	Young adults	
	High SE ^c groups	
	History of IM	
T/NK cell lymphoma	Chronic active EBV HIV infection	10–100%, depending on histological type
Primary effusion lymphoma	HIV infection	70–80%. 100% contain HHV8 ^d DNA
Non-lymphoid origin		
Nasopharyngeal carcinoma	S. Chinese and Inuit races—high incidence Malaysia, Indonesians Filipinos, Vietnamese—intermediate incidence	Undifferentiated 100%, nonkeratinized 100%, keratinized 30–100%
Gastric carcinoma	Not identified	Adenocarcinoma 5–15%
Leiomyosarcoma	HIV infection, immunodeficiency—mainly children	Not known

^aPTLD, post-transplant lymphoproliferative disease.

^bHIV, human immunodeficiency virus.

^cSE, socio-economic.

^dHHV8, human herpesvirus 8.

Other tumours with EBV associations: salivary gland tumours, breast carcinoma, thymoma.

Transmission

Detection of infectious EBV in multiple samples of saliva and throat washings indicates that oral excretion of the virus occurs for a prolonged period after IM and then either continuously or intermittently in most seropositive individuals. It is therefore assumed that primary infection occurs by the oral route, by close contact with a virus-excreting individual. Childhood infection probably occurs through salivary contact with family members or other children, whereas the peak of seroconversion in late adolescence, which coincides with the age at which new social contacts are often made, is likely to occur during kissing. However, EBV has also been rescued from the uterine cervix of a few IM patients and normal seropositive women (Sixbey *et al.*, 1986), and from semen from healthy males (Israele *et al.*, 1991), suggesting that sexual intercourse is a possible route of spread. This is backed up by recent data from a large study in university students showing a strong correlation between previous sexual intercourse and EBV seropositivity and IM (Crawford *et al.*, 2002), however these data do not exclude intimate kissing

associated with sexual intercourse as a means of transmission. EBV can also be acquired by transfusion of fresh blood or organ transplantation from a seropositive to a seronegative individual.

Pathogenesis

EBV usually enters the body through the mouth, and a productive infection occurs in the oropharynx, from which site infectious virus particles are shed into the oral cavity and can be recovered from saliva and throat washings. Currently there is much debate regarding the cell type first infected by EBV. Extensive examination of IM tonsils reveals infected B cells expressing lytic antigens, but no infection of the overlying epithelium (Anagnostopoulos *et al.*, 1995). Thus it is possible that EBV first infects B cells in tonsillar crypts where the surface epithelium is incomplete and that the virus could access lymphocytes directly. This initial infection of B cells would result in full latent gene expression (latency 3), cell activation and proliferation, thus amplifying the number of infected cells at the site of entry. These B lymphoblasts can be found in

peripheral blood early in IM, and are thereby disseminated throughout the body. Their presence in the circulation stimulates a massive T-cell response, which is characteristic of IM. The symptoms of IM are not caused directly by virus-infected B cells but are immunopathological in nature, resulting from massive cytokine production from CD8 T cells, and to a lesser extent CD4 T cells and natural killer (NK) cells. Together these cells are thought to control the infection by eliminating infected B lymphoblasts; however, some escape and establish lifelong persistence.

Humoral Immunity

The antibody responses to EBV-associated antigens during primary infection display a characteristic pattern (Figure 9.5). Classically, by the time of onset of clinical symptoms, IgM, and IgG antibodies to VCA are present in the serum, as are IgG antibodies to components of the

early-antigen and membrane-antigen complexes. Antibodies to the viral glycoproteins are neutralizing and probably agglutinate virus particles, thus preventing further infection and spread of the virus. IgM and IgA antibodies to VCA and IgG anti-EA antibodies rise to a peak during the acute disease and decline to low or undetectable levels during convalescence. IgG antibodies to EBNA1 are not usually detectable in the serum until the convalescent period. Heterophile antibodies regularly appear in the serum early in IM, but their relationship to the virus and their role, if any, in controlling infection remain unclear. A variety of autoantibodies may be found in IM, which include cold agglutinins, rheumatoid factors, anti-nuclear antibodies and antibodies to platelets and to smooth muscle. These antibodies, which may account for the raised total serum IgM level found in IM, are thought to be the result of the polyclonal activation of B cells caused by EBV infection. They are usually transient and harmless.

Figure 9.5 Basic pattern of serum antibodies to EBV antigens during and after primary infection. HA, heterophile antibody; VCA, viral capsid antigen; EA (D), diffuse form of early antigen; EBNA, EB nuclear antigen.

Figure 9.6 Photomicrograph of a May–Grunwald–Giemsa-stained peripheral blood film from acute infectious mononucleosis. An atypical mononuclear cell is illustrated (x 1000).

Cellular Immunity

One of the most distinctive features of IM is the presence, at the time of onset of clinical symptoms, of a lymphocytosis, and ‘atypical’ mononuclear cells in the peripheral blood (Figure 9.3). The rise of lymphocyte count, which may be very marked (up to $15 \times 10^9 \text{ l}^{-1}$), is due to a vast increase in absolute numbers of T lymphocytes. These are highly-activated, CD8-positive, HLA class I-restricted and CTL-specific for lytic (and to a lesser extent latent) antigens. During the acute phase of the disease up to 40% of the total peripheral CD8+ T-cell numbers may be directed against a single EBV epitope (Callan *et al.*, 1996). The lymphocytosis is accompanied by depression in most T-lymphocyte functions, including those measured by delayed-type hypersensitivity testing and *in vitro* mitogen stimulation.

Histological Findings

Generally, tissue from IM patients is not available for study, but occasionally liver, bone marrow or lymph node biopsies are performed before the diagnosis is made. Also, the histological findings on tissue from surgically-removed tonsils and ruptured spleens, and post-mortem specimens have been described. In all cases the tissues are infiltrated with mononuclear cells which are immunoblastic in appearance. These mainly consist of CD8+ T cells with a minority population of EBER-positive B cells. In the lymph node the pattern is generally described as ‘reactive’, with the infiltrate found in widely-dilated sinuses and intersinusoidal cords

extending into the interfollicular compartment, often obscuring the follicular centres. Virus-infected B cells are localized in the paracortical region, where occasional Hodgkin or Reed–Sternberg-like cells may be present. In the liver the portal areas are infiltrated and in the spleen the white pulp may be obscured by the extensive infiltrate which extends throughout the parenchyma. Small aggregates of monocytoïd cells and immunoblasts can be seen in the bone marrow. The histological findings are not diagnostic of IM and may be difficult to distinguish from other causes of immunoblastic proliferations, Hodgkin’s disease and non-Hodgkin’s lymphomas (NHLs).

Clinical Features

Incubation Period As the source of infection is generally not determined, the incubation period of IM is difficult to calculate. However, a period of 30–50 days is usual before symptoms occur.

Symptoms Characteristically, IM begins abruptly with a sore throat and swelling of the neck, accompanied by non-specific symptoms such as malaise, fever, sweating, chills, headaches, stiff neck, anorexia and vague abdominal discomfort. A prodromal period characterized by lassitude and slight fever is described by some patients. The sore throat, which occurs in 80–90% of patients, is usually mild and clears after 7–14 days. It may, however, be severe enough to cause extreme pain and difficulty with swallowing, and occasionally gross tonsillar enlargement may lead to pharyngeal obstruction. In 25% of cases secondary infection of the pharynx occurs, commonly with a β -haemolytic streptococcus. Less commonly, patients present with jaundice, cough, myalgia or symptoms of one of the neurological complications of IM (see below).

Physical Signs Lymphadenopathy is present in the majority of cases at some time during the acute illness. The cervical nodes are most obviously involved, but generalized lymphadenopathy may occur, with the nodes often remaining palpable for several weeks. Glands are discrete and not severely tender. The additional presence of rubbery small glands in the axilla and groin indicates IM rather than a throat infection with involvement of cervical glands. Clinically-detectable splenic enlargement occurs in 50–60% of patients and is usually accompanied by tenderness, however ultrasound scanning detects splenomegaly in almost all cases. Mild hepatomegaly occurs in 15–25% of patients, and jaundice is clinically apparent in 5–10% of patients. Fevers of 38–40°C are a regular feature during the first 1–2 weeks of IM, with the highest temperature often occurring at midday and being followed by drenching sweats.

Pharyngitis and palatal petechiae occur during the first week of the illness. These may be accompanied by a grey-white membrane, which, when associated with pharyngeal oedema and tonsillar enlargement, can result in obstruction to the pharynx or trachea. Periorbital oedema is common early in this disease.

Two types of skin rash can occur: a faint morbilliform eruption which lasts 24–48 hours, or a maculopapular rash which occurs in almost all patients receiving ampicillin. The cause of the latter is unknown, but its presence is regarded by some as diagnostic of IM.

Other associated clinical conditions include encephalitis, meningitis, delirium, coma, psychosis, transverse myelitis, polyneuritis, mononeuritis, pericarditis, myocarditis, interstitial pneumonia and pleural effusions. None of these are common.

IM in Children and the Elderly When IM occurs outside the classic age range of 15–25 years, it tends to present a less typical clinical picture. In children the disease is usually mild and does not require medical attention. Sore throat and cervical lymph-node enlargement are usually present but not invariably so. Occasionally children exhibit classic IM even as early as the age of two years, and in these cases the heterophile antibody (HA) test is often negative.

The clinical onset of IM in the elderly is often insidious and occasionally bizarre. The disease can be severe, with hepatic, neurological and renal involvement.

IM in Pregnancy IM during pregnancy is uncommon, but where it has occurred there has rarely been deleterious effect on the fetus, and termination of pregnancy is not indicated.

IM in the Immunosuppressed When primary EBV infection occurs in immunocompromised patients, particularly after organ transplantation, it is often asymptomatic due to the inability to mount a T-cell immune response. However, it may result in atypical disease with gastrointestinal symptoms and/or signs of renal-graft rejection and failure. Antibodies to EBV antigens may be slow to develop, with neither IgM antibodies to VCA nor the HA test being invariably positive. Some of these primary infections progress to lymphoproliferative disease and lymphoma (discussed later).

Course and Convalescence

The illness usually resolves in one to two weeks but may last for several weeks, often with continued exhaustion on the slightest exertion and complaints of an inability to concentrate for several weeks after apparent recovery. Occasional patients, particularly those over 25 years of age, may experience intermittent fatigue over the following

two years. Other patients suffer ‘relapses’ during the six months to one year following IM, with return of fever, sore throat and lymphadenopathy accompanied by a positive HA test. The exact nature of these relapses is unclear since the serological markers of primary infection may remain positive for up to a year even in subclinical cases of seroconversion.

Complications

In the vast majority of cases IM is a benign and self-limiting disease from which complete recovery is the rule. However, certain morbid complications have been described in the literature, which account for around 30 deaths per year in the United States. The main causes of death are neurological complications, splenic rupture, hepatic failure and secondary infection. Approximately half the deaths are associated with X-linked lymphoproliferative syndrome (X-LPS; see below).

Neurological Complications These include meningitis, encephalitis and the Guillain–Barre syndrome. Each of these conditions may precede, accompany or postdate IM by several weeks. Recovery is usual.

Hepatic Complications Although most IM patients have biochemical evidence of hepatocellular damage giving abnormal liver-function tests, overt jaundice is uncommon (5–10%) and complete recovery is the rule. However, more severe cases have been reported, and these include massive hepatic necrosis resulting in death if untreated by liver transplant.

Splenic Rupture This is a well-known but rare complication of IM, which may occur spontaneously or after mild trauma. The rupture gives rise to severe abdominal and shoulder pain and requires immediate surgical intervention.

Pharyngeal and Tracheal Obstruction These may occur due to massive enlargement and oedema of the tonsils, adenoids, uvula and epiglottis, giving rise to an inability to swallow or to stridor with eventual cyanosis. A short course of corticosteroids usually gives a dramatic improvement, but intravenous hydration and feeding or tracheotomy may be necessary as emergency measures.

Immunological Complications These include haemolytic and aplastic anaemia, thrombocytopenia, hypogammaglobulinaemia, agranulocytosis and haemophagocytosis. These disorders may result from excess autoantibody production, such as to the blood group antigens, due to B cell stimulation, or to abnormal suppression of haemopoiesis by T cells. Several of these conditions may be found in patients with X-LPS (see below).

Chronic Active EBV (CAEBV) (Reviewed by Kimura, 2006.)

Chronic active EBV (CAEBV) infection, where symptoms of IM persist for more than six months, occurs rarely and may result in death from hepatic failure, lymphoma, interstitial pneumonitis, sepsis or haemophagocytic syndrome. In these cases there is a persistence of the acute IM-like serological profile, usually with grossly elevated titres of IgG antibody to VCA and EA-D, absence of IgG antibody to EBNA1, a positive monospot test and often detectable IgM antibodies to VCA. An atypical lymphocytosis is also present. The viral load in saliva and peripheral blood is very high and in some cases EBNA-positive cells can readily be detected in the circulation. There is now growing evidence that there are clonal expansions of EBV-infected T or NK cells which infiltrate into the organs and play a central role in pathogenesis of CAEBV. These are likely to be due to inadequate immunological control of viral replication.

CAEBV has been treated with aciclovir and a variety of immunomodulating agents such as steroids, interferons, IL2, cyclosporine A and etoposide, but the results are disappointing. More recently, stem cell transplantation with cord blood and adoptive immunotherapy with autologous EBV-specific CTLs have been used with some success (Nakagawa *et al.*, 2007; Savoldo *et al.*, 2002).

CAEBV can be distinguished from chronic fatigue syndrome (CFS) on clinical grounds and by an EB viral antibody screen. Around 10% of CFS patients have mildly elevated VCA and/or EA antibody titres, but no gross abnormalities can be found. These changes do not denote a specific aetiological association between EBV and CFS.

Laboratory Findings

The classic finding in IM, after which the disease is named, is the 'atypical' mononuclear cells in the peripheral blood, which were first described by Downey and McKinlay (1923) (Figure 9.6). Morphologically, 'atypical' cells are large activated lymphocytes (10–20 µm in diameter), which, when stained with May–Grunwald–Giemsa stain, show abundant pale blue, vacuolated cytoplasm and an elongated or indented nucleus with coarse nuclear chromatin. These are mainly EBV-specific CD8+ CTLs and account for the leucocytosis regularly seen in the first two weeks of IM. A few atypical mononuclear cells occur in the peripheral blood in other acute virus infections, including cytomegalovirus, hepatitis B, influenza B and rubella, but they are most prominent in IM. Activated CD4+ cells and NK cells are also increased in numbers in acute IM. B lymphocytes are usually present in normal or slightly raised numbers and around 1 in 10⁴–10⁵ are infected with EBV and express all the latent viral proteins.

Diagnosis

The diagnosis of IM may be suspected on clinical grounds. However, infections with other agents such as cytomegalovirus, toxoplasmosis and human immunodeficiency virus (HIV) seroconversion should also be considered in the differential diagnosis. The diagnosis of IM is substantiated by the haematological findings of 'atypical' lymphocytes and is confirmed by the serological demonstration of antibodies to EBV-related antigens. A pre-illness specimen is rarely available to prove absence of antibody before the illness, and IgG antibodies to VCA are almost invariably present in the first serum sample received, having often already reached their peak. However, high levels of IgG anti-VCA antibodies are not of diagnostic significance since variable levels are reached during the illness, and higher levels may occur in other conditions. The presence of IgM antibodies to VCA, with or without IgG antibodies to EA (D) and an absence of IgG anti-EBNA1, are diagnostic. Commercial enzyme-linked immunosorbent assay (ELISA) tests are reliable and are widely used. False-positive results in the IgM test may result from cross-linking between specific EB viral IgG and anti-IgM conjugate by rheumatoid factor, and therefore if this factor is present in the serum it should be absorbed out before testing. There is also a simple slide-based test for detecting HA, called the monospot test (see below).

Following primary EBV infection, IgG VCA persists for life whereas IgM VCA can be detected for three to six months after infection. IgG EBNA becomes detectable six to eight weeks after the infection and persists for life (Figure 9.5).

The Monospot Test The presence of IgM HA in IM serum causes agglutination of red blood cells from species other than humans. Quick and reliable slide tests are available, which involve absorption of the serum with guinea-pig kidney (GPK) emulsion to remove nonspecific agglutinating Forssman antibodies, or with ox cell stroma (OCS) to remove HA, followed by the addition of horse red cells. Drops of serum are placed on two squares on a slide; GPK is stirred into one drop and OCS into the other. Horse red cells are then added to each square and stirred into the absorbed serum. Agglutination in the GPK square and not in the OCS square is indicative of IM.

The monospot test is positive in around 85% of IM cases (as confirmed by positive anti-VCA IgM) and can persist for up to six months after recovery. Negative results are more common in sera from children under 14 years with IM than in those from older children or adults. This may be because HA arise due to the polyclonal stimulation of memory B cells, so if the priming exposure to the unknown 'heterophile' antigen has not yet occurred,

no specific memory B cells will be present and no secondary rise can be induced. False-positive HA tests have been extensively recorded, particularly in association with pregnancy and autoimmune disease.

Treatment

This is largely supportive. High-dose aciclovir reduces virus production in the throat but does not shorten the duration of the illness, probably because the symptoms are immunopathological in nature and not caused directly by virus infection of B cells. The sore throat may be extremely painful and regular analgesics are then essential. Corticosteroids curtail the severity and duration of the symptoms, but are best reserved for severe cases of pharyngeal or tracheal obstruction, and neurological and haematological complications.

Burkitt's Lymphoma

BL is a tumour which occurs endemically in equatorial Africa and Papua New Guinea and sporadically worldwide. The African (endemic) form of the tumour is geographically restricted to those areas in which hyperendemic falciparum malaria occurs (Figure 9.7). These are

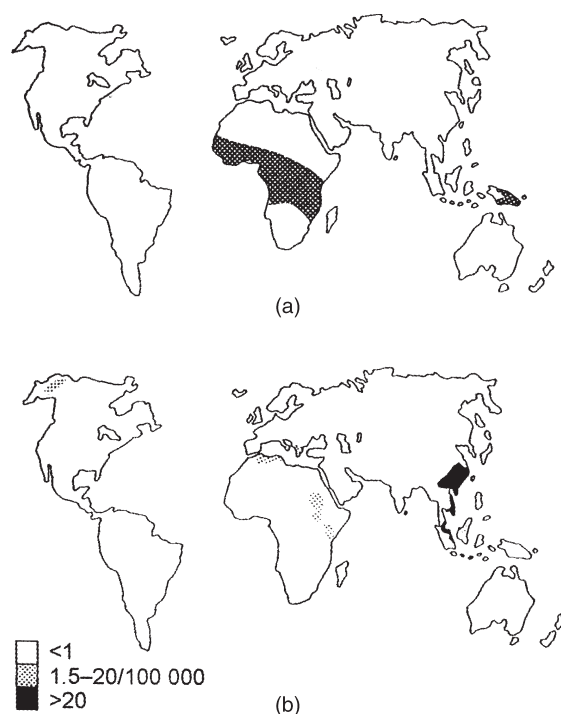

Figure 9.7 Maps showing the worldwide distribution of (a) Burkitt's lymphoma and (b) nasopharyngeal carcinoma.

the low-lying areas of equatorial Africa and Papua New Guinea with a rainfall of over 60 cm per year and a minimum temperature of 16°C.

The endemic and sporadic forms of BL are both monoclonal tumours of B lymphocytes which have indistinguishable histological appearances. However, whereas almost 100% of cases of African BL are associated with EBV, only 12–25% of the sporadic cases in developed countries are EBV-related. An intermediate incidence (25–80%) of EBV-associated BL is reported in countries in South America, such as Argentina and Brazil (Rao *et al.*, 2000).

Seroepidemiology

In the geographical areas where BL is endemic almost all children over the age of two years have been infected by EBV and have IgG antibodies to VCA. However, in BL the pattern of antibodies to EBV antigens is altered when compared to normal matched controls. Sera from BL patients have IgG antibody titres to VCA with a geometric mean 8–10 times greater than matched control sera. IgG anti-EA (R) and anti-MA antibodies are also raised, and the levels of these serum antibodies vary with clinical events. Thus, after treatment, a drop in anti-EA (R) indicates a good prognosis, whereas a rise in anti-EA (R) and a fall in anti-MA may precede a recurrence of clinical disease.

Pathogenesis

Association with EBV Although it is very difficult to obtain absolute proof that a virus is involved in the aetiology of a human tumour, there is now much evidence which points to the widely-accepted view that EBV is involved in the aetiology of BL. In addition to the seroepidemiological evidence outlined above, multiple copies of the viral genome can be detected in the tumour cells of around 97% of African BL biopsy samples. The viral genome is clonal in the monoclonal BL B-cell population, indicating that the infection event occurred before proliferation of the malignant cell. However, the viral gene expression is restricted to the latent antigen EBNA1, which is essential for maintenance of the viral genome in the cell and EBERS and BARTs (latency 1) (Table 9.1). No direct oncogenic role for these genes has been identified, although mice transgenic for EBNA1 develop lymphoma (Wilson *et al.*, 1996), and EBV has been suggested to increase cell survival by inhibiting apoptosis (Komano *et al.*, 1999) and inducing expression of the inhibitory cytokine IL-10 (Kitagawa *et al.*, 2000).

BL-derived Cell Lines Lymphoid cell lines that are grown directly from BL biopsy material show

the characteristic features of BL cells, with cellular markers consistent with a germinal-centre B-cell phenotype (CD10, CD77) and viral protein expression to restricted EBNA1 (latency 1). These differ from their *in vitro*, EBV-transformed counterpart in several important respects, which indicates their increased malignant potential. Thus, BL-derived cell lines grow as colonies in soft agar and subcutaneously in nude mice whereas *in vitro*-transformed LCLs do not. BL cell lines are monoclonal, with all cells bearing surface Ig of one heavy-chain isotype (usually M) and one light-chain type, whereas *in vitro* transformed cell lines are polyclonal in origin. There are also differences in growth characteristics, cellular gene expression and cytological appearances, reflecting their differing stages of B-cell maturation (germinal-centre cell versus activated lymphoblast). However, with prolonged culture, the viral and cellular gene expression in BL cell lines may drift to resemble LCLs. Finally, BL cell lines consistently carry specific chromosomal translocations which are not present in *in vitro*-grown LCL derived from normal individuals (see below).

Chromosomal Abnormalities It has been recognized for many years that fresh BL tumour cells and the derived cell lines (whether EBV-associated or not) show a reciprocal chromosomal translocation between the long arm of one chromosome 8 and chromosomes 14, 2 or 22. Each of these translocations results in the *c-myc* oncogene on chromosome 8 coming under the regulatory control of either the Ig heavy-chain genes on chromosome 14 or, more rarely, the κ or λ light-chain genes on chromosomes 2 and 22, respectively. The positions of the chromosomal break points suggest that these translocations are the results of mistakes occurring during Ig gene rearrangements, Ig class switching or somatic hypermutation in a germinal-centre cell. Furthermore, the translocated allele of *c-myc* frequently contains mutations. *c-myc* is a normal cellular gene which codes for a nuclear protein involved in the control of cell activation and proliferation. The BL translocations deregulate the gene, giving constitutive expression. In addition to this characteristic chromosomal translocation, BL cells often contain other genetic abnormalities, including a mutated p53 gene in about 30% of biopsy samples.

Cofactors in the Pathogenesis of BL Since EBV is a ubiquitous agent, whereas EBV-associated BL occurs almost exclusively in those geographical areas of the world where malaria is hyperendemic, it is probable that malaria infection acts as one factor in the multifactorial aetiology of this disease. The association between BL and malaria is further substantiated by the findings that where

malaria eradication has been successfully accomplished the incidence of BL has dropped dramatically, and that the incidence of BL in children with the sickle-cell trait, which confers partial protection from malaria, is low.

Malaria infection acts as a chronic stimulator of germinal-centre B cells and also as an immunosuppressant, causing a decreased EBV-specific CTL activity and increased numbers of EBV-infected B cells in the peripheral blood. It is postulated, therefore, that the combined lymphoid stimulation and immunosuppressive effects of malaria cause an increase in B-cell turnover and a decrease in the elimination of EBV-positive B cells. However, at present it is unclear whether EBV acts to increase the population of cells susceptible to a chromosomal translocation, or to enhance the survival and proliferation of a cell population bearing the translocation. Whichever scenario is correct, it is assumed that the latent EBV growth-promoting genes (latency 3) must be expressed at this early stage of lymphomagenesis, but that a switch to the nonimmunogenic EBNA1-only phenotype (latency1) occurs once their function is replaced by deregulated *c-myc*.

Clinical Features

African BL is a tumour which occurs in children aged 3–15 years, with a peak age incidence of 6–7 years. In those areas of Africa and Papua New Guinea where BL is endemic it occurs with an incidence of 15 per 100 000 children aged 5–10 years, and is the commonest malignancy in this age range. It is more common in boys than girls and arises extranodally, typically in the area of the jaw, giving a characteristic presentation (Figure 9.8). The tumour is usually found to be multifocal at presentation, the other sites commonly involved being the postorbital region, gastrointestinal tract, thyroid, liver, kidney, skeleton, testicles and ovaries, and the breast in adolescent girls. BL is a highly malignant tumour, with death supervening within a few months of clinical onset in untreated cases.

Diagnosis

The diagnosis of BL in an endemic area is very often clear from the clinical features described above; however, histological evidence should be sought (Figure 9.9). The tumour shows a characteristic histological picture of a poorly-differentiated lymphocytic lymphoma, with variable numbers of infiltrating histiocytes giving the classic 'starry sky' appearance. BL is a monoclonal tumour of B-cell origin, expressing the markers of a germinal-centre B cell: CD10, CD77 and, in over 90% of cases, IgM.

Figure 9.9 Histological section of Burkitt's lymphoma, showing a uniform population of nucleolated lymphoid cells and scattered vacuolated macrophages (H&E x 800). (Courtesy of Professor P. Isaacson, University College Hospital.)

Treatment

BL is very sensitive to chemotherapy, one dose of cyclophosphamide often being enough to cause complete regression of the tumour mass. Relapses do occur, however, and are progressively less responsive to therapy. For this reason a full course of treatment should be given initially, in which case the prognosis is good.

Prevention

The prevention of BL may theoretically be achieved by the eradication of malaria, which has been achieved in

the past in small areas, such as some of the islands of Papua New Guinea, with a coincident fall in BL in these regions. Alternatively, prevention of BL development by a vaccine which prevents EBV infection has been suggested (see later).

Nasopharyngeal Carcinoma

NPC is a malignant tumour of the squamous epithelium of the nasopharynx which is highly prevalent in southern China, where it is the commonest tumour in men and the second most common tumor in women. In most other areas of the world the tumour is rare, but pockets of high incidence occur in North and Central Africa, Malaysia, Indonesia, Vietnam, the Philippines and in the Inuit races of Alaska, Greenland and Iceland (Figure 9.7). The most undifferentiated form of the tumour, which is the most common, shows a 100% association with EBV regardless of the geographical location, whereas the association with the rarer, more differentiated forms is less consistent.

Seroepidemiology

The association between NPC and EBV was first demonstrated serologically (Old *et al.*, 1966) and later studies showed that sera from 100% of cases of undifferentiated NPC have high-titre antibodies to VCA. As in BL, the antibodies are present at a 10-times higher geometric mean titre than in matched controls and show a unique reaction

pattern. Thus the anti-EA (D) component is the most frequently seen and is present at a higher titre than anti-EA (R). IgG and IgA anti-EA (D) antibody titres rise as the disease progresses, fall in remissions, and may be undetectable in long-term survivors. Similarly, IgA antibodies to VCA are present in NPC sera and correlate with disease progression. These IgA antibodies are also found uniquely in the saliva of NPC patients.

Pathogenesis

Association with EBV The seroepidemiological data referred to above, and the finding of multiple clonal copies of the EBV genome in the malignant epithelial cells of 100% of undifferentiated NPC biopsy specimens, strongly suggest that the virus is involved in tumour aetiology. All the malignant epithelial cells express the EBV-coded antigen EBNA1, and LMP1 and 2 are expressed in around 50% of tumours (latency 2). Although the exact mechanisms involved in squamous epithelial cell transformation by EBV have not been resolved, the fact that LMP1 is a viral oncogene which can drive epithelial cell proliferation *in vitro* (Dawson *et al.*, 1990) and induce severe epithelial hyperplasia in transgenic mice (Wilson *et al.*, 1990) provides compelling evidence for an oncogenic role for EBV in NPC. However, a recent study using a quantitative real-time reverse transcriptase polymerase chain reaction (PCR) method detected significant levels of EBNA1, LMP2A and BART transcripts but failed to detect LMP1 transcripts in 12 NPC biopsies (Bell *et al.*, 2006). LMP2A has been shown to cause epithelial cell proliferation by stabilising β -catenin through PI3K and Akt signal transduction pathways (Morrison *et al.*, 2003).

Cofactors in the Pathogenesis of NPC NPC is a genetically-restricted tumour, being most common in southern Chinese and Inuits. It has been noted that the first-generation immigrants from southern China to the USA retain the high frequency of the disease, although later generations show a declining incidence which may be due to intermarriage with non-Chinese races. These data suggest a genetic factor in the aetiology of the disease, and this is backed up by family clustering and the finding of an association with certain HLA haplotypes (A2-BSin2, BW17-AW19, BW17-A blank). Polymorphism in the HLA-A locus has also been associated with the development of NPC (Lu *et al.*, 2005). Environmental factors may play a role in the aetiology of NPC, in particular dietary components such as salted fish which contain carcinogenic nitrosamines, and traditional herbal medicines containing phorbol esters, which are taken as snuff.

Clinical Features

NPC occurs at a rate of 98 per 100 000 of the population in southern China and is more common in men than in women. The age of onset of NPC varies with geographical location and histological type, the undifferentiated type being more common in high-risk areas in young patients, whereas the more differentiated types occur in older patients and constitute the bulk of sporadic cases. The tumour most commonly arises on the posterior wall of the nasopharynx in the fossa of Rosenmuller, where it often remains silent, and rapidly metastasizes to the draining lymph nodes. Thus the most frequent presenting symptom of NPC is bilateral enlargement of lymph glands in the neck, which are firm, nontender and fixed. The upper cervical chain of glands is most often involved in the initial spread. At this stage the primary tumour may be very small and difficult to locate. Less frequently, the presenting symptoms are associated with invasion by the primary tumour and include nasal obstruction, postnasal discharge, epistaxis, partial deafness and cranial nerve palsies. If untreated, the disease is rapidly fatal, with death being most often due to laryngeal and pharyngeal obstruction.

Diagnosis

The diagnosis of NPC is made on biopsy material from the primary tumour or an enlarged cervical lymph node. The cells are squamous epithelial in origin and three histological types are described in the World Health Organization classification: (i) *WHO1*, a well-differentiated squamous cell carcinoma with intercellular bridges and keratinization; (ii) *WHO2*, a nonkeratinizing carcinoma; and (iii) *WHO3*, an undifferentiated carcinoma in which a heavy lymphocytic infiltration is often present, which may be so extensive as to lead to the mistaken diagnosis of lymphoma (Figure 9.10). However, the lymphocytes, which are mainly T cells, are nonmalignant. The term 'lymphoepithelioma' has been used to describe this third type, which occurs most commonly in the high-risk areas.

Serum antibody titres to EBV antigens can be used to confirm the diagnosis of NPC and to monitor the progress of the disease. Large-scale screening programmes in China have identified individuals with persistent IgA antibodies to VCA in serum and/or saliva, and follow-up of these cases has successfully detected 'precancerous' and early lesions.

Treatment

NPC is difficult to treat surgically because of the characteristic feature of early metastasis to regional lymph

Figure 9.10 Histological section of undifferentiated nasopharyngeal carcinoma, showing scattered malignant epithelial cells and a heavy infiltrate of small lymphocytes (H&E x 400).

nodes. The tumour is resistant to chemotherapy, and therefore radiotherapy to the primary tumour and cervical lymph nodes is the treatment of choice. The overall prognosis is poor; however, five-year survival rate for early-stage disease is around 60%.

Prevention

Although the precise role of EBV in the aetiology of NPC remains to be elucidated, it has been argued that prevention of primary infection by EBV using vaccination may be enough to break the chain of events which culminates in tumour formation. Vaccine preparations are discussed later.

Hodgkin's Disease

An association between EBV and HD was long suspected because IM in the previous five years is a risk factor for HD, and HD patients have high antibody titres to EBV lytic-cycle antigens months or years before development of the disease. This association was firmly established when EBV DNA and expression of viral-coded proteins were demonstrated in malignant Hodgkin Reed–Sternberg (HR-S) cells in a proportion of cases. Multiple copies of clonal, circular EBV DNA can be detected in 40–60% of HD biopsies by Southern blotting, with confirmation of the HR-S cell location by detection of EBERS by *in situ* hybridisation (Anagnostopoulos *et al.*, 1989). These cells also express EBNA1 and high levels of LMP1 and 2A, in the absence of other latent or lytic proteins (latency 2). The mixed cellularity type of HD is most often associated with EBV.

The age distribution of HD is similar to that of primary EBV infection, showing a bimodal distribution with one peak in childhood and another in adulthood. Furthermore,

the age of the early peak varies with geographical location, being later in Western societies (15–35 years) than in developing countries (5–10 years). This similarity initially suggested that HD might represent an atypical outcome to primary EBV infection; however, although most childhood HD in developing countries is EBV-associated, in Western societies non-EBV-associated HD predominates in the young, with EBV association increasing with age (Jarrett, 2002).

The pathogenesis of EBV-associated HD is still unclear, although the presence of clonal viral DNA in HR-S cells indicates infection at an early stage. In addition, expression of LMP1 which induces cell activation and proliferation while inhibiting apoptosis, and LMP2A which enhances cell survival, is consistent with an oncogenic role for the virus. HR-S cells have been definitively identified as germinal-centre B cells with functional Ig-gene rearrangements but defective Ig-gene transcription (Marafioti *et al.*, 2000), and it is therefore possible that EBV infection of these atypical cells allows the survival of a cell which would otherwise undergo apoptosis in the germinal centre.

An association between EBV-positive HD and genetic microsatellite markers (D6S510 and D6S265) in the HLA-class-1 locus has recently been identified (Diepstra *et al.*, 2005). Similarly, others have found that these HLA-class-1 alleles are significantly more frequent in patients with IM when compared with EBV-seropositive individuals (McAulay *et al.*, 2007). Since IM is a well-documented risk factor for developing EBV-positive HD, the increased frequency of certain HLA-class-1 alleles in both diseases suggests that differences in the efficiency of EBV-peptide presentation to T cells can influence the effectiveness of the immune response and predispose to EBV-related diseases.

EBV INFECTION IN THE IMMUNOCOMPROMIZED HOST

EBV establishes a lifelong persistent infection in over 90% of the world's population with latency in B lymphocytes and virus production into saliva (see above). This persistent infection is controlled mainly by EBV-specific CTLs, and it is not surprising therefore that when cell-mediated immunity is decreased there is often increased EBV production in saliva, high antibody titres to lytic-cycle antigens (VCA and EA) and an increased viral load in peripheral blood lymphocytes. This pattern is sometimes called a 'reactivated infection', although generally no clinical symptoms ensue. In a few patients, however, EBV-associated lymphoproliferative lesions and lymphoma develop.

X-Linked Lymphoproliferative Syndrome (X-LPS)

(Reviewed by Gaspar *et al.* 2002.)

This rare syndrome (first called Duncan's syndrome) was recognized in 1974 by Purtilo *et al.*, who described a family in which six male kindred died of acute IM and/or malignant lymphoma (Purtilo *et al.*, 1974). Since then many such families have been reported, with affected members having an apparent inability to mount an effective immune response to primary EBV infection. X-LPS accounts for about half of the fatal IM cases reported, the other half being sporadic, with an equal sex distribution.

Clinically, the affected males are generally healthy until primary EBV infection occurs. The course of the disease is then fulminating and rapidly fatal in the majority of cases, with death commonly resulting from hepatic necrosis. A minority of patients progress to a chronic phase, often culminating in a fatal B-cell lymphoma. These tumours are mostly extranodal, commonly occurring in the central nervous system or gastrointestinal tract.

Histological studies on fatal cases show infiltration of tissues throughout the body with EBV-positive lymphoblastoid and plasmacytoid cells and activated T cells. These infiltrates are a particularly prominent feature in the liver, where dysregulated cytokine release from T cells leads to hepatic necrosis. Haemophagocytosis is seen in the tissues in almost all cases.

There is no elective treatment for this disease, although etoposide, a cytotoxic drug used in the treatment of malignancies such as small-cell carcinomas of lung, Hodgkin's lymphomas, retinoblastomas and testicular tumours, may have some effect. Recently success has been reported with bone marrow transplantation. Many abnormal immunological findings have been reported in X-LPS, although none is consistently found. These become more marked following EBV infection when combined T, B and NK cell abnormalities are seen.

The defective gene in X-LPS was identified in 1998 (Coffey *et al.*, 1998; Nichols *et al.*, 1998; Sayos *et al.*, 1998) and the development of a diagnostic test rapidly followed. This identified a spectrum of clinical manifestations associated with the syndrome, including dysgammaglobulinaemia (incorporating some cases of common variable immunodeficiency), aplastic anaemia, lymphoid vasculitis with aneurysm formation and, rarely, non-EBV-associated lymphoma.

The X-LPS gene codes for a small *src*-homology 2 (SH2) domain containing cytoplasmic protein, alternatively called SH2D1A or SAP (signalling lymphocytic activation molecule (SLAM) associated protein), which is expressed in T and NK cells. SAP appears to play a modulating role in T-cell activation and is required for NK-cell cytotoxicity; it is likely that the loss of these functions explains the X-LPS phenotype. However, this

does not explain the link between EBV and X-LPS, since SAP expression is not specific to primary EBV infection. In this regard, the finding of rare X-LPS lymphoma in EBV-negative individuals indicates that the syndrome is not restricted to primary EBV infection, and it is now postulated that X-LPS is a more generalized immunodeficiency which can be triggered by a variety of virus infections. However, the exact nature of the immunological abnormality is still unclear.

Post-transplant Lymphoproliferative Disease (PTLD)

(Reviewed by Burns and Crawford 2004.)

Iatrogenic immunosuppression following stem cell or solid organ transplantation results in an increased incidence of virus-associated tumours. B-cell lymphomas are the commonest tumour in paediatric transplant recipients and the second-commonest tumours in the adult transplant population (following skin tumours), and have a high morbidity and mortality.

Histology

These tumours are mainly diffuse large-cell lymphomas with the term 'post transplant lymphoproliferative disease' (PTLD) being used to reflect the morphological diversities. Histologically, PTLT is classified into three major categories: (i) *Hyperplastic PTLT*, which includes plasmacytic hyperplasia, IM-like lesions and other atypical lymphoid hyperplasias. These lesions are of early-onset, and characteristically noninvasive. They are typically polyclonal in composition, containing a mixture of B and T cells. (ii) *Polymorphic PTLT*, which characteristically invade and disrupt underlying tissue architecture. The majority of cells are B cells and most tumours are monoclonal. (iii) *Lymphomatous or Monomorphic PTLT*, which include monoclonal B cell tumours that resemble conventional NHL, with rare cases of Burkitt's and Burkitt's-like lymphomas.

Risk Factors and Association with EBV

PTLT develops in up to 10% of transplant recipients. Risk factors include high levels of immunosuppressive drugs (often in association with rejection episodes), EBV seronegativity before transplant and primary EBV infection following transplant (Haque *et al.*, 1997). The latter is more common in children, who therefore have a higher incidence of PTLT than adults. Over 90% of PTLTs are EBV-positive and the tumour cells generally express all the latent viral genes (latency 3) (Table 9.1). However, more restricted patterns of gene expression are detected in some lesions. Early lesions are often polyclonal-B-cell proliferations, but progression to a monoclonal lymphoma

regularly occurs. Although most PTLD tumours are of B-cell origin, rare T-cell and NK-cell tumours have also been described.

Pathogenesis

The pathogenesis of PTLD appears to be straightforward: immunosuppressive therapy following transplantation inhibits EBV-specific CTLs, leading to uncontrolled proliferation of EBV-infected B cells. However, the lesions are often single and monoclonal, suggesting that, in addition to EBV, cellular factors are required for tumour outgrowth. The finding of nonfunctional Ig genes in a proportion of these tumours (Timms *et al.*, 2003) suggests that EBV infection may have rescued an abnormal cell from apoptosis within the germinal centre. In a recent large multicentre retrospective study, the use of polyclonal Ig (which is likely to contain anti-VCA, EBNA and LMP antibodies) for cytomegalovirus prophylaxis during the first four months following cadaveric renal transplantation was shown to prevent PTLD development in the first post-transplant year, whereas antivirals (aciclovir or ganciclovir) had no protective effect (Opelz *et al.*, 2007).

Clinical Features

Clinically, PTLD may present as an IM-like syndrome, commonly in children undergoing primary infection (in which the virus may be acquired from the transplanted organ), and often within the first year of transplant. Alternatively, discrete tumours, frequently in the lymph nodes, gastrointestinal tract, brain or transplanted organ, are seen in seropositive recipients, often several years after transplant.

Diagnosis

Definitive diagnosis of EBV-associated PTLD is made on tumour biopsy materials by *in situ* hybridisation for EBERS and by immunostaining for EBNA and LMP antigens. Because of the variable clinical presentation, diagnosis is often difficult and measurement of the viral load in peripheral blood has been used as an indicator of risk. However, although high viral load is found in the majority of PTLD patients, levels are very variable in asymptomatic recipients, with some reaching those seen in PTLD. Therefore, single estimations are not helpful and regular monitoring of viral load in blood is required. In patients with rising high viral load, pre-emptive reduction of immunosuppression has been reported to reduce the incidence of PTLD when compared with historic control (Lee *et al.*, 2005).

Treatment

Reduction of immunosuppressive therapy is now the first line of treatment for PTLD, and the antiviral drugs aciclovir and ganciclovir are sometimes added to this regimen, although their role in tumour regression is unproven. Complete tumour regression may be achieved by this treatment alone, particularly in early lesions, but relapses and recurrences are common, and despite additional chemotherapy and/or radiotherapy the overall mortality is over 50%. Death is usually due to tumour progression, graft failure and/or opportunistic infections. Recent trials of immunotherapy for PTLD, including the humanized antibody to the B-cell surface antigen CD20, rituximab (Choquet *et al.*, 2006) and autologous (Rooney *et al.*, 1998) or allogeneic (Haque *et al.*, 2002) *in vitro*-grown EBV-specific CTLs, have reported some success, although randomized controlled trials have not been performed. In a recent multicentre Phase II clinical trial using partially HLA-matched allogeneic CTL, tumour response was seen in 64% of PTLD patients at five weeks and 52% of PTLD patients at six months (Haque *et al.*, 2007).

Acquired Immunodeficiency Syndrome (AIDS)

The incidence of NHL in individuals with untreated HIV is increased some 60-fold over the general population, and its development is an AIDS-defining illness. However, with the use of antiretroviral therapy, the incidence of NHL is falling (Kirk *et al.*, 2001). Three principal types of HIV-associated NHL have been described: (i) Primary central nervous system lymphoma (PCNSL) is a rare tumour in the general population which has a thousand-times increased incidence in HIV-infected individuals. It occurs at a late stage of AIDS and is invariably EBV-associated. Definitive ante-mortem diagnosis may be difficult, but EBV DNA can be found in cerebrospinal fluid in most cases and detection is considered to be diagnostic. Brain biopsy can be stained for EBV antigens (EBNA2, LMP1) and EBERS. (ii) BL develops at a relatively early stage of AIDS and all AIDS BL show the typical *c-myc* translocation. Around 25% are EBV-associated, showing the cellular and viral gene expression described for African BL (see above). (iii) Peripheral NHL occurs at a late stage of the disease and often presents at extranodal sites. Around 50% of cases are EBV-associated.

Other types of lymphoma seen in HIV-infected individuals include HD, which shows a modestly raised incidence and a strong EBV association, and the human herpesvirus 8-associated primary infusional lymphoma, of which 70–80% of cases show dual infection with EBV. All lymphomas associated with HIV infection respond poorly to treatment, due to the underlying disease.

OHL was first described in HIV-seropositive individuals, forming multiple characteristic corrugated white lesions on the lateral margin of the tongue. DNA hybridization and immunocytochemical staining revealed replicating EBV in these lesions (Greenspan *et al.*, 1985). OHL has now been recognized in other groups of immunocompromized patients. The lesion is painless and apparently harmless, and it can be successfully treated if required with continuous aciclovir therapy.

VACCINE DEVELOPMENT

Over the last two decades work has been undertaken to develop a vaccine which would prevent primary infection by EBV. The antigen chosen for vaccine development is the MA antigen gp340/220 (see above), since it is this antigen to which neutralizing antibodies are mainly directed. It was argued that this would prevent the development of BL and NPC by breaking a link in the chain of events which leads to the evolution of these diseases (Epstein, 1984). Such a vaccine preparation would have to be given very early in life to prevent natural infection in the BL- and NPC-susceptible populations. An effective vaccine preparation could also be useful in seronegative organ transplant recipients, and those at risk of developing severe IM, such as male offspring of X-LPS carriers.

The recently-published results of two randomized controlled studies using recombinant, subunit, gp350 EBV vaccine preparations in 148 healthy adult volunteers showed that the vaccines had a good safety profile and were well tolerated. They were also immunogenic, inducing gp350-specific antibody responses including neutralization antibodies. A total of 117 EBV-seronegative subjects were monitored over a period of seven months and there was only one possible case of IM. Seventeen individuals who were still seronegative at the end of the clinical trial were followed up for three years and no cases of IM were reported, although ten patients developed antibodies to EBV nonvaccine antigen without any disease. This observation suggests that the vaccine is efficacious in the prevention of symptomatic disease rather than in the induction of sterile immunity and prevention of infection (Moutschen *et al.*, 2007).

Roseoloviruses: Human Herpesviruses 6A, 6B and 7

Katherine N. Ward¹ and Duncan A. Clark²

¹University College Medical School, Department of Infection, Centre for Virology, UCL Campus, Windeyer Institute of Medical Sciences, London, UK

²Barts and The London NHS Trust, Department of Virology, Pathology and Pharmacy Building, London, UK

INTRODUCTION

Human herpesvirus (HHV)-6 and HHV-7, first discovered in 1986 and 1990 respectively, are genetically related to human cytomegalovirus (CMV) and as such are grouped with the latter in the *Betaherpesvirinae* subfamily. Two variants of HHV-6 have been defined (termed HHV-6A and HHV-6B). These have not been formally designated as individual virus species despite the fact that they meet the criteria of the International Committee on Taxonomy of Viruses (ICTVs) for such classification. There are readily discerned differences between the two variants found throughout their genomes, and recombinants between the two viruses have never been identified. They also differ in their biological, pathological and epidemiological properties. Where possible, the two variants of HHV-6 (A and B) are discussed here separately, and the more general term HHV-6 is reserved for studies where either the distinction was not made or there is no clear point to be elucidated.

In common with the other HHVs, HHV-6 and HHV-7 establish lifelong infection following initial exposure. Both HHV-6 and HHV-7 are highly prevalent worldwide and infection usually occurs in early childhood. Within this age group, HHV-6B is a causative agent of febrile illness including exanthem subitum (ES) and convulsions, and the same applies to HHV-7.

The more extensively studied HHVs (herpes simplex types 1 and 2, CMV, varicella-zoster virus and Epstein–Barr virus (EBV)) exhibit enhanced pathogenicity and fre-

quency of reactivation in the immunocompromised. There is now considerable evidence that active infections with both HHV-6 and HHV-7 are common in transplant recipients and have the potential to cause disease, for example HHV-6 encephalitis. For CMV, both the indirect and direct pathological effects of the virus are generally appreciated, and it may be that the other betaherpesviruses, namely HHV-6 and HHV-7, likewise have indirect effects, perhaps even more significant than their ability to cause direct-end organ disease.

A unique feature of HHV-6 amongst the HHVs is the persistence of viral genomic sequences in a chromosomally-integrated state in a minority of infected persons, with the capacity in these circumstances for vertical transmission. This feature highlights a most fascinating biological aspect of the virus which has unwittingly confused the interpretation of earlier studies examining disease associations and the pathogenicity of HHV-6. Importantly, it continues to confound laboratory diagnosis of active HHV-6 infection, potentially resulting in the unnecessary use of antiviral intervention.

BIOLOGY OF THE VIRUSES

Virus Structure and Replication

In common with all herpesviruses, HHV-6 and HHV-7 have a double-stranded DNA genome surrounded by an

Figure 10.1 HHV-6 cytopathic effect (CPE). Peripheral blood lymphocytes showing the characteristic CPE induced by HHV-6 infection. (a) Mock-infected cells; (b) HHV-6 infected ballooning cells within aggregates of cells. (Source: Di Luca *et al.*, 1990, with permission.)

icosahedral capsid that is separated by amorphous material, the tegument, from an outer envelope containing viral glycoproteins. HHV-6 and HHV-7 are characterized by growth in T lymphocytes (although, as described below, they can infect other cell types). Replication is slow *in vitro*, with the production of swollen (cytomegalic) cells (Figure 10.1), and results in cell death. Gene regulation for HHV-6 and HHV-7 appears to follow the same cascade as in other herpesviruses, with immediate-early (IE), early and late genes, although the temporal classification of the majority of HHV-6 and most HHV-7 genes has yet to be determined (for a recent account of the HHV-6 replication cycle, see review by De Bolle *et al.*, 2005).

Viral Genomics

Conserved genes (core genes) among the herpesviruses can be organized into seven gene blocks, the arrangement of which is subfamily-specific, and there is an additional block found only in the betaherpesviruses. The closer genetic relationship between HHV-6 and HHV-7 compared to CMV underlies their separate classification in the *Roseolovirus* genus. Table 10.1 gives a selected list of HHV-6 and HHV-7 genes and gene products—see two reviews (Black and Pellett, 1999; De Bolle *et al.*, 2005) for fuller descriptions of the genomic properties of HHV-6 and HHV-7.

HHV-6A and HHV-6B

The complete nucleotide sequences of HHV-6 variant A (U1102 strain) and variant B (strains Z29 and HST) are known. The genomes are 160–162 kb in size, including a unique (U) region of 143–144 kb bound by terminal direct

repeats (DRs) of 8–9 kb. Open reading frames (ORFs) encoded in the DR are prefixed ‘DR’, and those in the unique region are termed U1–100 from the left to the right hand of the sequence. HHV-6B strain Z29 is predicted to contain 119 ORFs, 9 of which are absent in HHV-6A (strain U1102), and splicing is predicted to result in 97 U genes (88 of which have counterparts in HHV-6A).

Comparative genomic analysis reveals that the HHV-6A and HHV-6B genomes are co-linear, with an overall nucleotide sequence identity of 90%. The differences are such that clinical isolates can be classified as variant A or B on the basis of characteristic restriction enzyme profiles. Regions of significant variation in the genome include DR and a 24 kb segment located to the right of U86 (the IE-1 region) where there are differences between splicing patterns and temporal transcription regulation in the two variants. An exception is U94, a gene with homology to the adeno-associated virus type 2 (AAV-2) *rep* gene, in which variants A and B differ by only 2.4% at the amino acid level. At present, the full implications of genomic and proteomic differences between variants are unknown, although it is clear that such differences may have profound biological effects.

Variation Within HHV-6A and HHV-6B There is little evidence for variation, although two distinct subgroups within HHV-6B (strains Z29 and HST) have been suggested by analysis of the IE-A regions of the viral genome. However, examination of the U94 gene from 13 HHV-6B isolates from the United States, Africa and Japan showed 100% amino acid identity (Rapp *et al.*, 2000), suggesting an intolerance of variation in this particular gene because

Table 10.1 Selected HHV-6 and HHV-7 genes and gene products

Gene/gene product	HHV-6A	HHV-6B	HHV-7

^aHomologue of adeno-associated virus type 2 (AAV-2) *rep* gene.

^bHomologue of CMV UL97.

^cOnly 80% amino acid identity between the variants.

^dMajor antigenic target for human antibody response.

^eOnly 79% amino acid identity between the variants.

it has an essential function (see ‘Viral Latency’ and ‘Chromosomal Integration of HHV-6’).

HHV-7

Two laboratory isolates of HHV-7 (strains JI and RK) have been fully sequenced. The genome is 153 kb in size and is arranged in the same way as HHV-6, with a unique region of 133 kb flanked at either end by a 10 kb DR region. Over 90% of the ORFs of HHV-7 are similar in amino acid sequence to those of HHV-6A and HHV-6B. There are only a small number of potential ORFs in HHV-6 that do not have a counterpart in HHV-7, and vice versa.

Intrastrain Variation of HHV-7 Comparison of the two fully-sequenced HHV-7 isolates (RK and JI) shows little variation overall, although it is more apparent in the repeat regions close to either end of the genome. However, analysis of three HHV-7 genes encoding the tegument phosphoprotein, glycoprotein B (gB) and major capsid protein in viral nucleic acid from 297 people derived from populations in Africa, Asia, Europe and America have suggested the presence of distinct variants (Franti *et al.*, 2001).

Cell Tropism

HHV-6A and HHV-6B

Both variants are tropic for T lymphocytes *in vitro* and can infect CD4⁺ T cells, but CD8⁺ T cells can only be

infected by HHV-6A. Typically, variant A viruses replicate in the lymphoblastoid T-cell line HSB-2 whereas variant B viruses grow in the less differentiated MOLT-3 T-cell line. HHV-6 also has the ability to infect a wide variety of other cell types. These include monocytes, epithelial cells, endothelial cells, fibroblasts and a range of neural cell types. Notably, HHV-6A has a greater capacity than HHV-6B for replication in cultured cells of neuronal origin, for example astrocytes. CD46 (also known as membrane cofactor protein, which functions as a regulator of the complement cascade) is a major cellular receptor for both HHV-6A and HHV-6B (Santoro *et al.*, 1999). The fact that CD46 is expressed on all nucleated cells is in keeping with the broad cellular tropism of HHV-6 *in vitro*, but activated peripheral blood CD4⁺ T cells and monocytes appear to be the site of fully permissive replication in HHV-6B primary infection *in vivo*, with monocytes mainly responsible for HHV-6 viraemia (Kondo *et al.*, 2002; Takahashi *et al.*, 1989).

Interaction with CD46 has been reported to involve the participation of the viral glycoproteins gH, gL and gQ (Mori *et al.*, 2003) and seems to be critical for HHV-6 fusion. In the case of gQ, there is only 79% amino acid identity between variants, which may influence their ability to target different cells (See ‘Tissue Tropism’). In this context it is interesting to note that a variety of cultured cells are susceptible to syncytium induction by HHV-6A but not HHV-6B—a fact with obvious implications for pathogenicity.

HHV-7

Tropism appears to be more restricted for this virus, which utilizes CD4 as a cellular receptor to infect T cells and replicates efficiently in the T-lymphoblastoid cell-line Sup-T1. Alternative receptors such as heparin sulphate, which binds to the HHV-7 protein gQ, are likely to be utilized for other cells (Skrincosky *et al.*, 2000).

Viral Latency

HHV-6 and HHV-7 remain in the host throughout life following primary infection. This persistence probably includes both a latent state (see below), with virions only produced during episodes of reactivation, and chronic replication, with continuous or frequent but intermittent production of infectious virus. Salivary glands are a candidate site for chronic replication of HHV-6B and HHV-7 (see 'Transmission').

Sites of Latency

HHV-6 and HHV-7 can be detected in the peripheral blood mononuclear cells (PBMCs) of healthy individuals by any sensitive polymerase chain reaction (PCR) when sufficient quantities of DNA are tested, with HHV-6B found more frequently than HHV-6A. The actual sites of latency have yet to be established, although candidates for HHV-6 include monocytes and early bone marrow progenitor cells. In the latter case, haematopoietic differentiation can lead to HHV-6 reactivation (Andre-Garnier *et al.*, 2004); thus there are obvious similarities to CMV, where latent virus is well established to reactivate in this way. For HHV-7, CD4⁺ T cells have been proposed as a site for latency (Miyake *et al.*, 2006).

Latency-associated HHV-6 Gene Expression

One group has reported the detection of U94 mRNA in the peripheral blood of healthy individuals, suggesting latency-associated gene expression (Rotola *et al.*, 1998). In addition, HHV-6 latency-associated transcripts that share the protein coding region of the IE1 and -2 transactivators and are maximally expressed in an intermediate stage between latency and reactivation have been identified (Kondo *et al.*, 2003); again, and as noted above, there are obvious parallels with CMV latency, where IE1 protein expression has been proposed as a control point for virus reactivation.

Reactivation from Latency

HHV-6 can be reactivated *in vitro* from latency by superinfection with HHV-7 (Katsafanas *et al.*, 1996). Razonable *et al.* (2002) investigated betaherpesvirus reactivation

in critically-ill immunocompetent hosts. Reactivation of HHV-6A, detected by PCR analysis of PBMC, was significantly increased in such patients compared to controls, suggesting that stress-related mechanisms may favour the reactivation of this variant. Further stimuli for HHV-6 or HHV-7 reactivation *in vivo* are uncharacterized, but are likely to include immunosuppression (see below).

Chromosomal Integration of HHV-6A and HHV-6B

An alternative form of persistence, characterized by very high HHV-6 DNA loads in blood (>6 log₁₀ HHV-6 DNA copies/ml), is due to integration of viral sequences into host leucocyte chromosomes; this situation occurs in a small but significant subset of the human population (see 'Epidemiology and Pathogenesis'). Such integration is unique amongst the HHVs in that it occurs naturally *in vivo*. Instances of EBV chromosomal integration have also been reported—but only very rarely—in Burkitt lymphoma cell lines after repeated passage *in vitro*, rather than as part of the normal virus biology.

The phenomenon of HHV-6 chromosomal integration was first described in 1993 by Luppi *et al.* (1993), who reported three individuals with HHV-6 DNA levels so high in PBMC that they could be detected even by Southern blotting rather than the very much more sensitive technique of PCR. Subsequently fluorescent *in situ* hybridization (FISH) using HHV-6-specific probes identified integrated viral sequences on chromosome 17 in all three cases (Torelli *et al.*, 1995). Further studies suggested that the sites of integration were close to, or in, the telomeres of the short arm of chromosome 17 (Morris *et al.*, 1999) (see example in Figure 10.2).

Sites of Chromosomal Integration

Since the earliest report from Italy (Luppi *et al.*, 1993), FISH-confirmed cases of integrated HHV-6 have also been identified in Japan and the United Kingdom. Both HHV-6A and HHV-6B sequences can be integrated but the sites of integration are not random, being within or close to telomeres, although on a seemingly random range of chromosomes and on either the short or the long arms (Table 10.2). Each individual with integration has viral sequences from either HHV-6A or HHV-6B on only one copy of the particular chromosome involved. Although only 23 individuals have now been reported worldwide, already 7 different chromosomal sites have been identified. Further epidemiological study is warranted to investigate the possibility of additional sites and of geographical or racial variation in them.

Copies of Viral DNA/Cell

In cases of viral chromosomal integration there is at least one copy of HHV-6 DNA/leucocyte (best estimate, about

Figure 10.2 HHV-6A integration at the telomeric end of the short arm of chromosome 17 as mapped by fluorescent *in situ* hybridisation (FISH). Example of a dividing cell showing an HHV-6 FISH signal at 17p13.3 from one homologue of the chromosome only. Please refer to this publication to see the original colour illustration showing the FISH signal as green.

four) (Nacheva *et al.*, 2008; Ward *et al.*, 2006). Where FISH was undertaken to identify the site of chromosomal integration, 100% of the metaphase spreads gave an HHV-6 signal from the involved chromosome. Notably there is also at least one copy of HHV-6 DNA/hair follicle cell (Ward *et al.*, 2006), and chromosomally-integrated HHV-6 has been found by FISH in both the skin fibroblasts and peripheral blood cells of a Japanese individual (Daibata *et al.*, 2000). Thus, it seems likely that viral DNA is present in every nucleated cell in the body; that is, present in the germ line (see ‘Vertical Transmission’).

Mechanism of Chromosomal Integration

Exactly how HHV-6A and HHV-6B sequences integrate into the ends of chromosomes is not understood, although the presence of telomeric-like repeats (similar to those found in vertebrate telomeres) at either end of the viral genome in the DR regions may plausibly mediate such targeted integration. Interestingly, another herpesvirus, Marek’s disease virus of chickens, has analogous telomeric repeat sequences within its genome, and has been shown to be integrated into avian chromosomes in newly-harvested lymphoma cells at several different telomeric sites. HHV-7 also contains telomeric-like repeat sequences within its DR regions, but notably lacks

an HHV-6 U94 homologue, as do all the other HHVs. There is no evidence to date that HHV-7 integrates into chromosomes. Finally, it is interesting to note that, in addition to a putative role in virus latency (see above), the HHV-6 U94 gene may be involved in chromosomal integration, since it is a homologue of the AAV *rep* gene, which is implicated in the integration of the AAV genome at specific chromosomal sites.

Chromosomal Integration and the Possibility of Reactivation

It seems that almost the full length of the HHV-6 genome, if not all of it, is integrated (Clark *et al.*, 2006a; Daibata *et al.*, 1999; Torelli *et al.*, 1995) but the very few studies conducted to date have not shown that integrated virus is capable of full replication *in vivo* or *in vitro*, although in one case there is evidence for transcription of a range of viral genes in PBMC (Clark *et al.*, 2006b). However, individuals with HHV-6 chromosomal integration have strikingly high levels of HHV-6 DNA in blood, despite the apparent absence of full virus replication. Such high levels of viral DNA are found not only in whole blood but also in serum. The explanation for the serum DNA lies in the fact that human chromosomal DNA is inevitably found in serum, originating

Table 10.2 The HHV-6 chromosomal-integration sites that have been identified so far, together with variant and country of origin.

from cells damaged before or during separation from clotted blood. Thus, where HHV-6 is integrated in a chromosome, viral DNA will be released into serum. This has important implications for epidemiological studies and for molecular diagnosis of active HHV-6 infections (see 'Epidemiology and Pathogenesis' and 'Laboratory Diagnosis').

EPIDEMIOLOGY AND PATHOGENESIS

Incidence and Prevalence

HHV-6A and HHV-6B

As regards the distribution of the two HHV-6 variants in the population, the antibody responses is unhelpful as variant-specific assays are not available (see 'Laboratory Diagnosis') and can only provide the combined seroprevalence of both variants. Virus detection is therefore required but distinction must be made between viral chromosomal integration and the very much more usual acquisition of active infection by the classical process of primary infection.

Chromosomal Integration This has been estimated in populations as between 1 and 3% in England and Wales

(Leong *et al.*, 2007; Ward *et al.*, 2005b) and as 0.2% in Japan (Tanaka-Taya *et al.*, 2004). About a fifth to a third of individuals with this phenomenon have HHV-6A integrated rather than HHV-6B (Tanaka-Taya *et al.*, 2004; Ward *et al.*, 2005b, 2007b).

HHV-6A and Primary Infection In contrast to HHV-6B, natural primary infection with this variant has never been identified. Variant A was initially isolated in cultured lymphocytes from immunocompromised adults but has since been detected in African (Kasolo *et al.*, 1997) and American (Hall *et al.*, 1998) subjects, although it was not determined whether these were actually cases of integration, as was found for British (Ward *et al.*, 2007b) and Japanese (Tanaka-Taya *et al.*, 2004) children with this variant. Thus the true prevalence of HHV-6A due to primary infection remains to be determined.

HHV-6B and Primary Infection This has occurred in almost all children worldwide by the time they are two years old, the peak age of acquisition being between 9 and 21 months (Figure 10.3).

HHV-7

Infection with HHV-7, like HHV-6B, is almost universal and likewise occurs early, but usually somewhat later than the latter, being gradually acquired over the first three or four years of life (Figure 10.3).

Tissue Distribution

HHV-6A and HHV-6B

The distribution of HHV-6A in the body differs from that of HHV-6B. Variant B is commonly found in saliva and blood whereas variant A has only rarely been found at these sites (Hall *et al.*, 1998; Ward *et al.*, 2005b). HHV-6B is also the predominant variant found in brain tissue (Challoner *et al.*, 1995; Tuke *et al.*, 2004). On the other hand, HHV-6A occurs relatively more frequently than variant B in lungs (in this case often accompanied by variant B) (Cone *et al.*, 1996), cerebrospinal fluid (CSF) (Hall *et al.*, 1998) and skin (Di Luca *et al.*, 1996), suggesting different natural histories for the two variants. Since the above studies were based on detection of HHV-6 DNA by PCR rather than by isolation of replicating virus, further work is required to elucidate the possible confounding contribution of chromosomal integration.

HHV-7

Although *in vitro* the host range is limited to T lymphocytes, *in vivo* HHV-7 is commonly found in blood and saliva but also in lungs, skin and mammary glands (Kempf

et al., 1998). In contrast, the virus has rarely been found in brain tissue.

Transmission

Horizontal Transmission of HHV-6B and HHV-7

Both viruses are frequently detectable in the saliva of seropositive individuals, and often at high level in the case of HHV-7, suggesting that *in vivo* salivary glands are a major site of viral replication and that saliva is therefore the source for transmission of both viruses. Molecular characterization of HHV-6 strains detected within a limited number of families suggests that the virus may be transmitted primarily from mother to child. Recently, it has been reported that being exposed to parental saliva and having older siblings were independently associated with HHV-6B infection in early childhood (Rhoads *et al.*, 2007). For HHV-7, genetic analysis of virus within families also suggests transmission within the family unit from both mothers and fathers (Thawaranantha *et al.*, 2002), and even through three generations in the same household (Takahashi *et al.*, 1997). Considering that HHV-6B and HHV-7 are both frequently shed in saliva, it is not obvious as to why infection with the latter virus is more delayed in childhood. One possibility is that the restricted cellular tropism of HHV-7 hinders its ability to replicate at the portal of infection, a restriction that does not affect the more widely tropic HHV-6. On the other hand the fact that titres of maternally-acquired neutralizing antibodies

to HHV-7 are higher than those to HHV-6 may account for the later acquisition of HHV-7.

Vertical Transmission of HHV-6A and HHV-6B

A large study by Hall *et al.* (2004) in Rochester, USA investigated the occurrence of congenital HHV-6 infection. Using nested PCR, HHV-6 DNA was detected in 57 of 5638 (1%) cord blood samples, and one third of the positives were variant A, as opposed to the control postnatal infections, all of which were variant B. The high proportion of variant A in cord blood is striking given its apparently low prevalence overall and it seems highly likely that a main route for HHV-6A infection is vertical. The question of vertical transmission of chromosomally-integrated HHV-6 was not investigated in this study, although the proportion of individuals estimated to exhibit such a phenomenon is similar to the actual incidence found (see 'Incidence and Prevalence'). In fact there is considerable evidence that chromosomally-integrated HHV-6A and HHV-6B can be inherited vertically. This has been reported in six different families in Japan (Daibata *et al.*, 1998, 1999; Tanaka-Taya *et al.*, 2004); in one from both parents and in another through two generations (Figure 10.4). In addition, two cases of transmission from mother to child have been reported in the United Kingdom (Ward *et al.*, 2005b).

Finally, a very recent report from Rochester (Caserta *et al.*, 2007) suggests the possibility of two routes of HHV-6 congenital infection, one being transmission of

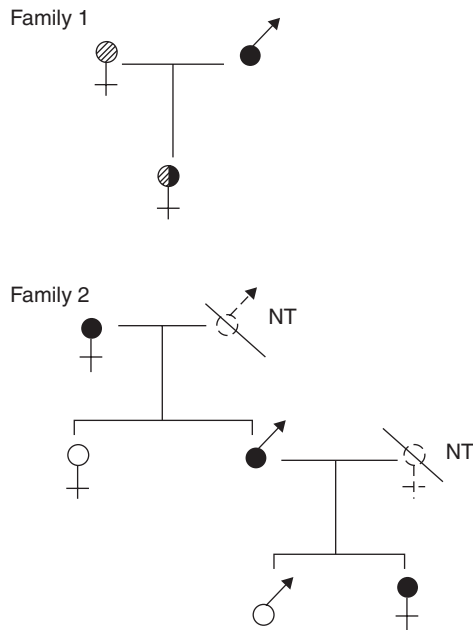

Figure 10.4 Vertical transmission of chromosomally-integrated HHV-6 from both parents in one family and through two generations in another. (Adapted from Daibata *et al.*, 1999 and Daibata *et al.*, 1998, respectively.)

Key: Chromosomal integration site 1q44 () and 22q13 (); female; ♂, male; NT, not tested.

integrated HHV-6 through the germ line and the other a conventional infectious process whereby virus has crossed the placenta.

Vertical Transmission of HHV-7

In contrast to HHV-6 there is no evidence for vertical transmission of HHV-7. In the same large study described above, Hall *et al.* (2004) investigated the occurrence of congenital HHV-7 infections, but even using nested PCR, HHV-7 DNA was not detected in 2129 cord bloods.

Perinatal Transmission of HHV-6 and -7

Although there is no general agreement as to whether perinatal transmission occurs, HHV-6 (predominantly variant B but also variant A) and HHV-7 DNA have been detected in 7.5 and 3% respectively of cervical swabs from pregnant women (Caserta *et al.*, 2007), pointing to this as a potential route. HHV-7 DNA, but not HHV-6, was detected in 3 of 29 breast-milk samples, suggesting that breast feeding may also be a route of transmission for HHV-7 (Fujisaki *et al.*, 1998).

Nosocomial/iatrogenic Transmission

Primary HHV-6 Infection Transmitted from a Solid Organ Donor This was first reported in 1989 after primary HHV-6 infection in a patient following liver transplantation from a seropositive donor (Ward *et al.*, 1989). More recent evidence supports transmission of HHV-6 infection to infants through liver transplantation from their HHV-6 seropositive mothers (Yoshikawa *et al.*, 2001). Similarly, since HHV-6 has been identified in bone marrow progenitor cells, it is likely that HHV-6 can be transmitted by donor marrow. Indeed, a case of HHV-6B transmission has been well documented in an infant who received a bone marrow transplant from his non-identical twin brother who had ES at the time of marrow donation (Lau *et al.*, 1998).

Chromosomally-integrated HHV-6 Transmitted from a Haematopoietic Stem Cell Donor This was reported for the first time by Clark *et al.* (2006a). In such cases the resultant extremely high HHV-6 DNA load in the blood of the engrafted recipient must always be distinguished from active infection (see also comments in ‘Laboratory Diagnosis’).

Immune Responses

Although fixed infected tissue culture cells and cell lysates have been the most common source of antigens in serological assays for HHV-6 and HHV-7, there is limited characterization of specific antigenic targets or of those antibodies that may be protective (for review see Black and Pellett (1999)). Maternal antibodies appear to be relatively effective in limiting primary infection in the first six months of life and the incidence of seroconversions increases after this time as passively-acquired maternal antibodies wane. For HHV-6, the tegument proteins—p100 for HHV-6A and 101K for HHV-6B—encoded by U11 are a major target of the antibody response. However, there is 80% amino acid identity between HHV-6A and HHV-6B in this ORF and substantial antibody cross-reactivity exists. Antibody responses to HHV-7 are directed predominantly against pp85 and pp89 (encoded by U14 and U11 respectively). There is a low level of cross-reactivity between the antibody responses to HHV-6 and HHV-7 in indirect immunofluorescence tests (see ‘Laboratory Diagnosis’). Neutralizing antibodies have been described for a number of HHV-6 glycoproteins including gB, the gH/gL complex and gQ. For HHV-7, neutralizing antibodies to the HHV-7 gQ homologue have been reported (Skrincosky *et al.*, 2000).

There is only a very limited characterization of the cellular immune responses to HHV-6 and HHV-7 but, as for antibodies, there seems to be some level of

Figure 10.5 Virological features of primary HHV-6 and -7 infections. For avidity see P. 233. (Source: Ward, 2005, with permission.)

cross-reactivity. In the case of HHV-6, virus reactivation is common after immunosuppression accompanying organ transplant, indicating the importance of T lymphocytes in controlling virus infection.

Primary Infection

HHV-6B IgM antibodies can be detected five days after the onset of infection and IgG antibodies by day 7, the latter increasing for up to three weeks and persisting thereafter. There is a transient viraemia that subsides with the appearance of neutralizing antibodies (Figure 10.5).

HHV-7 Although less well studied, the immune response after primary infection is similar to that of HHV-6; some cases are accompanied by a rise in HHV-6 antibodies (see 'Laboratory Diagnosis').

DISEASE ASSOCIATIONS

HHV-6 in particular has been alleged to cause many different diseases, although so far—apart from the well-established case of ES—without compelling evidence for an aetiological role. In fact, the association of HHV-6A, HHV-6B and HHV-7 with disease is fraught with difficulty since, as with all the herpesviruses, both primary infection and reactivation/re-infection may be asymptomatic, and virus replication may continue intermittently thereafter. In addition, HHV-6B and

HHV-7 are universal in the human population from an early age. Finally, in the case of HHV-6 A and HHV-6B, matters are further complicated by the phenomenon of viral chromosomal integration.

Chromosomally-integrated HHV-6 and Disease

Two decades ago a small group of patients with predominantly malignant lymphoid disorders were identified with an unusually high level of HHV-6 DNA in tissue biopsies (Jarrett *et al.*, 1988), suggesting a role for HHV-6 in neoplasia. In 1993 Luppi *et al.* (1993) reported similar high levels in three patients, one with Hodgkin's disease, one with a non-Hodgkin's lymphoma and one with multiple sclerosis (MS), and showed that this resulted from HHV-6 chromosomal integration. Since then viral chromosomal integration has been identified in patients with a variety of dissimilar clinical presentations, including acute lymphatic leukaemia (Daibata *et al.*, 1998), Burkitt lymphoma (Daibata *et al.*, 1999), aplastic anaemia (Hubacek *et al.*, 2007b), anticonvulsant hypersensitivity syndrome (also known as drug-induced hypersensitivity syndrome (DIHS), see below) (Watanabe *et al.*, 2008), various disparate neurological syndromes (Ward *et al.*, 2007b), and even one case of measles (Tanaka-Taya *et al.*, 2004). Thus, it seems that the phenomenon of viral chromosomal integration was come upon by chance rather than because it caused any of the above diseases. Indeed, HHV-6 chromosomal integration has also been found in several apparently healthy individuals, some of whom were blood

donors (Leong *et al.*, 2007) or stem cell donors (Clark *et al.*, 2006a; Kamble *et al.*, 2007).

There are nowhere near enough data available to unravel the possible long-term clinical consequences of HHV-6 integration at various telomeric chromosomal sites. The telomeric region of the chromosome is notoriously unstable and prone to homologous recombination in a mechanism involving the telomere repeats, and it is not known what effect HHV-6 integration may have on this propensity. Large-scale prospective epidemiological surveys are required to determine whether viral chromosomal integration has a role to play in any disease.

Although no clinical consequences have yet been linked to HHV-6 integration it is worth emphasizing that the phenomenon has important implications in clinical practice. Since every cell in the body of an affected person carries the viral genome, high levels of the viral DNA will be found in body fluids such as blood. Unless recognized as the consequence of chromosomal integration, such high viral DNA levels may be interpreted as 'chronic active' HHV-6 infection causing disease. This misunderstanding can lead to inappropriate use of antiviral drugs, such as ganciclovir or foscarnet, which can result in unnecessary toxicity but may well have no effect on the HHV-6 DNA load (Figure 10.6a).

Congenital HHV-6 Infection and Disease

In three surveys of congenital HHV-6 infection as defined by the detection of HHV-6 DNA in cord blood (Adams *et al.*, 1999; Dahl *et al.*, 1999; Hall *et al.*, 2004) no morbidity was found. Although the congenitally-infected children were asymptomatic at birth, more subtle long-term effects could not be excluded, nor could the likelihood that, as with CMV infection, only a low proportion of infected children might be adversely affected. None of these surveys took account of the possibility of germ-line transmission due to chromosomal integration. Prospective studies are needed that differentiate between a classical congenital infection and germ-line inheritance as there may be very different outcomes depending on the mode of transmission. The exact contribution of HHV-6A and HHV-6B to these two possibilities also remains to be determined.

HHV-6B and HHV-7 Primary Infection and Disease in Young Children

Exanthem Subitum

Primary infection with HHV-6B has been conclusively proven to cause ES ('roseola infantum' or sixth

disease) (Yamanishi *et al.*, 1988), a classic febrile rash illness of early childhood which is typically accompanied by a transient viraemia, reduced numbers of circulating leucocytes (both lymphocytes and neutrophils) and sometimes thrombocytopenia and hepatitis. Primary HHV-7 infection also causes ES in a minority of children (Tanaka *et al.*, 1994).

This childhood illness classically presents in an infant with three to five days of high fever with no localizing signs and hence is a worry to both parents and physicians. Defervescence follows, accompanied by the acute onset of a rose-pink, nonpruritic, macular rash, predominantly seen on the neck and trunk. Because of the abrupt onset of the rash, the disease was named exanthem subitum ('*subitum*' means 'sudden' in Latin). The clinical presentation of the disease is not always so characteristic and the rash is commonly misdiagnosed as measles, rubella or an allergic reaction to antibiotics. Finally, it should be noted that both HHV-6B and HHV-7 primary infections may cause a febrile illness without a rash or may be clinically silent.

Convulsions and Encephalitis/Encephalopathy

Although usually mild, it was known long before the aetiology of ES was established that convulsions, and rarely encephalopathy, can accompany this febrile illness. Since the discovery of HHV-6 and HHV-7 and the laboratory diagnosis of primary infection became available, primary HHV-6B infection has been confirmed as the cause of about a third of febrile convulsions (Hall *et al.*, 1994). HHV-7 also causes febrile convulsions, although these are less well documented (Caserta *et al.*, 1998).

As regards more severe neurological manifestations, the convulsions associated with primary HHV-6B infection are often recurrent or otherwise atypical (Hall *et al.*, 1994). Other severe central nervous system (CNS) complications of primary HHV-6B infection (such as meningoencephalitis), although not usually accompanied by pleocytosis in the CSF, have been suggested in isolated case reports. In the case of HHV-7, a primary infection associated with encephalitis/encephalopathy has been described (van den Berg *et al.*, 1999) in which the child recovered. These hints that primary HHV-6B and possibly HHV-7 infections may make a significant contribution to neurological morbidity have now been confirmed by a recent prospective British Isles-wide survey of young children with suspected encephalitis. Seventeen percent of serious neurological diseases in children up to two years old were found to be due to primary infection with HHV-6B or HHV-7; this is just the age when routine childhood

Figure 10.6 Comparison of the effects of antiviral drugs on (a) HHV-6 chromosomal integration and (b) active HHV-6 infection. (a) Failure of multiple antivirals to affect high HHV-6 DNAemia resulting from viral chromosomal integration in a case of severe aplastic anaemia. (Adapted from Hubacek *et al.*, 2007b.) (b) Virological response to antiviral therapy in a case of HHV-6-related graft failure following allogeneic bone marrow transplantation. (Adapted from Johnston *et al.*, 1999.)

vaccines such as measles, mumps, rubella (MMR) are administered and thus neurological complications wrongly attributed to the vaccine may in fact be due to coincidental primary HHV-6B or HHV-7 infections. Many of the cases of primary infection in the survey were in status epilepticus with fever (Ward *et al.*, 2005a) but fitted the criteria for complex febrile convulsions rather than encephalitis (Ward *et al.*, 2007a). In this connection, a recent preliminary study has identified HHV-6B in the mesial temporal lobe of patients with epilepsy originating

from this part of the brain (Fotheringham *et al.*, 2007) and such disease has been associated with complex febrile convulsions.

Summary of Clinical Manifestations of Primary Infection

In the case of HHV-6B, most children have at least some symptoms (only about 5% are asymptomatic), ranging from fever, occasionally accompanied by the rash of

ES (Zerr *et al.*, 2005), to febrile convulsions to status epilepticus with fever (Ward *et al.*, 2005a). The severity of disease depends on the population under study. It is mildest in the community (Zerr *et al.*, 2005), more serious in children requiring medical attention but not necessarily admitted to hospital (Hall *et al.*, 1994), and most severe in children admitted to hospital (Ward *et al.*, 2005a). Primary infection with HHV-7 has been much less extensively investigated but the pattern of disease is similar.

HHV-6B and HHV-7 Primary Infection in Older Children and Adults

With virtually all children acquiring HHV-6 infection by the age of two years and HHV-7 usually slightly later primary infections are bound to be unusual. But, by analogy with the other HHVs, such delayed primary infection might be expected to cause more severe disease than in early childhood. The evidence is scanty but in adults primary HHV-6B infection has been associated with heterophile antibody-negative mononucleosis (Akashi *et al.*, 1993) and primary HHV-7 infection with encephalitis and flaccid paralysis (Ward *et al.*, 2002).

HHV-6 and HHV-7 Reactivation and Disease in the Immunocompetent

Studies on this topic are more difficult to carry out than those on primary infection and depend on the detection of increased viral replication by one means or another (see 'Laboratory Diagnosis' for a discussion of the problems and pitfalls). In addition, the distinction between re-infection and reactivation has rarely, if ever, been attempted, and in what follows the blanket term 'reactivation' is used to cover both possibilities. Thus, HHV-6 reactivation has been described apparently without effect on morbidity or mortality in 3.3% of children (Caserta *et al.*, 2004), commonly in pregnancy (Dahl *et al.*, 1999), during infection with other viruses such as measles and dengue, and in critically-ill but otherwise immunocompetent patients (Razonable *et al.*, 2002).

HHV-6 Reactivation and Disease

Drug-induced Hypersensitivity Syndrome (DIHS)

This is also known as drug hypersensitivity syndrome (DHS) or drug rash with eosinophilia and systemic symptoms (DRESS) and is characterized by a severe multi-organ hypersensitivity reaction that usually appears three to six weeks after exposure to certain drugs, including anticonvulsants. The exact pathogenesis of this

syndrome is unknown although it is likely that a genetic predisposition is involved. Recently HHV-6 reactivation has been associated with DIHS because of very large increases in HHV-6 IgG titres three to four weeks after onset. However, it remains to be seen whether HHV-6 reactivation plays a causal role in this syndrome by contributing to either its initiation or its exacerbation, rather than merely being a consequence of pre-existing immune activation (Wong and Shear, 2004).

Multiple Sclerosis (MS) In 1995 Challoner and colleagues (1995) proposed an association of HHV-6 with MS. Their findings provoked substantial controversy and the generation of conflicting data from many later studies (for review see Clark (2004)). With hindsight it seems that the ready identification of HHV-6 DNA by representational difference analysis in an MS brain sample may have been due to viral chromosomal integration with its consequent high HHV-6 DNA load (Clark *et al.*, 2006a). Any link of either HHV-6 variant to MS remains unclear.

Chronic Fatigue Syndrome/Myalgic Encephalopathy

There is no convincing scientific evidence for an aetiological role of HHV-6 in this syndrome but the lingering belief in this unproven association leads to frequent unnecessary requests for HHV-6 diagnosis.

Encephalitis As regards neurological disease, since HHV-6B commonly persists in brain, viral reactivation from this site might be expected occasionally to cause encephalitis. HHV-6 was the only agent detected by PCR in CSF in a small proportion of cases of older children and adults with encephalitis (McCullers *et al.*, 1995), leading to the conclusion that the virus was replicating in the nervous system. Since then there have been about a dozen case reports suggesting HHV-6A or HHV-6B as the cause of encephalitis in adults. Moreover, several large surveys of the prevalence of HHV-6 DNA in the CSF of patients in America, Europe and the Middle East all gave a result of 1–2%. Although unrecognized in any of the above studies, their finding of HHV-6 DNA in about 1–2% of samples is of exactly the same order as that shown for the prevalence of HHV-6 chromosomal integration in UK blood donors. Indeed, a recent study (Ward *et al.*, 2007b) has demonstrated that chromosomal integration rather than active virus replication is the most likely cause of HHV-6A or HHV-6B DNA in the CSF of the immunocompetent—the higher the number of leukocytes in that fluid the greater the

amount of chromosomally-integrated HHV-6 that will be detected.

HHV-7 Reactivation and Disease

Very little is known about HHV-7 reactivation in the normal host although there is no evidence of this in critically-ill patients (Razonable *et al.*, 2002). HHV-7 DNA is rarely, if ever, found in the CSF of older children and adults and therefore no link between virus reactivation and encephalitis has been suggested. Likewise, a postulated association of HHV-7 with 'pityriasis rosea' remains unproven (Chuh *et al.*, 2004).

HHV-6 and HHV-7 and Immunomodulation

Both HHV-6 and HHV-7 infect CD4⁺ T lymphocytes, the cornerstone of the adaptive immune response, and it seems likely that in common with the other herpesviruses HHV-6 and HHV-7 have genes that function to facilitate the avoidance of immune surveillance during primary infection, latency and reactivation. It has therefore been suggested that infection with either of these two viruses (but primarily HHV-6; see Table 10.3) interferes with the functioning of the host immune response, and therefore contributes to overall mortality by enhancing the pathogenic effects of agents such as human immunodeficiency virus (HIV) and CMV, or exacerbates graft-versus-host disease (Ljungman and Singh, 2006; Lusso, 2006). Further studies are required to establish the clinical impact, if any, of immunomodulation due to HHV-6 and HHV-7.

HHV-6 and Disease in the Immunosuppressed after Organ Transplant

Since HHV-6 seroprevalence is almost universal in older children and adults, it is not surprising that HHV-6 reactivation is common after solid organ transplant and haematopoietic stem cell transplant (HSCT). Such reactivations occur up to half of all patients within two to four weeks of transplant. In addition, as discussed above, HHV-6 can sometimes be transmitted with the donor allograft. Unfortunately, very few studies of HHV-6 infection after transplant distinguish between the two variants, though in those that do it is clear that HHV-6B is identified much more frequently than variant A. Finally, associations between HHV-6 and disease are often based on case series, in which the described cases are frequently complex, involving several different possible pathological mechanisms, which makes conclusions about aetiology very difficult.

HSCT Recipients

In this context various nonspecific clinical manifestations have been attributed to HHV-6, including fever, skin rash and hepatitis, but the best documented are bone marrow suppression and encephalitis (Ljungman and Singh, 2006; Zerr, 2006).

Bone Marrow Suppression HHV-6 can infect haematological progenitor cells *in vitro* and reduce colony formation. *In vivo* HHV-6 infection has been associated with delayed engraftment after HSCT, especially of monocytes and platelets.

Table 10.3 Principal mechanisms of immunomodulation by HHV-6

Mechanisms	Viral variant
Lytic infection of CD4 ⁺ T cells	A, B
Lytic infection of cytotoxic effector cells (CD8 ⁺ T cells, $\gamma\delta$ T cells and natural killer cells)	A
Phenotypic and functional impairment of antigen-presenting cells (macrophages, dendritic cells)	A, B
Suppression of IL-12 secretion by macrophages and dendritic cells	A, B
Suppression of IL-2 secretion	A
Induction of inflammatory and immunosuppressive cytokines and chemokines (e.g. IFN- α , IL-1 β , IL-10, IL-15, TNF- α , RANTES)	A, B
Expression of viral chemokines and chemokine receptors	A, B
Downmodulation of the CD3/T-cell receptor complex	A, B
<i>De novo</i> induction of CD4	A
Downmodulation of CD46	A > B
Induction of T-regulatory type 1 cells	A, B
Synergy with HIV-1	A > B

IL, interleukin; IFN, interferon; TNF, tumour necrosis factor.
From Lusso (2006), with permission.

Encephalitis HHV-6 encephalitis is emerging as a significant but relatively rare clinical entity after HSCT, with a mortality of about 40%. In the first case of HHV-6 encephalitis described there was evidence of HHV-6B infection, namely viral protein in astrocytes and neurons, in the diseased area of the brain including the hippocampus, and the pathology was characterized by necrosis and demyelination (Drobyski *et al.*, 1994). Since then there have been many publications describing HHV-6 encephalitis in over 40 patients, mostly as single case reports, and in over three quarters of these a mismatched related or unrelated HSCT was involved (only one patient had received an autograft rather than an allograft). Where the virus had been typed it was predominantly variant B. Of these case reports about a third had a limbic encephalitis, for which the term post-transplant limbic encephalitis (PALE) has recently been suggested (Seeley *et al.*, 2007), whereas the remainder had a more diffuse or multifocal encephalitis. In addition, longitudinal observational studies have established a correlation between HHV-6 reactivation in peripheral blood and CNS disease.

Patients with HHV-6 encephalitis characteristically present early after transplant (median 24 days) with depressed consciousness, convulsions, confusion and disorientation, often with short-term memory loss. Few patients have focal findings on neurological examination. Apart from HHV-6 DNA in CSF, elevated CSF protein levels are present in about two thirds of patients, and about half have CSF pleocytosis. Computed tomography (CT) of the brain, especially when conducted early in the course of illness, is often normal. Acute abnormalities are seen more often in magnetic resonance imaging (MRI) of the brain; these include multiple non-enhancing, low-attenuation lesions in the grey matter, sometimes involving the temporal lobes (especially the medial temporal). Electroencephalography (EEG) studies are usually diffusely abnormal but sometimes involve the temporal region (Zerr, 2006). However, before the diagnosis of HHV-6 encephalitis is finally accepted, other infectious agents should be excluded by culture, microscopy or nucleic acid test. Malignant disease (based on CT or MRI, and microscopy and immune staining of CSF) and HHV-6 chromosomal integration must likewise be excluded.

Solid Organ Transplant Recipients

As for HSCT, there is some evidence for bone marrow suppression and encephalitis due to HHV-6 infection after solid organ transplant, although this occurs less frequently than after HSCT. Patients receiving a liver graft seem to be the most prone to developing symptoms due to HHV-6. However, a potential role for indirect effects of HHV-6

(see 'HHV-6 and HHV-7 and Immunomodulation') on disease in transplant recipients has been suggested by a number of prospective studies and these may be more significant than direct effects in terms of medical impact (Clark and Griffiths, 2003).

HHV-7 and Disease in the Immunosuppressed after Organ Transplant

In contrast to HHV-6, HHV-7 reactivation after HSCT is less common (Boutolleau *et al.*, 2003) and there is little evidence for an association with direct end organ disease, although a handful of cases with CNS symptoms have been ascribed to the virus (Ljungman *et al.*, 2008). However, as for HHV-6, findings from prospective studies suggest that there may be important indirect effects of HHV-7, such as an increased risk of CMV disease in renal transplant recipients.

LABORATORY DIAGNOSIS

Antibody Detection

IgG and IgM

The first tests for HHV-6 IgG were developed by Yamanishi and colleagues using indirect immunofluorescence (Yamanishi *et al.*, 1988). Many other assays have subsequently been introduced including those for neutralizing antibody, enzyme immunoassay (EIA) and immunoblot. However, systematic comparisons of these assays have rarely been carried out and more are urgently needed; furthermore, unfortunately none of them can distinguish between the antibody response to HHV-6A and B. In the case of HHV-7, much less developmental work has been done and indirect immunofluorescence is the most commonly used test.

Immunofluorescence tests are disadvantageous in that they are labour-intensive, subjective and limited by non-specific fluorescence. In addition, IgM is not always detected with primary infection because of low sensitivity, although this can be improved somewhat by separation of IgM from IgG, for example, by using ion-exchange chromatography. There is also cross-reactivity at the IgM level between HHV-6 and -7, and probably with CMV and EBV. Nevertheless, the indirect immunofluorescence tests for HHV-6 and -7 antibody remain the gold standard and are the most commonly used (kits are commercially available). Such tests allow evaluation of antibody development and titres in sequential serum samples, and when modified to detect IgG antibody avidity can distinguish primary from long-standing infection (see below).

IgG and Antigenic Cross-reaction

As discussed earlier there is antibody cross-reactivity between HHV-6 and HHV-7 IgG. However, in indirect immunofluorescence tests this is limited and titres >32 can be accepted as true positives. As regards other tests, immunoblot assays can eliminate cross-reaction by using the immunodominant antigen specific to each virus, namely for HHV-6 101k (or p100) and for HHV-7 pp89, but the reagents are not readily available. Likewise, some of these problems might be solved by the use of EIAs based on recombinant antigens specific to HHV-6 and -7 but much further developmental work is required. Finally, the neutralizing epitopes for HHV-6 and HHV-7 appear to be distinct and immunological cross-reactivity between neutralizing antibodies for the two viruses has not been reported (Yoshida *et al.*, 2002) but such tests are very labour-intensive.

It should be noted that rises in pre-existing IgG antibody to HHV-6 have been reported following primary CMV and EBV infections. These may be due to polyclonal stimulation, antigenic cross-reaction eliciting a secondary HHV-6 response, or reactivation.

Antibody Avidity Tests

In primary infection the first IgG antibodies produced are of low avidity but with time the immune response matures as specific B-cell clones undergo somatic mutation and IgG antibody of higher avidity is produced. *In vitro* tests for antibody avidity rely on the fact that a protein-denaturing agent disrupts the antigen-antibody reaction preferentially, affecting low- but not high-avidity antibody. Such tests have been used for the diagnosis of many different human virus infections. HHV-6 and HHV-7 IgG immunofluorescence tests are easily adapted for the assessment of antibody avidity by the use of a urea wash after the primary incubation with antibody; if antibody avidity is low this confirms recent primary infection but if the avidity is high primary infection must have occurred at least six weeks previously (Figure 10.5).

Virus Detection

Unlike antibody tests, these methods have the ability to discriminate between HHV-6A and HHV-6B.

Virus Isolation

HHV-6A and HHV-6B, and HHV-7 may be grown by co-culture of a sample of the individual in question's PBMC with phytohaemagglutinin-stimulated cord blood lymphocytes. The cytopathic effects (CPEs) for all three viruses are very similar (see Figure 10.1 for HHV-6 CPE) but they may be individually identified by the use of tests

for antigen or nucleic acid (see below). Unfortunately, although culture is the gold standard for diagnosis of active infections this is too labour-intensive for routine diagnostic use and cord blood cells are not generally available.

Antigen Detection

Although specific monoclonal antibodies are available (some commercially) (Wang and Pellett, 2007) and an HHV-6 antigenaemia test has been developed, there is very little experience with it as its use has not been widespread. Similarly, the use of monoclonal antibodies directed against virus structural proteins for the immunohistochemical diagnosis of tissue infections has only been used in research studies.

Detection of Viral Nucleic Acid

Both qualitative and quantitative PCR methods have been published but the optimal genomic target is not known. Multiplex PCR is recommended to distinguish HHV-6A, HHV-6B and HHV-7. As regards the detection of infection, real-time quantitative PCR is the method of choice, although no quantitative threshold has been formally established to differentiate latent HHV-6 and HHV-7 infection from active viral replication. The lack of a standardized upper limit is also a concern in the case of HHV-6, where abnormally high levels in whole blood and serum due to chromosomal integration will be misdiagnosed as active infection responsible for disease. Reverse transcription PCR directed against a gene activated in the lytic replication cycle of HHV-6 and HHV-7 is a potential alternative, although in the one case reported so far, low levels of HHV-6 transcripts from IE, early and late genes were detected in the PBMC of a person with chromosomally-integrated HHV-6 (Clark *et al.*, 2006b).

Diagnosis of HHV-6 Chromosomal Integration

This phenomenon should always be suspected if there is an abnormally high HHV-6 DNA load in blood. A way to confirm viral chromosomal integration is to test hair follicles for the presence of HHV-6 DNA but this is impractical for routine diagnosis. Instead, viral DNA load should be measured in both whole blood and serum, preferably alongside quantitation of cellular DNA, for example β -globin DNA, so as to calculate the number of HHV-6 copies per cell. If there is chromosomal integration of HHV-6 then there should be at least one copy of HHV-6 DNA per leucocyte, and similarly for serum at least one copy per lysed leucocyte.

Diagnosis of Primary Infection in Young Children

In all that follows, it should be remembered that maternally-acquired antibody may confuse the interpretation of results in children less than six months old.

Using Paired Sera

This is the traditional method, requiring an acute serum preferably taken within the first week of illness, and a convalescent serum taken 10–14 days later (Figure 10.5). Testing the two sera together will readily demonstrate IgG seroconversion and thus primary HHV-6 infection in an HHV-7 seronegative individual (Table 10.4, example 2) and vice versa (Table 10.4, example 4). However, difficulty commonly arises in primary HHV-7 infection in the presence of previous HHV-6 infection since rising titres of antibodies to both viruses may occur, presumably due either to antigenic cross-reaction eliciting a secondary HHV-6 response or to concomitant HHV-6 reactivation. Antibody avidity tests prove very useful in this situation, distinguishing the low-avidity IgG response in HHV-7 primary infection from the high-avidity HHV-6 response which may accompany it (Table 10.4, example 5). Coinciding HHV-6 and HHV-7 primary infections may also be differentiated in this way (Table 10.4, example 1).

However, differentiating primary HHV-6A from HHV-6B infection requires the detection and characterization of virus or viral nucleic acid.

Using Paired Saliva Samples

This innovative method using the detection of viral DNA in saliva samples was pioneered by Zerr *et al.* (2005). It is useful for field studies but the time interval between last negative test and first positive test should not be more than 14 days; the problem in using more extended intervals is that in the first few years after primary infection viral DNA will inevitably be found in saliva.

Using a Single Acute Serum

Viral DNA in serum in the absence of IgG is usually taken to reflect the transient viraemia that occurs in the acute phase of HHV-6 and HHV-7 primary infections (see Table 10.4, examples 1 and 2, and 3 and 4 respectively). However, in the case of HHV-6 the possibility of chromosomal integration must be borne in mind and excluded. Importantly, it is not always possible to detect viral DNA in serum or plasma in the acute phase of primary infection (see Table 10.4, example 1 primary HHV-7 infection) (see also Ward *et al.*, 2007b).

Table 10.4 Examples of HHV-6 and -7 antibody responses and detection of DNA in primary infections in young children (Source: Ward, 2005).

Example no. and type of infection	Day of illness	HHV-6 IgG		HHV-6 DNA ^a	HHV-7 IgG		HHV-7 DNA ^b
		Titre	Avidity		Titre	Avidity	
(1) Dual primary HHV-6B and -7 infections	1	nt	nt	+	< 16	nt	–
	2	< 16	nt	nt	nt	nt	nt
	17	2048	Low	nt	256	Low	nt
(2) Primary HHV-6B infection without HHV-7 infection	0	< 16	nt	+	< 16	nt	–
	4	< 16	nt	+	< 16	nt	–
	10	2048	Low	–	nt	nt	–
(3) Primary HHV-6B infection with past HHV-7 infection	55	512	High	nt	< 16	nt	nt
	3	32	nt	+	128	High	–
	14	128	Low	–	128	High	–
(4) Primary HHV-7 infection without HHV-6 infection	4	< 16	nt	–	< 16	nt	+
	11	16	nt	–	512	Low	–
	41	< 16	nt	nt	512	Low	nt
(5) Primary HHV-7 infection with past HHV-6 infection	168	16	nt	–	512	High	–
	3	512	High	–	64	Low	+
	15	8192	High	nt	8192	Low	nt
	96	1024	High	–	4096	Low	–
	119	512	High	–	256	High	nt

^aHHV-6B detected in plasma or serum.

^bDetected in plasma or serum.

nt, not tested.

See Ward *et al.* (2001) for details of methods. Low-avidity antibody results are highlighted in bold.

Using a Single Convalescent Serum

The high prevalence of both HHV-6 and HHV-7 makes it difficult to interpret single positive IgG results in convalescent sera, although low avidity antibody suggests infection within the previous six weeks.

Diagnosis of Convulsions with Fever and Encephalitis

If HHV-6 or HHV-7 is suspected as the cause of fever and convulsions in a young child, serological tests for primary infection are the key to diagnosis as viral nucleic acid is not always detected in CSF (Caserta *et al.*, 1998; Hall *et al.*, 1994). On the other hand it is not enough for the diagnosis of HHV-6 encephalitis to detect viral DNA in CSF. The amount of viral DNA must be quantitated and other possible causes, including HHV-6 chromosomal integration, must be excluded before any conclusions are drawn. Although, as discussed above, HHV-6 encephalitis is accepted as an emerging disease after organ transplant, formal proof of suspected HHV-6 encephalitis under any other circumstances requires evidence in CSF of active virus infection and cell destruction in the brain.

Diagnosis of Primary Infection or Reactivation in Older Children/Adults and the Immunosuppressed

It is of note that diagnosis of primary infections in older children/adults and those who have received chemotherapy definitely requires the use of avidity tests as antibody titres may have decreased to the point of seronegativity and a secondary antibody response may therefore appear to be that of a primary. The diagnosis of primary infection in the severely immunocompromised, for example HSCT patients, who are unable to make an antibody response, is especially difficult and requires rigorous exclusion of pre-existing infection by molecular means. IgM tests are unhelpful in this group since as many as 5% of adults may be positive at any given time, suggesting either re-infection/reactivation or nonspecific reactions.

As regards reactivation, antibody tests (even when including those for avidity) may be unhelpful, especially for HHV-6, since as noted previously pre-existing antibody may rise in primary CMV and EBV infections. In addition, as discussed earlier, the detection of HHV-6 DNA in CSF in those already HHV-6 seropositive may well be due to HHV-6 chromosomal integration rather than virus reactivation.

Diagnosis of Disease after Organ Transplant

As discussed above antibody tests have little to offer in the immunocompromised. Diagnosis therefore relies on the careful interpretation of the results of virus detection

in the context of clinical features and exclusion of other possible causes.

Pitfalls due to HHV-6 Chromosomal Integration

In the past, detection of HHV-6 DNA in the blood of transplant patients was interpreted as evidence of virus reactivation, with very high DNA levels taken to indicate high levels of active virus replication. Unfortunately such an interpretation should not be made in an individual with HHV-6 chromosomal integration and this phenomenon must be excluded before assuming active HHV-6 infection. For example, after HSCT from a donor with chromosomal integration of HHV-6 there will be asymptomatic elevation of HHV-6 DNA load in the recipient after transplant, rising to characteristically and strikingly high levels that correlate with leucocyte engraftment (Clark *et al.*, 2006a). On the other hand, if the stem cell recipient rather than the donor has viral chromosomal integration the converse will occur, although a persistent low-level HHV-6 DNA will remain in blood, presumably due to release of chromosomal DNA from the recipient's non-haematopoietic cells (Hubacek *et al.*, 2007a). A comparison of the different possible findings regarding HHV-6 after HSCT is given in Table 10.5. If HHV-6 chromosomal integration is suspected, it can most easily be established by checking donor and recipient blood prior to transplant for high levels of HHV-6 DNA using quantitative PCR.

HHV-6 Induced Bone Marrow Suppression or Encephalitis

The diagnosis of virus-induced bone marrow suppression must be based on delayed engraftment, together with HHV-6 DNA in blood or ideally virus isolation in culture. Similarly the diagnosis of encephalitis must be based on features consistent with HHV-6 disease, namely CNS symptoms and signs, together with an abnormal MRI, or diffuse EEG changes, together with detection of HHV-6 DNA in CSF. In both cases other possible causes of disease and HHV-6 chromosomal integration must be excluded.

Other HHV-6 or HHV-7 Disease

Symptoms and signs from the organ in question, together with HHV-6 or HHV-7 detection in blood, are not enough for the diagnosis of disease. Tests on tissue are required to establish evidence of viral replication and consequent pathology. Possible techniques include *in situ* hybridization and immunohistochemistry. PCR for viral DNA is not recommended as its detection may merely reflect the presence of virus in blood rather than tissue

Table 10.5 Comparison of findings after HSCT in various forms of HHV-6 infection

Clinical/laboratory observations	HHV-6 status		
	Horizontal acquisition	Donor chromosomal integration	Recipient chromosomal integration
≥ 1 HHV-6 copy/leucocyte	No	Yes ^a	No ^b
≥ 1 HHV-6 copy/hair follicle	No	No	Yes ^c
HHV-6 variant/prevalence	B/>95%	A or B/about 1%	A or B/about 1%
HHV-6 DNA in blood	No or intermittent	+ + + +	+/-
Disease due to HHV-6	Encephalitis, delayed engraftment	No?	No?
HHV-6 response to antiviral drugs	Yes, decrease in HHV-6 DNA level	No	No

^aHHV-6 found persistently at extremely high level (chromosomal integration) in haematopoietic tissue, for example blood, bone marrow and spleen.

^bChromosomally-integrated HHV-6 'not' found in the haematopoietic tissue.

^cHHV-6 found persistently at extremely high level (chromosomal integration) in cells and tissues of the body that are not involved in haematopoiesis.

cells, and hence the specificity and the positive predictive value are too low.

ANTIVIRAL THERAPY

To date there have been no controlled trials of antiviral drugs against either HHV-6 or HHV-7 (Clark and Griffiths, 2003). The drugs that might be effective, that is ganciclovir, foscarnet and cidofovir, all have serious side effects, although there are case reports in the literature of antiviral efficacy, as evidenced by reduction of HHV-6 DNA load or simply a clinical response to treatment. Therefore no specific recommendations can be made and it should be emphasized that use of antiviral drugs should not be contemplated for the immunocompetent patient, except perhaps in life-threatening situations. In particular, it should be remembered that there is good evidence that antiviral therapy will not reduce the HHV-6 DNA load in chromosomal integration, as was shown in a recent case report (Hubacek *et al.*, 2007). Figure 10.6 compares the lack of an antiviral response in chromosomal integration (Figure 10.6a) with the good response in a case of HHV-6-induced bone marrow suppression in which there was not only a rapid 10 000-fold reduction in amount of HHV-6 DNA (Figure 10.6b) but also a corresponding increase in white cell count (see Johnston *et al.*, 1999).

Organ Transplant Recipients

Given the low risk of HHV-6 disease and the toxicity of the available drugs, antiviral prophylaxis cannot be recommended (Ljungman *et al.*, 2008). In addition, it should be remembered that since ganciclovir and foscarnet

are commonly used in the HSCT setting for pre-emptive therapy against CMV, this may facilitate the emergence of drug-resistant HHV-6.

As regards HHV-6 encephalitis, most of the patients reported with HHV-6 encephalitis after HSCT received either foscarnet or ganciclovir (Ljungman and Singh, 2006; Zerr, 2006). However, although one series demonstrated a virological response to these drugs, there remained a high morbidity and mortality. Despite the lack of controlled trials and based solely on expert opinion, the International Herpes Management Forum recommends foscarnet or ganciclovir, either alone or in combination, for treatment of HHV-6 CNS disease (Dewhurst, 2004).

Future studies in organ transplant patients (in whom the relevant drugs are in any case used for control of CMV infection) are needed to determine the concurrent impact of antiviral therapy on HHV-6 and HHV-7 infections and hence the possible effectiveness of treatment.

CONCLUDING REMARKS

HHV-6 reactivation has been claimed as a cause of many different diseases, although for most there is no compelling evidence for an aetiological role. In some cases HHV-6 may play an immunomodulatory role, but alternatively it may merely be a bystander reactivated by inflammation or immune reactivation. In other cases association with active infection and disease may have been wrongly suggested by the phenomenon of HHV-6 chromosomal integration.

The scale of the contribution of HHV-6 and especially HHV-7 primary infections to serious neurological disease

in young children has not been appreciated in the past but such cases must now be fully investigated for these two viruses. This is most important where the illness is temporally related to vaccinations, which might otherwise be wrongly blamed for the condition.

It is clear that a great deal more is known about the behaviour and role of HHV-6 than of HHV-7 and it is therefore necessary for future studies to include the latter virus. Although much has been accomplished in the last decade, further improvements in the diagnosis of primary HHV-6 and -7 are required, in particular convenient rapid tests for use on acute specimens. It is anticipated that this will be achieved at least in part by the development of standardized quantitative real-time PCR and the use of antibody tests based on recombinant proteins.

The recently-recognized phenomena of chromosomal integration and germ-line inheritance of HHV-6 must always be borne in mind, and clearly require further study. It is also important that the role of HHV-6 variants A and B be distinguished in various situations by use of the appropriate tests, and that that of HHV-6A, in particular, be more fully explored.

Kaposi's Sarcoma-associated Herpesvirus (Human Herpesvirus 8)

Cornelia Henke-Gendo, Abel Viejo-Borbolla and Thomas F. Schulz

Hannover Medical School, Hannover, Germany

INTRODUCTION

The eighth human herpesvirus is associated with three forms of human neoplasia. It was first discovered in Kaposi's sarcoma (KS), with which it is strongly associated, hence the designation Kaposi's sarcoma-associated herpesvirus (KSHV) given to it by its discoverers (Chang *et al.*, 1994). It is also consistently found in a very rare form of B-cell lymphoma, body cavity-associated lymphoma (BCBL) or primary effusion lymphoma (PEL) (Cesarman *et al.*, 1995a). Finally, it is found in the plasma cell variant of multicentric Castleman's disease (MCD) (Soulier *et al.*, 1995), particularly in human immunodeficiency virus (HIV)-infected individuals, and may also play a role in occasional cases of bone marrow failure in immunosuppressed individuals (Luppi *et al.*, 2000b). To reflect its association with conditions other than KS, and to keep within the nomenclature adopted for other human herpesviruses, the term human herpesvirus 8 (HHV-8) is preferred by some authors.

The discovery of KSHV was initiated by careful epidemiological studies which had, for several decades, suggested the involvement of a transmissible agent in the pathogenesis of KS. In spite of these leads, attempts by several groups to identify such an organism by conventional culture or morphological approaches had been unsuccessful. The development of molecular techniques combining polymerase chain reaction (PCR) amplification with subtractive hybridization (representational difference analysis, RDA) allowed Chang *et al.* (1994) to search for unknown DNA sequences present in KS, but not a control tissue. They initially identified two small DNA fragments

with homologies to two oncogenic gammaherpesviruses, Epstein-Barr virus (EBV) and herpesvirus saimiri (HVS) of squirrel monkeys. These were later shown to be part of a complete viral genome (Russo *et al.*, 1996) present in the endothelial tumour (spindle) cells of KS lesions (Boshoff *et al.*, 1995). After the discovery of KSHV in PELs (Cesarman *et al.*, 1995a) several groups succeeded in establishing persistently-infected cell lines from such lymphomas, and subsequently in visualizing KSHV virions after chemical induction of the lytic replication cycle (Renne *et al.*, 1996). The viral particles show the characteristic morphological appearance of *Herpesviridae* (see Chapter 6). An example of a KSHV virion, produced by the PEL-derived KS-1 cell line after induction of the lytic cycle by treatment with phorbol esters, is shown in Figure 11.1.

ORIGIN AND EVOLUTION OF KSHV

Phylogenetic analysis of its genomic sequence (Russo *et al.*, 1996) places KSHV with the gamma-2 subgroup of herpesviruses, the rhadinoviruses. Following the discovery of KSHV, attempts to understand its origin have resulted in the isolation or identification of closely-related rhadinoviruses in many primates (reviewed in Greensill and Schulz, 2000). Thus, as shown in Figure 11.2, fragments of viral DNA polymerase genes with close similarity to KSHV have been found in chimpanzees (PtRV-1 or PanRHV1), gorillas (GoRHV-1), mandrills (MnRHV1), African green monkeys (ChRV1) and macaques (RFHVMm, RFHVMn). In addition, a second

Figure 11.1 Electron micrograph of KSHV in lytically-induced KS-1 cells. The KSHV virion has the characteristic features of a herpesvirus. (Courtesy of D. Ablashi, Advanced Biotechnologies.)

group of gamma-2 *Herpesviral* DNA polymerase fragments has been identified in various primate species, which appear to be slightly more distantly related to KSHV. The fact, that for many nonhuman primate species a member of each group has now been found suggests the existence of two distinctly evolved lineages of gamma-2 herpesviruses (rhadinoviruses), termed RV-1 and RV-2. The similarity of the different identified viral sequences mirrors that of their host species and would thus be in keeping with the accepted view of herpesvirus–host co-evolution (McGeoch *et al.*, 2000).

The study of genomic variation of KSHV isolates has also revealed the existence of particular KSHV variants in certain geographic regions, suggesting that KSHV has co-evolved with human populations. This is best, but not exclusively, illustrated by the pattern of sequence variability found in the K1 gene at the left end of the KSHV genome (see Figures 11.3 and 11.4). K1 encodes a type I transmembrane protein with an immunoglobulin superfamily-like extracellular domain containing two highly variable regions, VR1 and VR2, which allow classification of different viral isolates (Zong *et al.*, 1999). As illustrated in Figure 11.3, K1 variants can be grouped into four major clades, A–E. These five clades are all thought to be derived from one common ancestor, termed ‘P’ (‘prototype’). Clade B is found exclusively in Africa and individuals descended from an African ancestor, while clade D is confined to old Asian populations, such as the Ainu, an old population on Hokkaido in the north

of Japan (Meng *et al.*, 2001; Zong *et al.*, 1999). Clade E, which is closely related to clade D, was found in Amerindian populations of Brazil and Ecuador (Biggar *et al.*, 2000), an observation that would be compatible with the well-established migration of the original Amerindian people from Asia to the Americas. In contrast, KSHV clades A and C are now found in many parts of the world, most likely reflecting the mixing of populations over the last three millennia (Zong *et al.*, 1999). However, geographic or ethnic associations can occasionally still be seen within individual clades, for example K1 sequences found in Ashkenazi and Sephardi Jews in Israel belonging to particular A and C subtypes (Davidovici *et al.*, 2001).

In addition to this pattern of evolution within human populations, recombination between different KSHV genomes and, in at least two cases, with related gamma-2 herpesviruses, appears to be another important factor in the evolution of KSHV. Evidence for multiple recombination events among P-type sequences has been found in many KSHV sequences (Zong *et al.*, 2002). Further, remnants of two so-far unidentified but more distantly related gamma-2 herpesviruses have been found in currently circulating KSHV variants. One, the ‘M’ type, has recombined into P-type variants at the right end of the viral genome. Both the fact that this M type has been seen and the observation of two separate lineages of the M type indicate that this recombination event took place possibly in the order of 100 000 years ago (Zong *et al.*, 2002). The

Figure 11.2 Phylogenetic relationships among primate gamma-2 herpesviruses. The phylogenetic tree shown here was created by the neighbour-joining method of partial viral DNA polymerase sequences of the gamma-2 herpesviruses shown. Numbers at branchpoints denote bootstrap values to indicate the reliability of this analysis (values over 75% are taken to indicate a robust assignment to a branch). The figure shows that KSHV belongs to the RV1 subgroup of gamma-2 herpesviruses, with closely related viruses being found in many Old World primate species. In addition, a second group, RV2, comprises slightly more distantly related gamma-2 herpesviruses in many primate species (see text). The New World primate gamma-2 herpesviruses form a third branch (see text).

other type ('Q' type) also originated from a recombination event with yet another gamma-2 herpesvirus at the right end of the KSHV genome, but has so far only been seen in South Africa (Zong *et al.*, 2002).

WORLDWIDE DISTRIBUTION OF KSHV IN THE GENERAL POPULATION

In contrast with other human herpesviruses, the seroprevalence of KSHV varies widely in different geographic regions. Many seroprevalence studies to detect KSHV-specific antibodies have now been conducted using a variety of different immunologic techniques (see 'Diagnostic Assays'; for references see Schulz, 1999). As outlined below, none of these assays is 100% sensitive or specific. This means that exact seroprevalence rates, particularly in low-prevalence areas, have been difficult to determine. However, these assays have proved good enough to work out the distribution of KSHV in different countries and regions, and to define modes and risk

factors of transmission in endemic countries as well as in population groups at high risk for sexually-transmitted diseases (STDs) (see Schulz, 1999 for detailed references).

Europe

The currently available seroepidemiology data indicate that KSHV is relatively rare in most northern, western and central European countries, with less than 5% of blood donors having antibodies to either KSHV latency-associated nuclear antigen (LANA), the orf65-encoded SCIP protein or the K8.1-encoded virion membrane glycoprotein (different antigens were used in the individual studies and the results are therefore difficult to compare) (Simpson *et al.*, 1996). In comparison, infection with KSHV appears to be more widespread in the Mediterranean basin, namely some parts of Italy, Greece and, to a lesser extent, Spain (Gao *et al.*, 1996b; Simpson *et al.*, 1996; Whitby *et al.*, 1998). In Italy, infection with KSHV appears to be more common among blood donors from regions previously reported to have a

Figure 11.3 Evolution of the K1 gene of KSHV. K1, located at the 'left' end of the KSHV genome (see Figure 11.4), exists in five major variants. Some of these are associated with particular geographic regions or populations, indicating a possible co-evolution of K1 with human populations (see text) in isolates from different parts of the world.

higher incidence of classic KS, such as Sicily or Sardinia, than in the centre or in prealpine regions (Whitby *et al.*, 1998).

North America

In the United States, reported prevalence rates in blood donors vary between 0 and up to 25% in different assays (Gao *et al.*, 1996b; Kedes *et al.*, 1996; Simpson *et al.*, 1996). Data from the National Health and Nutrition Examination Survey III, however, post the seroprevalence in the general population to 1.6%, thus in the same range as many non-endemic European countries (Engels *et al.*, 2007). There may also exist remarkable regional and socio-economical variations in United States seroprevalence, since a higher prevalence rate is reported in particular parts of New York and individuals of African-American or Mexican descent (Engels *et al.*, 2007). These variations in seroprevalence may therefore reflect increased transmission in particular communities or risk groups (see below).

South America

In South America, the prevalence of antibodies to LANA among blood donors and healthy or young adults was in the range of 3–7% (Mohanna *et al.*, 2005). Like in the United States, higher prevalence rates (up to 16%) are found in socio-economically weaker populations of Belem, North Brazil (Freitas *et al.*, 2002). In contrast to the low prevalence of the non-native population, KSHV was found to be highly prevalent (LANA antibody prevalence rates 4–63%) in different Amerindian tribes and language groups in Brazil and Ecuador that had only little contact to the outside world (Biggar *et al.*, 2000). As mentioned above, these individuals are infected with a KSHV variant that is related to those found in old Asian populations.

Asia

In the Asian countries, like India, Sri Lanka, Thailand and Japan, KSHV prevalence was found to be low, ranging between 0 and 4% (Ablashi *et al.*, 1999; Fujii

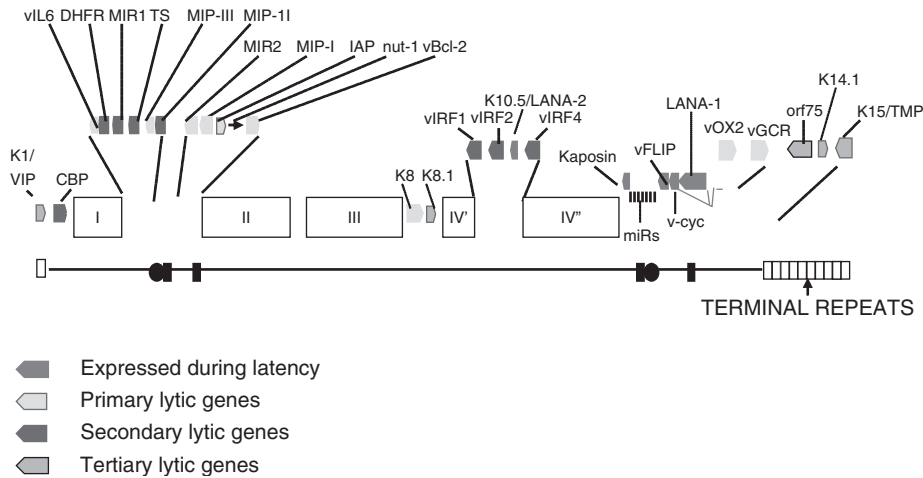

Figure 11.4 Genome diagram of KSHV. Open boxes with Roman numerals denote groups of structural or metabolic genes which are conserved among γ herpesviruses and many other herpesviruses. The solid line represents the long unique (coding) region; open rectangles, internal or terminal repeat regions; solid circles, putative origins of lytic replication (ori-(L), ori-(R)). The position and transcriptional orientation of viral genes discussed in the text is indicated by pointed boxes.

et al., 1999; Satoh *et al.*, 2001). For South East Asia the data are still inconclusive, spanning a seroprevalence of <5% in Eastern Melanesia and Malaysia to >20% in Melanesian residents of remote villages in Papua New Guinea (Ablashi *et al.*, 1999; Satoh *et al.*, 2006).

Middle East

Only a few data are available for the Middle East, where KSHV infection seems to be found only infrequently (Almuneef *et al.*, 2001). Intermediate KSHV prevalence rates have been found in Israel.

Africa

In contrast to the low or intermediate seroprevalence in the rest of the world, all studies reported so far concur that antibodies to KSHV are highly endemic in most African countries, particularly in sub-Saharan Africa. Antibodies to LANA, orf65/SCIP, K8.1 glycoprotein or undefined productive-cycle antigens are found in approximately 40–60% of adults and adolescents in most parts of sub-Saharan Africa investigated so far, for example Uganda, Tanzania, the Gambia, Cameroon, South Africa, Eritrea, Malawi, Kenya and Egypt (Gao *et al.*, 1996b; Simpson *et al.*, 1996; for detailed references see Schulz, 1999). Occasional studies have even reported higher antibody prevalence rates by immunofluorescence assays (IFAs) for lytic KSHV antigens. These high seroprevalence rates, obtained even with assays which detect antibodies to defined antigens, suggest that

KSHV is widespread in Africa, and does not only occur in those regions (east and central Africa) where KS was known to exist before the arrival of HIV-1 (endemic KS) (see below). This could suggest an involvement of additional cofactors in the pathogenesis of endemic KS.

General Observations

A consistently observed feature of all these studies investigating the distribution of KSHV in the general population is the increase of KSHV prevalence with age (for references see Schulz, 1999). This is likely to reflect ongoing transmission throughout adult life, but may also be due to increased viral replication after reactivation of a latent KSHV infection in elderly individuals.

Thus, these studies conducted in different parts of the world indicate that, in spite of being an 'old' human virus that has co-evolved with human populations, KSHV has apparently become rare in many geographic regions, although in some of these it may have been retained in defined populations. It has, however, remained common in Africa.

TRANSMISSION

Transmission in Childhood

In endemic countries or population groups (Africa, remote African or Amerindian populations in South America;

see above) the rapid increase of KSHV infection in children aged 1–12 years indicates that KSHV can be efficiently transmitted in childhood (Andreoni *et al.*, 2002; Plancoulaine *et al.*, 2000). In these situations young children are more likely to be infected if their mothers or siblings are infected, suggesting mother-to-child, or sibling-to-sibling transmission as a possible source of infection (Dedicoat *et al.*, 2004; Plancoulaine *et al.*, 2000). However, molecular analysis of KSHV strains found in Malawian families and Ugandan mother–child pairs have suggested that both intrafamilial and extrafamilial transmission of KSHV can occur (Mbulaiteye *et al.*, 2006). In keeping with this, an epidemiological study among Egyptian children found that contact with at least two other children in the community was a risk factor for KSHV infection (Andreoni *et al.*, 2002), indicating that—as is the case for cytomegalovirus—close or intimate contact with persons who are excreting the virus is necessary to acquire KSHV infection. There is increasing evidence that saliva is the main source of virus, as high viral loads are found in this specimen (Andreoni *et al.*, 2002; Dedicoat *et al.*, 2004). *In utero* or perinatal KSHV transmission has been described (Brayfield *et al.*, 2003) but is thought to be infrequent. Although low levels of KSHV DNA can occasionally be found in breastmilk, breastfeeding is thought to play only a minor role in mother-to-child transmission, in view of the steep rise in seroprevalence curves in children greater than one to two years (Dedicoat *et al.*, 2004). Using segregation analysis, one study (Plancoulaine *et al.*, 2003) predicted the existence of a recessive gene which increases susceptibility to KSHV infection in childhood.

Transmission in Adult Life

The gradual increase in seroprevalence during adult life, noted in many studies, would be compatible with the notion of continuing acquisition of KSHV infections. While in endemic countries or populations the majority of infections appear to occur before puberty, transmission during adulthood accounts for most infections in non-endemic countries. Sexual transmission is now believed to be the most common route of KSHV transmission in adults, even though viral loads found in vaginal, seminal and prostatic secretions are much lower than in saliva (de Sanjose *et al.*, 2002; Pauk *et al.*, 2000; further references in Schulz, 1999).

Homosexual Transmission

Evidence for sexual transmission came largely from studies of homosexuals in industrialized countries, who, in accordance with the high incidence of acquired immune deficiency syndrome (AIDS) KS in HIV-1-infected homo/bisexual men, are more frequently infected with KSHV than the general population of their country (Gao

et al., 1996a; Kedes *et al.*, 1996; O'Brien *et al.*, 1999; Pauk *et al.*, 2000; Rezza *et al.*, 2000; Simpson *et al.*, 1996). Numerous studies conducted on this topic agree that KSHV infection among gay men is linked to behavioural patterns that predispose to infection with a sexually-transmitted agent. Thus, KSHV infection is consistently seen to increase with the number of sexual partners as well as with a history of sexually-transmitted disease (Dukers *et al.*, 2000; Martro *et al.*, 2007; Melbye *et al.*, 1998; O'Brien *et al.*, 1999). Epidemiological studies investigating the impact of detailed sexual behavioural variables on KSHV transmission have, however, arrived at different conclusions. While several studies reported anal intercourse, either passive or active, as a risk factor (Melbye *et al.*, 1998; O'Brien *et al.*, 1999), others have identified oral–penile contact (Dukers *et al.*, 2000) or deep kissing (Pauk *et al.*, 2000) as predisposing behavioural variables. The use of amyl nitrate ('poppers') has also emerged as a risk factor in some (Pauk *et al.*, 2000) but not other (Melbye *et al.*, 1998) studies.

Interestingly, in some MSM cohort studies, a decline of KSHV prevalence or incidence has been noted during the last two decades (Melbye *et al.*, 1998; Renwick *et al.*, 1998), but in other cohorts the rate of KSHV infection has remained stable (Osmond *et al.*, 2002; Rezza *et al.*, 2000). KSHV appears to have spread in this group as a separate epidemic, independently of HIV-1 (Dukers *et al.*, 2000; Melbye *et al.*, 1998; O'Brien *et al.*, 1999). Attempts have been made to back-calculate the beginning of this epidemic, but these are associated with some uncertainty and the answers may well differ for homosexual communities in different countries; thus in Denmark KSHV may have been introduced into Danish homosexual men in the late 1970s through contact with US partners (Melbye *et al.*, 1998), whereas in Holland the beginning of this epidemic is inferred to have occurred much earlier (Dukers *et al.*, 2000), and KSHV was already highly prevalent in California in 1978–1979 (Osmond *et al.*, 2002).

Heterosexual Contacts

Among heterosexual adults, transmission during sexual contacts is not so obvious. On the one hand, there was no association between KSHV infection in husbands and wives in a population-based study among the Noir Marron of French Guyana (Plancoulaine *et al.*, 2000) or in the general population of the United States (Engels *et al.*, 2007). On the other hand, an elevated KSHV seroprevalence was found to be associated with an increased number of sexual partners and with a history of STDs in women with risk-taking sexual behaviour or prostitutes and men reporting contacts with prostitutes (de Sanjose *et al.*, 2002; Perna *et al.*, 2000). In particular, a history of genital warts seems to be a risk factor for KSHV infection.

Thus, given the well-documented transmission of KSHV during sexual contact among gay men, sexual transmission among heterosexual individuals would appear likely. The reasons why this is seen in some but not other studies are currently not clear.

Other Forms of Transmission

Another controversial issue is the importance of blood-borne transmission, as KSHV DNA can be detected in PBMCs, as well as in plasma or serum, of about 5–10% of infected individuals (Whitby *et al.*, 1995). Multiple parental routes of transmission have been discussed in recent years.

IVdrug Use

While early studies (Simpson *et al.*, 1996) and a large prospective cohort study of more than 1000 drug users in Amsterdam (Renwick *et al.*, 2002) found no evidence for an increased seroprevalence of KSHV among intravenous drug users, evidence for blood-borne transmission of KSHV among this cohort came from four US studies (Atkinson *et al.*, 2003; Cannon *et al.*, 2001; Goedert *et al.*, 2002; Greenblatt *et al.*, 2001), revealing a longer injection-drug use and concomitant HCV infection (as surrogate marker for IVdrug use) as risk factors for KSHV seropositivity. An association of increased KSHV seroprevalence with high-risk (sexual) behaviour for HIV infection supports the idea that KSHV may be transmitted via behaviour accompanying the use of drugs rather than through the drug use itself.

Blood Transfusions

Concern about an iatrogenic transmission via blood transfusion was expressed as early as 1997 (Blackbourn *et al.*, 1997), when viral DNA was found in blood (Whitby *et al.*, 1995), even blood from blood donors (Blackbourn *et al.*, 1997; Hladik *et al.*, 2006). Increasing evidence for KSHV transmission by this route came when Hladik *et al.* (2006) reported a significantly higher risk of seroconversion among Ugandan recipients of HHV-8-seropositive blood than among recipients of seronegative blood, with an excess risk of 2.8%. The occurrence of seroconversion between three and ten weeks after transfusion, as well as a decrease in the transmission rate when the storage of the blood products exceeded four days, further hinted at a viral transmission. However, transmissibility may be limited by the cell-associated nature of the virus and by the low frequency of circulating virus in the blood of asymptomatic seropositive individuals, suggesting that blood transfusion is associated with only a small risk of KSHV transmission (Dollard *et al.*, 2005; Mbulaiteye *et al.*, 2003).

Organ Transplantation

Among transplant patients, KSHV transmission from donor to recipient has clearly been documented in individual cases (Barozzi *et al.*, 2003; Luppi *et al.*, 2000a; Regamey *et al.*, 1998). KSHV-infected endothelial precursor cells may be transmitted from organ donor to recipient during transplantation and may develop into (donor-cell derived) KS (Barozzi *et al.*, 2003). Nevertheless, although transmission of KSHV through organ or bone marrow transplantation may occur, it appears that in endemic countries the majority of individuals who have developed post-transplant KS were already infected with KSHV at the time of transplantation, rather than being infected through the transplanted organ (Cattani *et al.*, 2001; Farge *et al.*, 1999; Parravicini *et al.*, 1997b). To what extent this also applies in non-endemic countries and whether there is therefore a need, in non-endemic countries, to screen organ or bone marrow donors, or blood to be transfused to immunosuppressed individuals, is still under investigation.

CLINICAL MANIFESTATIONS

Kaposi's Sarcoma

The 'classic' form of KS was first described in 1872 by the Austro-Hungarian dermatologist Moritz Kaposi and is characterized as a skin disease affecting elderly (>50 years) men of Mediterranean, Eastern European or Jewish heritage. It appears as indolent, firm, blue-reddish-brown patches/plaques and later on as nodules on lower extremities that may ulcerate and bleed. Internal organ involvement, mainly the gastrointestinal system and lungs, is only seen rarely today (although several of the clinical cases in Kaposi's early description did show visceral involvement). The 'endemic' form of KS was noted in East Africa before the spread of HIV. Visceral involvement is more frequent than in the classic form. 'AIDS-associated' KS is clinically more aggressive and is characterized by widespread cutaneous and visceral involvement and associated complications such as bleeding. While it has become less frequent in HIV-infected gay men in Western countries, it now represents the commonest tumour in sub-Saharan Africa (Dedicoat and Newton, 2003). Finally, 'iatrogenic' KS in immunosuppressed individuals, mainly after organ transplantation, is more frequent in transplant recipients from KSHV-endemic countries.

Epidemiological Findings

Epidemiological studies allow the conclusion that KS only develops in KSHV-infected individuals but that this remains a rare event unless there is additional immune

suppression, as a result of either organ transplantation or HIV infection. The presence of antibodies to KSHV in non-endemic areas is strongly associated with having KS, or being at increased risk for KS, and, among HIV-1-infected individuals, is strongly predictive of the subsequent appearance of KS lesions (Gao *et al.*, 1996b; Kedes *et al.*, 1996; Renwick *et al.*, 1998; Simpson *et al.*, 1996). However, while classic KS remains a rare tumour in immunocompetent KSHV-infected individuals—the incidence rate range from 1 to 3 per 100 000 inhabitants, even in regions of Italy where KSHV seroprevalence rates are in the range of 20–30% (Calabro *et al.*, 1998)—it is much more common in immunosuppressed individuals. Among transplant recipients, KSHV infection increased the risk of post-transplant KS by a factor of 40–80 in different studies (Cattani *et al.*, 2000; Farge *et al.*, 1999; Parravicini *et al.*, 1997b). Among HIV-infected homosexual men, approximately 40–50% of KSHV-infected individuals developed KS within 5–10 years after primary infection with KSHV before the introduction of highly active retroviral therapy (HAART) (O'Brien *et al.*, 1999; Renwick *et al.*, 1998). Individuals who are already HIV-infected when they contract KSHV progress more rapidly towards disease than those who acquire HIV after KSHV (Renwick *et al.*, 1998). In the Gambia, West Africa, AIDS KS is markedly more common among HIV-1-infected than HIV-2-infected individuals, although the KSHV prevalence appears to be comparable in these two groups (Ariyoshi *et al.*, 1998). In Africa, endemic KS is mainly found in east and central Africa, in spite of a high KSHV prevalence in most of sub-Saharan Africa (Dedicoat and Newton, 2003). This observation strongly suggests the existence of other environmental cofactors that promote the development of KS in KSHV-infected individuals.

Pathology and Molecular Biology Findings

KSHV is present in the neoplastic component of KS lesions, the endothelial cell-derived spindle cell (Boshoff *et al.*, 1995; Rainbow *et al.*, 1997; further references in Schulz, 2001). Latent viral genes (orfK12/kaposin; orfK13/vFLIP (viral FLICE (Fas-associated death-domainlike IL-1b-converting enzyme)-inhibitory proteins); orf72/v-cyclin; orf73/LANA) are expressed in these cells (Parravicini *et al.*, 2000; Rainbow *et al.*, 1997; further references in Schulz, 2001) (see Figure 11.4). KS biopsies contain mainly circular episomal viral DNA, which is consistent with the latent infection (Judde *et al.*, 2000). However, some spindle cells in KS lesions can undergo lytic replication of KSHV (Katano *et al.*, 2000). Given the functional properties of some KSHV lytic-cycle genes, for example induction of vascular

endothelial growth factor (VEGF), angiogenic properties, and so on (see 'Pathogenesis', below), it is thought that some viral proteins expressed during the lytic cycle could contribute to the development of KS.

Primary Effusion Lymphoma (PEL)

PEL, also called BCBL, is a rare lymphoma in AIDS patients, characterized by its presentation as a malignant effusion in the peritoneal, pleural or pericardial space, most often in the absence of an obvious tumour mass. The lymphoma cells have pleomorphic or anaplastic features combining morphological aspects of large-cell immunoblastic and anaplastic large-cell lymphomas (references in Schulz, 2001). They are usually monoclonal and of B-cell origin, as shown by a rearranged immunoglobulin locus and monotypic immunoglobulin light-chain pattern, but express only a few of the usual markers of B-cell differentiation. The majority of PEL cases described so far have been from AIDS patients, but there are also several reports of PEL in HIV-uninfected individuals (Cesarman *et al.*, 1996). The presence of KSHV is now often considered an essential criterion for the diagnosis of PEL. However, rare cases of KSHV-negative effusion lymphomas of the B-cell lineage, with an indeterminate surface marker phenotype and pleomorphic appearance, some of them CD30-positive, have been described (references in Schulz, 2001). In most PEL cases the lymphoma cells are co-infected with EBV (Cesarman *et al.*, 1995a, 1995b; further detailed references in Schulz, 2001). However, several examples of PEL which contain only KSHV have now been reported and stable cell lines have been derived from some of these. Such 'KSHV-only' cell lines can induce lymphomas with malignant effusions in immunodeficient (SCID, BNX) mice, suggesting that—at least in this experimental model—the presence of EBV is not required for the induction of lymphoma (detailed references in Schulz, 2001).

During latency, EBV and KSHV genomes persist as covalently-closed episomal circles of defined length, whereas lytic replication is associated with the presence of linear concatameric genomes of varying lengths. As judged by this criterion, different PEL cases have been shown to harbour either latent or lytically-replicating KSHV genomes (Judde *et al.*, 2000). Where latent (i.e. circular episomal) KSHV genomes were found, these were present as either a single episome or as multiple episomes with a varying number of terminal repeat units, indicating, respectively, a monoclonal or an oligoclonal population (Judde *et al.*, 2000). Experiments on several PEL cell lines, as well as immunohistochemistry, immunofluorescence and *in situ* hybridization studies on pathology specimens, indicate that four viral genes, LANA, v-cyc, vFLIP and kaposin/K12, may

be expressed in a substantial proportion of lymphoma cells (Katano *et al.*, 2000; Parravicini *et al.*, 2000; Rainbow *et al.*, 1997; further references in Schulz, 1999, 2001). Where pathology samples have been studied by immunohistochemistry or immunofluorescence, LANA has been found to be expressed in the vast majority, while vIL-6 protein expression is confined to a small proportion (2–5%) of tumour cells (Katano *et al.*, 2000; Parravicini *et al.*, 2000). Other lytic proteins, for example K8 (a homologue of EBV Zta), K8.1 (a viral membrane glycoprotein), K9, K10 and K11 (proteins with sequence homology to interferon regulatory factors (IRFs)), orf59/PF-8 (a processivity factor) and orf65 (a minor capsid protein) have been detected in very few cells (<1%) or not at all (Katano *et al.*, 2000; Parravicini *et al.*, 2000). This expression pattern is consistent with the notion that KSHV persists in most PEL tumour cells in a latent form, but that a small population of cells can switch into lytic viral replication. That vIL-6 is expressed in more lymphoma cells (2–5% by immunohistochemistry/immunofluorescence; significantly more by *in situ* hybridization) than other lytic viral proteins (0–<1%) could be due to the fact that it is among the first 'early' genes to be expressed after induction of the lytic cycle in PEL cell lines *in vitro* (Sun *et al.*, 1999). Its increased detection in uncultured PEL cells may therefore reflect higher protein levels in cells during the early stages of the lytic cycle. Alternatively, it has been suggested that there may be a particular latency program for KSHV in PEL cells and that vIL-6 expression can occur independently from the activation of the lytic cascade, perhaps indicating a tissue-specific regulation of viral gene expression (Parravicini *et al.*, 2000). Another example for preferential expression of a KSHV gene in B cells is the recently-described homologue of IRFs, vIRF 10.5/LANA-2 (Rivas *et al.*, 2001).

Multicentric Castleman's Disease (MCD)

Castleman's disease is a localized lymphoproliferative condition, often found in the mediastinum or in mesenteric or peripheral lymph nodes and characterized histologically by expanded germinal centres with B-cell proliferation and vascular proliferation. Two histological types have been recognized; one is characterized by a pronounced plasma-cell proliferation and persistence of the nodal architecture ('plasma-cell variant') and the other by abnormal germinal centres and abundant hyalinized vessels ('hyaline vascular variant'). Variants combining the features of these two types also occur. Involvement of multiple lymph node sites occurs in MCD. MCD in AIDS patients is often associated with KS and usually belongs to the plasma-cell variant. KSHV can nearly

always be detected by PCR in the lymph nodes or spleen affected by MCD in AIDS patients, but is much less common in MCD outside HIV infection (Soulier *et al.*, 1995). By immunohistochemistry or *in situ* hybridization, KSHV is found in the B cells surrounding the follicular centres of MCD. As assessed by immunohistochemistry, KSHV-infected B cells express LANA, a hallmark of all KSHV-infected cells; 10–50% of follicular-mantle cells have been found to express LANA in different studies. About 5–25% of LANA-expressing follicular-mantle B cells in MCD tissue also express vIL-6 and vIRF-1/K9 (Katano *et al.*, 2000; Parravicini *et al.*, 2000; further references in Schulz, 2001) (Figure 11.5). Another viral vIRF homologue, vIRF-3/K10.5/LANA-2, is also expressed in a significant number of KSHV-infected B cells (Rivas *et al.*, 2001), and a third vIRF homologue, encoded by orfK10, in about 5% of all mantle zone cells (Katano *et al.*, 2000). In addition, a small proportion of mantle-zone cells also express other viral proteins that are associated with the early stages of lytic viral replication, such as PF-8 (encoded by orf59) and the K8 protein, a homologue of EBV BZLF-1, an activator of the lytic replication cycle (Katano *et al.*, 2000; Parravicini *et al.*, 2000). Compared to PEL and KS tissue, KSHV thus appears to adopt a less restrictive pattern of gene expression in MCD tissue and this suggests that MCD may represent the result of active lytic viral replication in lymphoid tissue. In keeping with this notion, the intensity of clinical symptoms in MCD patients such as fever, or of laboratory parameters reflecting disease activity such as C-reactive protein, have been shown to correlate with the KSHV viral load in peripheral blood (Grandadam *et al.*, 1997; Oksenhendler *et al.*, 2000). Fluctuations of KSHV viral load in HIV-infected

Figure 11.5 Expression of vIL6 in B cells of MCD. vIL6 is expressed in a small number of KSHV-infected B cells, but may affect others through paracrine action (see text). (Photograph kindly provided by Drs Y. Chang and P. Moore.)

patients with MCD also mirror fluctuations in the plasma levels of human IL-6 and IL-10 and in plasma HIV RNA copy numbers, indicating that active HIV infection can increase the severity of MCD by increasing KSHV viral load (Oksenhendler *et al.*, 2000). MCD can be a manifestation of a primary infection with KSHV in an HIV-infected individual or in transplant recipients (Oksenhendler *et al.*, 1998; Parravicini *et al.*, 1997a). This is in keeping with the idea that MCD may reflect active viral lytic replication in lymphoid tissue. It also highlights that co-infection with HIV-1, which can have a marked effect on KSHV replication (Goudsmit *et al.*, 2000; Oksenhendler *et al.*, 2000), may however not be required and that immunosuppression is sufficient to allow lytic replication in lymphoid tissue to an extent that produces clinically-visible MCD lesions. Clinically-visible MCD is, however, a rare outcome of primary KSHV infection, despite about 10% of HIV-1-infected individuals that seroconvert to KSHV having detectable KSHV viraemia in their peripheral blood (Goudsmit *et al.*, 2000). Given the functional properties of vIL-6 (see below), it is likely that this viral protein plays a role in the pathogenesis of MCD. The plasmacytic phenotype of B cells in KSHV-associated cases of MCD may be the result of the activity of vIL-6 in this condition. Some authors prefer the term 'plasmablast' for these cells, to describe their large size and large vesicular nucleus with one or two prominent nucleoli (Dupin *et al.*, 2000). Interestingly, these KSHV-infected plasma cells have expressed IgM with λ -immunoglobulin light chains in all cases examined so far, indicating light-chain restriction and the presence of a monotypic cell population (Dupin *et al.*, 2000). In some cases, these KSHV-infected plasmablasts are found in small clusters surrounding or replacing follicles, suggesting the emergence of microscopic plasmablastic lymphomas in MCD lesions (Dupin *et al.*, 2000).

Other Disease Associations

KSHV has been detected in occasional cases of HIV-negative angioimmunoblastic lymphadenopathy and germinal-centre hyperplasia (detailed references in Schulz, 2001). Histologically, there may be prominent plasma-cell proliferation and angiogenic changes in these cases, suggesting that viral proteins like vIL-6 and viral macrophage inflammatory protein (vMIP)-I/II may have induced these transient changes. In addition, a small number of case reports indicate that primary infection with KSHV, or KSHV reactivation, in transplant recipients may be associated with a transient thrombocytopenia, leukopenia and/or anaemia (Luppi *et al.*, 2000b), or a febrile maculopapular skin rash in immunocompetent children (Andreoni *et al.*, 2002; further references in Schulz, 2001).

PATHOGENESIS

This section focuses on the biochemical and cell-biology features of individual KSHV genes. Understanding their contribution to pathogenesis is currently still hampered by the lack of a good animal model. However, a broad understanding of the functional roles of individual KSHV proteins has been developed. Below, these are discussed in groups defined by their main functions, and these groups are illustrated in Figures 11.4, 11.6 and 11.7.

The KSHV Genome

KSHV contains a long unique region (LUR) of 140.5 kb, with a GC content of 53.5%, flanked by 801 bp terminal tandem repeats (TRs) rich in GC (84.5%) (Neipel *et al.*, 1997; Russo *et al.*, 1996) (see Figure 11.4). Within the LUR there are at least 90 putative open reading frames (ORFs). These ORFs are named and numbered following the nomenclature initially adopted for the prototypic rhadinovirus, HVS. Genes unique to KSHV are designated by the letter K, followed by a number.

Culture Systems

PEL-derived cell lines may be latently infected with KSHV only, or may be co-infected with EBV if the original tumour also contained EBV (Renne *et al.*, 1996; further references in Schulz, 2001). In some cell lines (e.g. BCP-1, BCBL-1, KS-1) most cells only express latent KSHV genes (see below) but some will spontaneously switch into lytic replication, whereas in others, for example the KSHV/EBV dually-infected cell line HBL-6 (or BC-1), KSHV is much more strictly latent. The lytic replication programme can be switched on in all these cell lines by treatment with either phorbol esters (Renne *et al.*, 1996) or sodium butyrate, but some cell lines are better virus producers (e.g. KS-1, BCBL-1, JSC-1, Cro-AP3) than others. KSHV virus preparations obtained in this manner can be used to infect a number of permanent cell lines or primary endothelial cell cultures (Ciufo *et al.*, 2001; Flore *et al.*, 1998; Moses *et al.*, 1999; Renne *et al.*, 1998). In primary endothelial cell cultures most cells are infected in a latent form, with minimal viral gene expression, expression of the viral 'LANA' (see below) in the majority and evidence of lytic-cycle or structural viral proteins in only a few cells (Ciufo *et al.*, 2001; Moses *et al.*, 1999). Stable persistence of KSHV in endothelial cells *in vitro* may depend on the culture system used: in primary endothelial cell cultures and telomerase-immortalized endothelial cells KSHV appears not to be retained in infected cultures upon subsequent passage, whereas stable persistence has been found in an HPV-immortalized endothelial cell line (Moses *et al.*, 1999). Infection of endothelial

Figure 11.6 Overview of some KSHV-encoded proteins that may contribute to pathogenesis. See text for detailed explanation of the pathways and receptors engaged by KSHV proteins.

cells results in morphological changes (spindle-cell formation, piling up of infected cells) that vary with the cell culture system used (Ciufo *et al.*, 2001; Moses *et al.*, 1999). It is also possible to isolate replicating KSHV on 293 cells from saliva (Vieira *et al.*, 1997), but this is very inefficient and requires detection of replicating KSHV by PCR. The inefficient persistence of KSHV in endothelial or epithelial cells is reminiscent of the rapid loss of KSHV from primary cultures of KS biopsies (Lebbe *et al.*, 1997) and contrasts with its stable long-term persistence in PEL-derived cell lines. It is therefore possible that cell-lineage-specific factors affect the long-term latent persistence of KSHV *in vitro* as well as *in vivo*.

Cell Entry

Cell-free infection *in vitro* is inefficient and only low titres are achieved with virus produced from PEL cell

lines (Flore *et al.*, 1998; Moses *et al.*, 1999; Renne *et al.*, 1998). These virus stocks appear to have a particle : infectivity ratio in the range of 10^3 – 10^4 , and there is some evidence that a significant proportion of virions in these stocks are defective (Nealson *et al.*, 2001). Four structural glycoproteins, gB, gD, gH and the orfK8.1-encoded glycoprotein, have been documented in KSHV virions. These glycoproteins are candidates for promoting initial contact with KSHV receptor(s) and initiating cell entry. KSHV interacts with ubiquitous host-cell-surface heparan sulphate and $\alpha 3\beta 1$ integrin molecules through gpK8.1 and gB (orf8) (Akula *et al.*, 2002; Birkmann *et al.*, 2001) (see Figure 11.6). The gB glycoprotein contains an RGD motif, known to be important for interaction with cell-surface integrins. KSHV and its counterpart in macaques, RFHV (see 'Origin and Evolution of KSHV' and Figure 11.2), are the only herpesviruses known to date to have a gB protein containing an RGD motif. It has been shown that this motif plays a central role in KSHV entry at a

Figure 11.7 KSHV-encoded proteins involved in apoptosis. Two apoptosis pathways exist in human cells and are regulated by a number of cellular and viral components. The extrinsic pathway is initiated by Fas-L or tumour necrosis factor (TNF) and assembly of the procaspase-8 complex is inhibited by FLIP (FLICE inhibitory protein; see text). A KSHV-encoded FLIP homologue, vFLIP, acts in a similar manner. The intrinsic pathway is triggered by DNA damage, cytokine withdrawal and cytotoxic drugs, and is regulated by the Bcl/Bad/Bax group of proteins. A viral bcl-2 homologue, vbcl-2, acts at this stage. Finally, vIAP acts in the intrinsic pathway and on procaspase 3, as discussed in the text.

post-adhesion step, suggesting the presence of more than one receptor for KSHV entry (Akula *et al.*, 2002). In addition, xCT, the 12-transmembrane segment light chain of the cystine/glutamate exchange transporter system, has recently been identified as a receptor mediating membrane fusion and entry of KSHV (Kaleeba and Berger, 2006).

Entry experiments using the human B-cell-line BJAB indicate that KSHV is endocytosed. KSHV infection induced the integrin-mediated activation of focal adhesion kinase (FAK), implicating a role for integrin and the associated signalling pathways in the entry of the virus, which results in morphological changes and cytoskeletal rearrangements (Naranatt *et al.*, 2003). Also, a role for phosphatidyl-inositol (PI) 3-kinase in the early stages of the entry process, and for PKC- α , MEK and Erk at later stages, has been proposed (Naranatt *et al.*, 2003). It has been suggested that the interaction of KSHV with

cell-surface molecules, such as integrins, might generate a cellular state more prone to infection.

Latent Replication

KSHV persists in a latent form in the majority of infected cells. During latency, the KSHV genome replicates and persists as extrachromosomal episomal DNA circles in the absence of virion production. Persistence is very efficient in rapidly-dividing B-cell lines obtained from PEL patients (PEL cell lines). Cell cultures established from KS tumours rapidly lose the KSHV genome after a few passages (Lebbe *et al.*, 1997). Primary endothelial cells, as well as endothelial and epithelial cell lines, infected in culture also lose the virus after several passages. The reason for the efficient persistence of KSHV in PEL cell lines is currently unknown. Latency is characterized by the presence of episomal viral DNA (Judde *et al.*, 2000) (see above) and a restricted

pattern of viral gene expression (see Figure 11.4). Only five viral genes are currently known to be expressed during latency: the latency-associated nuclear antigen-1 (LANA-1/orf73); the viral homologue of a D-type cyclin (v-cyc/orf72); a homologue of the cellular inhibitor of the FLICE apoptosis complex (vFLIP/orfK13); and a group of short membrane-associated proteins, kaposin A, B, C (orfK12) (see Figure 11.4 and above). In addition, a cluster of virally-encoded miRNAs, located in the vicinity of orfK12 (see Figure 11.4), is generated by processing a latent transcript (Cai *et al.*, 2005; Pfeffer *et al.*, 2005; Samols *et al.*, 2005). One of these, miRK12-11, may be a functional homologue of a cellular miRNA, miR-155, and appears to modulate the expression of several cellular genes known to be involved in cell-growth regulation (Gottwein *et al.*, 2007; Skalsky *et al.*, 2007). A considerable proportion of persistently-infected B cells and B lymphoma cells in PEL and MCD, but not in KS endothelial cells, express K10.5/LANA-2, one of the KSHV vIRF homologues (Rivas *et al.*, 2001) (see above). Among these five proteins, only LANA-1 has been detected in virtually all KSHV-infected cells by IF or IHC (Katano *et al.*, 2000; Rainbow *et al.*, 1997). LANA-1 is required for the persistence of the KSHV episomal genome (Ballestas *et al.*, 1999; Garber *et al.*, 2002; reviewed in Viejo-Borbolla *et al.*, 2003). LANA-1 binds to mitotic chromosomes through its amino-terminal region and to two short motifs of 16 nucleotides (LANA-binding sites (LBS)-1 and -2) in the terminal repeat subunit (TR) of the KSHV genome via its carboxy-terminal region (Garber *et al.*, 2002) (see Figures 11.4 and 11.6). In this way, LANA-1 tethers viral episomes to mitotic chromosomes, and it is assumed that this ensures the distribution of KSHV genomes to daughter cells upon mitosis, at least in PEL cells. LANA-1 also mediates the replication of TR-containing plasmid DNA in transfected cells, thus illustrating its role in the replication of latent episomes (Garber *et al.*, 2002; further references in Viejo-Borbolla *et al.*, 2003). LANA-1 has also been shown to bind to p53 and retinoblastoma protein (pRb) (see Figure 11.6) and, in this way, to inhibit the activation of p53-dependent promoters and induce the activation of E2F-dependent genes (Friborg *et al.*, 1999; Radkov *et al.*, 2000). Moreover, LANA-1 can transform cells in cotransfection assays with a constitutively-active Ha-ras (Radkov *et al.*, 2000). Furthermore, LANA-1 acts as a transcriptional activator and/or repressor, and associates with the mSin3 repressor complex as well as cellular factors involved in the methylation of DNA (DNMT3a) and in interaction with methylated DNA (MeCP2) (Krithivas *et al.*, 2002; Shamay *et al.*, 2006). Further cellular interaction partners of LANA-1 include brd2 (RING3), brd3 and brd4 (HUNK), members of

the BET protein family involved in transcriptional regulation (Ottinger *et al.*, 2006; Platt *et al.*, 1999) (see Figure 11.6).

Activation of the Viral Lytic Replication Cycle

Despite KSHV remaining latent in most of the infected cells (see above), a small population of virus-infected cells undergoes lytic (productive) viral replication, which allows the production and release of viral particles. This process, required for virus spread, normally results in cell death. Nevertheless, it is thought that periodic or continuous infrequent activation of the lytic cycle contributes to disease progression. This hypothesis is supported by two clinical observations: drugs that inhibit lytic KSHV replication prevent the development of clinical KS (see below); and an increase in KSHV replication is associated with the appearance of MCD lesions in immunocompromized patients (see above). Moreover, several observations (Bais *et al.*, 1998; Flore *et al.*, 1998; Montaner *et al.*, 2003; further detailed references in Schulz, 2001; Viejo-Borbolla *et al.*, 2003) indicate that lytic genes with autocrine and paracrine effects might play an important role in KSHV-related malignancies. The switch between latent and lytic cycle is mediated by transcriptional activators of early and late lytic genes. The viral immediate-early transactivator RTA, encoded by orf50, is the key element in the activation cascade. Ectopic expression of RTA in PEL cells triggers the lytic cycle, leading to the production of infectious virus (Sun *et al.*, 1998; further references in Viejo-Borbolla *et al.*, 2003).

RTA acts through binding to specific DNA sequences (Chang *et al.*, 2002) and by interacting with cellular transcription factors (Wang *et al.*, 2003). RTA can activate its own promoter and cellular genes. The product of KSHV orfK8, K-bZIP (Gruffat *et al.*, 1999), represses or enhances RTA-mediated gene activation (Izumiya *et al.*, 2003; Wang *et al.*, 2003). K-bZIP also binds to p53, thereby repressing p53-mediated apoptosis, promotes both CCAAT/enhancer binding protein alpha (C/EBPa) and p21CIP-1 expression and, through interaction with C/EBPa, is able to promote p21CIP-1-mediated inhibition of entry into S phase (Park *et al.*, 2000; Wu *et al.*, 2002). Together, these features of K-bZIP probably contribute to the creation of a suitable environment for lytic viral replication by antagonizing apoptosis and preventing competition with host-cell DNA synthesis for limited resources. C/EBPa, RTA and K-bZIP form a complex that associates with and activates the K-bZIP promoter (Wang *et al.*, 2003). Therefore, C/EBPa and K-bZIP can activate each other.

Regulation of the Cell Cycle and DNA-Damage Response

Infection of primary endothelial cells with KSHV results in the induction of antiproliferative checkpoints and DNA-damage response pathways; these effects are also seen in early KS lesions (Koopal *et al.*, 2007). The viral D-type cyclin homologue, v-cyc, plays an important role in this process. On its own, v-cyc mediates phosphorylation, and thereby inactivation, of pRb through association with CDK6, and promotes the progression of resting cells into the S phase of the cell cycle (Chang *et al.*, 1996; Swanton *et al.*, 1997) (see Figure 11.6). In contrast to cellular D-type cyclins, v-cyc targets a broader range of cellular proteins for phosphorylation, including histone H1, the cdk inhibitor p27kip and bcl-2 (detailed references in Verschuren *et al.*, 2004). Also, unlike cellular D-type cyclin/CDK6 complexes, the CDK6/v-cyc complex required for phosphorylation of pRb is resistant to the cellular CDK inhibitors p16, p21 and p27 and to p16INK4a, conferring resistance to the antiproliferative action of these inhibitors (Platt *et al.*, 2002; Swanton *et al.*, 1997). However, in spite of these biochemical properties, v-cyc induces a growth arrest and cytokinesis defects in primary cells by activating DNA-damage response pathways (Koopal *et al.*, 2007; Verschuren *et al.*, 2002). This v-cyc-mediated growth arrest is dependent on a functional p53 (Koopal *et al.*, 2007; Verschuren *et al.*, 2002).

LANA-1 is also able to promote the entry into S phase of transfected cells by interacting with, and sequestering, GSK-3 β , a kinase involved in phosphorylation and consequent degradation of β -catenin by the proteasome (Fujimuro *et al.*, 2003). Association of GSK-3 β with LANA-1 leads to its transfer to the nucleus, the stabilization of β -catenin and increased β -catenin levels in infected cells, which allows activation of promoters containing Lef/Tcf binding sites and entry into S phase (Fujimuro *et al.*, 2003).

Angiogenesis and B-cell Proliferation: vIL-6, vMIP-I-III, vGCR

KSHV-associated diseases express high levels of VEGF and its receptor, kinase insert domain-containing receptor (KDR), which induces angiogenesis (for a review see Hayward, 2003). In KS lesions, VEGF and other angiogenic factors stimulate the inflammatory and neovascular responses determining proliferation of spindle cells, the predominant cell type within these lesions (Bais *et al.*, 1998; detailed references in Hayward, 2003).

There is considerable evidence of a role for vIL-6 in the proliferation of infected B cells (reviewed in Schulz, 2001). Like its cellular counterpart, hIL-6—known to be important in B-cell proliferation—vIL-6 is able to support

the growth of IL-6-dependent B cells *in vitro*. However, there are differences between the two cytokines. Human IL-6 needs both subunits of the cell-surface IL-6 receptor, IL-6Ra and gp130, to fulfil its stimulatory role, whereas vIL-6 only requires the latter (see Figures 11.4 and 11.6). IL-6Ra and gp130 differ in expression patterns, with gp130 being more widely expressed. This may allow vIL-6 to stimulate a broader spectrum of cells. In line with this prediction, vIL-6 has been shown to induce neurite outgrowth in the rat pheochromocytoma cell line PC12 and to promote colony formation of human CD34⁺ bone marrow progenitor cells. *In vivo*, vIL-6-transfected fibroblasts inoculated into nude mice induced hepatosplenomegaly, lymphadenopathy and polyclonal hypergammaglobulinaemia, accompanied by increased haematopoiesis of the myeloid, erythroid and megakaryocytic lineages and plasmacytosis in spleen and lymph nodes. Tumours developing in these animals were more extensively vascularized than those in control animals and expressed high levels of VEGF, which correlated with the amount of vIL-6 in these tumours. VEGF is also expressed in PEL-derived cell lines, and a neutralizing antibody to VEGF blocked the formation of effusion lymphoma and bloody ascites in mice inoculated with PEL cell lines. VEGF can also be detected in the malignant effusions of PEL patients. VEGF-induced stimulation of vascular permeability may therefore be critical to the formation of the malignant ascites characteristic for this AIDS lymphoma. Finally, vIL-6 can also activate STAT 3, Janus tyrosine kinase (JAK1) and the mitogen-activated protein kinase (MAPK) pathway (detailed references for the effects of vIL-6 can be found in Schulz, 2001).

A viral homologue of a G-protein-coupled receptor (vGCR) is encoded by KSHV orf74. KSHV vGCR is homologous to the human IL-8 receptor. In contrast to the latter, KSHV vGCR shows ligand-independent, constitutive activity due to the presence of a point mutation in a sequence motif (DRY) that is highly conserved among GCRs (Arvanitakis *et al.*, 1997; Burger *et al.*, 1999). vGCR transforms murine cells and induces VEGF-dependent angiogenesis and KS-like lesions in transgenic mice, animals inoculated with transfected cells and transgenic animals following endothelial cell-specific infection by a retroviral vector expressing vGCR (Bais *et al.*, 1998; Montaner *et al.*, 2003; Yang *et al.*, 2000). Survival of vGCR-immortalized human umbilical endothelial cells (HUVECs) was dependent on autocrine signalling through KDR, a protein present in KS lesions, leading to the activation of the phosphatidylinositol 3'-kinase Akt/PI3K pathway and consequent NF- κ B transcription factors (Bais *et al.*, 2003; Montaner *et al.*, 2001). The transcription of angiogenesis-regulating genes, cytokines and pro-inflammatory genes, including

angiopoietin 2, was also found to be modulated upon vGCR expression. vGCR activates the MAP kinases p38 and ERK-2, augments transcription of several KSHV lytic genes (e.g. orf57) and increases production of vIL-6 and VEGF (Cannon *et al.*, 2003). Interestingly, despite its tumorigenic and angiogenic functions, vGCR is only expressed in approximately 10% of the KS cells (Chiou *et al.*, 2002). Similarly, infection of transgenic mice with a retroviral vector allowing endothelial cell-specific expression of vGCR resulted in the development of KS-like lesions, but expression of vGCR was confined to a small proportion of tumour cells. Expression of vGCR appeared to lead to the recruitment of other endothelial cells, suggesting that vGCR acts through paracrine mechanisms, probably by secreting angiogenic factors (Montaner *et al.*, 2003). The role of vGCR in disease progression in haematopoietic cells was analysed by using PEL cell lines expressing vGCR under the control of an inducible promoter (Cannon *et al.*, 2003). In an animal model of KS, involving murine bone marrow endothelial cells transfected with a complete KSHV genome and transplanted into mice, down-modulation of vGCR by siRNA reduced the formation of endothelial cell tumours (Mutlu *et al.*, 2007). All these observations point to vGCR as a major player in the angiogenesis and thereby pathogenesis of KSHV.

Three chemokine homologues, vMIPs I–III, encoded by KSHV orfK6, orf4 and orf4.1, respectively, have been proposed to be important in promoting leukocyte chemotaxis, eosinophil migration and angiogenesis. They are members of the MIP family, hence their name. Among them, vMIP-I has been reported to induce the expression of VEGF in PEL cell lines, in a similar way to vIL-6 (Liu *et al.*, 2001) (see above). Other viruses, such as mouse and human cytomegaloviruses, also encode functional chemokines (Alcami, 2003). The vMIPs are also required for evading the immune response and inhibiting apoptosis (see below).

Inhibition of Apoptosis

Programmed cellular death, or apoptosis, is a complex process involving several cellular proteins. Viral infection triggers pathways resulting in apoptosis. To overcome this, viruses have developed mechanisms interfering with apoptotic pathways. This allows them to increase the survival rate of virus-infected cells, thus increasing the time available for viral replication and spread within the host and to other individuals. Since inhibition of apoptotic pathways is one of the hallmarks of tumour cells, it is possible that viral proteins interfering with apoptosis could also contribute to virus-mediated transformation. Figure 11.7 summarizes some of the ways by which KSHV inhibits programmed cellular death. Two different

apoptotic pathways in mammalian cells result in the activation of effector caspases. The extrinsic pathway requires the activation of procaspases 8 and 10 by so-called 'death receptors', which belong to the tumour necrosis factor (TNF) receptor gene superfamily, whereas in the intrinsic pathway mitochondria release caspase-activating proteins.

vFLIP, encoded by orf K13, is expressed on the same bicistronic transcript as v-cyc (Rainbow *et al.*, 1997). It can block Fas-induced apoptosis and has been postulated to act as a tumour progression factor by interfering with apoptotic signals induced by virus-specific T-killer cells (Djerbi *et al.*, 1999) (see Figure 11.7). It has also been proposed to contribute to the continuous NF- κ B activation observed in PEL cells (Liu *et al.*, 2002). Inhibition of NF- κ B and down-modulation of vFLIP by RNA interference induces apoptosis in PEL cell lines, indicating that vFLIP-induced NF- κ B activation may be important for their survival (Guasparri *et al.*, 2004). Transduction of vFLIP into primary endothelial cell cultures induces spindling, suggesting that the vFLIP-induced NF- κ B activation may also play an important role in the formation of spindle cells, the histological hallmark of KS lesions (Grossmann *et al.*, 2006).

K7 is a glycoprotein structurally related to the apoptosis regulator survivin, as revealed by computational analysis (Wang *et al.*, 2002). Human survivin, a member of the IAP family, protects cells from apoptosis by an unknown mechanism. K7 anchors to cellular membranes in the vicinity of Bcl-2 and binds to Bcl-2 (but not Bax), as shown by GST-pulldown assays, via its putative BH2 domain, and to caspase-3 via its BIR domain (Wang *et al.*, 2002) (see Figure 11.7). Thus, K7 seems to be an adaptor molecule bringing together Bcl-2 and effector caspases, allowing the inhibition of the latter by Bcl-2 (Wang *et al.*, 2002).

Like all other gammaherpesviruses for which genomic sequences are available, KSHV expresses a viral homologue of human Bcl-2 (Cheng *et al.*, 1997). The vBcl-2 mRNA is detected in PEL cell lines (Sarid *et al.*, 1997) and protein expression could be shown for late stages of KS lesions. vBcl-2 forms heterodimers with hBcl-2 (Sarid *et al.*, 1997) and it is believed that it may inhibit apoptosis in KSHV-infected cells (Cheng *et al.*, 1997; Sarid *et al.*, 1997). While human Bcl-2 forms heterodimers with members of the Bcl-2 family with pro-apoptotic roles (such as Bax and Bak), the viral homologue does not seem to do so (Cheng *et al.*, 1997). As mentioned above, the CDK6–v-cyc complex phosphorylates and inactivates human Bcl-2, which results in apoptosis. In contrast, vBcl-2 is not phosphorylated by the CDK6–v-cyc complex, allowing KSHV to overcome the v-cyc-induced apoptosis (Ojala *et al.*, 2000). These differences seem to be due to variations in the protein structure between the two proteins.

IRFs are a family of interferon-responsive transcription factors that regulate expression of genes involved in pathogen response, cell proliferation and immune modulation through binding to interferon-stimulated response elements (ISREs) in the promoters of interferon-responsive genes. Among the members of the IRF family, IRF-3 and IRF-7 seem to be the key regulators for the induction of type I interferons (IFNs), the primary response against viral infection (for a review, see Stark *et al.*, 1998). KSHV encodes four IRF homologues, named vIRFs (Moore *et al.*, 1996; Russo *et al.*, 1996). vIRF-1, encoded by orfK9, is a multifunctional protein that inhibits signalling (Gao *et al.*, 1997; Li *et al.*, 2000; Moore *et al.*, 1996). Expression of vIRF-1 inhibits IFN-signal transduction in reporter assays, downregulates expression of the cell-cycle inhibitor p21WAF-1/CIP-1 and transforms NIH 3T3 cells (Gao *et al.*, 1997). vIRF-1 is weakly expressed in KSHV-infected B cells, while it is absent from spindle KS cells (Gao *et al.*, 1997).

KSHV orfK10 encodes vIRF-2 (Burysek and Pitha, 2001), another protein that also inhibits IFN-mediated cell death. It is conceivable that, by blocking interferon-induced signal transduction and/or apoptosis, vIRF-1 and vIRF-2 allow KSHV-infected cells to escape the effect of virus-specific T cells (see below).

KSHV orfK10.5 is a latent gene whose product is another KSHV IRF homologue (vIRF-3), also referred to as LANA-2 in view of its latent expression in KSHV-infected B cells (Rivas *et al.*, 2001). vIRF-3/LANA-2 inhibits the activation of p53-dependent promoters and thereby restrains p53-mediated apoptosis (Rivas *et al.*, 2001). It also interferes with the activation of caspase 3 induced by interferon-activated protein kinase (PKR) and can therefore be considered part of the KSHV defense mechanism against the interferon system (Esteban *et al.*, 2003). Furthermore, vIRF-3/LANA-2 has been reported to inhibit the transcriptional activity of FOXO3a and to block the G2/M arrest induced by 14-3-3 protein overexpression (Munoz-Fontela *et al.*, 2007).

KSHV Proteins with Transforming and Intracellular Signalling Activity

Kaposin

A group of transcripts originating in the K12/kaposin locus has been reported to encode several proteins (Sadler *et al.*, 1999). Among these, kaposin A, a type II transmembrane protein, is able to transform rodent fibroblasts to tumourigenicity (Kliche *et al.*, 2001; Muralidhar *et al.*, 1998). Kaposin A induces lymphocyte aggregation and adhesion, probably through direct interaction with cytohesin-1 (Kliche *et al.*, 2001), a guanine nucleotide exchange factor for ARF GTPases and regulator

of integrin-mediated cell adhesion (Figure 11.6). Kaposin B binds to the cellular kinase MK2 and enhances the stabilization of certain cytokine mRNAs that are normally regulated by the p38/MK2 pathway (McCormick and Ganem, 2005).

ORFsK1, K9, 74 and K15

The products of three early and late genes, orfK1, orfK9 and orf74 (VIP, vIRF-1 and vGCR, respectively), have been shown to have transforming properties and to induce intracellular signalling pathways. K1/VIP and vGCR cause tumours in transgenic mice and activate several intracellular signal transduction pathways, including stress- and mitogen-induced kinases (Lee *et al.*, 1998) (for references for vGCR, see above). K1/VIP transforms rodent fibroblasts and is able to immortalize T lymphocytes when replacing the saimiri transforming protein (STP) in the HVS genome (Lee *et al.*, 1998).

In line with their classification as early or late lytic genes, neither K1/VIP nor K9/vIRF-1 have so far been found to be expressed in the majority of tumour cells of KS, MCD or PEL, although low-level expression remains a possibility. The expression of vGCR in a small percentage of tumour cells in PEL, MCD and KS lesions has been observed by immunohistochemistry (Chiou *et al.*, 2002), in accordance with a proposed role for this membrane-signalling protein in paracrine effects (Bais *et al.*, 1998; Montaner *et al.*, 2003) (see above).

A family of alternatively-spliced transcripts is transcribed late in the lytic replication cycle from eight exons located between orf75 and the TR. Proteins (terminal membrane proteins (TMPs)) derived from these transcripts are predicted to contain up to 12 transmembrane domains and a common cytoplasmic domain containing a putative TRAF as well as SH2 and SH3 (Src homology domain) binding sites (Glenn *et al.*, 1999; Poole *et al.*, 1999) (Figure 11.6). The largest K15-derived protein activates the NF- κ B, MEK/Erk and JNK pathways and induces the production of inflammatory cytokines (Brinkmann *et al.*, 2007). Intracellular localization studies have shown that TMP resides in the endoplasmic reticulum (ER) and mitochondria, where it interacts with HS1-associated protein X-1 (HAX-1), an inhibitor of Bax-induced apoptosis (Sharp *et al.*, 2002).

Escape from the Immune System

The interaction between viruses and their hosts during evolution is thought to have conditioned the host immune system and has resulted in the development of viral strategies to evade the immune system. Many viruses encode proteins that target essential pathways of the immune system. KSHV has also acquired several mechanisms to protect infected cells from an attack by the immune system.

The K3 and K5 proteins, unique to KSHV, are involved in protecting virus-infected cells against NK cells or cytotoxic T lymphocytes (Coscoy and Ganem, 2000). These membrane proteins, also termed modulator of immune recognition (MIR) 1 and 2, respectively, have been shown to downregulate major histocompatibility complex (MHC) class I molecules (Coscoy and Ganem, 2000). MIR1 targets HLA-A, B and C, whereas MIR2 primarily targets HLA-A, ICAM-1 (intercellular adhesion molecule 1; CD 54) and B7.2 (CD 86); both also target the gamma interferon receptor 1 (Li *et al.*, 2007). MIR1 and MIR2 increase the rate of endocytosis and degradation of their target proteins by acting as E3 ubiquitin ligases and mediating their ubiquitination (Lorenzo *et al.*, 2002; Means *et al.*, 2002) (Figure 11.6). Downregulation of MHC-I molecules by MIR1 involves the formation of lysine-63-linked polyubiquitin chains on MHC-I, followed by endocytosis and lysosomal degradation (Duncan *et al.*, 2006). Both MIR1 and MIR2 contain an amino terminal RING finger motif required for their function as E3 ligases. This domain and the carboxy-terminal region are responsible for MIR-mediated endocytosis, whereas the transmembrane region is required for target specificity. Reports studying the expression of these proteins have shown that both MIR1 and MIR2 are expressed as early and late lytic genes following reactivation in PEL cell lines, whereas K3 transcripts were not detected in KS lesions (Rimessi *et al.*, 2001; Sun *et al.*, 1999).

Like many other viruses, KSHV has also developed defense mechanisms against components of the interferon system. The initial immune response against viral infection is regulated by IRFs through binding to ISREs in the promoters of interferon-responsive genes. The KSHV vIRFs are involved in counteracting these effects. The mechanism by which vIRFs inhibit IFN-signal transduction seems to involve direct binding to IRFs p300/CREB binding protein (CBP) and other transcription factors impeding the formation of the transcriptional active complexes (Li *et al.*, 2000; Lin *et al.*, 2001).

vIRF-1 is able to bind to the transcriptional coactivator CBP and inhibit its transcriptional activity, and it also interacts with the histone acetyl transferase p300, impeding its activity and modifying chromatin structure and blocking IRF3 recruitment of p300/CBP (Li *et al.*, 2000; Lin *et al.*, 2001) (see 'Inhibition of Apostosis', above).

Similarly, vIRF-2 can also bind to IRFs and CBP/p300 and thereby inhibit virus-mediated induction of IFN type I gene transcription (Burysek and Pitha, 2001). Another mechanism of action of vIRF-2 involves the interaction with the IFN-induced, double-stranded, RNA-activated serine-threonine kinase (PKR) (Burysek and Pitha, 2001), a main component of the host antiviral defence (for a review on PKR, see Levy and Garcia-Sastre, 2001).

Such interaction blocks autophosphorylation of PKR and subsequent phosphorylation of PKR targets (Burysek and Pitha, 2001). The role of vIRF-3/LANA-2 in the PKR pathway has been discussed above. The KSHV orf45 protein blocks phosphorylation and nuclear accumulation of IRF-7, and thereby virus-mediated induction of type I IFN-activated genes (Zhu *et al.*, 2002).

The three viral β chemokines, vMIPs I–III (see 'Angiogenesis and B-cell Proliferation: vIL-6, vMIP-I-III, vGCR', above) may also play a role in modulating the immune response. Other herpesviruses and poxviruses encode homologues of chemokines (see Alcami, 2003 and references cited therein). Little is known regarding the role of vMIP-III. vMIP-II binds to several chemokine receptors, either as an agonist or as an antagonist (Boshoff *et al.*, 1997; Kledal *et al.*, 1997), whereas vMIP-I is more selective, binding exclusively to and acting as an agonist of CCR8 (Endres *et al.*, 1999). The leukocyte infiltrate within KS lesions is composed mainly of mononuclear phagocytes and T cells, with the CD4⁺ and CD8⁺ cells having a marked type II cytokine profile. This is probably due to the fact that both vMIP-I and -II act as chemoattractants for monocytes and Th2 cells and not Th1, NK or dendritic cells (Weber *et al.*, 2001). This may allow the virus to skew the immune response from a type I, antiviral, response pattern towards a type II pattern (Weber *et al.*, 2001).

The product of orf4, named KCP for KSHV complement control protein, has kinetics characteristic of a lytic protein which specifically increases the decay of classical C3-convertase (Spiller *et al.*, 2003). It is conceivable that KCP could enhance virus pathogenesis through evading complement attack, opsonization and anaphylaxis (Spiller *et al.*, 2003).

DIAGNOSTIC ASSAYS

Serological Assays

Several serological assays of varying sensitivity and specificity, such as immunofluorescence, enzyme-linked immunosorbent assays and immunoblotting, have been developed. Among the first KSHV antibody assays, latently-infected PEL cell lines, such as BCP-1 or BCBL-1, were used as antigens for IFA by incubating these cells, dried on to microscope slides, with patient sera and detecting specific antibody bindings with fluorescein-conjugated secondary antibodies (Gao *et al.*, 1996b; Kedes *et al.*, 1996) (see Figure 11.8). Positive cells show a typical speckled nuclear pattern, which represents the main latent nuclear antigen of KSHV, the 225–234 kDa LANA-1 protein encoded by orf73 (Rainbow *et al.*, 1997). The sensitivity of this assay

Figure 11.8 Immunofluorescence pattern for (a) latent and (b) lytic KSHV antigens in PEL cells. (a) shows the characteristic speckled nuclear pattern for the ‘latency-associated nuclear antigen’, LANA (Kedes *et al.*, 1996; Gao *et al.*, 1996b), which is encoded by orf73 (Rainbow *et al.*, 1997). (b) shows the diffuse nuclear and cytoplasmic fluorescence seen on TPA- or sodium-butyrate-induced PEL cells with patient sera.

lies in the order of 80% or higher when suitable PEL cell lines (e.g. BCP-1) and sera from KS patients are used as standards. A 3% reactivity rate in this assay among healthy individuals from low-prevalence countries indicates a high specificity. In addition, an IFA performed on PEL cell lines, in which the lytic cycle can be efficiently induced by treatment with phorbol esters or sodium butyrate (e.g. BCBL-1; KS-1), detects antibodies to several viral structural proteins, in particular the orf K8.1-encoded virion membrane glycoprotein (Rezza *et al.*, 1998) (see Figure 11.8). While thought to be more sensitive than the IFA for LANA-1 antibodies, the ‘lytic’ IFA suffers from a lower specificity in many laboratories. However, with some protocols good specificities for this assay have been reported (Rezza *et al.*, 1998), although the issue of inter-laboratory comparability still remains problematic.

Enzyme-linked immunosorbent assays (ELISAs) are based on either whole-virus lysates, recombinant viral proteins—in particular LANA-1, K8.1 glycoprotein and orf65/vSCIP—or short chemically-synthesized peptides derived from a combination of these three proteins (Lam *et al.*, 2002; Raab *et al.*, 1998; Simpson *et al.*, 1996; see Schulz, 1998 for further references). Sensitivity and specificity of these ELISAs are in the range of 81–94% and 70–80%, respectively. Specificity of these assays can be increased by verifying a positive result in a more specific immunoblot. ELISAs based on the highly immunogenic K8.1 glycoprotein, which has no homologue in other herpesviruses, seem to perform with a comparatively high specificity.

Combinations of different antigens or assays increase sensitivity and thus make it possible to detect even lower antibody titres, as in the early stages of asymptomatic infection or in the late stages of AIDS when KSHV-specific antibodies can vanish.

These assays have proved useful in epidemiology studies of KSHV. However, serological diagnosis of a KSHV infection in an individual, particularly from a low-risk population, may still be associated with a degree of uncertainty if antibodies to only one KSHV antigen or reactivity in only one assay are found. Simultaneous reactivity in several assays affords much higher certainty.

Molecular Biology Assays

By qualitative PCR, KSHV is easily detectable in fresh or frozen biopsies of KS, PEL or MCD, although the amount of KSHV DNA can be quite variable, particularly in KS biopsies. Detection in paraffin-embedded specimens generally may require the use of nested PCR, as does detection in peripheral blood, saliva or semen. Detection of KSHV DNA in the peripheral blood of HIV-infected individuals has long been known to predict the onset of KS (Whitby *et al.*, 1995). Several quantitative PCR protocols, including competitive and real-time PCR assays (de Sanjose *et al.*, 2002) have been developed. In several, but not all, studies, peripheral blood viral load has been found to predict clinical progression. MCD in particular seems to be associated with a high KSHV viral load (Boivin *et al.*, 2002; Oksenhendler *et al.*, 2000). In AIDS patients, KSHV viral load is higher in patients with active KS than in patients with KS in complete remission, and highest among patients with progressing KS (Laney *et al.*, 2007; Marcelin *et al.*, 2004). However, in HIV-unrelated KS patients KSHV viral load does not correlate significantly with clinical stage (Guttman-Yassky *et al.*, 2007; Marcelin *et al.*, 2004), suggesting KSHV viral load might only reflect the intensity of immunosuppression rather than the extension of KS in a patient. Nevertheless, as KSHV viral load not only increases with progressing disease but

also decreases and/or becomes negative after complete or partial clinical response (Laney *et al.*, 2007; Lebbe *et al.*, 1998), quantifiable PCR methods can serve as a diagnostic tool to monitor immunocompromised patients at high risk of KSHV-related diseases.

ANTIVIRAL THERAPY

HAART

Since the introduction of HAART in 1996 the incidence of AIDS KS in Western countries has markedly reduced. This may be the consequence of an enhanced KSHV-specific immune response following restoration of patients' immune systems by effective suppression of HIV, but a direct effect of HIV proteinase inhibitors, for example indinavir, on KS has also been postulated (Sgadari *et al.*, 2003).

Anti-herpesviral Drugs

Nevertheless, virus-specific therapy of KSHV-associated diseases still remains a problem, since the classical anti-herpesviral drugs known so far are only effective in combating lytic and not latent infection. As discussed above, most tumour cells in KS, PEL and MCD are latently infected with KSHV; of these, MCD is characterized by the highest percentage of cells expressing lytic KSHV proteins. In keeping with this observation, ganciclovir treatment may lead to substantial clinical improvement in MCD cases (Casper *et al.*, 2004). *In vitro* assays have established that the replicative cycle of KSHV in PEL cell lines can be inhibited with cidofovir, ganciclovir and foscarnet, but not with aciclovir (Kedes and Ganem, 1997; Medveczky *et al.*, 1997). However, clinical studies with these antiviral drugs have produced controversial results. The use of intravenous ganciclovir, foscarnet or cidofovir therapy to treat cytomegalovirus disease did not affect the KSHV DNA load in PBMCs, but was associated with disease progression (Boivin *et al.*, 1999; Little *et al.*, 2003). On the other hand, some retrospective studies and anecdotal reports do support the notion that these drugs are active against KSHV *in vivo*. Thus, both foscarnet and ganciclovir, but not aciclovir, had some activity in preventing the occurrence of KS (Mocroft *et al.*, 1996). It therefore appears that ganciclovir and foscarnet can inhibit the replication and dissemination of KSHV prior to the emergence of KS, but that they are of limited benefit in treating established disease.

Experimental Approaches

The growing knowledge on KSHV pathogenesis now offers multiple starting points for the development of new

therapeutic strategies, some of them already being tested in phase I and phase II clinical trials. In addition, it may explain the modes of action of long-established therapeutic regimens. Thus there are hints that the silencing of the still-functional p53 tumour suppressor gene by viral oncogenes like LANA can be overcome by the application of p53-activating drugs such as the liposomal anthracyclines. These DNA-damaging, hence p53-activating, chemotherapeutic drugs are known to induce KS regression (Petre *et al.*, 2007; Sarek *et al.*, 2007). Similarly, nutlin 3a, an inhibitor of the interaction between p53 and its ubiquitin E3 ligase, mdm-2, has been shown to restore p53 function and p53-mediated apoptosis in a PEL-tumour model (Sarek *et al.*, 2007). Another promising strategy is the inhibition of the VEGF-induced Akt/mTOR pathway, which emerged as a major driving force in KS development, by for example rapamycin, an immunosuppressive drug used to prevent organ rejection after transplantation. By switching a cyclosporine-based regimen to rapamycin, which unlike cyclosporine inhibits mTOR, all 15 renal allograft recipients with cutaneous KS showed complete regression (Stallone *et al.*, 2005). Nevertheless, failures to rapamycin have also been described (Lebbe *et al.*, 2006). Other angiogenesis-inhibiting drugs like COL-3 (inhibits MMP-2 and -9) or interleukin-12 (Dezube *et al.*, 2006; Little *et al.*, 2006) are currently being evaluated.

Other antiviral agents might also be effective against KSHV infection. Glycyrrhonic acid, a component of liquorice, decreases the expression of LANA and increases that of v-cyclin, which results in apoptosis of latently KSHV-infected cells. Although the required concentration of glycyrrhonic acid is far too toxic, better components may be developed by pharmacological engineering, expanding anti-herpesviral treatment options to the reservoir of latently-infected cell (Curreli *et al.*, 2005). KSHV encodes a dihydrofolate reductase (DHFR) (orf2). Although this early lytic enzyme has been shown to be non-essential for viral replication in cultured PEL cells and its activity was not detected in PBMCs, DHFR inhibitors like methotrexate (MTX) or trimethoprim might represent starting points for the design of new specific anti-KSHV agents (Cinquina *et al.*, 2000). MTX has already been shown to completely prevent TPA-induced lytic viral DNA replication and to strongly decrease viral lytic transcript levels *in vitro* (Curreli *et al.*, 2002). Whether this is suitable for a therapeutic approach has to be further examined.

Hepatitis Viruses

Tim J. Harrison, Geoffrey M. Dusheiko and Arie J. Zuckerman

UCL Medical School, London, UK

INTRODUCTION

Hepatitis, characterized by necrosis and inflammation in the liver, may result from infection with a variety of viruses and is the main clinical outcome of infection with viruses from several different families. The predominantly hepatotropic viruses, which vary in prevalence throughout the world, may be considered together, although the biology of these viruses and the spectrum of disease they cause differ considerably (see Table 12.1 for an overview).

The clinical spectrum of acute disease ranges from an asymptomatic or mild anicteric illness to acute disease with jaundice to severe prolonged jaundice or fulminant hepatitis (acute liver failure). Where the infection persists, chronic hepatitis may ensue and, here, the outcome is also variable. Inapparent or subclinical and anicteric infections are common. Hepatitis A virus (HAV) and hepatitis E virus (HEV) do not persist in the liver and there is no evidence of direct progression to chronic liver damage. However, hepatitis B virus (HBV), with or without its satellite, hepatitis D virus (HDV or the delta agent) and hepatitis C virus (HCV), may be associated with persistent infection, a prolonged carrier state and progression to chronic liver disease, which may be severe. In addition, there is substantial evidence of an aetiological association between infection with chronic hepatitis B or C and hepatocellular carcinoma.

Hepatitis A, B and D can be differentiated by sensitive laboratory tests for specific antigens and antibodies, and the respective viruses have been characterized. Enzyme immunoassays (EIAs) and recombinant immunoblot assays (RIBAs) have been developed for the detection of antibodies to HCV, and viraemia may be confirmed by testing for the viral genome, for example by using the

polymerase chain reaction (PCR). Assays for the nucleocapsid antigen of this virus currently are under evaluation. EIAs have been developed for the detection of antibodies to HEV and the genome may be detected using PCR.

Pathology

Acute Hepatitis

The pathological features that are constant in all types of acute viral hepatitis consist of parenchymal cell necrosis and histiocytic periportal inflammation. The reticulin framework of the liver is usually well preserved, except in some cases of massive and submassive necrosis. The liver cells show necrotic changes that vary in form and intensity. The necrotic areas are usually multifocal, but necrosis tends to be frequently zonal, with the most severe changes occurring in the centrilobular areas. Individual hepatocytes often are swollen and may show ballooning, but they can also shrink, giving rise to acidophilic bodies.

Dead or dying rounded liver cells are extruded into the perisinusoidal space. There are variations in the size and staining quality of the nuclei. Fatty changes in the liver are usually not marked, but some steatosis can be observed in chronic HCV infection. A monocellular infiltration, which is particularly marked in the portal zones, is the characteristic mesenchymal reaction. This is also accompanied by some proliferation of bile ductules.

Kupffer cells and endothelial cells proliferate and the Kupffer cells often contain excess lipofuscin pigment. In the icteric phase of typical acute hepatitis, the walls of the hepatic vein tributaries may be thickened and frequently are infiltrated, with proliferation of the lining cells in the terminal hepatic veins. Cholestasis may occur in the early stages of viral hepatitis, and plugs of bile thrombi may

be found in the bile canaliculi; this is a more common feature in hepatitis E.

Spotty or focal necrosis with the associated mesenchymal reaction may also be found in anicteric hepatitis, but on the whole the lesions tend to be less severe than in the icteric type of illness. At the other extreme, there is rapid massive necrosis of the liver cells in fulminant hepatitis.

Repair of the liver lobules occurs by regeneration of hepatocytes; frequent mitoses, polyploidy, atypical cells and binucleated cells are found. There is gradual disappearance of the mononuclear cells from the portal tracts, but elongated histiocytes and fibroblasts may remain. The outcome of acute viral hepatitis may be complete resolution or fatal massive necrosis.

Chronic Hepatitis

The pathological features of chronic hepatitis B depend upon the stage of the disease, the host immune response and the degree of virus replication. In chronic hepatitis B with mild activity, only rare piecemeal necrosis is seen. Characteristic hepatocytes with eosinophilic 'ground-glass' cells are relatively common in anti-HBe-positive patients with low levels of virus replication. Lobular hepatitis is more common in patients with active virus replication and raised serum aminotransferases. CD8-positive cells predominate in areas of piecemeal necrosis. Hepatitis B surface antigen (HBsAg) and hepatitis B core antigen (HBcAg) can be detected by immunoperoxidase staining in routinely-fixed liver biopsy sections. Patients with high levels of viraemia may have minimal hepatitis.

The pathological features of HCV infection are quite characteristic, albeit not pathognomonic. The presence of HCV RNA in serum tends to correlate with some degree of hepatitis, and disappearance of HCV RNA, for example following successful interferon alpha (IFN- α) treatment, is

Figure 12.1 Section of a liver biopsy from a patient with chronic hepatitis C seen at low magnification. There is a moderate lymphocytic infiltrate in the portal tracts, with piecemeal necrosis. A scattered mild parenchymal inflammatory infiltrate is also present. Stained with haematoxylin and eosin. (Courtesy of Dr A.P. Dhillon, Department of Histopathology, Royal Free Hospital and UCL Medical School.)

followed by histological improvement. Typically, patients with chronic hepatitis C have mild portal tract inflammation with lymphoid aggregates or follicles and mild periportal piecemeal necrosis (Figure 12.1). Parenchymal steatosis, apoptosis and mild lobular inflammation are present and portal fibrosis or portal-central fibrosis may be present in later stages of disease. Bridging necrosis is not common. Rarely, granulomas can be observed. Although many of the lymphoid follicles are associated with bile ducts, ductopaenia is not observed. Advanced disease, with cirrhosis or hepatocellular carcinoma, is not generally associated with distinguishing features.

HCV antigens have been detected in scattered groups of cells, with granular cytoplasmic staining. The periportal lymphocytes around lymphoid follicles are mixed, but

contain relatively large numbers of CD4 lymphocytes. A characteristic histological pattern of mild chronic hepatitis with portal lymphoid follicles and varying degrees of lobular activity is found in many patients with persistent hepatitis C infection.

Biochemical Tests of Liver Function

The serum levels of aspartate and alanine aminotransferase (ALT) are elevated in acute hepatitis, as are levels of other enzymes released by the damaged liver cells. Usually, the levels of ALT are higher than those of aspartate aminotransferase (AST), a difference particularly marked in hepatitis C. However, with progression of the disease to cirrhosis, the AST/ALT ratio may be reversed. Elevation of these enzymes may be the only abnormality to be found in individuals with asymptomatic and anicteric infections who are tested because of known exposure. Bilirubin is found in the urine and conjugated and total serum bilirubin levels are raised in most symptomatic infections. The leukocyte count is usually normal but some atypical lymphocytes are frequently found.

A progressive decline in serum albumin concentrations and prolongation of the prothrombin time are characteristically observed after decompensated cirrhosis has developed. A subset of patients with chronic hepatitis C infection may test positive for autoantibodies, including LKM1 antibody.

Clinical Manifestations

Differences between the clinical syndromes of acute hepatitis A, acute hepatitis B and other forms of viral hepatitis become apparent on analysis of large numbers of well-documented cases, but these differences are not sufficiently reliable for the diagnosis of individual patients with icteric disease. Epidemiologic risk factors, for example travel, injections or sexual risk, can indicate a possible aetiology. Fever and headache are more frequent during the prodrome of acute hepatitis A. The late incubation period–early clinical phase is frequently heralded by a variety of nonspecific symptoms such as fatigue, anorexia, malaise and myalgias. A few days later, anorexia, nausea, vomiting and right-upper-quadrant abdominal pain can appear, followed by passage of dark urine and clay-coloured stools and the development of jaundice of the sclera and skin. With the appearance of jaundice there is usually a rapid subjective improvement in symptoms. The jaundice usually deepens during the first few days and persists for one or two weeks. The faeces then darken and the jaundice diminishes, at first rapidly and then more slowly, over an additional period of two weeks or so. The liver may be palpable in acute severe hepatitis, but only a minority of patients have palpable splenomegaly. Convalescence

may be prolonged, although complete recovery in adults usually takes place within a few months. In children, the prodromal features may be mild or even absent, although anorexia, when present, tends to be severe. The icteric or post-icteric phase in children is short. The prodromal phase of hepatitis B and C is often prolonged and more insidious. Low-grade fever, arthralgias and skin rashes, particularly in hepatitis B, are not uncommon. The clinical features of the icteric phase are similar in all types of acute viral hepatitis. The mortality rate of acute hepatitis is low, approximately 0.1–3 deaths per 1000 cases.

Fulminant hepatitis can occur following acute hepatitis A–E; it is more common in hepatitis B. Hepatocellular failure develops rapidly; the patient may be deeply jaundiced or encephalopathy may occur before conspicuous jaundice is evident. Widespread haemorrhage occurs. The prothrombin time is prolonged; an altered prothrombin time is a more reliable indicator of prognosis, and of the need for liver transplantation, than the serum bilirubin or serum aminotransferases.

Fulminant hepatitis is unusual following hepatitis C infection, but has been reported, particularly following chemotherapy or withdrawal of chemotherapy. High mortality rates for hepatitis occurring during pregnancy have been reported from India, the Middle East and north Africa, associated particularly with HEV infection.

HEPATITIS A

Hepatitis A is endemic in all parts of the world, but the precise incidence is difficult to estimate because of the high proportion of asymptomatic and anicteric infections, differences in surveillance and differing patterns of disease. The degree of under-reporting is known to be very high. Serological surveys have shown that infection with HAV is almost universal and, in developing countries, 80–90% of children have serological markers of past infection by the age of five. In industrialized countries (particularly in northern Europe, North America and Australia) improvements in sanitation have decreased the incidence of hepatitis A. The prevalence of antibodies in young adults in such countries is 5–20%.

Incubation Period

The incubation period of hepatitis A is between three and five weeks, with a mean of 28 days. Subclinical and anicteric infections are common, particularly in children, and, although the disease has, in general, a low mortality, adult patients may be incapacitated for many weeks. There is no evidence of persistence of the infection in the liver and progression to chronic liver damage does not occur.

The virus replicates *in vivo* in the liver but it seems likely that the initial site of virus replication may be in the gut. This is not proven and the mechanism by which the virus reaches the liver is unknown, although a transient viraemia has been postulated.

Mode of Spread

HAV is spread by the faeco-oral route, most commonly by person-to-person contact, and infection is particularly common in conditions of poor sanitation and overcrowding. Common source outbreaks result most frequently from faecal contamination of drinking water and food, but water-borne transmission is not a major factor in industrialized communities. On the other hand, many food-borne outbreaks have been reported in developed countries. This can be attributed to the shedding of large amounts of virus in the faeces (Figure 12.2) during the incubation period of the illness in infected food handlers, and the source of outbreaks often can be traced to uncooked food or food which has been handled after cooking. The consumption of raw or inadequately-cooked shellfish cultivated in polluted water is associated with a high risk of HAV infection. For example, raw clams were implicated as the source of an epidemic with approximately 300 000 cases in Shanghai in 1988. However, although hepatitis A is common in developed countries, the infection occurs mainly in small clusters and often with only a few identified cases. Sporadic cases result from person-to-person contact. Hepatitis A is highly endemic in many tropical and subtropical areas, with the occasional occurrence of large epidemics. The infection is acquired frequently by travellers from areas where it is of low prevalence to areas where hepatitis A is hyperendemic.

Figure 12.2 Electron micrograph showing HAV in faecal extracts obtained during the early acute phase of illness. The particles measure about 27 nm in diameter ($\times 170\,000$). (From a series by Anthea Thornton and A.J. Zuckerman.)

Age Incidence

All age groups are susceptible to hepatitis A and disease severity increases with age. As noted above, most individuals in highly-endemic areas are infected before five years of age but in many countries in northern Europe and in North America most clinical cases occur in adults. In countries where there has been improvement in socio-economic conditions and sanitation, such as southern Europe and China, there has been an increase in the mean age of infection. In many developed countries, the prevalence of antibodies to hepatitis A has fallen to 5–10% of young adults and there is thus a large susceptible population. The diminishing incidence of hepatitis A is now matched by an increasing incidence of clinically-apparent disease. This shift in age incidence is similar to that which occurred with poliomyelitis during and after the Second World War, reflecting improvements in socio-economic and hygienic conditions and a consequent shift in herd immunity.

The Biology of Hepatitis A Virus

The hepatitis A virion is a non-enveloped particle measuring 25–28 nm in diameter (Figure 12.3) and containing a linear genome of positive-sense, single-stranded RNA, approximately 7500 nucleotides in length and coding for three major structural polypeptides with molecular weights of 33 000, 29 000 and 27 000 (VP1, VP2 and VP3). A fourth polypeptide (VP4) of only 17 amino acids has been predicted from the nucleotide sequence of the virus but has not been detected experimentally. X-ray crystallographic studies have not yet been reported but the

Figure 12.3 Electron micrograph showing a large aggregate of HAV particles heavily coated with antibody, giving the appearance of a 'halo'. 'Full' and 'empty' particles are shown ($\times 340\,000$). (From a series by Anthea Thornton and A.J. Zuckerman.)

basic structure of the capsid may be predicted from such studies of other picornaviruses; the antigenic structure has been defined further by analysis of neutralization-escape mutants selected by monoclonal antibodies. These studies suggest that the immunodominant neutralization site is a conformational epitope comprising residues of VP1 and VP3. It is believed that secondary or higher orders of protein structure may play essential roles in this antigenic site, because it has not been possible to detect this predominant antigen in virus preparations disrupted with detergent or following expression of recombinant protein (although expression of the entire HAV polyprotein may enable assembly of antigenic virus-like particles in cell culture).

HAV is exceptionally stable; it is ether-resistant, stable at pH 3.0 and relatively resistant to inactivation by heat and to degradation by environmental conditions. HAV retains its physical integrity and biological activity at 60 °C for 10 hours but is inactivated after 5 minutes at 100 °C. The virus may also be inactivated by ultraviolet irradiation and by treatment with a 1 : 4000 concentration of formaldehyde solution at 37 °C for 72 hours. There is also evidence that HAV is inactivated by chlorine at a concentration of 1 mg l⁻¹ for 30 minutes.

Genetic Organization

The organization of the genome of HAV is similar to other picornaviruses and it was classified originally as *Enterovirus* type 72. However, there are substantial differences between HAV and the *Enteroviruses* and other genera of the *Picornavirus* family and it has been reclassified in its own genus of the *Picornaviridae*, *Hepatovirus*.

Cloning and sequencing data indicate that the genome of HAV consists of 7478 nucleotides with a 5' noncoding region of 733 nucleotides and a shorter noncoding region and poly(A) tract at the 3' terminus. A small protein (VPg) is bound covalently at the 5' terminus. A single open reading frame (ORF) extends from nucleotide 710–750 to about 60 nucleotides in advance of the 3' terminal poly(A) tract. Comparison of the predicted amino acid sequence of the polyprotein with other *Picornaviruses* suggests that the 5' region of the ORF codes for the three

major structural proteins of the virus along with the fourth, small VP4. The 3' region encodes a protease, the polymerase and other functions involved in genome replication. Dipeptide cleavage sites which have been identified in a number of *Picornavirus* polyproteins are not conserved in HAV, but attempts have been made to predict the cleavage pattern and post-translational processing of the polyprotein (Figure 12.4). The cellular receptor for HAV has been identified as TIM1, a member of the T-cell immunoglobulin mucin family.

Cell Culture

The successful propagation of HAV in primary monolayer and explant cell cultures, and in continuous cell lines of primate origin, was a major advance and opened the way to the preparation of hepatitis A vaccines. The viral capsid antigens are detectable by immunofluorescence and radioimmunoassay, and the viral RNA by an indirect, quantitative autoradiographic plaque assay and by complementary DNA–RNA hybridization and reverse transcriptase polymerase chain reaction (RT-PCR). HAV does not induce cytopathic changes in culture but tends to establish persistent infections and remain largely cell associated. However, primary isolation of wild-type virus is difficult and several weeks elapse before antigen is detectable; thus, virus isolation is not a practical diagnostic technique in routine laboratories.

Adaptation to growth in cultured cells occurs with repeated passage, with more rapid production of intracellular antigen and higher final yields. Virus adapted to growth in cell culture may become attenuated and the nucleotide sequences of wild-type and attenuated strains have been compared. There is evidence that changes in the 5' noncoding region and the region encoding non-structural (2B/2C) polypeptides may be associated with attenuation and adaptation to cell culture.

Only one serotype of hepatitis A has been identified in human volunteers infected experimentally, in patients from different outbreaks of hepatitis A and in naturally- and experimentally-infected chimpanzees and other primates. This also has been confirmed by cross-neutralization tests and by the protective efficacy

Figure 12.4 Organization of the HAV genome. See text for details.

of pooled human immunoglobulin obtained from different geographical regions. However, strain-specific differences exist, at least at the level of genomic nucleotide sequences from different isolates of HAV. Phylogenetic analysis of the nucleotide sequences of various HAV strains reveals that these can be classified into six genotypes; genotypes I, II and III are of human origin and genotypes IV, V and VI were isolated from Old World monkeys. All strains have a highly-conserved single immunodominant epitope which generates cross-reactive, neutralizing antibodies.

Pathogenesis

The mechanisms underlying liver injury in hepatitis A are not understood. The initial noncytopathic phase, during which virus replicates and is released, is followed by decreased virus multiplication and inflammatory cell infiltration, suggesting that immune mechanisms are involved in pathogenesis. Experimental evidence suggests that HLA-restricted, virus-specific T cells play a significant role in HAV-related hepatocellular injury. T-cell clones have been derived from patients with acute hepatitis A and analysed for their phenotype. CD8⁺ clones isolated during the acute phase of the disease predominate over CD4⁺ clones; these CD8⁺ clones have cytotoxic activity and show specific cytotoxicity against autologous fibroblasts infected with HAV. These data support the hypothesis that liver-cell injury in acute HAV infection is mediated by HAV-specific CD8⁺ T lymphocytes and is not entirely due to an intrinsic cytopathic effect of the virus itself. The molecular targets of these cells are unknown. Serum-neutralizing antibodies protect against HAV infection.

Laboratory Diagnosis

Specific diagnosis of hepatitis A can be established by demonstrating the virus in faeces by EIA and radioimmunoassay, or by immune electron microscopy (IEM) and RT-PCR. Isolation of the virus in cell cultures is not appropriate for routine diagnosis.

As stated above, the capsid antigen is highly conserved and there is only a single serotype of HAV. Specific serological tests for hepatitis A antigen (HAAg) and antibodies include radioimmunoassay and EIAs. Hepatitis A antibody (anti-HAV) is always demonstrable by such assays during the early phase of the illness, and titres increase rapidly (Figure 12.5). Because antibody develops very early in the course of the infection, serological diagnosis of recent infection can be established by titrations of serial samples of serum or, more conveniently, by the demonstration of hepatitis A antibody of the immunoglobulin M (IgM) class, which is the simplest and most economical method of establishing the diagnosis. Hepatitis A IgM is detectable in serum for 45–60 days after the onset of symptoms. Liver biopsy is not usually required in acute hepatitis A. Titres of anti-HAV IgG rise with convalescence and the antibody usually persists for many years. Recovery from infection is associated with lifelong immunity.

Clinical Course

Clinical disease with jaundice is uncommon in infants and young children and the infection may pass unnoticed in this group. The high seroprevalence of anti-HAV antibodies in developing countries (more than 70% of adults) is largely due to a high rate of asymptomatic

Figure 12.5 Serological profile during uncomplicated hepatitis A.

infection in childhood. Infection in adulthood results in acute icteric hepatitis in more than 70% of cases. The case fatality rate is 0.3–1.8%; the risk of serious complication increases significantly with age, and severe hepatitis is correspondingly more common in older persons. Recurrent hepatitis has been observed in patients (and experimentally-inoculated Saimiri monkeys with acute disease) and may be associated with shedding of virus in stools. The relapses are generally benign, with eventual complete resolution. The absence of chronic infection indicates the effectiveness of the host immune response to HAV. In genetically-susceptible individuals, with a defect in suppressor-inducer T lymphocytes controlling immune responses to the asialoglycoprotein receptor, it is possible that hepatitis A may trigger an autoimmune chronic hepatitis. Such individuals may develop a persistent response to the asialoglycoprotein receptor and, rarely, autoimmune hepatitis after subclinical hepatitis A. Approximately 5% of patients with acute hepatitis A will develop cholestatic hepatitis, characterized by pruritis and steatorrhea.

Prevention and Control of Hepatitis A

Control of infection is difficult. Strict isolation of cases is not a useful control measure because faecal shedding of the virus is at its highest during the late incubation period and prodromal phase of the illness. Spread of hepatitis A is reduced by simple hygienic measures and the sanitary disposal of excreta.

Normal human immunoglobulin (NHIG), containing at least 100 IU/ml of anti-HAV, will prevent or attenuate a clinical illness if given intramuscularly before exposure to the virus or early during the incubation period. The dosage should be at least 2 IU of anti-HAV/kg body weight, but in special cases such as pregnancy or in patients with liver disease the dosage may be doubled. Immunoglobulin does not always prevent infection or excretion of HAV, and inapparent or subclinical hepatitis may develop. The efficacy of passive immunization is based on the presence of hepatitis A antibody in the immunoglobulin, but the minimum titre of antibody required for protection has not been established. Immunoglobulin is used most commonly for close personal contacts of patients with hepatitis A and for those exposed to contaminated food. Immunoglobulin has also been used effectively for controlling outbreaks in institutions such as homes for the mentally handicapped and in nursery schools.

Prior to the availability of a vaccine, pre-exposure prophylaxis with immunoglobulin was recommended for persons without hepatitis A antibody visiting highly-endemic areas. After a period of six months the administration of immunoglobulin for travellers had to be repeated, unless it could be demonstrated that the recipient had developed

his own hepatitis A antibodies. Because the shift in herd immunity led to reduced titres of anti-HAV in normal immunoglobulin in developed countries and a highly immunogenic vaccine became available, a single dose of vaccine may be offered to travellers, with the option of a booster dose 6–12 months later. NHIG (given at a contralateral site) is a valuable addition to the vaccine for individuals who may have been exposed to infection.

Hepatitis A Vaccines

There has been considerable interest in the development of both killed and attenuated hepatitis A vaccines, and inactivated vaccines are now licensed in many countries. The virus grows poorly in cell culture but yields have been improved by adaptation and are sufficient to permit gradient purification. This virus is inactivated with formaldehyde; the antigen is adsorbed to aluminium hydroxide and given intramuscularly. These preparations are safe and immunogenic in man and have been shown to induce a protective immune response. Safety and immunogenicity studies and efficacy trials have been undertaken in volunteers with formaldehyde-inactivated, Al(OH)₃-adsorbed vaccines (Havrix, GlaxoSmithKline (GSK), or Vaqta, Merck Research Laboratories). The anti-HAV response includes neutralizing antibodies. The currently-licensed vaccines appear to be well tolerated and immunogenic at doses of 720–1440 arbitrary ELISA units (GSK) or 125–50 U (Merck). In the case of the GSK vaccine licensed in the United Kingdom, a single dose of 720 ELISA units of hepatitis A viral protein is sufficient for protection of adults of 16 years and over, with the option of a booster dose 6–12 months later. A juvenile formulation with 320 ELISA units per dose is available. Active immunization induces higher levels of both total and neutralizing antibodies than NHIG.

Inactivated vaccines of this type are useful for the protection of travellers from prosperous countries but are likely to be too costly for use in the developing world, where exposure usually occurs early in life. In developed countries the vaccine should be given to travellers to countries where HAV is endemic, as well as to armed forces personnel, diplomats, staff of children's day-care centres and institutions for intellectually-handicapped individuals, male homosexuals, intravenous drug abusers, haemophiliacs and sewage workers. The addition of human immunoglobulin used to be recommended when travel was to occur within four weeks of receipt of vaccine, because of concern about the time taken to develop neutralizing antibodies. However, a single dose of vaccine (1440 ELISA units) is effective. Vaccine should be offered even when given up to the day of travel; ideally travellers should be given prophylaxis at least four weeks before, but they should not be denied prophylaxis on the strength

of the available evidence. After vaccination, anti-HAV antibodies may be detectable rapidly, although the minimum protective antibody level is uncertain.

Data in chimpanzees suggest protection against infection if vaccine is administered shortly after exposure. The curtailment of Alaskan and Italian outbreaks, achieved by immunization with a single dose without concurrent administration of immune globulin, provides supportive evidence for at least some efficacy of one dose for post-exposure prophylaxis (McMahon *et al.*, 1996; Sagliocca *et al.*, 1999). Serological screening for susceptibility may be indicated in appropriately-selected patients. The cost-benefit ratio of HAV vaccination is probably most beneficial when vaccine is given to frequent travellers to endemic areas. Where practical, testing for antibodies to hepatitis A prior to immunization may be indicated in those aged 50 years or over, those born in areas of high endemicity and those with a history of jaundice. HAV vaccine also is recommended for individuals with significant chronic liver disease due to hepatitis B or C and who may have an increased risk of fulminant hepatic failure following HAV infection. A combined hepatitis A and B vaccine is available and licensed for use in adults and children at risk of both infections, and a combined hepatitis A and typhoid vaccine is available and appropriate for use in travellers to areas where typhoid is endemic. Other combined inactivated polyvalent vaccines are under development (Zuckerman, 2006).

Attenuated strains of HAV have been developed and potentially may be useful as vaccines. This approach is attractive because live vaccines may be cheaper to produce (the attenuated virus grows more efficiently in cell culture), can be given orally and may induce a mucosal antibody response. As for vaccine strains of polioviruses, attenuation may be associated with mutations in the 5' noncoding region of the genome which affect secondary structure. There is also evidence that mutations in the region of the genome encoding the nonstructural polypeptides (Figure 12.4, region 2B/2C) may be important for adaptation to cell culture and attenuation. However, the markers of attenuation of HAV are not as well defined as those of the *Polioviruses* and reversion to virulence may be a problem also. There is also concern that 'over-attenuated' viruses may not be sufficiently immunogenic. However, despite these caveats, live attenuated hepatitis A vaccines (H2 and L-A-1 strains) are licensed and used effectively in China.

HEPATITIS E

Epidemic hepatitis, which resembled but was serologically distinct from hepatitis A, was reported initially in

the Indian subcontinent and later in central and South East Asia, the Middle East, north Africa and Central America (reviewed by Panda *et al.*, 2007). The disease is also a common form of acute sporadic hepatitis in these areas and other developing countries. Sporadic cases have been observed in developed countries among migrant labourers and travellers returning from such areas. In contrast to prior epidemics of enterically-transmitted non-A, non-B hepatitis (ET-NANBH), HEV was found to be a common cause of acute hepatitis in a paediatric population in Egypt. Seroprevalence studies in Hong Kong suggest that hepatitis E accounts for a third of non-A, non-B, non-C hepatitis, and that co-infection of hepatitis A and E can occur. More recently, indigenous cases of hepatitis E have been reported in the United States and several European countries, including the United Kingdom. Rarely, HEV may be transmitted by blood transfusion in countries where the disease is endemic.

The average incubation period is slightly longer than for hepatitis A, with a mean of six weeks. The infection is acute and self-limiting. Clinical disease occurs predominantly in young adults, and high mortality rates (up to 20%) have been reported in the third trimester of pregnancy. The infection is spread by the ingestion of contaminated water and probably by food, but secondary clinical cases seem to be uncommon.

Virus-like particles have been detected in the stools of infected individuals by IEM using convalescent serum (Figure 12.6). However, such studies have often proved inconclusive and a large proportion of the excreted virus may be degraded during passage through the gut. The particles are slightly larger than those of hepatitis A, with a mean diameter of 32–34 nm. Cross-reaction studies between sera and virus in stools associated with a variety of epidemics in several different countries suggest a single viral serotype.

Biology of HEV

HEV was first transmitted to cynomolgous macaques, and subsequently to a number of other species of monkeys and chimpanzees. The gallbladder bile of infected monkeys was found to be a rich source of virus, enabling the molecular cloning of DNA complementary to the HEV (RNA) genome and elucidation of the entire 7.5 kb sequence (Tam *et al.*, 1991). The organization of the genome is distinct from the picornaviruses; the non-structural polypeptides are encoded in the 5' region and the structural polypeptides at the 3' end. Although HEV resembles the *Caliciviruses* in the size and organization of its genome, as well as the size and morphology of the virion, the HEV genome differs in having a capped 5' end (rather than a genome-linked protein) and in the organization of the ORFs. Therefore, HEV has been classified

Figure 12.6 IEM of HEV from a faecal extract. (a) Particle coated with predominately IgG. (b) Particles coated with predominately IgM. (Source: Purcell and Ticehurst, 1988, with permission.)

in its own genus, *Hepevirus*, but has not been formally assigned to a virus family.

Organization of the HEV Genome

The HEV genome is a polyadenylated, positive-sense RNA of around 7500 nt and contains three ORFs (Figure 12.7). The first, of approximately 5 kb, begins 28 nt from the 5' end of the genome and encodes motifs associated with NTP-binding, helicase and RNA-dependent RNA polymerase activities. A second ORF of around 2 kb begins 37 nt downstream of the first, terminates 68 nt from the poly(A) tail and is believed

to encode the structural polypeptides. The third ORF is very short (369 nt) and overlaps the other two. The viral proteins may be subject to proteolytic processing and other post-translational modifications.

Sequencing of the HEV genome has enabled the development of a number of specific diagnostic tests. For example, HEV RNA was detected using RT-PCR in stool samples obtained during an epidemic in Kanpur (north India) and may also be detected in infected liver. EIAs, which detect IgG and IgM anti-HEV, have been developed and are commercially available.

Pathogenesis

Macaque monkeys develop changes in acute viral hepatitis associated with a rise in liver enzymes, the presence of HEV-specific viral particles in the stool and histological changes in the liver from 21 to 45 days after HEV inoculation. Subclinical hepatitis E also may occur in experimental primates, and subclinical infections of humans may provide a reservoir for transmission. Ultrastructural changes in the livers of these experimental monkeys include infiltration of lymphocytes and polymorphonuclear leucocytes around the necrotic area, swelling of mitochondria, dilation of smooth endoplasmic reticulum (ER) and the presence of 27–34 nm virus particles during the acute phase of the disease. It is not known whether these changes reflect cytopathic liver injury or are immune-mediated.

Diagnosis

With the availability of recombinant antigens and synthetic peptides, serological assays were developed to test for antibody to hepatitis E virus (anti-HEV). IgM is detected infrequently at initial presentation and disappears by three months after jaundice. IgG titres initially can be quite high, but tend to wane over time. The diagnosis can be confirmed by RT-PCR on faecal material from acutely-infected patients, and the serum may also be positive with a transient

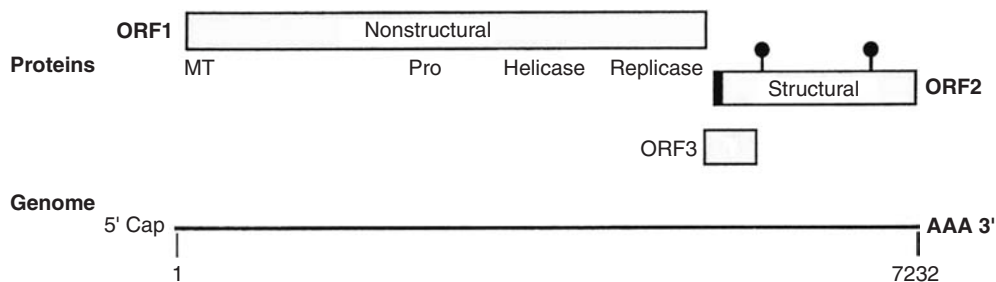

Figure 12.7 Organization of the hepatitis E virus genome. Motifs within the ORF1 protein include a methyl transferase (MT), protease (Pro), helicase and RNA-dependent RNA polymerase (replicase). The shaded area at the amino terminus of the ORF2 protein indicates a signal sequence, and 'lollipops' indicate potential glycosylation sites.

viraemia. Attack rates have been higher in males than females and for adults rather than children. Evidence of secondary intra-familial spread is uncommon.

Clinical Features

In general, the disease is self-limited, with no evidence of chronic infection. Cholestatic features are common and may be prolonged. Liver biopsies obtained during the acute illness show portal inflammation and cytoplasmic cholestasis. Stool specimens may reveal 27–32 nm virus-like particles when tested by IEM but RT-PCR is a more reliable assay for the virus. An observational study appears to confirm a high rate of severe or fulminant hepatitis in pregnant women, with a mortality rate of 20% during the third trimester. Babies born to women with acute disease are at risk of vertical transmission and may be at risk of perinatal morbidity, and infant mortality of up to 30% has been observed. Liver transplantation is indicated for fulminant hepatitis E if survival otherwise seems unlikely.

Immunization

Although individuals who recover from hepatitis E mount an antibody response, including to putative capsid antigens, it is not clear whether these antibodies protect against subsequent infection or, if so, how long that immunity lasts. Adult populations in endemic areas are susceptible to hepatitis E, with high attack rates in epidemics. The degree and longevity of protective immunity of macaque monkeys following recovery from experimental infection or immunization with recombinant DNA or antigen preparations is controversial. Immunization with a bacterially-expressed fusion protein, derived from the capsid region of the Burmese strain, protected cynomolgus macaques from challenge with the homologous strain of virus. However, monkeys challenged with the Mexican strain excreted virus in their faeces, although there was no biochemical evidence (i.e. raised serum aminotransferases) of liver disease and in another study an immunogen derived from the capsid region of the Pakistan strain was found to protect against infection with the Mexican strain. Aside from the duration of a protective antibody response, other caveats are that animals are frequently challenged intravenously with HEV, rather than via the natural (oral) route, and that macaques do not suffer overt symptoms of hepatitis during infection; protection often is defined as the absence of elevated aminotransferases despite evidence of virus replication (excretion in the faeces). Nonetheless, a baculovirus-expressed HEV vaccine (spanning aa 112–607 of the ORF 2 protein of the Pakistan strain) is undergoing a phase II/III clinical trial in Nepal, and the initial data show that the immune response protects against infection (Shrestha *et al.*, 2007).

Sporadic Hepatitis E in Industrialized Countries Is Predominantly Zoonotic in Origin

The genomic sequences of HEV initially isolated from several Asian countries (Pakistan, China, India) were found to be similar to the Burmese prototype (now recognized as genotype 1) and less closely related to the strain isolated from Mexico (genotype 2). Genotype 1 viruses are associated with epidemic and sporadic hepatitis E throughout Asia and Africa, and genotype 2 viruses have been described in Nigeria. A third genotype of HEV was discovered in several herds of swine in the United States (Meng *et al.*, 1997) and has been implicated as the cause of rare cases of indigenous hepatitis E in individuals in North and South America, Europe and Japan. Genotype 4 HEV, which has been described in China (Wang *et al.*, 2000), Taiwan, Japan, Vietnam and India, seems to be the major cause of sporadic hepatitis E in some Asian countries and has also frequently been found infecting pigs. Thus, it seems that genotype 3 and 4 HEV are responsible for sporadic cases of hepatitis E in humans that arise from zoonotic infection, with farmed pigs as a major reservoir. In contrast, genotype 1 viruses, which have been implicated in all the major Asian epidemics of hepatitis E, including in the Xinjiang Uighur autonomous region of China in 1988–1990, have not been isolated from or transmitted to pigs. Such epidemics typically result from massive faecal contamination of the water supply and the source of such contamination remains to be elucidated. In the United Kingdom, the rare, sporadic cases of hepatitis E are typically genotype 1 infections of travellers returning from endemic areas or genotype 3 infections acquired locally (Ijaz *et al.*, 2005).

HEPATITIS B

Epidemiology

The discovery in 1965 of Australia antigen (now referred to as hepatitis B surface antigen, HBsAg) and the demonstration by Blumberg and his colleagues, and others, of its association with type B hepatitis (Blumberg *et al.*, 1965) led to rapid and unabated progress in the understanding of this complex infection. Hepatitis B remains a globally-important disease and over one third of the world's population has been infected with HBV. Low- (less than 2% of the population seropositive for HBsAg), intermediate- (2–8%) and high- (more than 8%) prevalence areas are recognized (Table 12.2). Several epidemiological studies indicate that the reported rates of hepatitis B infection have declined in western and northern Europe and the United States. Infection rates in children have declined in high-prevalence areas where universal immunization of infants has been introduced.

Table 12.2 Prevalence of hepatitis B

	Northern Europe	Eastern Europe	Parts of China
	Western Europe Central Europe North America Australia	Mediterranean USSR South-west Asia Central America South America	South East Asia Sub-Saharan Africa
HBsAg	0.2–0.5%	2–7%	8–20%
Anti-HBs	4–6%	20–55%	70–95%
Neonatal infection	Rare	Frequent	Very frequent
Childhood infection	Infrequent	Frequent	Very frequent

In the past, hepatitis B was diagnosed on the basis of infection occurring approximately 60–180 days after the injection of human blood or plasma fractions or the use of inadequately-sterilized syringes and needles. The development of specific laboratory tests for hepatitis B confirmed the importance of the parenteral routes of transmission, which may result from accidental inoculation of minute amounts of blood or fluid contaminated with blood during medical, surgical and dental procedures; immunization with inadequately-sterilized syringes and needles; intravenous and percutaneous drug abuse; tattooing; body piercing; acupuncture; laboratory accidents; and accidental inoculation with razors and similar objects that have been contaminated with blood. However, several factors have altered the epidemiological concept that hepatitis B is spread exclusively by blood and blood products. These include the observations that under certain circumstances the virus is infective by mouth, that it is endemic in closed institutions and institutions for the mentally handicapped, that it is more prevalent in adults in urban communities and in poor socio-economic conditions, that there is a reservoir of over 350 million carriers of HBV in the human population, and that the carrier rate and age distribution of the surface antigen vary in different regions. There is much evidence for the transmission of hepatitis B by intimate contact and by the sexual route. Those with a large number of sexual partners, particularly male homosexuals, are at very high risk. HBsAg has been found in blood and in various body fluids such as saliva, menstrual and vaginal discharges, seminal fluid, colostrum and breast milk, and serous exudates, and these have been implicated as vehicles of transmission of infection.

Perinatal Transmission

Viraemic mothers, especially those who are seropositive for hepatitis B e antigen (HBeAg), almost invariably transmit the infection to their infants. The mechanism of perinatal infection is uncertain, but it probably occurs during or shortly after birth as a result of a leak of maternal

blood into the baby's circulation, or of its ingestion or inadvertent inoculation. Such perinatal infections lead to a high rate of chronicity, estimated at around 90%, and individuals infected at such an early age exhibit a high degree of immune tolerance and may remain viraemic for decades. Perinatal transmission is an extremely important factor in maintaining the reservoir of the infection in high-prevalence regions. There is also a substantial risk of perinatal infection if the mother had acute hepatitis B in the second or third trimester of pregnancy or within two months of delivery. Although HBV can infect the fetus *in utero*, this appears to be rare and is generally associated with ante-partum haemorrhage and tears in the placenta.

However, mother-to-infant transmission does not account for at least 50% of infections in children, and horizontal transmission—that is, from child to child—is equally important. The prevalence in children is quite low at 1 year of age but increases rapidly thereafter, and in many endemic regions reaches a peak in children 7–14 years of age. Clustering of HBV also occurs within family groups, but does not appear to be related to genetic factors and does not reflect maternal or venereal transmission. The probability of a childhood infection becoming persistent declines with age, from around 90% in neonates to below 5% in adolescence.

Chronic Hepatitis B

Chronic hepatitis B is defined as persistence of HBsAg in the circulation for more than six months. The 'carrier state' may persist for life and may be associated with liver damage, varying from mild chronic hepatitis to severe, active hepatitis, cirrhosis and primary liver cancer. Several risk factors have been identified in relation to its development. It is more frequent in males, more likely to follow infections acquired in childhood than those acquired in adult life, and more likely to occur in patients with natural or acquired immune deficiencies. Chronic hepatitis B infection occurs in 90% of neonates or young infants, but in only 1–5% of immunocompetent adults. In countries

where hepatitis B infection is common, the highest prevalence of HBsAg is found in young children, with steadily declining rates among older age groups. HBeAg has been reported to be more common in young than in adult carriers of hepatitis B, whereas the prevalence of anti-HBe seems to increase with age.

Survival of HBV is ensured by the reservoir of carriers, estimated to number over 350 million worldwide. The prevalence of carriers, particularly among blood donors, in northern Europe, North America and Australia is 0.1% or less; in central and eastern Europe it is up to 5%; in southern Europe, the countries bordering the Mediterranean, and parts of Central and South America the frequency is even higher; and in some parts of Africa, Asia and the Pacific region as much as 20% of the apparently healthy population may be HBsAg positive (Table 12.2).

Biology

In addition to the human HBV, a number of similar viruses which infect mammals and birds (but are not infectious for humans) have been described and the virus family has been named *Hepadnaviridae* (hepatotropic DNA viruses). The viruses have a similar genetic organization and mode of replication and are characterized by a high degree of host specificity and tropism for the liver. Of the mammalian viruses, the woodchuck hepatitis virus (WHV) and Beechey ground squirrel hepatitis virus (GSHV) have been well characterized, the former being of interest as a model system for primary liver cancer because there is a high probability of progression to tumour for WHV-infected woodchucks. Of the avian viruses, the Pekin duck hepatitis B virus (DHBV) has been well characterized, and this animal model has been valuable in the elucidation of the *Hepadnavirus* replication process and for testing antiviral drugs.

Structure of Hepatitis B Virus

Electron microscopy of HBV-positive serum reveals three morphologically-distinct forms of particle (Figure 12.8). The small, 22 nm spherical particles and the tubular forms of roughly the same diameter are composed of the virus-surface protein embedded in lipid and are synthesized in vast excess over the 42 nm, double-shelled virions. The latter comprise a 27 nm, electron-dense core surrounded by HBsAg that is distinct from the 22 nm spheres in that pre-S1 epitopes are present (see below). The core or nucleocapsid consists of the genome surrounded by a second protein, HBcAg. HBeAg is found in soluble form in virus-positive sera and is related to the core antigen as described below. The genome is DNA (Figure 12.9) and comprised of two strands held in a circular configuration by base-pairing at the 5' ends (cohesive

Figure 12.8 Electron micrograph of serum containing HBV after negative staining. The three morphological forms of the antigen are shown: (1) small pleomorphic spherical particles 20–22 nm in diameter (hepatitis B surface antigen); (2) tubular structures (a form of the surface antigen); (3) the 42 nm double-shelled virions, with a core surrounded by the surface antigen ($\times 300\,000$). (Source: (Zuckerman, 1975).)

end regions). One of the strands is incomplete (usually 50–80% of full length) and is associated with a polymerase which is able to fill in the single-stranded region when provided with suitable substrates.

The genomes of a variety of isolates of HBV have been cloned, and the complete nucleotide sequences determined. There is some variation in sequence (up to 12% of nucleotides) between these isolates, and up to eight genotypes (A to H) have been described on the basis of >8% nucleotide sequence divergence, and recombinant forms have also been recognized. However, the genetic organization and other essential features are conserved. The genome is around 3200 bp in length and analysis of the protein-coding potential reveals four conserved ORFs, the products of which are described below. These four ORFs are located on the same DNA strand, and the strands of the genome have accordingly been called 'plus' (incomplete strand) and 'minus' (complete strand), as shown in Figure 12.9. Other features include a motif of 11 bp, which is directly repeated near to the 5' end of each strand of genomic DNA (DR1 and DR2) and plays an essential part in the replication strategy, two transcriptional enhancer

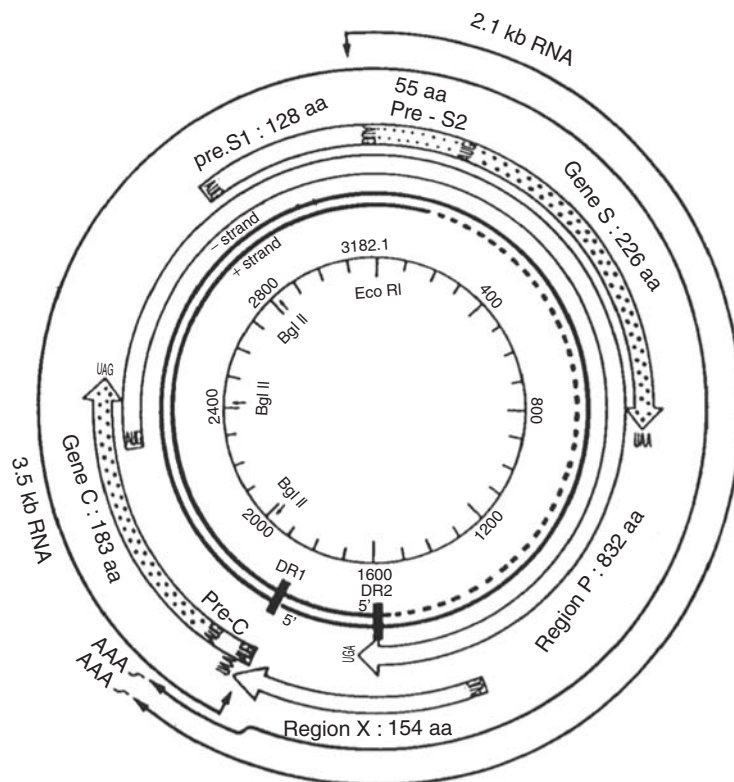

Figure 12.9 Structure and genetic organization of the HBV genome. The broad arrows surrounding the genome represent the four large ORFs of the L (–) strand transcript. The number of amino acids (aa) encoded is indicated in each case. The two thin arrows surrounding the broad arrows represent the two major HBV mRNAs. elements and binding sites for glucocorticoids and other cellular factors.

Hepatitis B Surface Antigen, HBsAg

The major (or small) surface protein is 226 amino acids long and found in nonglycosylated (p24) and glycosylated (gp27) forms. It is encoded in the 3' half of the surface ORF and translated from the third of three in-phase initiation codons. Larger, pre-S proteins are translated utilizing the two upstream initiation codons; translation from the second results in two intermediate-sized glycoproteins (gp33 and gp36) with a glycosylated 55 amino acid N-terminal extension, the pre-S2 domain. These middle surface proteins are minor components of virions and subviral particles. Translation of the entire ORF (pre-S1 + pre-S2 + S) gives rise to the large surface proteins (p39 and gp42) which are found predominantly in virions, but also in the 22 nm tubular forms. A domain within the pre-S1 region seems to be responsible for the attachment

of the virus to the (unidentified) receptor on the hepatocyte. Synthesis of the pre-S1 protein also may act as a signal for virion assembly in the infected cell.

The subviral particles and the virion surface are composed of HBsAg anchored in a lipid bilayer derived from the ER of the host cell. The major antigenic determinant on the particles is the common, group-specific antigen, *a*, which may form a 'double loop' structure (aa 124–137 and aa 139–147) on the surfaces of the virions and subviral particles. The formation of anti-*a* antibodies following vaccination seems to be sufficient to confer protective immunity. The major HBsAg protein also carries a pair of mutually-exclusive subdeterminants, *d* or *y* and *w* or *r*, which, in each case, correlate with variation at single amino acid positions (aa 122 and 160, respectively). Thus, four principal phenotypes of HBsAg are recognized—*adw*, *adr*, *ayw* and, more rarely, *ayr*—and these show differing geographical distributions. For example, in northern Europe, the Americas and Australia subtype *adw* predominates, whilst *ayr* occurs in a

broad zone that includes northern and western Africa, the eastern Mediterranean, eastern Europe, northern and central Asia and the Indian subcontinent. Both *adv* and *adr* are found in Malaysia, Thailand, Indonesia and Papua New Guinea, whereas subtype *adr* predominates in other parts of South East Asia, including China, Japan and the Pacific Islands. Historically, the subtypes provided useful epidemiological markers of HBV, but today phylogenetic analysis is rather more informative.

Unusual variants which lack the group-specific antigen *a* may be selected by antibody in immunized infants infected perinatally and in persistently-infected individuals following treatment with hepatitis B immune globulin or a natural antibody response. Surface variants of HBV were first described in Italy, infecting children and adults in the presence of specific hepatitis B surface antibodies (anti-HBs) several months after successful immunization with two generally-licensed hepatitis B vaccines given with and without hepatitis B immunoglobulin (HBIG). Epitope mapping of HBsAg in these patients revealed that monoclonal antibodies which normally bind to the *a* determinant failed to bind, and further work established that, in at least one case, the infection was caused by a variant with a mutation leading to a substitution of arginine for glycine at amino-acid position 145 in the immunodominant domain. This change, which seems to have been selected by antibody, has since been observed independently in the United States, Singapore, Japan and elsewhere. Other mutations that lead to altered HBsAg, which escapes neutralization by anti-HBs, have been described, but the arginine-for-glycine substitution at aa 145 seems to be the most common (reviewed by Harrison, 2006).

Hepatitis B Core Antigen and Other Viral Proteins

The core protein (p22) is the major component of the nucleocapsid and has, at its carboxyl terminus, an arginine-rich domain which presumably interacts with the viral nucleic acid. The importance of antibodies to this protein (anti-HBc) in diagnosis of infection is discussed below. The core protein is translated from the second initiation codon in the core ORF (Figure 12.9). Translation from the upstream initiation codon yields a precursor protein (p25), which is processed to yield HBeAg. The precore region, between the two initiation codons, encodes a signal sequence which directs p25 to the ER, where it is cleaved by a cellular signal peptidase. HBeAg is secreted following further proteolysis, which removes the carboxyl-terminal domain. HBeAg is also expressed on the surface of the infected hepatocyte and is a major target for the cellular immune system. HBeAg is not an essential protein of the virus but it may cross the placenta during pregnancy, inducing tolerance in

the fetus and increasing the probability that a perinatal infection will progress to chronicity. Variants of HBV with mutations in the precore region (precore mutants), and which are defective for the synthesis of HBeAg, are discussed below.

The P ORF, which overlaps the other three, encodes the viral polymerase. This enzyme has both DNA- and RNA-dependent activities and the predicted amino acid sequence has been shown to have homology with retroviral reverse transcriptases (RTs). The polymerase protein also acts as the primer for minus-strand DNA synthesis and has an 'RNase H' activity which degrades the RNA pregenome during minus-strand synthesis. The fourth ORF has been termed X because the function of its product originally was obscure. It is now known that this protein acts as a transcriptional transactivator and may enhance the expression of the other viral proteins. Experiments using the woodchuck model (see below) confirm that a functional X gene is required for the establishment of infection *in vivo*.

Replication of the Virus

The essential elements of the replication strategy of the *Hepadnavirus* genome were elucidated by Summers and Mason (1982) in an elegant series of experiments utilizing subviral cores isolated from DHBV-infected duck hepatocytes. The *Hepadnaviruses* are unique among animal DNA viruses in that they replicate through an RNA intermediate (Figure 12.10). On infection of the hepatocyte, the viral DNA is uncoated and converted to covalently-closed circular deoxyribonucleic acid (cccDNA) in the nucleus and forms a minichromosome that is the template for transcription of the viral RNAs. There are at least four viral promoters and all of the RNAs are 3'-co-terminal, being polyadenylated in response to a signal in the core ORF. The largest RNAs are greater than genome length (approximately 3500 nucleotides) and comprise the precore RNA, the messenger ribonucleic acids (mRNAs) for the synthesis of HBeAg, and the pregenomic RNA, which, in addition to being the mRNA for HBcAg and the viral polymerase, is also the template for reverse transcription. Binding of the polymerase to the packaging signal (ϵ) at the 5' end of the pregenome leads to packaging into immature viral cores in the cytoplasm (Figure 12.10, step 1). The amino terminal domain of the viral polymerase acts as the primer for minus-strand DNA synthesis and, following synthesis of a four-nucleotide nascent strand, translocates to a complementary four-base sequence (τ) near to the 3' end of the RNA template (Figure 12.10, steps 2a and 2b) This protein remains covalently attached to the 5' end of that strand in the mature virion. Minus-strand synthesis proceeds with

Figure 12.10 The replication strategy of the HBV genome: (1) priming of minus (-) strand synthesis by the terminal protein (cross-hatched) on the bulge of the ϵ signal near the 5' end of 3.5 kb pre-genomic RNA; (2a) translocation of the primer to a position (τ) near the 3' end of the RNA template; (2b) the template shown as a linear structure, solid boxes indicate the direct repeat (DR) sequences and R the redundancy of the RNA; (3) minus (-) strand DNA synthesis by reverse transcription with concomitant hydrolysis of the RNA template (RNase H-like activity); (4) and (5) translocation of the remaining 5' oligoribonucleotide from DR1 to DR2 and priming of plus (+) strand DNA synthesis; (6) circularization of the genome through the redundancy in the minus (-) strand and continuation of plus (+) strand synthesis.

reverse transcription of the pre-genome by the viral polymerase and with concomitant degradation of the template (RNase H-like activity; Figure 12.10, step 3). The remaining oligoribonucleotide (which was the 5' end of the pregenome) is at the position of the direct

repeat, DR1 (Figure 12.10, step 4), and is now believed to translocate to the other copy of the direct repeat, DR2, on the minus strand, and to prime synthesis of the plus strand (Figure 12.10, step 5). The minus strand has a short terminal redundancy (approximately eight

nucleotides) which permits the circularization of the genome as the plus strand is synthesized (Figure 12.10, step 6). Completion of the core presumably starves the polymerase of precursor nucleoside triphosphates, leaving the plus strand incomplete. The cores then bud through internal membranes embedded with HBsAg to form mature virus particles.

HBV Infection and Chronic Hepatitis B

Following infection, the first marker to appear in the circulation is HBsAg, which becomes detectable two to eight weeks prior to biochemical evidence of liver damage or the onset of jaundice (Figure 12.11). Next to appear are the markers of the virion, such as the virus-specific DNA polymerase activity and the viral DNA, along with the soluble antigen, HBeAg. Antibody to the core (anti-HBc) is detectable two to four weeks after the appearance of the surface antigen; this persists throughout the infection and

after recovery. In acute infections, clearance of the virus is marked by seroconversion, with the disappearance of HBeAg and the appearance of antibodies to it (anti-HBe). Later, during convalescence, HBsAg also disappears, with the production of anti-surface antibody (anti-HBs).

In 2–10% of infected adults, and a much larger percentage of children infected perinatally, the immune system fails to clear virus replication and the infection persists. Chronic hepatitis B may be divided into several phases (Figure 12.12). In the first, the immune-tolerance phase, high levels of virus replication occur and the patient is seropositive for markers of the virion and for HBeAg but lacks biochemical or histological evidence of hepatitis. During the immune-clearance phase, viraemia and HBeAg continue but with increasing inflammatory necrosis of hepatocytes, often leading to clearance of HBeAg and the development of anti-HBe. In the immune-control phase, the patient is anti-HBe-positive with low levels of HBV

Figure 12.11 Serological profile of acute, resolving hepatitis B.

Figure 12.12 Serological profile of chronic hepatitis B with seroconversion.

replication and little inflammatory activity. However, viraemia and hepatitis may return in the absence of HBeAg, reflecting the emergence of the HBe-negative virus (pre-core or core promoter mutants).

Thus, although HBeAg correlates with the presence of the virus, in some cases when virus replication declines to very low levels, or when precore or core promoter mutants are present, seroconversion to anti-HBe may occur without cessation of virus replication. Direct tests for the virus, for example detection of viral DNA by hybridization or PCR, are more reliable for establishing infectivity. During the first phase of chronicity, replicative forms of the HBV genome may be detected in the liver by southern hybridization of DNA extracted from biopsy material (Figure 12.13, lane A7). This replicative phase may persist for years, and even lifelong in individuals who were infected perinatally and whose immune systems are tolerant of the virus. More usually, levels of virus replication decline gradually until this is eliminated with seroconversion to anti-HBe. Rarely, there will also be seroconversion to anti-HBs, but in many cases HBsAg will persist in the absence of detectable levels of virus

replication. Examination of liver biopsies from patients in this later phase of chronicity often reveals that HBV DNA is now integrated chromosomally in the hepatocytes (Figure 12.13, lane B), and HBsAg seems to be produced following transcription of this integrated DNA. In fact, integration of virus DNA into the hepatocyte chromosomes seems to take place throughout the period of virus replication, and expansion of clones of such cells may be a stage in progression to neoplasia (see below). Integration of the viral genome is not required for replication and seems to be a 'dead-end' for the virus. Although replicative and integrated HBV DNA may sometimes be observed in an individual biopsy specimen (Figure 12.13, lane C) it is not clear that both may be present in an individual hepatocyte.

Occurrence of HBV in Extra-hepatic Tissues

As stated above, *Hepadnaviruses* are essentially hepatotropic and it is not clear that they can replicate in other tissues. Sensitive hybridization techniques have, however, enabled the detection of viral DNA at other sites, particularly in peripheral leucocytes, the bone marrow and

Figure 12.13 Analysis of the state of HBV DNA in the hepatocyte using the southern blot hybridization technique. Lane A1: integration of HBV DNA in the PLC/PRF/5 cell line. Lane A6: HBV DNA replicative intermediates in the liver biopsy from an HBeAg-positive patient. Lane B: integration of HBV DNA in an anti-HBe, HBsAg-positive patient without tumour. Lane C: biopsy from an HBeAg-positive patient with both replicative forms and integrated HBV DNA. Lane D: biopsies from an anti-HBe, HBsAg-positive patient with primary liver cancer; 1: biopsy from the nontumorous part of the liver; 2: biopsy from the tumour showing integration of HBV DNA at three sites. All DNA samples were digested with the restriction enzyme Hind III. The leftmost lane shows radioactively-labelled Hind III fragments of bacteriophage DNA as size markers—sizes are given in kilobase pairs alongside. (Source: Modified from (Harrison *et al.*, 1986).)

spleen. Viral DNA in white blood cells usually occurs as monomeric or multimeric episomes, or, rarely, it may be integrated, and there have been reports that replicative forms may also be found. These findings have implications for virus transmission and for the possible recurrence of hepatitis B in individuals who have cleared virus replication from the liver.

Diagnostic Assays

Hepatitis B is usually diagnosed following the detection of HBsAg in serum. Current immunoassays for HBsAg detect 100–200 pg HBsAg/ml of serum, corresponding to roughly 3×10^7 particles/ml. Most HBeAg-positive carriers have more than 10^5 genomes/ml of serum. Detection of HBsAg is the standard assay for infection and is used widely for screening, for example in transfusion centres.

As noted above, HBeAg is a marker of viraemia, but anti-HBe does not necessarily indicate clearance of virus replication. Immunity after infection with HBV is characterized by the presence of anti-HBs together with anti-HBc in serum. Immunity after vaccination is characterized by the presence of anti-HBs alone. Anti-HBc of the IgM class is a valuable marker of acute infection. A simplified guide to the interpretation of the test results is shown in Table 12.3.

Detection of viral DNA is the optimal method for establishing hepatitis B viraemia, and quantitative assays are valuable for monitoring virus loads during antiviral therapy. Tests based on hybridization of labelled probes or branched oligonucleotides are reliably quantitative but lack the sensitivity required to monitor the low virus levels achieved during successful therapy with nucleoside analogues. Currently, commercial assays based on real-time PCR combine the requisite sensitivity with a wide dynamic range and are valuable for monitoring the response to antiviral therapy.

Acute Hepatitis B

The diagnosis of acute hepatitis B generally rests upon the finding of HBsAg and IgM anti-HBc in the serum of a patient with clinical and serum biochemical evidence of acute hepatitis. HBsAg is the first marker to appear in serum, followed by HBV DNA, HBeAg and DNA polymerase, and anti-HBc. Levels of HBV DNA usually reach $10^5 - 10^8$ genome equivalents/ml with the onset of symptoms, after which the levels decrease. In contrast, in patients who develop chronic hepatitis B, levels of HBV DNA remain high. A positive IgM anti-HBc test typically distinguishes acute from chronic hepatitis B (but IgM anti-HBc can also be detected in patients with severe exacerbations of chronic hepatitis B). By the time the patient consults a physician, HBV DNA and HBeAg are often no longer detectable in serum. The loss of HBeAg is a sign that the patient will clear HBsAg. HBsAg may only be present transiently in serum; the only evidence of infection may therefore be the presence of IgM anti-HBc or subsequent development of anti-HBc and anti-HBs.

Serum ALT concentrations typically rise in acute hepatitis B. Serum bilirubin concentrations increase in proportion to the severity of hepatic damage. During this phase, IgM anti-HBc in serum correlates with active hepatitis in patients. Antibodies to pre-S components appear early in the disease and correlate with the disappearance of serological markers of HBV replication, suggesting a role in immunological clearance of HBV. Immune complexes may be responsible for some of the manifestations of the acute disease. A mild decrease in serum C3 and C4 concentrations occurs in acute hepatitis B and may reflect antigen–antibody complex formation. Autoantibodies, including abnormalities in rheumatoid factor and anti-nuclear and anti-smooth-muscle antibodies, are also detectable in acute hepatitis.

Table 12.3 Interpretation of results of serological tests for hepatitis B

HBsAg	HBeAg	Anti-HBe	Anti-IgM	HBc IgG	Anti-HBs	Interpretation

In fulminant hepatitis B (FHB), extremely rapid clearance of HBeAg and HBsAg may occur. FHB is a life-threatening form of acute hepatitis B that is complicated by encephalopathy and bleeding due to liver failure. HBsAg may be negative at the time of presentation, and the diagnosis rests on the detection of IgM anti-HBc. HBeAg-negative variants have frequently been implicated as a cause of FHB.

Chronic Hepatitis B

Many carriers are detected through routine screening for HBsAg or the presence of abnormal liver function tests. Older patients may present for the first time with complications of cirrhosis, or even hepatocellular carcinoma. Typically serum levels of aminotransferases are elevated in patients with HBeAg, HBV DNA-positive chronic hepatitis, but some patients may have normal values. Many patients go on to develop moderate-to-severe HBeAg-positive chronic hepatitis with raised serum ALT after several decades of infection, which can ultimately progress to cirrhosis. The levels of aminotransferases fluctuate with time.

As noted above, several phases of chronic hepatitis B are recognized: typically in the immunotolerant phase, serum HBsAg and HBeAg are detectable; serum HBV DNA levels are high (usually $>10^7$ copies/ml); serum aminotransferases are normal or minimally elevated. This phase is common in young who are infected in the neonatal period, and may last 10–30 years after perinatal HBV infection. The immunotolerant phase is frequently followed by an ‘immunoactive’ phase, when symptoms of hepatitis may be present and serum aminotransferase levels are elevated. Exacerbations in serum aminotransferases may be observed, accompanied by a decrease in serum HBV DNA levels and ultimately followed by HBeAg seroconversion (i.e. HBeAg becomes undetectable, and anti-HBe detectable, in serum). Seroconversion rates are higher in those with raised serum ALT, and in patients with genotype D and (in Asia) genotype B infection. Seroconversion may occur following a sudden, asymptomatic exacerbation in serum aminotransferases. Once HBeAg is cleared, the disease remits temporarily and serum aminotransferases become normal.

Chronic hepatitis also may be observed in HBeAg-negative patients in whom HBsAg and anti-HBe are present in serum and serum HBV DNA is detectable using non-PCR-based methods; serum aminotransferase levels are elevated and liver biopsy shows necro-inflammation. HBeAg is undetectable in these patients because of the predominance of mutant HBV genomes that cannot express HBeAg. Patients with HBeAg-negative (also called

precore mutant) chronic hepatitis tend to be older, male, and to present with severe necroinflammation and cirrhosis (Hadziyannis *et al.*, 1983). HBeAg-negative chronic hepatitis has a variable course, often with fluctuating serum aminotransferases and serum HBV DNA levels. HBeAg may also become detectable transiently in these patients during acute flares. It is now known that such patients are frequently infected with variants of HBV with mutations in the precore region which cannot synthesize HBeAg (reviewed by Harrison, 2006). Precore variants may be selected during the process of seroconversion to anti-HBe, when hepatocytes expressing HBeAg are targeted for lysis by cytotoxic T cells. Different patterns of anti-HBe-positive disease can be discerned, but typically patients tend to have recurrent flares. Precore mutants can be detected in patients with FHB but it is controversial whether infection with these variants *ab initio*, in the absence of wild-type virus, often leads to acute liver failure. Not all patients with FHB are infected with precore mutants, and other mutations, such as in the core promoter (Sterneck *et al.*, 1996), as well as host factors, may be important. HBVs with double mutations in the core promoter have been associated with primary liver cancer in some regions of the world (Fang *et al.*, 2002).

A spontaneous remission in disease activity may occur in approximately 10–15% of HBeAg-positive carriers each year, characterized by a marked reduction in the titre of HBV DNA in the serum, followed by loss of HBeAg and seroconversion to anti-HBe. The inactive carrier state is characterized by very low serum HBV DNA levels in serum ($<10^5$ copies/ml) and normal serum aminotransferases. Liver biopsies are not performed routinely in inactive HBsAg carriers and they usually show little or no necroinflammation and mild or no fibrosis (although inactive cirrhosis may be present if transition to an inactive carrier state has occurred after many years). The prognosis of these patients, if stable without pre-existing advanced disease, is benign. However, active viral replication may reappear in a proportion of patients, leading to raised ALT concentrations. Histologically, chronic hepatitis is always associated with viral replication. If low levels of replication persist, serum HBsAg may become undetectable in serum, and anti-HBs may become detectable. HBsAg may be lost in 1–2% of patients a year. However, a proportion of anti-HBe-positive individuals with low levels of HBV DNA may later develop higher levels of HBV replication and raised ALT and progress to HBeAg-negative chronic hepatitis. The clinical significance of different levels of HBV DNA is incompletely understood. There may be a threshold level of HBV DNA below which the disease is less likely to be progressive. The set point of this concentration is uncertain but a value of 10^5 copies/ml has

been proposed as a threshold to separate high from low levels of serum HBV DNA associated with less active disease.

HBV genotypes A to H have been reported to correlate with spontaneous and IFN-induced HBeAg seroconversion, activity of liver disease and progression to cirrhosis and HCC, but further study is required. In China and Japan, where genotypes B and C circulate, there is evidence for increased pathogenicity, and increased likelihood of development of HCC, of genotype C over B.

Liver-biopsy assessment by an experienced pathologist is considered to be an integral investigation by many hepatologists. The biopsy can be used to assess progression of disease and response to antiviral therapy. Normal concentrations of albumin, ALT and AST can be encountered in patients with established cirrhosis.

In HBeAg-positive patients, progression to cirrhosis occurs at an annual rate of 2–5.5%, with a cumulative five-year incidence of progression of 8–20%. Progression to cirrhosis is generally faster in HBeAg-negative patients, at an annual rate of 8–20%. Recurrent exacerbations and bridging fibrosis with severe necroinflammatory change characterize patients more likely to progress. Recent retrospective studies have examined survival in compensated cirrhosis due to hepatitis B. The reported yearly incidence of hepatic decompensation is about 3%, with a five-year cumulative incidence of 16%. In a European multicentre longitudinal study to assess the survival of 366 cases of HBsAg-positive compensated cirrhosis, death occurred in 23% of patients, mainly due to liver failure or hepatocellular carcinoma. The cumulative probability of survival in this cohort was 84 and 68% at 5 and 10 years, respectively. The worst survival was in HBeAg- and HBV DNA-positive subjects (Fattovich *et al.*, 1997). Chinese patients remaining HBeAg-positive were more likely to develop HCC.

Occult Hepatitis B

Occult hepatitis B (reviewed by Raimondo *et al.*, 2007) is defined as the presence of (usually low levels of) HBV DNA in serum in the absence of detectable HBsAg. Anti-HBc and/or anti-HBs may be present, but these are undetectable in a significant percentage of cases. Occult hepatitis B is of particular concern in individuals who are infected with HCV and in whom there is a high risk of development of advanced fibrosis and cirrhosis. The reported incidence in patients with hepatitis C varies from 0% in the United Kingdom to as high as 70–95% in Japan. There are several reports of HBV genomic sequences from such infections and a variety of mutations have been detected, including in the core promoter and surface ORF.

Pathogenesis of Hepatitis B Infection

HBV is not cytopathic and host immunity plays an important role in cellular injury; there is little correlation between the severity of the illness and the level of HBV replication. Patients with a poor T-cell response may have high concentrations of virus in liver, yet mild disease. The development of chronic infection is due to a failure of an adequate immune response, but the immune response is also responsible for disease pathogenesis during chronic infection. The subsequent expression of the disease involves a poorly-understood interplay between viral and host factors. The nucleocapsid antigens (HBcAg and HBeAg) expressed on the cell membrane contain important targets of the immune response and cytotoxic T cells in acute hepatitis B.

Studies using transgenic mice and of acute hepatitis B in chimpanzees suggest that antiviral mechanisms of clearance of HBV may involve both targeted lysis of infected hepatocytes and inhibition of viral replication by noncytolytic mechanisms (Canvaugh *et al.*, 1997; Guidotti and Chisari, 2001; Guilhot *et al.*, 1993). Inactivation of hepatitis B by CTL-elaborated cytokine expression conceivably occurs via elimination of HBV nucleocapsids and destabilization of HBV RNAs. Natural killer (NK) cells may also contribute to liver inflammation by TRAIL-mediated death of hepatocytes via a non-antigen-specific mechanism, which may be switched on by cytokines produced during active HBV infection (Dunn *et al.*, 2007).

Intense hepatocyte lysis occurs in acute hepatitis B, apparently as a result of a polyclonal, multispecific cytotoxic lymphocyte immune response. The specific epitopes recognized by B as well as T cells are currently being mapped. However, experimental studies in the transgenic mouse model suggest that HBV replication may also be reduced by a complex interplay of cytotoxic T-cell responses, apoptosis and down-regulation of hepatitis B gene expression by several inflammatory cytokines. An association of major histocompatibility complex (MHC) class II alleles (DRB*1302) with lack of persistent HBV infection has been reported (Thursz *et al.*, 1995).

The elimination of virus-infected hepatocytes is dependent on the recognition by cytotoxic T cells of viral determinants, in association with HLA proteins on the infected cells. Data derived from most experimental systems suggest that an acute, polyclonal and vigorous cytolytic T-cell response usually occurs in acute symptomatic icteric hepatitis B and that patients with acute self-limiting hepatitis B develop a polyclonal HLA class I-restricted, cytotoxic T-cell response against numerous epitopes in the HBV envelope, nucleocapsid and polymerase proteins. Several

HLA-A2-restricted cytotoxic T-cell epitopes have been defined.

Perinatal infection is almost always asymptomatic, and chronic infection ensues in 90% of cases. Rarely, infection acquired from an anti-HBe-positive mother may lead to severe hepatitis in the infant. The failure to eradicate HBV reflects an inadequate immune response to the virus, but the precise impairment of humoral and cellular immunity that determines the development and outcome of hepatitis B has not been characterized. Persistent infection is an unusual outcome in those patients with acute icteric hepatitis B and the mechanisms that lead to viral persistence are not well understood. In neonates, specific suppression of the cell-mediated immune response may favour infection, perhaps because intrauterine exposure to HBeAg (at a time when the immune system is ontogenically immature) induces tolerance to epitopes that are usually the target of the cytotoxic T-cell response. Clonal deletion of HBV-specific T cells may occur as a consequence of transplacental infection of the developing fetus or transplacental passage of viral antigens. In contrast to the vigorous polyclonal class I- and class II-restricted T-cell response that can be identified in patients with acute icteric hepatitis B, in chronic disease the response in peripheral blood is relatively weak and focused, and insufficient to clear replicating virus.

Other mechanisms may also operate to prevent clearance of HBV: mutations abrogating the recognition of the wild-type hepatitis, including the natural variants of the HBcAg 18–27 core epitope that interfere with the recognition of the wild-type epitope and act as T-cell receptor antagonists. There is some evidence of a failure of IFN production in patients with chronic hepatitis B.

Prevention and Control of Hepatitis B

Passive Immunization

HBIG is prepared from pools of plasma with high titres of hepatitis B surface antibody and may confer temporary passive immunity under certain defined conditions. The major indication for the administration of HBIG is a single acute exposure to HBV, such as occurs when blood containing HBsAg is inoculated, ingested or splashed on to mucous membranes and the conjunctiva. The optimal dose has not been established but doses in the range of 250–600 IU have been used effectively. HBIG should be administered as early as possible after exposure and preferably within 48 hours, usually 3 ml (containing 200 IU/ml anti-HBs) in adults. It should not be administered seven days or more after exposure. It is generally recommended that two doses of HBIG should be given 30 days apart.

Results following the use of HBIG for prophylaxis in babies at risk of infection with HBV are good if the immunoglobulin is given as soon as possible, and certainly within 12 hours of birth, and the chance of the baby developing persistent infection is reduced by about 70%. More recent studies using combined passive and active immunization indicate an efficacy approaching 90%. The dose of HBIG recommended in the newborn is 1–2 ml (200 IU/ml anti-HBs) combined with a full course of hepatitis B vaccine given at a contralateral site.

Other indications for administration of HBIG include sexual exposure to hepatitis B; prevention of reinfection with HBV after liver transplantation, with or without specific antiviral drugs; and nonresponse to hepatitis B vaccine following acute exposure to HBV (Zuckerman, 2007).

Active Immunization

The major response of recipients of hepatitis B vaccine is to the common *a* determinant, with consequent protection against all subtypes of the virus. First-generation vaccines were prepared from 22 nm HBsAg particles purified from plasma donations from asymptomatic (healthy) chronic carriers. These preparations are safe and immunogenic, but have been superseded in many countries by recombinant vaccines produced by the expression of HBsAg in yeast cells. The expression plasmid contains only the 3' portion of the HBV surface ORF, and only the major surface protein, without pre-S epitopes, is produced. Vaccines containing pre-S2 and pre-S1 as well as the major surface proteins expressed by recombinant DNA technology are available.

In many areas of the world with a high prevalence of HBsAg carriage, such as China and South East Asia, the predominant route of transmission is perinatal. Administration of a course of vaccine with the first dose immediately after birth is effective in preventing transmission from an HBeAg-positive mother in approximately 70% of cases, and this protective efficacy rate may be increased to more than 90% if the vaccine is accompanied by the simultaneous administration of HBIG.

Immunization against hepatitis B is now recognized as a high priority in preventive medicine in all countries, and strategies for immunization are being revised. Universal vaccination of infants and adolescents is recommended as a possible strategy to control the transmission of this infection. More than 160 countries now offer hepatitis B vaccine to all children, including the United States, Canada, Italy, France and most western European countries (Zuckerman *et al.*, 2007).

However, in a number of countries with a low prevalence of hepatitis B immunization is at present only

recommended to groups which are at an increased risk of acquiring this infection. These groups include individuals requiring repeated transfusions of blood or blood products, patients undergoing prolonged in-patient treatment, patients who require frequent tissue penetration or need repeated circulatory access, patients with natural or acquired immune deficiency and patients with malignant diseases. Viral hepatitis is an occupational hazard among health-care personnel, the staff of institutions for the mentally handicapped and in some semi-closed institutions. High rates of infection with hepatitis B occur in narcotic drug addicts and intravenous drug abusers, sexually-active male homosexuals and prostitutes. Individuals working in highly-endemic areas are, however, at an increased risk of infection and should be immunized.

Young infants, children and susceptible persons (including travellers) living in certain tropical and subtropical areas where present socio-economic conditions are poor and the prevalence of hepatitis B is high should also be immunized. It should be noted that in about 30% of patients with hepatitis B the mode of infection is not known, and this is a powerful argument for universal immunization (Zuckerman *et al.* 2007).

Site of Injection for Vaccination and Antibody Response

Hepatitis B vaccination should be given in the upper arm or the anterolateral aspect of the thigh and not in the buttock. Many studies have shown that the antibody response rate is significantly higher in centres using deltoid injection than centres using the buttock. On the basis of antibody tests after vaccination, the Advisory Committee on Immunization Practices of the Centers for Disease Control, United States, recommended that the arm be used as the site for hepatitis B vaccination in adults, as has the Department of Health in the United Kingdom.

Nonresponse to Current Hepatitis B Vaccines

Apart from the site of injection, there are several other factors which are associated with a poor or no antibody response to currently-licensed vaccines. Indeed, all studies of the antibody response to the plasma-derived and recombinant DNA vaccines containing the single antigen only have shown that between 5 and 10%, or more, of healthy immunocompetent subjects do not mount an anti-HBs antibody response to the HBsAg present in these preparations ('nonresponders') or respond poorly ('hyporesponders') (Zuckerman, 1996; Zuckerman *et al.*, 1997). Nonresponders remain susceptible to infection with HBV.

While several factors are known to adversely affect the antibody response to HBsAg, including the site and route of injection, gender, advancing age, body mass (overweight), immunosuppression and immunodeficiency, evidence is accumulating that there is, at least in part, an association between immunogenetics and specific low responsiveness in different populations. Considerable experimental evidence is available suggesting that the ability to produce antibody in response to specific protein antigens is controlled by dominant autosomal class II genes of the MHC in the murine model and in humans. Other mechanisms underlying nonresponsiveness to current hepatitis single-antigen vaccines remain largely unexplained.

The Kinetics of Anti-HBs Response to Immunization and Booster Doses

The titre of vaccine-induced anti-HBs declines, often rapidly, during the months and years following a complete course of primary immunization. The highest anti-HBs titres are generally observed 1 month after booster vaccination, followed by rapid decline during the next 12 months and thereafter. Mathematical models have been designed and an equation was derived consisting of several exponential terms with different half-life periods. It is considered by some researchers that the decline of anti-HBs concentration in an immunized subject can be predicted accurately by such antibody kinetics, with preliminary recommendations on whether or not booster vaccination is necessary (see review by Zuckerman, 1996).

If the minimum protection level is accepted at 10 IU/l, consideration should be given to the diversity of the individual immune response and the decrease in levels of anti-HBs, as well as to possible errors in quantitative anti-HBs determinations. It would then be reasonable to define a level of >10 IU/l and <100 IU/l as an indication for booster immunization. It has been demonstrated that a booster inoculation results in a rapid increase in anti-HBs titres within four days. However, it should be noted that even this time delay might permit infection of hepatocytes.

Several options are therefore under consideration for maintaining protective immunity against hepatitis B infection:

- Relying upon immunological memory to protect against clinical infection and its complications, a view which is supported by *in vitro* studies showing immunological memory for HBsAg in B cells derived from vaccinated subjects who have lost their anti-HBs, but not in B cells from nonresponders, and by post-vaccination surveys.

- Providing booster vaccination to all vaccinated subjects at regular intervals without determination of anti-HBs. This option is not supported by a number of investigators because nonresponders must be detected. While an anti-HBs titre of about 10 IU/l may be protective, this level is not protective from a laboratory point of view, since many serum samples may give nonspecific reactions at this antibody level.
- Testing anti-HBs levels one month after the first booster and administering the next booster before the minimum protective level is reached.

No empirical data are available for the anti-HBs titre required for protection against particular routes of infection or the size of the infectious inoculum. The minimum protective level has been set at 10 IU/l against an international standard. However, the international standard is a preparation of immunoglobulin from pooled plasma of individuals recovered from infection rather than from immunized subjects and the antibody avidity is likely to be different. Furthermore, studies carried out in the 1980s indicated asymptomatic infection after immunization in subjects and health-care workers who had antibody titres below 50 IU/l.

There are studies which show that hepatitis B vaccine provides a high degree of protection against clinical symptomatic disease in immunocompetent persons despite declining levels of anti-HBs. These studies encouraged the Immunization Practices Advisory Committee of the United States, the National Advisory Committee on Immunization of Canada and the European Consensus Group (2000) to recommend that routine booster immunization against hepatitis B is not required. Caution, however, dictates that those at high risk of exposure, such as cardiothoracic surgeons and gynaecologists, would be prudent to maintain a titre of 100 IU/l of anti-HBs by booster inoculations, more so in the absence of an appropriate international antibody reference preparation. Breakthrough infections have been reported and, whereas long-term follow-up of children and adults has indicated that protection is attained for at least nine years after immunization against chronic hepatitis B infection even though anti-HBs levels may have become low or declined below detectable levels (reviewed by the European Consensus Group, 2000), brief periods of viraemia may not have been detected because of infrequent testing. Longer follow-up studies of immunized subjects are required to guide policy. This is illustrated by a cross-sectional study carried out in Gambian children, which showed that the efficacy of hepatitis B vaccination against chronic carriage of HBV 14 years after immunization was 94% in all age groups, whilst the efficacy against infection was 80%, but was

lower (65%) in those aged 15–19 years (Whittle *et al.*, 2002).

Hepatitis B Surface Antigen Variants

Neutralizing antibodies induced by immunization are targeted principally to the conformational epitopes of the *a* determinant, and there is evidence that amino-acid substitutions within this region of the surface antigen can allow replication of HBV in vaccinated persons, since antibodies induced by current vaccine do not recognize critical changes in the surface antigen domain.

The emergence of variants of HBV, possibly due to selection pressure associated with extensive immunization in an endemic area, was suggested by the findings of hepatitis B infection in individuals immunized successfully (Zanetti *et al.*, 1988). These studies were extended subsequently by the finding of noncomplexed HBsAg and anti-HBs and other markers of hepatitis B infection in 32 of 44 vaccinated subjects, and sequence analysis from one of these cases revealed a mutation in the nucleotide encoding the *a* determinant, the consequence of which was a substitution from glycine to arginine at amino-acid position 145 (G145R).

Various mutations and variants of HBsAg have since been reported from many countries. However, the most frequent and stable mutation was reported in the G145R variant. A large study in Singapore of 345 infants born to carrier mothers with HBsAg and HBeAg, who received HBIG at birth and plasma-derived hepatitis B vaccine within 24 hours of birth and then one month and two months later, revealed 41 breakthrough infections with HBV despite the presence of anti-HBs. There was no evidence of infection among 670 immunized children born to carrier mothers with HBsAg and anti-HBe, nor in any of 107 immunized infants born to mothers without HBsAg. The most frequent variant was a virus with the G145R mutation in the *a* determinant. Another study in the United States of serum samples collected between 1981 and 1993 showed that 94 (8.6%) of 1092 infants born to carrier mothers became HBsAg positive despite post-exposure prophylaxis with HBIG and hepatitis B vaccine. Following amplification of HBV DNA, 22 children were found with mutations of the surface antigen, most being in amino acids 142–145; 5 had a mixture of wild-type HBV and variants and 17 had only the 145 variant.

Another important aspect of the identification of surface-antigen variants is the evidence that HBsAg mutants may not be detected by all of the blood-donor screening tests and existing diagnostic reagents. Such variants may therefore enter the blood supply or spread by other means. This is emphasized by the finding

in Singapore, between 1990 and 1992, that 0.8% of 2001 people were carriers of HBV variants in a random population survey (Oon *et al.*, 1996). These findings add to the concern expressed in a study of mathematical models of HBV vaccination, which predict, on the assumption of no cross-immunity against the variant by current vaccines, that the variant will not become dominant over the wild-type virus for at least 50 years—but that the G145R mutant may emerge as the common HBV in 100 (or more) years' time. It is important, therefore, to institute epidemiological monitoring of HBV surface mutants employing test reagents which have been validated for detection of the predominant mutations, and consideration should be given to incorporating into current hepatitis B vaccines antigenic components which will confer protection against infection by the predominant mutant(s).

The Pre-S1 and Pre-S2 Domains and Third-Generation Vaccines

There is evidence that the pre-S1 and pre-S2 domains of the surface antigen have an important immunogenic role in augmenting anti-HBs responses, preventing the attachment of the virus to hepatocytes and eliciting antibodies which are effective in viral clearance, stimulating cellular immune responses and circumventing genetic nonresponsiveness to the S antigen.

These observations led to the development of a new triple-antigen hepatitis B vaccine (Hepacare), a third-generation recombinant DNA vaccine containing pre-S1, pre-S2 and S antigenic components of HBsAg of subtypes *adw* and *ayw*. All three antigenic components are glycosylated, closely mimicking the surface protein of the virus itself, produced in a continuous mammalian cell line, the mouse c127 clonal cell line, after transfection of the cells with recombinant HBsAg DNA. The vaccine is presented as an aluminium hydroxide adjuvant preparation of purified antigenic protein. Animal studies showed that the vaccine was well tolerated and a viral challenge study in chimpanzees demonstrated protective efficacy. This vaccine was evaluated for reactogenicity and immunogenicity in a number of clinical trials (reviewed by Zuckerman and Zuckerman, 2002). The major conclusions from these studies were that the vaccine was safe and immunogenic and overcame the nonresponsiveness to the single S antigen vaccines used widely in some 70% of nonresponders, and that even a single dose of 20 mg of the triple antigen provided significant seroprotective levels of antibody.

However, the anticipated high costs of this triple-antigen vaccine will limit its use initially to the following groups:

- Vaccination of nonresponders to the current single-antigen vaccines, who are at risk of exposure to HBV infection
- Subjects with inadequate humoral immune response to single-antigen hepatitis B vaccines, for example those over the age of 40 years, males, the obese, smokers and other hyporesponders, and
- Persons who require protection rapidly, for example health-care employment involving potential exposure to parenteral procedures involving blood-to-blood contact (current schedules of immunization with single-antigen hepatitis B vaccines involve three doses at zero, one and six months).

Studies are required to determine the efficacy of the triple antigen in patients who are immunocompromised, and also to determine whether the inclusion of pre-S1 and pre-S2 antigenic components in this new vaccine will protect against the emergence of HBV surface-antigen mutants.

Combined Immunoprophylaxis

Whenever immediate protection is required, as, for example, for infants born to HBsAg-positive mothers (see above) or after accidental inoculation, active immunization with the vaccine should be combined with simultaneous administration of HBIG at a different site. It has been shown that passive immunization with up to 3 ml (200 IU/ml anti-HBs) of HBIG does not interfere with an active immune response. A single dose of HBIG (usually 3 ml for adults; 1–2 ml for the newborn) is sufficient for healthy individuals. If infection has already occurred at the time of the first immunization, virus multiplication is unlikely to be inhibited completely, but severe illness and, most importantly, the development of the carrier state of HBV may be prevented in many individuals, particularly in infants born to carrier mothers.

Indications for Immunization against Hepatitis B

The current indications for the use of hepatitis B vaccines in the United Kingdom are given below. Many countries, including the United States and Italy, introduced universal immunization for infants in 1992. The World Health Organization recommended a decade ago that universal immunization should be in place in areas with a prevalence of HBsAg greater than 8% by 1994 and in all countries by 1997, with integration of hepatitis B vaccine into the Expanded Programme of Immunization (EPI). These targets were not met and universal immunization of infants worldwide remains a goal.

In 1996 the Department of Health and other government offices in the United Kingdom recommended immunization for the following risk groups:

Babies born to mothers who are chronic carriers of HBV or to mothers who have had acute hepatitis B during pregnancy.

In addition, babies born to mothers who are HBeAg positive, who are HBsAg positive without e markers (or where HBeAg/anti-HBe status has not been determined) or who have had acute hepatitis B during pregnancy, as well as babies who are low birth weight (<1500 g). Premature babies should receive HBIG as well as active immunization. Currently, vaccine without HBIG is recommended for babies born to mothers who are HBsAg positive but known to be anti-HBe positive.

Parenteral drug misusers.

Close family contacts of a case or carrier.

Sexual contacts of patients with acute hepatitis B should also receive HBIG.

Families adopting children from countries with a high prevalence of hepatitis B.

Particularly some countries in eastern Europe, SE Asia and S America.

Haemophiliacs (and others receiving regular blood transfusions or blood products).

Including carers responsible for the administration of such products.

Patients with chronic renal failure.

Higher doses of vaccine may be required in those who are immunocompromised.

Health-care workers, including students and trainees.

Staff and students of residential accommodation for those with severe learning disabilities.

Other occupational risk groups.

Including certain members of the emergency and prison services.

Inmates of custodial institutions.

Those travelling to areas of high prevalence.

Despite the availability of a vaccine, infection persists worldwide. In populous regions where mass immunization has not started, there has not been a significant decline in HBsAg carrier rates, and therefore the carrier pool has increased with the increase in population. Nonetheless, notable successes through vaccination have emerged, in particular in Taiwan and Alaska. In Taiwan, the long-awaited impact of vaccination on the risk of hepatocellular carcinoma has been discernible (Chang *et al.*, 1997).

Antiviral Therapy for Hepatitis B

Most icteric patients with acute hepatitis B resolve their infection and do not require treatment. FHB is a severe form of acute infection complicated by encephalopathy

and liver failure. Subgroups of FHB, including hyperacute, acute and subacute, are defined by the interval between jaundice and encephalopathy. Subacute hepatic necrosis is characterized by a more protracted acute course and transition to chronic hepatitis with ongoing hepatitis B replication. Patients with fulminant hepatitis and liver failure (including acute and subacute forms) should be considered for liver transplantation, if appropriate. There are no controlled trials of lamivudine or other antiviral agents for patients with acute fulminant or subacute fulminant hepatitis. Historical reports suggest some efficacy of lamivudine in these patients, and carefully-administered antiviral therapy could be tried, if administered early, and if there is evidence of ongoing HBV replication.

Prolonged treatment for years is required for most patients. Several difficulties remain in formulating treatments for HBV infection and areas of disagreement exist. Current guidelines are not always consistent or agreed and will require rapid adjustment as new therapies become available. In general, treatment of chronic hepatitis B should be targeted at patients with active disease and viral replication, preferably at a stage before signs and symptoms of cirrhosis or significant injury have occurred (Dusheiko *et al.*, 1985). Eradication of the infection is possible only in a minority of patients and the optimal treatments for hepatitis B are still being defined. Recombinant IFN- α , pegylated IFN- α and a number of new nucleoside and nucleotides have been licensed. Thus the array of nucleosides may shortly include the licensed therapies (lamivudine, adefovir, entecavir, telbivudine), tenofovir, emtricitabine (licensed for human immunodeficiency virus (HIV)), as well as clevudine, elvucitabine, valtorcitabine, amdoxovir, racivir, MIV 210, β -L-FddC, alamivovir and hepavir B. The licensed agents have to date mostly been used as monotherapies. The efficacies of suitable combination therapies are currently being evaluated. Response rates in HBeAg-positive patients are higher for all currently-licensed agents for those patients with higher baseline ALT. Single measures of ALT (and HBV DNA) are not useful in a disease as dynamic as hepatitis B, and there is controversy regarding the level below which HBV DNA concentrations are indicative of 'inactive' disease, or indicate a threshold for initiating treatment.

HBeAg-positive Chronic Hepatitis B

Patients with mild disease and normal ALT may not require immediate treatment and should be monitored carefully at appropriate intervals. Most clinicians believe that therapy should be considered only if there is evidence of moderate-to-severe activity. HBeAg-positive patients should be followed for a few months to ascertain their status, and antiviral therapy should be considered if there is active HBV replication (HBV DNA above

1×10^5 copies/ml (20 000 IU/ml)) and elevated ALT after observation, with a biopsy showing active hepatitis, that is inflammation, necrosis or accumulating fibrosis. HBeAg-positive patients with greater disease activity may be more likely to seroconvert to anti-HBe within one year of treatment.

HBeAg-negative patients should be considered for antiviral therapy when the serum ALT is raised and there is active viral replication (HBV DNA above 1×10^4 – 1×10^5 copies/ml (2000–20 000 IU/ml)) and active hepatitis, that is inflammation, necrosis or accumulating fibrosis. The threshold for treatment remains debated. No definite consensus criteria have been established for initiating treatment in this group. Anti-HBe-positive patients with normal ALT and low levels of DNA ($< 10^4$ copies/ml, < 2000 IU/ml) should be monitored. Indeed, both HBeAg-positive and -negative patients require careful and regular monitoring to ascertain a change in the pattern of disease.

Many clinicians consider a liver biopsy helpful for ascertaining the degree of necroinflammation and fibrosis in HBeAg-positive and -negative disease. In many centres a biopsy would be considered to assess the stage and grade of inflammation, as hepatic morphology can assist the decision to treat. There are several established methods for scoring histology, measuring activity (necroinflammation) separately from stage (fibrosis). There are, however, several limitations of biopsy, including sampling error, subjectivity and reproducibility, and of course costs, risks and discomfort to the patient. Progression of disease is often punctuated by episodes of activity which are injurious to the liver. There is growing interest in the use of non-invasive methods, including serum markers and transient elastography to assess hepatic fibrosis.

Goals of Treatment

The major goals of therapy for hepatitis B are to prevent progression of the disease to cirrhosis, end-stage liver disease or HCC. If HBV replication can be suppressed, the accompanying reduction in histological chronic active hepatitis lessens the risk of cirrhosis and hepatocellular carcinoma. Patients may request treatment to reduce infectivity. Extra-hepatic manifestations of hepatitis B such as glomerulonephritis or polyarteritis nodosa require treatment. The immediate objectives depend upon the stage of disease, but cirrhosis can be prevented, or decompensation can be prevented in patients with established cirrhosis.

End Points

The end points of treatment are not clearly defined, and differ in HBeAg-positive and -negative disease. However,

it is reasonable to infer improvement in disease outcome if HBV replication is suppressed with an accompanying improvement in serum ALT and hepatic necroinflammatory disease. The accompanying reduction in histological chronic active hepatitis lessens the risk of cirrhosis and hepatocellular carcinoma (Niederau *et al.*, 1996). Newer potent agents are capable of suppressing most patients to less than 1×10^3 (200 IU/ml), or even to levels undetectable by current PCR assays; that is, < 200 copies/ml (50 IU/ml), which may become the important benchmark.

HBeAg-positive Disease

In our current state of knowledge, antiviral therapy for HBeAg-positive disease is directed to attaining loss of HBeAg and, ideally, durable seroconversion to anti-HBe. In HBeAg-positive disease, reduction in HBV replication leads to an accompanying reduction in ALT. A reduction of HBV DNA concentrations within six months to less than 10^4 copies/ml (2000 IU/ml), or preferably levels undetectable by sensitive PCR to levels of around 200 copies/ml (or 50 IU/ml) or lower, may enhance the rate of loss of HBeAg and reduce the rate of resistance. Loss of HBeAg and associated suppression of viral replication leads to biochemical remission, histological improvement and, in a small percentage, loss of HBsAg. Histological improvement follows suppression of necroinflammatory disease.

Loss of HBeAg and seroconversion to anti-HBe is a potential stopping point in HBeAg-positive patients, although treatment with nucleoside analogues should be prolonged for at least six months after loss of HBeAg. Unfortunately, a variable T-cell response and antiviral resistance suggest that finite courses with such circumscribed responses occur in only a minority of HBeAg-positive patients, and the majority still require long-term maintenance suppressive therapy. Categorical analysis has not clarified what relative or absolute reduction in ALT and DNA predicts histological improvement and HBeAg seroconversion and will alter the natural history of the disease, although there are some pointers. It is not clear whether profound reductions in DNA titre (for example 6–7 \log_{10}) are critical for long-term therapy. However, the rapidity and efficacy of HBV DNA reduction to less than 10^3 copies/ml or to undetectable by sensitive PCR (< 200 – 300 copies/ml) clearly has implications for development of resistance and loss of HBeAg.

HBeAg-negative Disease

Because such patients are already HBeAg-negative, reduction in ALT and HBV DNA, and the accompanying reduction in cccDNA and histological improvement, are the end points. Stopping points and finite courses of

treatment are less commonly achieved because of higher rates of relapse in these patients, but progression can be halted if HBV DNA remains suppressed and resistance or relapse does not occur. Successful treatment with nucleoside(s) or nucleotide is characterized by a decline in HBV DNA to less than 10^4 copies/ml (<2000 IU/ml) or preferably levels undetectable by sensitive PCR. Maintaining the response is the objective, defined by a low viral load during therapy. As for HBeAg-positive disease, a rapid lowering of viral load lessens the risk of developing viral drug resistance.

Treatment of Cirrhosis

Immediate, prolonged and profound suppression of viraemia confers benefit, reducing the risk of progression to decompensated liver disease and, possibly, HCC. Clinical studies indicate that prolonged and adequate suppression of viraemia may stabilize patients and delay or even obviate the need for transplantation. Recent longer-term studies have suggested the clinical utility of HBV DNA suppression with lamivudine; Kaplan–Meier estimates of disease progression after three-year treatment of patients with cirrhosis are reduced to 5% in treated versus 21% in placebo recipients. However, the development of lamivudine resistance significantly reduces the clinical benefit in treated patients. HCC remains a persistent risk, albeit a lessened one. Hepatic decompensation may occur, with exacerbations of disease occurring after instituting nucleoside analogues, and these patients should be monitored carefully.

Prophylactic therapy with a nucleoside is recommended for all patients undergoing liver transplantation for end-stage hepatitis B, to reduce levels of HBV DNA to at least less than 10^5 copies/ml before transplantation. End-stage liver disease should be treated as a matter of urgency. Patients may show slow clinical improvement over a period of three to six months. However, some patients with advanced hepatic disease with a high Child–Pugh score and jaundice will not benefit. All such patients require long-term therapy, with careful monitoring for resistance and flares. Regression of fibrosis has been reported. There is less data for the efficacy and safety of newer potent agents such as entecavir, telbivudine and tenofovir in this group, but these could be utilized.

Recurrent HBV infection in the transplanted liver has previously been a major problem. Lamivudine for pre-transplant prophylaxis, in combination with HBIG, reduces the risk of graft infection to less than 10%, as long as the HBV is suppressed before transplantation. With the advent of lamivudine and adefovir, outcomes have improved further. Currently both HBIG and lamivudine and/or adefovir are used prophylactically and recurrent HBV is now rare. Other licensed nucleosides

could also be considered; profound suppression and low rates of resistance are advantageous.

Specific Therapies

Alpha Interferons

IFN remains a benchmark therapy for chronic hepatitis B. IFN- α s are naturally-occurring intercellular signalling proteins used therapeutically for their properties of inducing an antiviral state in cells, inhibiting cellular proliferation and immunomodulation. The IFNs have been classified into two types, based on receptor specificity. Type 1 IFNs (viral IFNs) include IFN- α (leukocyte), IFN- β (fibroblast) and IFN omega. Type 2 IFN is also known as immune IFN, that is IFN- γ . The cellular activities of IFN- α are mediated by the products of the IFN inducible genes. The natural IFN- α -producing cell is the precursor dendritic cell. IFN- γ is produced by cells of the immune system, including NK cells, CD4 Th1 cells and CD8T cells following antigen-specific stimulation, and acts via a separate cell receptor. IFN- γ is critical for innate and adaptive immunity.

The main advantages of IFN- α over nucleoside analogues are the absence of resistance and the possibility of immune-mediated clearance of hepatitis B. A meta-analysis of 15 randomized controlled trials in HBeAg-positive patients showed a 33% HBeAg seroconversion rate after 16 weeks of IFN- α treatment, compared with 12% in untreated control patients. The incidences of HBsAg loss were 7.8% and 1.8% respectively. The recommended regimen for HBeAg-positive adult patients is 5 MU daily or 10 MU thrice weekly for four to six months (Lok and McMahon, 2004). Pre-treatment factors predictive of response to IFN- α are low viral load, high serum ALT levels, increased activity scores on liver biopsy and shorter duration of infection. The HBeAg seroconversion rate correlates with baseline ALT levels and reaches 30–40% for baseline ALT greater than five times the upper limit of normal (ULN). An increase of ALT levels during the second or third month of therapy can be observed.

Relative or absolute contraindications to IFN- α therapy include severe depression, Childs B/C cirrhosis, cirrhosis and hypersplenism, autoimmune hepatitis, hyperthyroidism, coronary artery disease, renal transplant, pregnancy, seizures, concomitant drugs including several herbal remedies, diabetes/hypertension and retinopathy, thrombocytopenia, leucopenia, anaemia, high titre autoantibodies and hyperthyroidism. The side effects of IFN- α are relatively common, but are acceptable in most patients. Toxicity can be predicted in patients with low baseline white cell counts or thrombocytopenia, or pre-existing

thyroid disease (Dusheiko, 1997). The risk of serious complications from IFN- α is rare. However, serious idiosyncratic complications such as immune disorders, pneumonitis, retinal disease, renal disease or deafness can occur and the drug must always be prescribed with caution. Close monitoring is required throughout therapy. Monitoring requires regular clinical examinations, vital signs, urinalysis and usually monthly measurement of serum chemistries, complete blood counts and thyroid function tests including thyroid-stimulating hormone. A serum pregnancy test should be done to exclude pregnancy before starting treatment.

Polyethylene Glycol-linked Interferons (PEG IFNs)

The efficacy of IFN- α therapy is restricted by protein characteristics including poor stability, a short half-life and immunogenicity. The half-life varies from 4 to 16 hours with peak concentrations 3–8 hours following IM or SC injection. By 24 hours, little IFN- α remains in the circulation. Thus frequent dosing is required to achieve effective therapeutic concentrations of drug in the plasma. Large fluctuations in serum concentrations occur, resulting in peaks and troughs in the drug concentration. Polyethylene glycol (PEG) is an inert nontoxic polymer which can be used to modify the pharmacological properties of biologically-active proteins without completely inactivating their intrinsic biological activity. Recent technology has enabled activation of the PEG moiety through substitution of the hydroxyl group by an electrophilic functional group. The reactive functional group of activated PEG can be attached to a specific site, for example amine, sulfhydryl group or other nucleophile on the protein. Until recently, monofunctional PEG derivatives used for protein pegylation were linear with molecular weights of 12 kDa. New advances in pegylation technology have resulted in the development of branched PEGs of high molecular weights up to 60 000 kDa. The PEG polymer increases the half-life of the conjugated protein, protecting the protein from proteolysis and reducing renal clearance. This enables once per week dosing.

Reduced clearance of pegylated interferon results in increased circulation time and sustained systemic exposure of the pegylated compound. When the biological activity of a pegylated protein is measured *in vivo*, a direct relationship between the mass of the PEG conjugate and its biological activity is frequently observed, with increasing mass associated with increased activity.

HBeAg-positive Patients A study in HBeAg-positive patients compared treatment for 48 weeks with polyethylene glycol-linked interferon (PEG IFN)- α 2a versus PEG IFN- α 2a plus lamivudine versus lamivudine monotherapy. At the end of 24 weeks follow-up, HBeAg seroconversion

rates were 32%, 27% and 19% respectively. ALT normalization occurred in 41%, 39% and 28% of the same groups. HBeAg levels higher than 100 IU/ml at weeks 12 and 24 was highly predictive of failure to achieve seroconversion. Conversely, low HBeAg levels at baseline, week 12 and week 24 correlated with improved rates of seroconversion.

PEG IFN- α 2b has also been shown to be active in HBeAg-positive patients, with similar seroconversion rates. There may be an effect of genotype and other baseline factors on response to PEG IFN- α 2a in HBeAg-positive chronic hepatitis B: patients with genotype A and B tend to respond better than patients with genotype C and D.

HBeAg-negative Patients In a similar study of HBeAg-negative patients, at the end of 48 weeks follow-up HBV DNA less than 400 copies/ml was maintained in 17% of an observational subset of PEG IFN- α 2a-treated patients followed for three years post-treatment. Baseline ALT and HBV DNA levels, patient age, gender and infecting HBV genotype significantly influenced response at 24 weeks post-treatment (Bonino *et al.*, 2007). HBsAg loss occurred in 8% after three years.

Frequent side effects and the necessity for monitoring patients closely are the main disadvantage of PEG IFN treatment. There is no role for IFN- α in the treatment of acute or fulminant hepatitis B. The role of IFN in patients with decompensated hepatitis B is more problematic, given the effect on platelets and neutrophils, and the pro-inflammatory effects. IFN should be used with caution and regular monitoring in patients with compensated cirrhosis, since there is a risk of hepatic decompensation with prolonged treatment (Keeffe *et al.*, 2004). Moreover, serious bacterial infections have been reported in this group of patients.

Nucleoside Analogues

The patterns of response observed with nucleosides are broadly similar, although these agents have different structures and inhibit different phases of hepatitis B replication. Nucleosides and nucleotides have variable mechanisms of action and their pharmacokinetics, inhibitory capacity, onset of action, resistance patterns and rates of HBeAg seroconversion vary during the first year of treatment. Nucleoside analogues have similar structures to the natural nucleotides and compete at the HBV polymerase catalytic site during the synthesis of viral DNA. They lack a hydroxyl group, preventing the formation of a covalent bond with the adjoining nucleotide, causing chain termination during DNA synthesis. Although all nucleotide analogues act on HBV polymerase, their mechanism differs; thus adefovir inhibits the priming of

reverse transcription, lamivudine and emtricitabine inhibit the synthesis of the viral minus-strand DNA, entecavir inhibits three major stages of HBV replication, and clevudine inhibits the elongation of the plus-strand DNA and has a weaker effect on priming, and may have additional effects of cccDNA. Nucleic acids in general are less effective against cccDNA formation after viral entry to the hepatocyte, and thus residual viraemia persists during antiviral treatment.

Lamivudine

Lamivudine (2',3'-dideoxy-3'thiacytidine or 3TC) is a cytidine analogue and competes for cytosine in the synthesis of viral DNA. It is a (–) enantiomer and a phosphorylation step is required for the transformation to active drug. The drug has a strong track and safety record, and reliably reduces HBV DNA concentrations in serum by 2–4 log₁₀. Elevated serum ALT levels predict a higher likelihood of HBeAg loss in patients with chronic hepatitis B treated with lamivudine. Lamivudine is a relatively inexpensive drug, and the lack of side effects in patients with advanced disease is attractive. As a result lamivudine has become a widely used first-line drug for the treatment of HBeAg and anti-HBe-positive disease. The major disadvantage of lamivudine treatment is the high rate of resistance observed in both HBeAg and anti-HBe-positive patients. Elimination of lamivudine occurs mainly by renal elimination and dosages should be adapted to creatinine clearance.

Lamivudine in Acute Hepatitis B Although 95% of immune-competent adults clear HBsAg spontaneously, lamivudine may have a role in acute HBV infection, preventing progression to fulminant hepatic failure in small uncontrolled studies of patients.

Lamivudine in Chronic Hepatitis B Much information has been gleaned from the early controlled trials of lamivudine and by the use of lamivudine as the control arm in trials of newer agents. Longer-term studies have also been informative.

In HBeAg-positive patients reductions in HBV DNA concentration, HBeAg seroconversion, ALT normalization and histological improvement observed after one year of treatment reach 44%, 17%, 41% and 52% respectively. Pre-treatment factors predictive of response are high baseline serum ALT levels and high degree of histological necroinflammation. Several factors, including genotype and the presence of cirrhosis, may predict the durability of response to lamivudine; higher rates of resistance have been reported in serotype *adw* (genotype A) than *ayw* (genotype D) (54% vs. 8%, Zollner *et al.*, 2004). Early viral suppression, in particular HBV DNA levels either

below 200 copies/ml or less than 3 log₁₀ after six months of treatment predict a lower risk of resistance after one year of treatment (Lai *et al.*, 2005b; Yuen *et al.*, 2001).

In HBeAg-negative patients after one year of treatment with lamivudine, HBV DNA became 'undetectable' with a nonstandardized assay in 70% of patients, serum ALT normalized in 75% and histological improvement was noticed in 60% (Tassopoulos *et al.*, 1999). However, the overwhelming majority of patients relapsed after treatment cessation.

Long-term lamivudine therapy can prevent complications of HBV-related liver disease as long as viral suppression is maintained. There has been wide experience of lamivudine to prevent chemotherapy-associated exacerbations of hepatitis B. The argument for 'deferred' or 'pre-emptive therapy' is probably weighted in favour of early treatment and prolonged therapy.

Resistance to Lamivudine Lamivudine resistance is conferred through acquired selection of HBV with mutations of the HBV DNA polymerase gene. Variants emerging during lamivudine therapy display mutations in the viral polymerase, within the catalytic domain (C domain)—which includes the YMDD motif (e.g. M204V or M204I)—and within the B domain (e.g. L180M or V173L). These mutants have a reduced replicative capacity compared to the wild-type virus. Four major patterns have been observed: L180M + M204V; M204I; L180M + M204I; V173L + L180M + M204V; and occasionally L180M + M204V/I. The L180M + M204V pattern occurs most frequently. The incidence of lamivudine resistance is 15–20%/year, with 70% of patients becoming resistant after five years of treatment. In patients treated with lamivudine monotherapy and decompensated cirrhosis, early detection of viral breakthrough is critical. A 1 log₁₀ rise of previously undetectable HBV DNA levels is taken as indicative of phenotypic resistance; adding adefovir before waiting for an ALT rise would be helpful for those patients (see below). The value of lamivudine monotherapy is being questioned because of the likelihood of subsequent resistance to a lineage of drugs including entecavir, telbivudine and possibly adefovir. Lamivudine could form (as will other nucleosides with even lower rates of resistance) the backbone of maintenance combination therapies. Lamivudine resistance has typically been managed by sequential treatment with adefovir (or more recently entecavir).

Adefovir Dipivoxil

Adefovir dipivoxil is an orally-bioavailable prodrug of adefovir, a phosphonate-acyclic nucleotide analogue of adenosine monophosphate. Adefovir diphosphate acts by selectively inhibiting the RT-DNA polymerase of HBV

by direct binding in competition with the endogenous substrate deoxyadenosine triphosphate (dATP). Adefovir is monophosphorylated and is not dependent on initial phosphorylation by viral nucleoside kinases to exert its antiviral effect. Clearance of adefovir is by renal excretion. Nephrotoxicity is the major side effect of higher doses of adefovir. However, in the two largest hepatitis B phase III trials involving 695 patients, no renal toxicity was found at the 10 mg dose.

Adefovir in HBeAg-positive Disease Adefovir 10 mg daily resulted in significant improvement when compared with placebo: improvement in liver histology (53% vs. 25%), reductions in HBV DNA (3.52 vs. 0.55 log₁₀ copies/ml), normalization of ALT (48% vs. 16%) and HBeAg seroconversion (12% vs. 6%). The 10 mg dose was chosen because of the more favourable risk–benefit ratio, but this dose is not optimal for a proportion of patients. A variable proportion of patients, particularly HBeAg-positive patients with higher body mass index and high viral load, have slower and poor primary responses.

Adefovir in HBeAg-negative Chronic Hepatitis B

These patients require long-term treatment to suppress viraemia. In the pivotal anti-HBe-positive adefovir study (Hadziyannis *et al.*, 2003), 185 patients were randomized to placebo or adefovir 10 mg daily for 48 weeks. At 48 weeks the adefovir-treated group had significant improvement compared to placebo: improvement in liver histology (64% vs. 33%), reduction in HBV DNA (3.91 vs. 1.35 log₁₀ copies/ml), an undetectable HBV DNA (< 400 copies/ml, 51% vs. 0%) and normalization of ALT (72% vs. 29%). Adefovir may have particular benefit in HBeAg-negative HBV infection. Longer-term results indicate that continued therapy with adefovir resulted in suppression of HBV DNA to levels of < 1000 copies/ml in 79% of patients after 144 weeks of treatment. Resistance mutations were noted in 5.9% of patients after 144 weeks.

Adefovir-resistant Mutations Development of resistant mutations has been reported with adefovir monotherapy in both HBeAg-positive and HBeAg-negative patients. Sequencing of the RT domain of the HBV polymerase suggests that mutations rtA181V/T (the B domain) and rtN236T in the D domain confer resistance to adefovir. The reported mutations correlate with HBV DNA rebounds of >1 log above nadir, suggesting phenotypic resistance.

Life table analysis has suggested a cumulative incidence of 3.9%–5.9% (in naïve patients) after three years of treatment. A figure of 18% has been reported at four years of therapy. Adefovir resistance is apparently uncommon in treatment-naïve patients treated with adefovir and

emtricitabine (2′3′-dideoxy-5′-fluoro-3′thiacytidine (FTC)) or adefovir and lamivudine in combination.

Adefovir mutants remain sensitive to lamivudine, emtricitabine, telbivudine and entecavir. Adefovir is an important drug for the treatment of lamivudine-resistant HBV infection. The early addition of adefovir at the time of detection of a log rise in HBV DNA is advocated. Resistance and clinical events are reduced if adefovir is added at lower concentrations of HBV DNA.

Entecavir

Entecavir is a cyclopentyl guanosine analogue. Recently activity against HIV has been suggested. Entecavir inhibits base priming, reverse transcription of the negative strand from the pregenomic messenger RNA and synthesis of the positive strand of HBV DNA. Phase III trials have been completed.

HBeAg-positive Patients A randomized study of entecavir 0.5 mg daily vs. lamivudine 100 mg daily for 52 weeks in 715 naïve patients showed histological improvement in 72% of entecavir- and 62% of lamivudine-treated patients. HBV DNA was suppressed to <300 copies/ml in 67% and 36% of entecavir- and lamivudine-treated patients (Chang *et al.*, 2006). The mean changes from baseline were −6.9 log and −5.4 log, respectively. HBeAg seroconversion occurred in 21% and 18% of entecavir- and lamivudine-treated patients.

HBeAg-negative Patients A phase III trial of 638 patients treated with entecavir 0.5 mg daily or lamivudine 100 mg for 52 weeks showed histological improvement in 7% and 61% of entecavir- and lamivudine-treated patients. HBV DNA suppression to less than 300 copies/ml occurred on treatment in 90% of entecavir- and 72% of lamivudine-treated patients. The mean changes of HBV DNA from baseline were −5.0 log₁₀ and −4.5 log₁₀, and ALT normalized in 78% and 71%, respectively. Rebound to levels detectable by PCR occurred in the majority of patients after cessation of treatment (Lai *et al.*, 2006).

Entecavir for Lamivudine-resistant Patients Entecavir shows some efficacy against lamivudine-resistant HBV, but the effect is partial, and higher doses of entecavir (1.0 mg) are required.

Entecavir Resistance After four years of follow-up, a cumulative resistance rate of approximately 1.2% of a subset of naïve treated and monitored patients has been reported. Virological responders however have not been evaluated in this protocol analysis. Virological rebound and resistance has been reported in 43% of

lamivudine-resistant patients after four years of switching treatment to entecavir. A complex picture of entecavir resistance is emerging, suggesting a requirement for new changes in the *rt* domain, in combination with those conferring lamivudine resistance, to reduce susceptibility to entecavir. Entecavir resistance requires M204V/I + L180M mutations + T184, S202 or M250 mutations (Tenney *et al.*, 2004).

Although entecavir is superior to lamivudine in terms of viral suppression, HBeAg seroconversion rates are not different between the two analogues at one year (21% and 18% respectively), although these could change with time (but not at a linear rate, apparently) given the lower rates of resistance to entecavir. Carcinogenicity after exposure to levels more than 35-fold greater than the dose administered in humans has been reported in rodents. These lesions include lung adenomas and carcinomas, and liver adenomas and carcinomas. The cumulative human risk will require post-marketing surveillance.

Telbivudine

Telbivudine is a thymidine analogue and belongs to a new class of β -L-configuration nucleoside analogues with specific activity against *Hepadnaviruses*. Preliminary studies have shown a pronounced inhibition of HBV replication with a safe profile and no effect on mitochondrial metabolism. Pharmacokinetic studies indicate once-daily dosing. Telbivudine is cleared by the kidneys, and dosing adjustments are recommended for patients with estimated creatinine clearance <50 ml/minute.

HBeAg-positive Patients A greater therapeutic response with telbivudine at week 104 has been noted in HBeAg-positive patients (64% of those receiving telbivudine vs. 48% of those on lamivudine). The mean decline was $-5.7\log_{10}$ vs. $-4.4\log_{10}$ in recipients of telbivudine versus lamivudine. In particular, HBV DNA was not detectable by PCR in 56% of the HBeAg-positive patients receiving telbivudine versus 39% of those on lamivudine. HBeAg seroconversion occurred in 30% at year 2, and 70% had normal ALT.

Histological responses, ALT normalization and HBeAg loss were greatest for patients whose week 24 HBV DNA was below $3\log_{10}$ (46% in the combined lamivudine/telbivudine groups) compared to those whose level of HBV DNA was $>4\log_{10}$ (45% of HBeAg-positive patients and 80% of the HBeAg-negative patients treated with telbivudine had undetectable HBV DNA by 24 weeks of treatment). Limited follow-up information suggests that patients may discontinue treatment after HBeAg seroconversion; responses are durable in approximately 80% (Lai *et al.*, 2006). Other studies have been completed (Chan *et al.*, 2006).

Anti-HBe-negative Patients The mean \log_{10} decline was -5.0 and -4.2 in telbivudine and lamivudine recipients, respectively. At two years, HBV DNA was undetectable by PCR in 82% of HBeAg-negative patients versus 52% of lamivudine recipients. 78% had normal ALT.

Viral resistance (defined as resistance mutations documented in HBV DNA amplified from serum from patients with viral breakthrough) was found in 17.8% and 7.3% of the HBeAg-positive and -negative patients after two years. Telbivudine-associated resistant mutations were all M204I or M204I + L180I/V. Lamivudine-associated resistant mutations were a mixture of M204V, M204I and + L180M double mutants. The explanation for this lies in the pathways of selection for YMDD-mediated HBV resistance and the fact that telbivudine is active against M204V, whereas lamivudine has reduced activity against both M204V and M204I mutants. Response at week 24 also predicted resistance. Resistance at two years was observed in 4% of HBeAg-positive patients and 2% of HBeAg-negative patients who had undetectable HBV DNA at 24 weeks, but the rates of resistance increased substantially in patients with higher levels of viraemia at this time point.

Tenofovir

Tenofovir is related to adefovir and has a similar mechanism of action. Tenofovir disoproxil fumarate is the prodrug of tenofovir. Tenofovir diphosphate inhibits the activity of RT by competing with the natural substrate deoxyadenosine 5' triphosphate, and after incorporation into DNA by DNA chain termination. The drug is approved at a dose of 300 mg for the treatment of HIV. There is emerging clinical evidence of the efficacy of tenofovir in chronic hepatitis B, with less nephrotoxicity. The drug is active against wild-type and precore mutant hepatitis B, as well as lamivudine-resistant HBV *in vitro* (Benhamou *et al.*, 2003; Bruno *et al.*, 2003; Dore *et al.*, 2004; Lacombe *et al.*, 2005; Nelson *et al.*, 2003; Van Bommel *et al.*, 2006). It is possible that the greater efficacy of tenofovir is a result of the higher active dose. A large-scale randomized phase III controlled trial comparing the efficacy of adefovir and tenofovir disoproxil in HBeAg-positive and -negative patients is underway.

Small sub-studies in HBV mono-infected and HIV-HBV co-infected patients have demonstrated the activity of tenofovir against HBV. In the ACTG 5127 study, 51 HIV-HBV co-infected patients with lamivudine resistance were randomized to tenofovir versus adefovir. Tenofovir-treated patients showed a greater time-weighted average DNA change and log suppression of HBV with tenofovir 300 mg (4.0 log vs. -3.1 log with adefovir 10 mg). Recent trials show a favourable effect of tenofovir

(72–130 weeks) and adefovir (60–80 weeks) in patients with lamivudine-resistant HBV infection and high baseline HBV DNA ($>10^6$ copies/ml) (Benhamou *et al.*, 2006; Van Bommel *et al.*, 2004). Patients treated with tenofovir (300 mg/day) had a faster and greater suppression of HBV DNA than those treated with adefovir (10 mg/day). The absence of phenotypic HBV resistance to tenofovir suggests a favourable resistance profile.

Although tenofovir has not yet been licensed for HBV treatment, it may become an important treatment of highly-replicative HBV infection and HIV–HBV co-infection. Phase III results are awaited. The pharmacokinetics of tenofovir are altered in patients with renal impairment, and it is recommended that the dosing intervals of tenofovir be adjusted for creatinine clearance. Lactic acidosis, hepatomegaly, steatosis and renal impairment have rarely been reported in patients with HIV infection treated with antiretrovirals and tenofovir. Exacerbations of hepatitis B may occur. Decreases in bone mineral density have rarely been reported in HIV-positive patients.

Emtricitabine

Emtricitabine (FTC) is a 5-fluoro oxathiolane derivative, closely related to lamivudine. Like lamivudine, emtricitabine is a cytosine nucleoside analogue. Early studies indicate that it is effective in both HBeAg-positive and HBeAg-negative patients (Gish *et al.*, 2005; Korba *et al.*, 2000). Emtricitabine shows a dose-related efficacy with an average 3 \log_{10} decrease of HBV DNA levels after eight weeks of treatment on the highest doses. In a randomized study of 48 weeks assessing treatment with 25, 100 or 200 mg for the first year and 200 mg for the second year, the median decreases in viral load were 2.6 \log_{10} , 3.1 \log_{10} and 2.9 \log_{10} respectively. HBeAg seroconversion rates were 23%, 24% and 23% respectively.

A major double-blind study has been completed. Patients were treated with 200 mg of emtricitabine or placebo once daily for 48 weeks. At the end of treatment, 62% of 167 patients receiving emtricitabine had improved hepatic histological findings versus 25% of 81 receiving placebo. HBV DNA concentrations were less than 400 copies/ml in 54% of patients in the emtricitabine group versus 2% in the placebo group. At week 48, 13% patients in the emtricitabine group with HBV DNA measured at the end of treatment had detectable virus with resistance mutations. The rate of seroconversion to anti-HBe (12%) and the HBe antigen loss were not different between arms (Lim *et al.*, 2006).

Due to its resemblance to lamivudine, emtricitabine selects the same HBV polymerase mutations associated with resistance. These rates of resistance are relatively high and limit its role as a monotherapy regimen. Like

lamivudine, emtricitabine may form a backbone of combination therapy.

Clevudine

Clevudine (L-FMAU or 2'-fluoro-5-methyl- β -L-arabino-furanosyluracil) is a novel L-nucleoside analogue derived from deoxythymidine (Chong and Chu, 2002; Marcellin *et al.*, 2004). Clevudine has potent anti-HBV activity. The mechanism of action is mainly inhibition of viral plus-strand DNA synthesis. A marked decrease of 9 \log_{10} in the viral load was observed in the woodchuck model. In the same model, clevudine combined with emtricitabine resulted in a sharp decrease in viraemia levels that was more pronounced than with the single drugs alone (Jacquard *et al.*, 2004). A unique characteristic of clevudine is the slow rebound of viraemia after cessation of treatment, which was observed also in patients; in an early phase II trial, the median decrease of HBV DNA levels varied from 2.48 to 2.95 \log_{10} with three different doses after 28 days of treatment. At the end of the 20 week follow-up period, a slow increase of HBV DNA levels was noticed. The drug does not accumulate.

In a further study, HBeAg-positive patients were randomized to placebo 30 mg or 50 mg clevudine (Lee *et al.*, 2006). Patients were followed up after 12 weeks of treatment for a further 24 weeks off-therapy. Median serum HBV DNA reductions from baseline at week 12 were 0.20, 4.49 and 4.45 \log_{10} copies/ml in the placebo, 30 mg clevudine and 50 mg clevudine groups, respectively.

Phase III placebo-controlled trials of 24 weeks duration have been completed. HBV DNA levels were significantly lower at the end of treatment ($-4.2\log_{10}$) and at 24 weeks follow-up for patients receiving clevudine. HBV DNA was undetectable at the end of treatment in 59% of patients receiving clevudine.

In vitro studies suggest that there may be cross-resistance with lamivudine-resistant HBV mutants. In animal studies resistance occurred in the B domain of the polymerase gene within 12 months of treatment.

Other New Agents

LB80380 is an oral nucleotide prodrug which is chemically similar to adefovir dipivoxil and tenofovir disoproxil fumarate. LB80380 is rapidly converted to the parent drug LB80331 in the liver and intestine. LB80331 is further metabolized to LB80317, a nucleotide analogue of guanosine monophosphate. After phosphorylation to the di- and triphosphate forms, the molecule inhibits viral replication following incorporation into viral DNA. The antiviral efficacy of a four-week course of LB80380 has been reported. The mean maximal HBV DNA changes during the four-week treatment period were

–3.02 to –3.80log₁₀ copies/ml for doses ranging from 30 to 240 mg daily. LB80380 has also been shown to be effective against YMDD mutants, including rtM204I and rtM204V in both *in vitro* and *in vivo* study. Further trials of LB80380 are being conducted for efficacy in patients with lamivudine-resistant HBV (Lai *et al.*, 2005a). Val LdC and LdA are also small molecule inhibitors of the hepatitis B DNA polymerase. These agents induce marked viral-load reduction in the woodchuck infected with woodchuck hepatitis B.

Pradefovir mesylate, a PMEA prodrug that was formerly known as remofovir, is preferentially metabolized into its active form in the liver, resulting in targeting to the liver and higher PMEA concentrations in that organ. The lower concentrations in the kidneys result in a potentially lower risk of nephrotoxicity than with adefovir. The efficacy, pharmacokinetics and safety of pradefovir at various doses compared with adefovir in patients with chronic hepatitis B has been evaluated in 242 patients randomized to receive pradefovir 5, 10, 20 or 30 mg/day or adefovir 10 mg/day. The declines in HBV DNA were greater for pradefovir 30 mg than for adefovir. In addition, metabolism of pradefovir in the liver was associated with less systemic drug exposure than with adefovir. HBV DNA viral-load reduction was 5 log₁₀ with the highest dose of 30 mg/day.

PMEO-DAPym, a novel acyclic pyrimidine analogue, has been assessed *in vitro*. Most drug-resistant mutants, including multidrug-resistant strains, remained sensitive to tenofovir and PMEo-DAPym. Therefore, the latter molecule deserves further evaluation for the treatment of HBV infection, given the need for agents that do not share cross-resistance (Brunelle *et al.*, 2007).

Biological Response Modifiers

Relatively little progress has been made with biological response modifiers. Interleukin-12 (IL-12) is a 75-kDa heterodimeric protein and a member of the tumour necrosis factor (TNF) receptor superfamily. This cytokine is a product of macrophages and dendritic cells (i.e. antigen-presenting cells). IL-12 promotes Th-1 and suppresses Th-2 cell development, suggesting that IL-12 may be useful therapeutically to promote a cellular immune response. The compound induces secretion of IFN- γ from T and NK cells, increases the lytic activity of NK cells and facilitates specific CTL responses.

Previous studies suggest that a predominance of HBeAg-specific Th-2-type cells may contribute to chronicity in HBV infection. Pilot studies in HBV-infected patients have been conducted but this agent is not in clinical use.

Thymosin is an immune stimulant which is known to enhance suppressor T-cell activity and B-cell synthesis

of IgG *in vitro*. Peptide preparations of thymosin have been evaluated in small controlled trials and HBV DNA has been noted to become undetectable in some of these patients and in chimpanzees with chronic hepatitis. It is given parenterally by subcutaneous injection. This agent's possible therapeutic role was evaluated in a larger controlled trial, in which HBeAg seroconversion rates were not significantly different from recipients given placebo. Thymosin α 1, a synthetic 28 amino acid peptide with multiple biological activities primarily directed towards immune-response enhancement, has been developed for the treatment of HBV infection. Although approval for the treatment of hepatitis B has been granted in a few countries, the place of this drug is still being appraised. Few side effects are observed with thymosin injected subcutaneously.

Immunotherapy

It remains important to consider the possibility of therapeutic immunization of chronically-infected, HBV-positive patients to activate an immune response and eradicate viraemia. Progress remains slow however, and no therapeutic vaccination strategy has advanced beyond phase III assessment or to licensing. In a study of 32 patients with HBeAg-positive, HBV-DNA-positive chronic hepatitis B, three standard doses of GenHevac vaccine were given at monthly intervals. Six months after the first injection, 37% had undetectable DNA. Eight responders were given IFN- α to maintain virus inhibition (Pol, 1995). More recent results have not suggested successful immunotherapy using HBV vaccine.

Because of the interest in the possibility of provoking a cytotoxic or noncytolytic immune response to HBV core epitopes, attempts are continuing to invoke a strong response to decrease HBV DNA replication. An immune response has been observed in HLA A2.1 individuals with acute hepatitis B against an epitope (FLPSDFF-PSV) that contains an HLA A2 binding motif located between residues 18–27 of the hepatitis B nucleocapsid protein. This identification has led to development of an experimental therapeutic vaccine (Theradigm HBV tm), in which the CTL epitope derived from the hepatitis B core protein amino acids 18–27 has been incorporated into a vaccine also comprised of a T-helper cell epitope and two palmitic acid residues (CY-1899). In a pilot study, 90 patients with chronic hepatitis B infection received CY-1899. No significant changes in liver biochemistry or viral serology were observed during follow-up. Thus administration of the single-epitope vaccine, CY-1899, initiated CTL activity, but of a magnitude lower than that observed during spontaneous HBV clearance, which did lead to viral clearance (Heathcote *et al.*, 1999).

Recently, DNA-based immunization was tested using purified plasmid DNA containing protein coding sequences and the regulatory elements required for their expression. The DNA was introduced by means of a parenteral injection and the number of cells transfected and the amount of protein produced were sufficient to produce a broad-based immune response to a wide variety of foreign proteins. A response to HBsAg was achieved using this form of antigen presentation. A CD8+ CTL response was induced in BALB/C mice, suggesting a pathway for exogenous presentation of hepatitis B envelope protein via MHC class I expression (Davis *et al.*, 1995). A Pekin duck infected by DHBV was immunized with a plasmid encoding DHBV large (L), leading to sustained decrease in viral replication and even to clearance of intrahepatic viral cccDNA pool in some animals. Combination therapy data with lamivudine showed a pronounced antiviral effect of DNA vaccine to DHBV envelope protein (Thermet, 2003). If the safety of DNA-mediated immunization can be assured, this form of vaccination may also have therapeutic potential (Whalen and Davis, 1995).

The combination of nucleoside analogues to inhibit viral production with immunomodulatory approaches may prove useful. Phase I–II trials are in progress. At present, immunomodulatory therapy remains an unrealized goal of treatment. Use of a DNA vaccine approach relying on the administration of a DNA plasmid encoding the viral envelope gene with a prime boost strategy is perhaps most advanced.

HIV–HBV Co-infection

The management of hepatitis B is made more complex with co-infection with HIV. HIV and HIV treatment profoundly affect the natural history of HBV. HIV–HBV co-infected patients whose immune status is preserved on highly active antiretroviral therapy (HAART) should be considered for anti-HBV therapy, with appropriate therapy for HIV infection if indicated in order to minimize resistance. If HAART is indicated for a patient co-infected with HIV, lamivudine can be utilized, as lamivudine is active against HIV and HBV. Tenofovir is also active against HBV and HIV. Thus treatment of co-infection offers the opportunity to utilize combination treatments for hepatitis B. Adefovir is a useful agent for the treatment of hepatitis B in HIV co-infected patients where treatment of HIV is not deemed necessary as the drug has no effect on HIV at a dose of 10 mg/day, or for lamivudine-resistant HBV. Entecavir has anti-HIV activity.

Hepatitis B Virus and Primary Liver Cancer

Persistent infection with HBV is associated with a high risk of developing HCC. However, the precise role played

by the virus in causing this tumour remains to be elucidated (Kremsdorf *et al.*, 2006).

Epidemiological Evidence

Hepatocellular carcinoma is one of the 10 most common cancers in the world, with over 250 000 new cases each year. In areas where the tumour is particularly common, for example some regions of sub-Saharan Africa, China and South East Asia, the age-adjusted incidence of HCC is over 30 new cases per 100 000 population each year, whereas it is less than 5 cases per 100 000 per year in western Europe and North America. Primary liver cancer is more common in males than among females and the incidence of the tumour increases with age, reaching a peak in the 30–50 age group.

When specific tests for the serological markers of HBV infection became available, it was clear that the geographical areas with a high incidence of primary liver cancer were coincident with those with a high prevalence of seropositivity for HBsAg. Furthermore, most patients from high-risk areas presenting with primary liver cancer proved to be HBsAg-positive or to have high titres of anti-HBc. There is often a considerable interval between the initial virus infection and development of HCC, although the tumour does occur in younger age groups in high-risk populations.

The relative risk of developing primary liver cancer was estimated in an elegant prospective study carried out in Taiwan by Beasley and coworkers. Over 22 000 men, including more than 3000 HBsAg carriers, were followed for 75 000 man-years. The HBsAg carriers proved more than 200-fold more likely to develop HCC than members of the noncarrier group and more than 50% of the deaths in the former group were due to the tumour or to cirrhosis, another consequence of long-term HBV infection (Beasley and Hwang, 1991).

HBV DNA in Primary Liver Tumours

If HBV does indeed play a causal role in the development of primary liver cancer then the tumours might be expected to contain virus-specific nucleic acid and perhaps also to express viral proteins. Immunohistochemistry of HBV-associated tumours shows that a minority produce HBsAg, but production of HBcAg seems to be rather less common. Following the molecular cloning of the HBV genome, which made available hybridization probes of high specific activity, the PLC/PRF/5 cell line was shown to contain HBV DNA integrated chromosomally at several sites (Figure 12.13, lane A1). Further analysis reveals considerable rearrangement of the viral DNA, although it is not clear whether these rearrangements were present

in the original tumour or occurred during the establishment of the cell line (the genotype of the cultured cells appears to be stable with respect to the integrated HBV sequences). Other cell lines derived from HBV-associated primary liver tumours have also been shown to contain integrated HBV DNA.

Analysis by southern hybridization reveals integrated HBV DNA in approximately 80% of primary liver tumours from HBsAg carriers. An example is illustrated in Figure 12.13, lane D2. It is possible that more sensitive techniques, such as PCR, may enable the detection of viral DNA sequences in tumours which test negative by hybridization. In most cases, the tumours seem to be clonal with respect to the integrated viral DNA and seem to have arisen from a single cell. There is, however, considerable variation between tumours in terms of the number of integrants and their location. Although HBV DNA is often found integrated into Alu or other satellite sequences, this is likely to reflect the size of such targets and it seems that the sites of integration in the cellular chromosomes are random.

Nucleic-acid sequencing of the junctions between viral and cellular DNA shows that the direct repeats in the virus genome (see the account of the replication of the viral genome above) are frequently located close to these junctions and may be hot spots for recombination with host DNA. Because synthesis of progeny viral DNA in infected cells is cytoplasmic, it is likely that it is an intermediate in the process of conversion of virion DNA, or progeny HBV DNA recycled from the cytoplasm to the nucleus, which is involved in the recombination.

Mechanisms of Oncogenesis

Because primary liver cancer most often develops in a liver which is affected by chronic hepatitis or cirrhosis (or both) it has been suggested that the involvement of HBV is mediated through these pathological changes and subsequent regeneration. However, it is clear that HCC is much more likely to develop in an HBV-infected cirrhotic liver than in the cirrhotic liver of an uninfected patient and that tumours often develop in the livers of HBV-infected patients without an intermediate cirrhotic stage. The common finding of integrated viral DNA in tumours implies a more direct role of viral oncogenesis. However, the fact that up to 20% of tumours from HBsAg carriers may be negative for viral DNA suggests that other mechanisms may sometimes be involved.

Integrated viral DNA may also be detected in the livers of some HBsAg-carriers without tumour, both in patients with ongoing virus replication and in those who have cleared replicating virus. The hybridization techniques used are able to detect these integration events only if they occur at the same site in many cells and, because

the sites of integration in the chromosomes appear to be random, this implies the clonal expansion of a cell with integrated viral DNA. The establishment of such clones in the liver may be the first step in a multistage process leading to carcinoma and there may be a role for other environmental factors (such as mycotoxins in the diet) in such a process. The long interval often seen between the initial virus infection and tumour development fits with this concept. Furthermore, because integration seems to occur repeatedly throughout the period of virus replication, the continuing accumulation of pre-neoplastic clones within the liver might increase the probability of progression to tumour for patients with long-term chronic infection.

Production of HBsAg in the livers of carriers who have cleared virus replication, as well as by some tumours, indicates that the surface mRNA may be actively transcribed from integrated viral DNA. The activity of this promoter makes attractive the promoter-insertion hypothesis that aberrant transcription of cellular genes may result in loss of growth control. Recent studies suggest that, in up to 90% of tumours with integrated HBV DNA, the viral genome may be integrated into cellular genes, potentially providing cell-growth advantage (Murakami *et al.*, 2005). Another mechanism whereby viruses cause neoplastic transformation of cells is via the expression of a transforming gene introduced in the integrated viral genome. The HBV genome does not seem to contain such a gene and it has not been possible to transform cells *in vitro* using virus or viral DNA. Nevertheless, the X gene of HBV encodes a transcriptional transactivator and the possibility that this protein plays a role in disrupting the normal transcriptional control of the cell cannot be ruled out. Transactivation by the X protein seems to be through responsive elements such as the transcription factor AP-1 (*junfos*), AP-2, NF- κ B and the CRE site. It has been shown that truncated pre-S proteins may also have transactivating properties. These may be produced in tumour cells by expression of integrated HBV DNA with virus/host junctions in the surface ORF.

HEPATITIS D

Delta hepatitis was first recognized following detection of a novel protein, delta antigen (HDAG), by immunofluorescent staining, in the nuclei of hepatocytes from patients with hepatitis B (Rizzetto *et al.*, 1977). HDV is now known to be defective and to require a helper function from HBV for its transmission. HDV is coated with HBsAg, which is needed for release from the host hepatocyte and for entry in the next round of infection. The agent is unique among human viruses and consists of a particle

measuring 35–37 nm in diameter, with an internal nucleocapsid comprising the genome surrounded by the delta antigen and enveloped by an outer protein coat of HBsAg. The genome consists of a single-stranded, circular RNA of around 1700 nucleotides, the delta antigen being encoded by antigenomic RNA (reviewed by Taylor, 1997).

Two major modes of delta hepatitis infection are known (Hadziyannis, 1997). In the first, a susceptible individual is co-infected with HBV and HDV, often leading to a more severe form of acute hepatitis caused by HBV. Vaccination against HBV prevents such infections. In the second, an individual infected chronically with HBV becomes superinfected with HDV. This may accelerate the course of the chronic liver disease and cause overt disease in asymptomatic HBsAg carriers. HDV may be cytopathic, and HDAg directly cytotoxic. A less common type of infection has been seen in HDAg-positive patients who have received liver transplants. Hepatocytes in the graft become infected with HDV circulating at the time of transplantation. In the absence of HBsAg there is no cell-to-cell spread of the virus but HDV replication persists in isolated hepatocytes.

Epidemiology

Limited serological studies indicate a worldwide distribution of hepatitis D in association with HBV. The infection is important epidemiologically in southern Europe, the Middle East (the Gulf States and Saudi Arabia), Japan and Taiwan, and parts of Africa and South America. However, there is evidence that the prevalence of delta infection is declining in southern Europe, particularly Italy (Gaeta *et al.*, 2000). It has been estimated that 5% of HBsAg carriers worldwide (approximately 15 million people) are also infected with HDV. In areas of low prevalence of HBV, those at risk of hepatitis B, particularly intravenous drug users, are also at risk of HDV infection. Delta infection is associated with acute and chronic hepatitis, always in the presence of hepatitis B, and superinfection in a carrier of HBV often leads to exacerbation of severe hepatitis. Epidemics with high mortality have been described in South America in association with severe hepatitis B. Three genotypes (I to III) of HDV are recognized on the basis of phylogenetic analysis, and these are found, respectively, in southern Europe, Japan and Taiwan, and South America.

The mode of transmission of hepatitis D is similar to parenteral spread of hepatitis B, so serological evidence of infection is found most frequently in western Europe and North America in multiply-transfused individuals, such as patients with haemophilia, and in drug addicts, and is endemic in the Mediterranean Basin, the Middle East, West Africa, the Amazon Basin and some South Pacific Islands.

Structure and Replication of HDV

The HDV particle is approximately 36 nm in diameter and composed of an RNA genome associated with HDAg, surrounded by an envelope of HBsAg. The virus reaches higher concentrations in the circulation than HBV; up to 10^{12} particles/ml have been recorded. The HDV genome is a closed circular RNA molecule of 1679 nucleotides with extensive sequence complementarity that permits pairing of approximately 70% of the bases to form an unbranched rod structure. The genome thus resembles those of the satellite viroids and virusoids of plants and, similarly, seems to be replicated by the host RNA polymerase II, with autocatalytic cleavage and circularization of the progeny genomes via *trans*-esterification reactions (ribozyme activity). Consensus sequences of viroids, which are believed to be involved in these processes, also are conserved in HDV.

Unlike the plant viroids, HDV codes for a protein, HDAg, in an ORF in the antigenomic RNA. Around 600 copies of a polyadenylated mRNA, approximately 800 nt in length, may be detected in the cytoplasm of infected hepatocytes. The antigen, which contains a nuclear localization signal, was originally detected in the nuclei of infected hepatocytes and may be detected in serum only after stripping off the outer envelope of the virion with detergent. The delta antigen is detectable in two forms in the infected hepatocyte. The 195 aa (small) form is required for HDV RNA replication and binds to the rod-like structures of the genome and genome complement. The larger (214 aa) form, which is structural, and therefore required for virion assembly, seems to be synthesized following RNA editing. This process converts the termination codon at the end next to the ORF in the short form to a tryptophan codon, resulting in a 19 aa carboxyl-terminal extension.

Laboratory Diagnosis of HDV Infection

Specific serological tests are available to detect antibody to HDV—anti-HD IgM and anti-HD IgG—and HDV RNA and HDAg. Co-infection and superinfection can be distinguished by correlation of the results of these tests with those for markers of HBV infection. Thus, in co-infection, HBsAg, HBeAg and HBV DNA become detectable in serum, along with HDAg and HDV RNA. Co-existence of anti-HBc IgM with markers of HDV infection is a reliable indication of co-infection; anti-HD IgM becomes detectable, followed by anti-HD IgG. Markers of virus replication usually become undetectable during convalescence.

Superinfection of HBV carriers with HDV frequently results in persistent HDV infection. HD viraemia is followed by an anti-HD IgM, and then IgG, response.

Markers of HBV replication may be suppressed during acute HDV infection. Anti-HD IgM persists with HDAG and HDV RNA in serum in chronic delta hepatitis.

Pathogenesis

The pathogenesis of the disease is uncertain. It was believed that HDV is pathogenic and that the liver injury in hepatitis D is related to HDV itself, but this concept has been challenged with the observation that HDV re-occurs in liver-transplanted patients soon after grafting, but without signs of HBV recurrence or evidence of liver damage. In these individuals, HDV may establish latent infection that is not dependent upon HBV for replication, and which is only associated with recrudescence liver injury after the acquisition of HBV. Hepatitis D virions cannot be released from the infected hepatocytes without an envelope supplied by HBV. There is also a large body of data to suggest that the pathogenesis of HDV hepatitis is in part immunologically mediated.

Fulminant hepatitis may occur in acute HDV and HBV infection, and outbreaks of severe hepatitis have been reported in Indians of the Amazon basin and in areas of Central Africa. Degenerative changes were observed in these patients, characterized by fine steatotic vacuolization of hepatocytes, in keeping with a cytotoxic inflammatory lesion. It is known that hepatitis D may interfere with HBV replication but the molecular mechanism has not been established. An increase in HDV replication has been noted in concurrent HDV and HIV replication, but this may not necessarily cause more severe hepatitis.

Clinical Features

Hepatitis D causes acute, fulminant and chronic hepatitis either as a co-infection with hepatitis B or as a superinfection in patients with chronic hepatitis B. Clinically there is a spectrum of disease, and in some co-infected or superinfected persons HDV appears to be a pathogenic agent and to aggravate the underlying HBV infection. There is much interest in the study of pathogenicity caused by this agent.

Treatment

The mainstay of treatment remains long-term IFN or PEG IFN. A proportion of patients become HDV RNA-negative, or even HBsAg-negative, with accompanying improvement in histology. To date, treatment with nucleoside analogues has proven disappointing. IFN remains the only feasible treatment. Newer agents, such as clevudine or prenylation inhibitors, may prove useful (Andreone *et al.*, 2000; Farci, 2006). Patients with decompensated liver disease should be considered for transplantation with prophylaxis against reinfection with HBV.

Prevention and Control

Prevention and control measures of HDV are similar to those for HBV. Immunization with hepatitis B vaccine protects against HDV. There is, however, the problem of protecting many millions of carriers of HBV against superinfection with HDV. Studies are in progress to develop specific immunization of hepatitis B carriers against HDV using vaccines based on HDAG.

HEPATITIS C

Hepatitis C Virus is Responsible for Almost All Cases of Parenterally-transmitted Non-A, Non-B Hepatitis

The specific diagnosis of hepatitis types A, B and D revealed a previously-unrecognized form of hepatitis which was clearly unrelated to any of these three types. Results obtained from several surveys of post-transfusion hepatitis in the United States and elsewhere provided strong epidemiological evidence of an infection of the liver termed non-A, non-B hepatitis. This was the most common form of hepatitis occurring after blood transfusion in some areas of the world following the introduction of tests for HBsAg. Studies also showed that this infection was common in haemodialysis and other specialized units, that it occurs in a sporadic form in the general population and that it can be transmitted by therapeutic plasma components. There was also considerable evidence that the parenterally-transmitted infection, like hepatitis B, may become persistent and progress to chronic liver disease, cirrhosis and HCC. Transmission studies in chimpanzees helped establish that the main agent of parenterally-acquired non-A, non-B hepatitis was likely to be an enveloped virus with a diameter of 30–60 nm. These studies made available a pool of plasma known to contain a relatively high titre of the agent and enabled the molecular cloning of the genome of what we now know as HCV (Choo *et al.*, 1989).

The Organization of the HCV Genome

The genome of HCV (Figure 12.14) resembles those of other members of the family *Flaviviridae*, the *Pestiviruses* and *Flaviviruses*. It comprises around 9400 nt of positive-sense RNA, lacks a 3' poly(A) tract and has a similar gene organization. It has been proposed that HCV should be designated the prototype of a third genus in the family *Flaviviridae*, *Hepacivirus*. All of the viral genomes from this family contain a single large ORF which is translated to yield a polyprotein (of around 3000 amino acids in the case of HCV) from which the viral proteins are derived by post-translational cleavage and other modifications.

Figure 12.14 Organization of the hepatitis C virus genome. See text for details.

There is a short, untranslated region (UTR) at the 5' end of the genome of HCV and a further UTR at the 3' end, the large ORF accounting for over 95% of the sequence. The genome is not capped and translation is mediated by an internal ribosome entry site (IRES) in the 5' UTR. The structural proteins are encoded towards the 5' end and the nonstructural proteins towards the 3' end of the ORF. The first product of the polyprotein is the nonglycosylated capsid protein, C, which complexes with the genomic RNA to form the nucleocapsid. A hydrophobic domain anchors the growing polypeptide in the ER and leads to cleavage by a cellular signal peptidase. The amino acid sequence of the nucleocapsid protein seems to be highly conserved among different isolates of HCV.

The next two domains in the polyprotein also have signal sequences at their carboxyl termini and are processed in a similar fashion. The products are two glycoproteins, E1 or gp35 and E2 or gp70, which are found in the viral envelope. These glycoproteins have not been visualized *in vivo* and the molecular sizes are estimated from sequence data and expression studies *in vitro*. These envelope proteins are the focus of considerable interest as potential targets in tests for the direct detection of viral proteins and for anti-HCV vaccines. As with many other RNA viruses, replication of the HCV genome is an error-prone process and the resulting mutations lead to the generation, within an infected individual, of a population of viruses with closely-related, but different, nucleotide sequences (quasispecies). The effect is particularly noticeable in the region of the genome (the hypervariable region, HVR-1) which encodes a domain at the amino terminus of E2. Sequences within this region are highly variable within each individual, as well as between isolates of the virus, and divergence seems to be driven by the generation of neutralizing antibodies which are targeted to that domain of E2. This hypothesis is supported by the observation that much less variability occurs in agammaglobulinaemic individuals. Thus, efforts to develop hepatitis C vaccines are hampered by variability of the most obvious target molecule and the efficacy of candidate vaccines is likely to be impaired by the rapid evolution of antibody escape mutants.

Cleavage at the carboxyl terminus of E2 generates a small protein, p7, which oligomerizes to form an ion

channel. The remainder of the nonstructural region of the HCV genome is divided into regions NS2 to NS5 (Figure 12.14). HCV encodes a protease activity at the NS2/NS3 junction which cleaves that site *in cis*. Following cleavage, the nonstructural proteins remain associated with each other and with cellular membranes (so-called membranous web), forming a replication complex. NS3 has two functional domains, a protease which is involved in cleavage of the remainder of the nonstructural region of the polyprotein and a helicase which is assumed to be involved in RNA replication. The HCV protease, which uses NS4a as a cofactor, is a major target of efforts to develop specific antiviral agents. The HCV NS5, unlike that of the *Flaviviruses*, is cleaved to yield NS5a and NS5b. NS5b contains the gly-asp (GDD) motif common to viral RNA-dependent RNA polymerases and so is likely to be the HCV replicase, and NS5a may also be involved in genome replication. The biology of HCV was reviewed recently by Lindenbach and Rice (2005).

Recent progress in cell culture of HCV has helped advance our understanding of the biology of the virus. Subgenomic replicons comprising a selectable marker (such as the gene for neomycin resistance) driven by the HCV IRES coupled to the nonstructural region of the HCV genome, driven by a heterologous IRES, are able to replicate when transfected into Huh7 cells (derived from a human HCC) (Lohmann *et al.*, 1999). One strain of HCV, JFH-1 (for Japanese fulminant hepatitis), has been shown to be able to replicate in Huh7 cells (Wakita *et al.*, 2005). In addition, pseudoviruses enveloped with the HCV glycoproteins, E1 and E2, have been valuable in the analysis of early events in HCV replication. Several candidate receptors have been identified, including the tetraspannin CD81, the low-density lipoprotein receptor, scavenger receptor class B type I and heparin; and Claudin-1 (a tight junction component) has been shown to be an important co-receptor (Evans *et al.*, 2007).

Epidemiology of Hepatitis C

Infection with HCV occurs throughout the world, currently estimated at 170 million people. Many of the seroprevalence data are based on blood donors, who represent

a carefully-selected population in many countries. Almost 4 million Americans (1.8% of the population of the United States) have antibody to HCV, indicating ongoing or previous infection with this virus. Higher rates have been found in southern Italy, Spain, central Europe, Japan and parts of the Middle East, with as many as 19% in Egyptian blood donors. Until screening of blood donors was introduced, hepatitis C accounted for the vast majority of non-A, non-B post-transfusion hepatitis. However, it is clear that while blood transfusion and the transfusion of blood products are efficient routes of transmission of HCV, these represent a small proportion (about 15%) of cases of acute clinical hepatitis in the United States and a number of other countries (with the exception of patients with haemophilia). Current data indicate that in some 40–50% of patients in industrialized countries the source of infection cannot be identified; 35% or more of patients have a history of intravenous drug misuse; household contact and sexual exposure appear not to be major factors in the epidemiology of this common infection; and occupational exposure in the health-care setting accounts for about 2% of cases. Transmission of HCV from mother to infant occurs in about 10% of viraemic mothers and the risk appears to be related to the level of viraemia. HCV can be transmitted by organ transplantation.

Diagnosis of HCV Infection

Cloning of the HCV genome made possible the development of specific diagnostic tests, including EIAs for antibody and RT-PCR for viraemia. Because expression of the original clone was detected by antibodies from the serum of an infected patient, it was an obvious candidate for development of an EIA to detect anti-HCV antibodies. A larger clone, C100-3, was assembled from a number of overlapping clones and expressed in yeast as a fusion protein using human superoxide dismutase sequences to facilitate expression. This fusion protein formed the basis of first-generation tests for HCV infection. It is now known that antibodies to C100 are detected relatively late following an acute infection. Furthermore, the first-generation assays were associated with a high rate of false positivity when applied to low-incidence populations and there were further problems with some retrospective studies on stored sera. Data based on this test alone should, therefore, be interpreted with caution.

Second- and later generation tests include antigens from the nucleocapsid and further nonstructural regions of the genome. The former (C22) is particularly useful; the sequence of the HCV core protein is relatively highly conserved compared to other HCV proteins, and antibodies appear relatively early during infection. Supplementary tests involving several viral antigens bound to a solid substrate, RIBAs, are available and give a more detailed

evaluation of the antibody profile of the patient. Antibody tests based on synthetic peptides also are available.

Routine testing of blood donations is now in place in most industrialized countries and prevalence rates vary from 0.2–0.5% in northern Europe to 1.2–1.5% in southern Europe and Japan. Many of those who are found to be antibody-positive have a history of parenteral risk such as transfusion or administration of blood products or intravenous drug use. Sexual and perinatal transmission of HCV are uncommon, so it is not clear what the 'natural' routes of transmission are.

The availability of the nucleotide sequence of HCV made possible the use of PCR as a direct test for the (genome of the) virus itself. The first step is the synthesis of a complementary DNA copy of the target region of the RNA genome using RT primed by the antigenomic PCR primer or random hexadeoxyribonucleotides. The product of this reaction is a suitable target for amplification (RT-PCR). The concentration of virus in serum samples is often very low, so that the mass of product from the PCR reaction is insufficient for visualization on a stained gel. Therefore, a second round of amplification (with nested primers) or detection of the primary product by southern hybridization is required. There is considerable variation in nucleotide sequences among different isolates of HCV, and the 5' UTR, which seems to be highly conserved, is the preferred target for diagnostic PCR. Hepatitis C viral load may be estimated by quantitative RT-PCR or by using a hybridization assay based on branched oligonucleotides (branched-chain deoxyribonucleic acid (bDNA) assay). An immunoassay for the direct detection of the HCV core protein is also available and provides an alternative means of quantifying viraemia in patients with relatively high viral loads.

Interpretation of Serological Tests for HCV

A negative EIA test is sufficient to rule out infection in individuals, such as blood donors, without risk factors for HCV infection. For those of low risk, a positive EIA requires confirmation, and a supplementary assay for antibodies, such as RIBA, is valuable. Where the RIBA is negative, the EIA result is likely to have been a false positive. If the RIBA is positive, the patient is likely to have (or to have had) hepatitis C. RT-PCR may then be used to determine whether the patient is viraemic. Follow-up RT-PCR also is indicated where the result of the RIBA is indeterminate.

Individuals with even slightly raised serum aminotransferases should be tested for anti-HCV by EIA and any positive results should be confirmed by RT-PCR. In patients with biochemical or clinical evidence of liver disease, a positive EIA is sufficient to diagnose hepatitis C,

though testing for HCV RNA is valuable for confirmation. Quantitative assays for HCV RNA are valuable in monitoring the efficacy of antiviral therapy and may help predict long-term outcome.

Persistence of HCV Infection is Common

Current data suggest that 60–80% of infections with HCV progress to chronicity. Thus, in contrast to HBV infection, where persistent infections of immunocompetent adults is rare, persistent HCV infection seems to be the norm. The morbidity of chronic hepatitis C is affected by many interactive factors, including age of acquisition, concomitant alcohol abuse, gender, co-existing viral disease and the host immune response. Histological examinations of liver biopsies from 'healthy' HCV-carriers (blood donors) reveal that none has normal histology and that up to 70% have chronic active hepatitis and/or cirrhosis. It is not clear whether pathological changes result from direct cytopathology of the virus or are mediated by the immune response to infection. HCV infection is also associated with progression to HCC. For example, in Japan, where the incidence of HCC has been increasing despite a decrease in the prevalence of HBsAg, HCV is the major risk factor. There is no DNA intermediate in the replication of the HCV genome or the integration of viral nucleic acid, and viral pathology may contribute to oncogenesis through cirrhosis and regeneration of liver cells. HCV infection rarely seems to cause acute liver failure. In the United States, HCV accounts for 60–70% of chronic hepatitis, up to 50% of cirrhosis, end-stage liver disease and HCC, and causes an estimated 8000–10 000 deaths annually. Chronic HCV is the major reason for requiring liver transplantation in most countries.

Genotypes

The tremendous variation in the sequence of the genomes of various isolates of HCV has led to their classification into types and subtypes (Simmonds *et al.*, 2005), and six major genotypes are recognized (Figure 12.15). There is some evidence of variation between genotypes of viral pathogenicity and responsiveness to treatment (see below) but data are incomplete for most genotypes and other variables such as the age of the patient and the duration of infection confound interpretation.

Infections with types 1b and 1a are relatively common in Europe; infection with type 1b is frequent in southern Europe. Epidemiological differences in age distribution of major types and the risk factors associated with particular genotypes have become apparent. In Europe, types 3a and 1a are relatively more common in young individuals with a history of intravenous drug use. Type 1b accounts for most infections in those aged 50 or more. Type 4 infection

is the most prevalent infection in Egypt, and in many parts of the Middle East and Africa.

Although an inherently greater pathogenicity of type 1 HCV has been implied, these studies have not always been based on prospective follow-up, or appropriately controlled to account for the influences of several interdependent parameters and cofactors. Moreover, several clinical investigations have documented severe and progressive liver disease after infection with each of the well-characterized genotypes (1a, 1b, 2a, 2b, 3a, 4a, 5 and 6) so there is little evidence so far for variants of HCV that are completely nonpathogenic.

HCV genotypes differ from each other by 31–33%, and subtypes by 20–25%, at the nucleotide level (Simmonds *et al.*, 2005). Typically, genotypes may be assigned by analysis of amplicons derived from the 5' UTR, which is frequently targeted in diagnostic assays, by detecting particular nucleotide polymorphisms through direct sequencing, or indirectly by using hybridization probes or changes in restriction sites. These approaches are sufficient for most clinical purposes, such as prediction of likely responses to treatment (see below), but do not provide a definitive assignment of genotype and subtype; this requires sequence and phylogenetic analysis of other regions, such as core/E1 and NS5b.

Treatment of Hepatitis C

Acute Hepatitis C

Early identification of acute hepatitis C is important, but may be difficult as the disease may be relatively silent in the acute phase; 75% of patients are not jaundiced and have nonspecific symptoms. Management of acute sporadic hepatitis C includes conventional supportive treatment and specific antiviral therapy. Therapeutic trials of IFN- α have been undertaken. Recent studies have indicated that treatment benefits those patients who have been treated early, but it may be reasonable to allow one to three months to determine which patients might convalesce spontaneously (Jaeckel *et al.*, 2001). In those who do not appear to be convalescing two to four months after onset of the disease, antiviral treatment should be considered, as a high percentage of patients (>80%) may respond. The optimal form of treatment for acute hepatitis C is not yet determined but weekly pegylated IFN- α and ribavirin can be considered. Studies are in progress to determine whether a wait-and-see strategy is detrimental compared to immediate treatment.

Chronic Hepatitis C

There is evidence that alcohol and hepatitis C may synergistically aggravate hepatic injury and the drinking of excess alcohol is discouraged because of this (Miyakawa

Figure 12.15 Evolutionary tree of complete ORF sequences for each HCV genotype. (Source: (Simmonds *et al.*, 2005).)

et al., 1993; Sawada *et al.*, 1993). The patient should be advised not to donate blood. Patients can be told that the parenteral route is the most important route of transmission and that the virus is not easily transmitted except by this route.

Treatment of hepatitis C has improved considerably. The aim of therapy is to achieve an undetectable HCV RNA six months following therapy (sustained virological response, SVR). A sustained response is associated with reduction in inflammation and severity of fibrosis. A substantial proportion of patients with chronic hepatitis C can be cured, although current treatments have limitations. HCV RNA should be measured in all patients

to confirm viraemia. If the test is reproducibly positive, serum aminotransferases, bilirubin, alkaline phosphatase and prothrombin time should be measured. In patients whose lifestyle or geographic origin suggest they are at risk of other forms of viral hepatitis, HBsAg and HIV infection must also be considered. Because autoimmune hepatitis is treated differently, it is particularly advisable to exclude this diagnosis by measuring titres of anti-smooth muscle and anti-liver-kidney microsomal antibodies, even in patients with a positive anti-HCV test.

A liver biopsy is helpful in grading the degree of inflammation and staging the degree of fibrosis. Earlier guidelines recommended antiviral therapy for those

patients with chronic hepatitis C who were deemed to be at highest risk of developing cirrhosis; that is, patients with chronic hepatitis C who had persistently increased serum ALT levels, detectable levels of HCV RNA and histological evidence of portal or bridging fibrosis or inflammation and necrosis. However, recent guidelines have been modified in the light of improved treatment responses, so that all patients with hepatitis C are potential candidates for treatment; a liver biopsy can be informative and provides unique clinical information, but may not be mandatory for all patients.

Careful clinical monitoring is suggested as an alternative to antiviral therapy for patients with less severe histological changes in whom cirrhosis may not develop.

IFN- α is difficult to apply in decompensated cirrhosis and may precipitate deterioration. These patients should be considered for liver transplantation.

Treatment with Interferon- α and Ribavirin

As noted above for HBV, IFN acts via species-specific surface target cell receptors. The cellular activities of IFN- α are mediated by the products of the IFN-inducible genes.

Ribavirin is a guanosine nucleoside analogue. This agent shows only modest activity against hepatitis C, but it increases the activity of IFN- α when the two agents are used in combination. The drug exerts its action after intracellular phosphorylation to mono-, di- and triphosphate nucleotides. The precise mode of action probably includes perturbation of intracellular nucleoside triphosphate pools, interference with the formation of the 5' cap structure of viral mRNA by competitive inhibition of both guanyltransferase- and methyltransferase-capping enzymes (although this mechanism does not apply to HCV), direct inhibition of the viral mRNA polymerase complex and possibly enhancement of macrophage inhibition of viral replication. Ribavirin may also induce mutations in the hepatitis C genome, inducing error catastrophe and thus affecting HCV replication. The combination of ribavirin and IFN- α has been shown to produce SVRs in about 40–50% of patients (Khakoo *et al.*, 1998).

Pegylated Interferons (See Above)

Twelve-kilodalton pegylated α 2b (Viraferon PEG, Schering) and forty-kilodalton PEG IFN- α 2a (Pegasys, Roche) have been licensed for the treatment of hepatitis C. There do not appear to be major differences in efficacy between the two IFNs, although they have different pharmacokinetic profiles and molecular structures. The efficacy of pegylated α -2a has been investigated in several controlled trials, and the outcome compared to standard IFN or IFN

plus ribavirin, based on virological, biochemical and histological responses.

Forty-eight weeks of PEG IFN- α -2b 1.5 μ g kg⁻¹ QW in combination with weight-based ribavirin 800 mg/day achieved a 54% SVR overall (42% for genotype 1, 80% for genotypes 2 and 3), compared to 47% for IFN- α -2b plus ribavirin. Analysis of response by patient weight demonstrated that the optimum dose of ribavirin is 10.6 mg/kg/day, and those receiving this dose achieved SVR of 48% for genotype 1 and 88% for genotypes 2 and 3 (Manns *et al.*, 2001).

Similar results have been obtained with PEG IFN- α 2a plus ribavirin (Fried *et al.*, 2002). However, a fixed ribavirin dose of 800 mg/day was shown to be adequate for those with genotypes 2 and 3. Additionally, 24 weeks of combination therapy was adequate for those with genotypes 2 and 3, a finding which has generally been extrapolated and applied to the use of PEG IFN- α 2b and ribavirin.

Current Treatment Protocols PEG IFN- α 2b is administered at a dose of 1.5 μ g/kg/week by subcutaneous injection. Ribavirin is administered according to body weight of the patient, for patients infected with genotypes 1–6. For patients less than 65 kg the dose of ribavirin is 800 mg orally/day. For patients between 65 and 85 kg the dose of ribavirin is 1000 mg/day. For patients more than 85 kg the dose of ribavirin is 1200 mg. Pegylated IFN- α 2a is given at a fixed dose of 180 μ g/week. Ribavirin is given at a dose of 1000 mg if the patient weighs less than 75 kg or at a dose of 1200 mg for patients greater than 75 kg in all patients with genotype 1 infection. However, patients with genotypes 2 and 3 are treated with a dose of 800 mg daily of ribavirin.

The pivotal studies suggested that a 24-week schedule for HCV genotype 2 or 3 is sufficient, whereas patients with HCV genotype 1 require 48 weeks of therapy. Thus patients with genotypes 1 and 4 are treated for 12 months whereas patients with genotypes 2 and 3 are treated for 6 months. Few patients with genotype 4 have been studied. However, an SVR of 79% may be achieved following a 48-week course of PEG IFN- α plus ribavirin. There is limited published data on treatment outcome in patients with genotypes 5 and 6.

Patients with genotype 1 who do not show an HCV RNA decline of at least 2 log₁₀ after 12 weeks of therapy have no opportunity of achieving an SVR and therapy should be discontinued in these patients. At week 24 HCV RNA should be measured by a sensitive qualitative PCR. Patients who are HCV RNA-positive at six months should stop therapy. As patients with genotype 2 or 3 infrequently fail to respond to treatment (4%), it is unnecessary to check the viral load at 12 weeks.

The major early side effects of IFN include influenza-like syndrome, chills, fever, malaise, muscle aches and headaches. These symptoms may be ameliorated by paracetamol. Headaches, poor appetite, weight loss, increased need for sleep, psychological effects (irritability, anxiety and depression), hair loss, thrombocytopenia and leukopenia are also common side effects. Depression can be modified by serotonin uptake inhibitors. Dose modifications may be necessary, particularly in patients with cirrhosis who have low white cell counts and platelets due to portal hypertension. Unusual or severe side effects include seizures, acute psychosis, bacterial infections, autoimmune reactions and thyroid disease. Hyperthyroidism or hypothyroidism is relatively common and can be seen in up to 5% of patients, particularly in those with pre-existing antithyroid antibodies. Proteinuria, myocardopathy, skin rashes and IFN antibodies may also occur. There have been reports of patients developing interstitial lung disease with IFN- α , though this is rare, and a neuroretinitis may occur, particularly in patients with diabetes. This is a medical emergency and treatment must be stopped immediately if patients report visual symptoms or visual field abnormalities. Careful retinal examination is mandatory. There are rare reports of bone marrow suppression resulting in bone marrow aplasia.

The major side effects of ribavirin are haemolytic anaemia, myalgia (muscle pain), hyperuricaemia, some gastrointestinal upset and dyspepsia. Some patients also report irritability. Patients should be appropriately clinically monitored for the above side effects, and white cells, haemoglobin and platelets, as well as AST, ALT, uric acid, albumin, bilirubin and thyroid function tests should be measured every four weeks.

Adherence to therapy is an important factor for improving SVR. Unfortunately, side effects frequently necessitate dose reductions, and discontinuation of therapy in 14%. It is important to motivate patients and to provide appropriate support. Patients with hepatitis C should be advised to minimize their intake of alcohol. Those who are not immune should be vaccinated against hepatitis A and B. The risk of sexual transmission in monogamous partners is low.

Supportive therapies such as antidepressants, erythropoietin and GCSF have been demonstrated to reduce the incidence of IFN-induced depression, anaemia and neutropenia respectively, and to enhance adherence to therapy, but have not yet been shown to benefit the SVR rate. These treatments add to the expense of therapy.

Nonresponders to PEG IFN and ribavirin combination therapy have a poor response to retreatment, and at present no treatment regimen is generally recommended. Those who relapse after IFN monotherapy, or standard IFN and ribavirin therapy, may achieve an SVR with PEG IFN

and ribavirin, particularly if they do not have genotype 1. However, treatment should be stopped if patients do not show an early viral response with retreatment. Several major trials including EPIC3 and HALT-C are currently investigating the long-term use of low-dose PEG IFN in nonresponders and relapsers.

There is an attempt to abbreviate courses of treatment for patients with genotype 1 and low viral loads (600 000 IU/ML) who show a rapid viral response; that is, those who are negative for HCV RNA by PCR at one month. Similarly, it may be possible to stop treatment at 16 weeks for patients with genotypes 2 and 3 who show a rapid viral response and are negative by PCR at 4 weeks. Optimal dosing of ribavirin may be necessary to achieve a rapid viral response in order to shorten treatment. HCV RNA levels higher than 800 000 IU/ML in genotype 3 may be disadvantageous.

Several small trials have suggested that IFN therapy improves liver function and reduces the incidence of HCC in patients with cirrhosis due to hepatitis B or C (Nishiguchi *et al.*, 1995). A retrospective analysis of data for 913 patients from Italy and Argentina with chronic viral hepatitis and cirrhosis showed that IFN treatment lowered the rate of progression to HCC twofold (International Interferon α -Hepatocellular Carcinoma Study Group, 1998). The risk reduction was apparently greater for patients with chronic hepatitis C and no evidence of infection with HBV.

New Treatments on the Horizon

Important progress is being made in the development of new treatments, in particular new specific inhibitors of hepatitis C. To date, most of the early trial results have only been published in abstract form. Infergen (interferon alphacon 1), a consensus IFN, is more potent than natural IFN- α , and could provide increased efficacy. IFN- β has been used for retreatment for HCV relapsers after failure of IFN- α . Virmidine is a prodrug of ribavirin which may cause less haemolytic anaemia. Pharmacokinetic studies in animals have shown the drug to be preferentially taken up by the liver, with reduced exposure of ribavirin in plasma and red blood cells. Phase III studies showed that a fixed dose of virmidine (600 mg twice daily) resulted in lower efficacy but less anaemia than a weight-based dose of ribavirin.

Albuferon (alphaferon) is a novel 85.7 kDa protein consisting of IFN- α genetically fused to human serum albumin. The fusion with serum albumin extends the half-life of the IFN. Albuferon may be dosed at intervals of two and possibly four weeks. Phase III studies are in progress.

Pilot studies with amantadine, IFN and ribavirin have been completed. The role of triple therapy with pegylated IFN is being assessed but a marked effect is not immediately apparent. Thymalfasin plus pegylated IFN- α 2a plus ribavirin has been suggested to add to the efficacy of IFN and ribavirin treatment in nonresponders. There is no advantage to treating nonresponders with pegylated IFN- α 2a plus mycophenolate mofetil.

Several new polymerase and protease inhibitors of HCV show some promise and are in phase I or phase II study. MN283 is a prodrug of MN107, the triphosphate of which competitively inhibits NS5b RNA polymerase. The activity of NM283 when orally administered once a day has been examined in chimpanzees and in phase II studies. In treated animals HCV RNA concentrations dropped rapidly, with a mean viral load reduction of 1.05 and 0.83 log at day 7 of therapy in the high- and low-dose groups. Phase II studies in humans in combination with IFN in both naïve and nonresponder patients have resulted in unacceptable gastrointestinal toxicity. VX-950 is a peptidomimetic protease inhibitor of the hepatitis C NS3-4A protease. Encouraging results in phase I and phase II studies have been reported in a small number of patients. Genomic analysis of HCV sequences attained after a few weeks of monotherapy have shown that the emergence of resistance develops relatively quickly. A 28-day, phase II study of VX-950 in combination with PEG IFN and ribavirin showed that plasma HCV RNA levels were below the limit of detection (10 IU/ml) in 12 of 12 patients at the end of 28 days of treatment. Further studies are planned; phase II studies assessing the efficacy of 12 weeks and 24 weeks of treatment with VX950 (750 mg every 8 hours) together with PEG IFN- α or in combination with PEG IFN- α and ribavirin have begun. In addition, VX-950 is being studied in other treatment regimens and patient populations, including nonresponders. The further development of BILN-2061, an HCV protease inhibitor, has been stopped because of preclinical cardiac toxicity. SCH 503034 is a novel ketoamide, peptidomimetic protease inhibitor of HCV replication *in vitro*. Phase II studies in combination with IFN- α 2b have begun. Other protease inhibitors are in development.

Isatoribine is a toll-like receptor 7 agonist. It has no direct *in vitro* activity but induces hepatic 2'/5'-oligoadenylate synthetase, leading to activation of the innate immune response. Some change in viral load has been noted in a varying dose study. CPG 10101 is a toll-like receptor agonist; a preliminary dose-finding study indicates suppression of viraemia. Nuclease-resistant ribozymes targeting the minus-strand complement of the highly-conserved 5' UTR of HCV RNA are an experimental treatment of chronic HCV infection. Antisense inhibitors, for example ISIS 14803, a

20-base phosphorothioate antisense oligodeoxynucleotide that inhibits HCV replication and protein expression, are being tested in cell culture and mouse models.

Prevention of Hepatitis C

There are no vaccines available to protect contacts of individuals with hepatitis C. Difficulties in vaccine development include the sequence diversity between different viral groups and the substantial sequence heterogeneity among isolates in the N-terminal region of the E2 glycoprotein. However, secondary transmission should be relatively easy to prevent because it is inefficient. The role of intra-familial transmission requires clarification, but is relatively infrequent. Sexual transmission is possible and has been described, but fortunately this is a relatively inefficient and infrequent route. Young sexually-active adults should be told of the advisability of condom use in general for casual sexual contact.

Mother-to-infant transmission has been observed, but appears to be unusual. Differences in the rates of maternal-infant transmission in different countries remain unexplained, and the importance of this route in perpetuating the reservoir of human infection is unknown, but could be relevant. Maternal-infant transmission is more likely in mothers with HCV RNA concentrations higher than 10^7 genomes/ml. Transmission from infected surgeons to their patients has been documented and verified by molecular epidemiological evidence (Esteban *et al.*, 1996).

Immunization

There are currently no vaccines for the prevention of HCV infection. Physicians should consider vaccinating patients with chronic hepatitis C against HAV and HBV.

GB Virus C (GBV-C) and Torque Teno Virus (TTV)

Shigeo Hino

Medical Scanning, Kanda-Surugadai, Tokyo, Japan

INTRODUCTION

Most blood-borne hepatitis viruses have been discovered with hepatitis A–E, but researchers are still striving to find additional examples. Toward the end of the last decade, newly-established molecular biological techniques identified two candidate viruses, known as GB virus C (GBV-C) and torque teno virus (TTV). The real impact of these viruses on liver diseases is still unclear and their biology remains obscure due to a lack of suitable cell culture systems.

While GBV-C is a member of the family *Flaviviridae*, it has not been assigned a specified genus. Closely related hepatitis C virus (HCV) is classified within the genus *Hepacivirus*. TTV is the first human virus to be found with a circular single-stranded (ss) DNA genome with an anti-sense orientation, similar to that of chicken anaemia virus (CAV). The prevalence of GBV-C is 1–4% in the general population, while that of TTV is over 90%. Animals were found to harbour similar viruses specific to each species. Where donors are screened for hepatitis B and C viruses, the incidence of post-transfusion hepatitis is not high enough to be explained by these highly-prevalent viruses.

GB VIRUS C (GBV-C)

History of GBV-C

In 1967, Deinhardt *et al.* (1967) reported four tamarins (*Saguinus* spp.) inoculated with a day 3 acute-phase serum sample from a surgeon (whose initials were G.B.).

All four contracted acute hepatitis with elevation of serum transaminase levels 14–53 days post-inoculation, and one developed hyperbilirubinemia. The agent (GBV) remained hepatogenic in tamarins after passages (Table 13.1). Tamarins have proved susceptible to the GB agent, but common marmosets (*Callithrix jacchus*) and baboons (*Papio* spp.) were not. Presence of indigenous pathogens in tamarins created ambiguous results. In early phases of the investigations it was not easy to distinguish GBV from hepatitis A virus (HAV), even though GBV was reported to be small, heat labile and ether sensitive, unlike HAV. GBV was suggested to be of tamarin origin, because some control animals exhibited similar symptoms and the disease associated with the GB agent was not easily transmissible between tamarins reared in the same cage. However, the conclusions remained controversial. Only the serum and liver extracts of an infected tamarin were infectious, whereas its faeces were not (Reviewed in Hino and Miyata, 2007).

In 1995, almost two decades after the first observation of this transmissible hepatitis, representational difference analysis identified two related RNA viral sequences in the GB agent, which came to be designated GBV-A and GBV-B (Simons *et al.*, 1995). The genome of each virus was over 9 kb long and had a limited sequence similarity to the isolates of HCV. The original serum of GB did not contain either virus, but instead harboured another related virus, called GBV-C. Another group of investigators independently discovered a viral sequence they designated 'hepatitis G virus', which was closely related, if not identical, to GBV-C (Linnen *et al.*, 1996).

Table 13.1 Summary of GBV

Source	Remarks	Virus
Human serum of G.B.	Hepatitis in tamarin, transmissible, but not in marmoset	GBV
Serum of tamarin with hepatitis	Nonpathogenic in tamarin, transmissible. Found also in mystax, owl monkey and marmoset	GBV-A
	Acute hepatitis in tamarin, transmissible. Found transmissible to marmoset	GBV-B
Human serum (1–4%) (G.B. serum)	Nonpathogenic. Transmissible to cause persistent infection. Not transmissible to tamarin. Found also in chimpanzee.	GBV-C (HGV) (Not GBV-A or -B)

GB Agents in Animals

GBV-A was found in tamarins (*Saguinus labiatus*), mystax (*Saguinus mystax*), owl monkey (*Aotus trivirgatus*) and common marmoset (*Saimiri* spp.), while GBV-B was detected in tamarins (Linnen *et al.*, 1996). GBVs from different species are divergent from each other and cluster according to the genetic similarity of their original animal species, suggesting that GBV-A and GBV-B originated in New World monkeys. GBV-C was also identified in chimpanzees (*Pan troglodytes*) and similarly clustered within the host species but was divergent from human GBV-C (Adams *et al.*, 1998).

GBV-A does not cause a significant elevation of alanine aminotransferase (ALT), even in tamarins. The natural course of GBV-B infection in tamarins has been investigated extensively. In tamarins, transient hepatitis caused by GBV-B was confirmed by elevation of liver enzyme levels as well as inflammation and focal necrosis in liver biopsies. Peak viraemia levels exceeded 10^9 copies/ml, after which the virus was cleared within 14–16 weeks. A strong protective immune response after the initial infection was suggested, because challenge with the same virus induced only a brief period of viraemia. After intrahepatic inoculation of infectious synthetic RNA, one of two healthy tamarins (*Saguinus oedipus*) was persistently infected with GBV-B for more than two years. High-titre viraemia (10^8 – 10^9 copies/ml) and transiently elevated serum ALT levels were detected at 4–12 weeks post-inoculation in both animals. While some tamarins are infected persistently, the induction of chronic liver disease has not been reported in them (Reviewed in Hino and Miyata, 2007).

A tamarin became persistently infected after transfection with the poly(U) deletion mutant of GBV-B (Nam *et al.*, 2004). This animal developed viraemia and hepatitis, and died at week 90; the recovered virus contained eight amino acid (aa) changes in the genome. Tamarins inoculated with serum of this animal developed an acute resolving infection. Jacob *et al.* (2004) found that a widely

available, non-endangered primate species, the common marmoset (*C. jacchus*), is susceptible to GBV-B infection and develops a characteristic acute hepatitis. Thus, the questions raised in the original experiments performed by Deinhardt *et al.* (1967) remain unanswered: If GBV-C does not replicate in tamarins, why did all the tamarins inoculated with the GB serum develop hepatitis? If GBV-C can replicate in tamarins, why did it disappear from the GB agent after several passages?

The GBV Genome

GBVs have genomes consisting of $\sim 9.3 \times 10^3$ nt, and a single large open reading frame (ORF) that encodes a precursor polyprotein of around 2850 aa. The genome is organized much like that of HCV, with genes encoding the structural and nonstructural proteins located towards the 5' and 3' ends, respectively (Figure 13.1) (Linnen *et al.*, 1996; Simons *et al.*, 1995). The core protein of GBV-B and GBV-C seems to be truncated, while that of GBV-A is almost missing (Linnen *et al.*, 1996; Simons *et al.*, 1996). The 5' termini of GBVs contain a 5' noncoding region (nontranslated region (NTR)) with an internal ribosome entry site (IRES) as in HCV (Simons *et al.*, 1996). The core-coding sequences of GBV-B are not only found to be a part of the IRES but also take part in the replication process. The C-terminal half of p13 of GBV-B, located between E2 and NS2, showed clear similarity to p7 of HCV, a small membrane-spanning protein (Ghibaudo *et al.*, 2004).

Schleicher and Flehmig (2003) reported that genotyping by restriction fragment length polymorphism (RFLP) for the 5' NTR is capable of identifying known genotypes (types 1–5) with a 99.6% accuracy. The phylogenetic analysis of human GBV-Cs has revealed that they cluster into six groups: genotype 1 (West Africa), genotype 2 (USA/Europe), genotype 3 (Asia), genotype 4 (South East Asia), genotype 5 (South Africa) and genotype 6 (Indonesia) (Muerhoff *et al.*, 2006). The hypervariability of the HCV E2 protein is one of the main factors in maintaining chronic HCV infection. However, GBV-C E2 seems

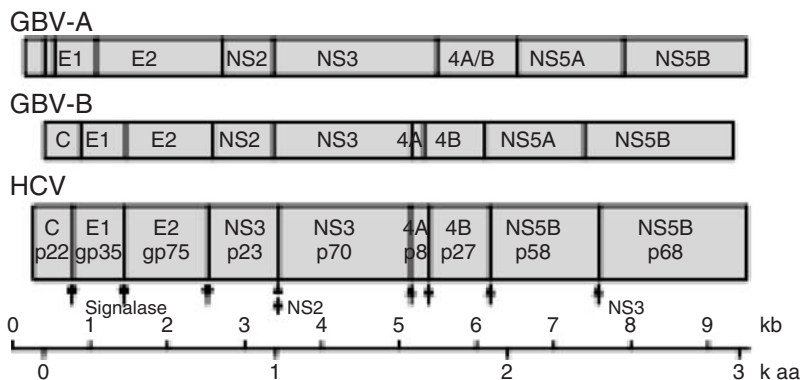

Figure 13.1 Genomic structure of GBV-A, GBV-B and HCV. Untranslated regions at 3' and 5' termini are not shown in the figure.

to be 100 times more stable than HCV E2 in six patients with acute hepatitis (Reviewed in Hino and Miyata, 2007). No aa substitutions in the loop domain were observed in seven additional patients with persistent GBV-C viraemia over a course of more than two years. How does GBV-C maintain persistent viraemia in some individuals without substantial variations in the envelope protein?

GBV in Cell Culture

GBV-C replicates in cells that originate from CD4⁺ T cells, B cells and hepatocytes. In every case, however, the replication of GBV-C was not efficient enough to serve for classic virological analyses (Reviewed in Hino and Miyata, 2007). In contrast, GBV-B replicates in primary cultures of normal tamarin hepatocytes with rapid amplification of the cell-associated viral RNA and secretion of $\sim 10^7$ copies/ml. In addition, the virus passage could be monitored by immunofluorescence staining of the NS3 protein. Despite reducing GBV-B replication in cell culture, ribavirin exhibited no significant decrease of viraemic titres in tamarins. GBV-B replication was reduced by more than two logs in hepatocyte cultures supplemented with an inhibitor of HCV NS3 protease (pyrrolidine-5,5-trans-lactams) and by three logs in marmosets given it *in vivo* (Bright *et al.*, 2004).

In a quest for gene therapies, HD-TET-tIFN, a helper-dependent adenovirus vector expressing tamarin IFN- α (tIFN- α) under the control of the tetracycline-inducible transactivator (rtTA2s-S2) was constructed (Aurischio *et al.*, 2005). tIFN- α efficiently inhibited a GBV-B replicon in an Huh-7 hepatoma cell line at low HD-TET-tIFN- α doses. A certain degree of transcriptional control of tIFN- α was also achieved in tamarins. In spite of this progress with GBV-B, the recent success in robust replications of the entire HCV in culture

(Lindenbach *et al.*, 2005) may make this GBV-B system in cell culture less attractive as a surrogate for HCV research.

Replication Site of GBV-C

The *in vivo* replication site of GBV-C is of interest because it may provide an insight into the possible pathogenicity of GBV-C. Surveillance of 17 liver-transplantation patients revealed that 70% had significantly lower GBV-C RNA titres in the liver than in the serum, while the remainder had viral RNA only in the serum. In another study, GBV-C RNA was undetectable in liver, colon or gall bladder, but detectable in serum and appendix. In a study to investigate the negative-strand RNA in serum and 23 tissue samples taken from 4 individuals who had died in accidents, the spleen and bone marrow were invariably positive. Individual instances of positive kidney and liver were also found. No negative strands were detected elsewhere. Still another study for detection of the negative-strand RNA found that five bone marrow samples were positive. Although most of these studies suggest that GBV-C replicates mainly in extrahepatic tissues, samples were probably obtained from chronically-infected people. The negative-strand RNA was detected in four of six (67%) explanted liver specimens, as well as hepatocyte-restricted infection *in situ* hybridization. Given that the hepatitis induced by GBV-B in tamarins is acute and transient, significant intrahepatic replication may occur only in the acute phase of infection (Reviewed in Hino and Miyata, 2007).

GBV-C in the Healthy Population

Most studies of GBV-C in the healthy population have been based on volunteer blood donors, using reverse transcriptase polymerase chain reaction (RT-PCR) for

the 5' NTR of GBV-C to detect GBV-C viraemia and anti-E2 antibody. Most individuals exposed to GBV-C (GBV-C-positive) were either RNA-positive or antibody-positive. The prevalence of GBV-C viraemia is reported to be 1–4% in most countries; a high rate of GBV-C viraemia is usually associated with frequent HCV-positive donors in the various regions. Although the viraemic population was within a 1–4% range throughout generations, the antibody-positive population was age-dependent: <1, 9, 12 and 13% in age groups of <15, 18–29, 30–39 and 40–49 respectively. This suggests that most children who acquire GBV-C at birth or in early childhood enter a long period of viraemia, whereas most adults tend to have acute infections with a relatively short period of viraemia. Among injecting drug users, the viraemic population exceeded 20% (Reviewed in Hino and Miyata, 2007).

Transmission of GBV-C

In a multicentre study, 34/175 (19%) anti-HCV-positive mothers were positive for GBV-C RNA. All 21 (62%) of the 34 babies to whom GBV-C had been transmitted remained persistently viraemic during 3–19 months after birth, except for one who seroconverted at 18 months. Seven of them (35%) developed marginally elevated ALT, excluding the one co-infected with HCV. Elective Caesarean section did not significantly reduce the rate of mother-to-child infection. An even higher transmission rate has been reported, in which 7/11 (64%) children born to mothers co-infected with HCV and GBV-C were infected, and their mothers' GBV-C RNA loads were significantly higher than those without transmission. In another study, 26/34 (77%) babies born to viraemic mothers were infected, including 23/24 (96%) babies born to mothers with viral loads of $>10^6$ copies/ml. They claimed that elective Caesarean sections reduced the transmission rate, but carrying these out solely to avoid nonpathogenic GBV-C transmission would not be justified. In regard to the possibility of transmission through saliva, the titre of GBV-C RNA in saliva was 10^{-2} – 10^{-4} -fold of that in the corresponding serum (Reviewed in Hino and Miyata, 2007).

Among 98 relatives of RNA-positive donors, 14 (14%) were viraemic and 29 (30%) were antibody-positive, whereas among the relatives of RNA-negative donors, only 1/95 (1.1%) was viraemic and 8/94 (8.5%) were antibody-positive. The prevalences of viraemia were high among the sexual partners of viraemic individuals: 7/32 (22%) and 4/12 (33%). However, 5/7 (71%) spouses in the former series exhibited parenteral risk factors, such as blood transfusions, acupuncture and major surgery. Even in the apparently healthy population, people at risk of parenteral infection exhibited a much higher prevalence,

usually in excess of 20%. Thus, GBV-C does not seem to be efficiently transmitted via sexual intercourse (Reviewed in Hino and Miyata, 2007).

Blood transfusion is one of the major transmission routes for GBV-C. RNA-positive blood products were infectious at the rate of 40–60%. None of 37 vials of clotting factor concentrates manufactured in the United States from 1981 to 1995 treated by pasteurization, solvent detergent or dry heat for 144 hours were negative for GBV-C RNA (Alonso-Rubiano *et al.*, 2003).

GBV-C in Patients

Among patients with acute non-A–E hepatitis, most studies found the prevalence of GBV-C viraemia to be less than 6%; not significantly higher than that in the general population. Most studies could not find evidence of significant ALT elevation, either. However, in a series of 62 patients with acute non-A–E hepatitis, 19 (31%) were found with GBV-C viraemia. Mild portal inflammatory lesions as well as steatosis were reported more frequently in the patients with persistent and isolated GBV-C viraemia (Reviewed in Hino and Miyata, 2007).

Potential technical bias may affect the interpretation of obtained results. Souza *et al.* (2006) pointed out that the specificity of RT-PCR with their E2 primers was 100%, but the sensitivity was only 77%. Assays utilizing additional three-primer sets deduced from conserved regions of other genes were more sensitive, but associated with higher false-positive rates. Recently, Ruiz *et al.* (2006) applied a competitive RT-PCR, which can discriminate between positive and negative strands, and measure viral loads over a wide range.

Co-infection with GBV-C might moderate the course of HCV infection, since HCV RNA levels were significantly lower in the 15 HCV/GBV-C co-infected patients than in the 48 patients with HCV infection alone (2.2 vs 10.8×10^6 copies/ml, $P = 0.02$). The role of GBV-C in patients infected with human immunodeficiency virus (HIV) is more interesting. GBV-C viraemia did not aggravate the course of patients with HIV infections, but was associated with slower progression of HIV infections. All parameters (survival, CDC stage B/C, HIV RNA load and CD4 T-cell count) were significantly better in terms of the cumulative progression rate (Reviewed in Hino and Miyata, 2007).

In evaluating participants infected with HIV for five to six years, GBV-C viraemia was significantly associated with a prolonged survival among the long-follow-up group, but not among the short-follow-up group, and the loss of GBV-C RNA was associated with the poorest prognosis in the long-follow-up group (Williams *et al.*, 2004). African patients with acquired immunodeficiency syndrome (AIDS) treated with highly active anti-retroviral

therapy (HAART) for 52 weeks were also studied. The patients co-infected with GBV-C showed a faster decline in HIV viral load ($P = 0.03$) and fewer opportunistic infections (14.3% vs 50%, $P = 0.18$) without any serious adverse events (none vs 61%, $P = 0.008$) after HAART (Mosam *et al.*, 2007). Patients viraemic with GBV-C ran a significantly lower risk of HIV rebound than those negative for GBV-C ($P = 0.03$) (Antonucci *et al.*, 2005). GBV-C RNA was cleared in 50% of patients after 24 weeks of HCV therapy, although this was not associated with changes in HIV load or CD4⁺ cell counts (Schwarze-Zander *et al.*, 2006). If an HIV patient is co-infected with HCV and GBV-C, how should their HCV be treated—with IFN?

Among patients infected with HIV, while IL-2 and IL-12 levels decreased in association with significant increase of IL-4 and IL-10 levels in the GBV-negative group, they stayed constant in the GBV-viraemic group, suggesting that the co-infection with GBV-C may help maintain the T-helper population (Nunnari *et al.*, 2003). On the other hand, an enhanced activation of the IFN system (2-5-OAS, MxA, IFN AR-1 and PKR in peripheral blood mononuclear cells (PBMCs) was observed in the GBV-viraemic and HIV-positive group (Capobianchi *et al.*, 2006).

Jung *et al.* (2005) have shown that GBV-C infection of PBMC leads to significant reduction of HIV mediated by expression of GBV-C structural glycoproteins and/or nonstructural proteins NS2/NS3. Upon GBV-C infection, CD4 and CD8 T lymphocytes are stimulated by GBV-C to secrete anti-retroviral factors, such as stromal cell-derived factor, SDF-1. The glycoprotein E2 of GBV-C interferes with the early replication steps of both X4- and R5-tropic HIV strains, and the inhibitory effect is abrogated by pre-incubation with anti-E2 antibody (Jung *et al.*, 2007). This was confirmed by the *in vitro* expression of E1/E2 encoding GBV-C RNA. GBV-C NS5A protein expressed in Jurkat induced a dose-dependent inhibition of HIV replication, independent of PKR inhibition (Xiang *et al.*, 2006). NS5A induced release of SDF-1 and decreased surface expression of HIV co-receptor CXCR4, potentially explaining the HIV inhibition. Deletion mapping of the NS5A protein identified an 85 aa region (152–237) that inhibits HIV-1 replication.

TORQUE TENO VIRUS (TTV)

History of TTV

TTV was found in 1997 as a naked ssDNA virus by the use of differential display technology (Nishizawa *et al.*, 1997). The index serum was obtained from a hepatitis patient with initials T.T. who did not possess any

markers of known hepatitis viruses. Okamoto *et al.* (1998) reported a linear 3739 nt sequence of TTV (TA278). A 113 nt GC-rich stretch was added, to complete its circular genome to 3852 nt (Miyata *et al.*, 1999; Mushahwar *et al.*, 1999). It was the first human virus with a circular ssDNA genome, and was tentatively classified as a *Circovirus*.

Despite intensive studies to define the pathogenicity of TTV, the real impact of TTV on liver disease still remains uncertain (Reviewed in Hino and Miyata, 2007). The vast majority of virological efforts have focused on the molecular epidemiology of diverse spectra of the TTV genome (Peng *et al.*, 2002). The considerable diversity of TTVs and lack of suitable conventional virological systems to study them are still limiting our knowledge about these viruses.

Classification of TTV

Viruses possessing circular ssDNA genomes have been well known for some time, even though their classifications have been reformed recently, such as the bacterial viruses *Inoviridae* and *Microviridae*, the plant viruses *Geminiviridae* and *Nanoviridae* and the animal viruses *Circoviridae* (Table 13.2). Members of the *Geminiviridae* and *Nanoviridae* have more than one circular DNA genome. Within the *Circoviridae*, the genus *Circovirus* includes animal viruses such as the porcine circovirus (PCV) and psittasine beak and feather disease virus (PBFVDV). The genome of *Circovirus* is ambisense and has a common 9 nt stem-loop structure at its replication origin. The largest rep protein of *Circovirus* is coded for by the genomic strand, with the other two proteins encoded by the anti-genomic strand (Figure 13.2) (Niagro *et al.*, 1998). Plant viruses, such as banana bunchy top virus (BBTV), have been moved into a new family, *Nanoviridae*, whose genome has six segments of sense-strand circular DNA (International Committee on Taxonomy of Viruses, 2007).

TTV has a 3.8 kb circular genome of ssDNA. One third of the genome is an NTR and has a high degree of similarity within extremely divergent TTVs (Takahashi *et al.*, 1998). The 36 nt region (nt 3816–3851 of TA278) in the GC-rich stretch and its immediate vicinity constitutes a stem-loop structure, serving for the origin of DNA replication (Mushahwar *et al.*, 1999). Moreover, multiple transcription modifier motifs, such as ATF/CREB, AP-2, SP-1 and NF- κ B binding sites, are found in this region (Miyata *et al.*, 1999).

Some researchers still refer to TTV as ‘transfusion-transmitted virus’, even though it has been made explicit that the acronym TTV is based on the initials of the original patient (Takahashi *et al.*, 2000). Current spelled-out names for TTV and TTV-like mini virus (TLMV) were approved as ‘torque teno virus’ and ‘torque teno mini

Table 13.2 Viruses with a single-stranded circular DNA genome

Family	Genus	Representative viruses	Strandedness	Number of circles
Unassigned ^a	<i>Anellovirus</i>	TT virus (human, nonhuman primates and other animals), TTV-like mini virus (TTMV), Small anellovirus (SAV)	Antisense	1

^aA new family, *Anelloviridae*, is proposed, and the National Center for Biotechnology Information has incorporated the family name into the taxonomic table.

virus' (TTMV) by the International Committee on Taxonomy of Viruses (ICTV). These acronyms were devised to incorporate 'torques' (necklace) and 'tenuis'/'teno' (thin) into the established TTV name. TTV is currently classified in the unassigned genus *Anellovirus* (ring) within ssDNA viruses, but a family *Anelloviridae* has been proposed; the new family name is widely used already, since the Third International ssDNA Comparative Virology Workshop at Ouro Preto, Brazil, held over 20–26 May 2007 (Table 13.3).

The TTV Group

TTVs are composed of a wide variety of viruses (Figure 13.3) (Peng *et al.*, 2002). According to the proposed classification, all human TTVs with the 3.8 kb genome belong to the genus *Alphatorquevirus*, and they are divided into six groups (Table 13.3). Human TTMVs with the 2.9 kb genome (Takahashi *et al.*, 2000) and small anelloviruses (SAVs) with 2.2 and 2.6 kb genomes (Jones *et al.*, 2005) (Figure 13.2) are classified into separate genera, *Beta-* and *Gammatorquevirus* respectively (Table 13.3). The diversity is dependent not only on the mutations but also on frequent recombinations among

TTVs (Reviewed in Hino and Miyata, 2007; Manni *et al.*, 2002). Why and how these viruses can survive with such a wide spectrum of diversity is still unclear. A single host can be infected with different species of TTV. Do TTVs and TTMVs continue to mutate within a given host to escape its immunosurveillance system, as is the case for HCV or HIV?

Although the genomic sizes of TTV and TTMV are different, they share several common features. The NTRs occupying the approximately one third of the genome inclusive of the GC-rich stretch are similar to each other. The structures of the coding regions in these two virus groups are also similar to each other (Figure 13.4). The largest, ORF1, which accounts for approximately two thirds of the viral genome, is common to all these viruses. Two other double-spliced mRNAs have been found in TTV and TTMV. A single host can be infected with both virus groups, but there are some hosts with only one virus, indicating that the replications of these viruses are not dependent upon each other. Recently isolated 3.2 kb TTVs exhibiting 76–99% identity with SAVs were phylogenetically distinguishable from all reported TTVs and TTMVs. These small viruses are proposed as deletion mutants (Ninomiya *et al.*, 2007).

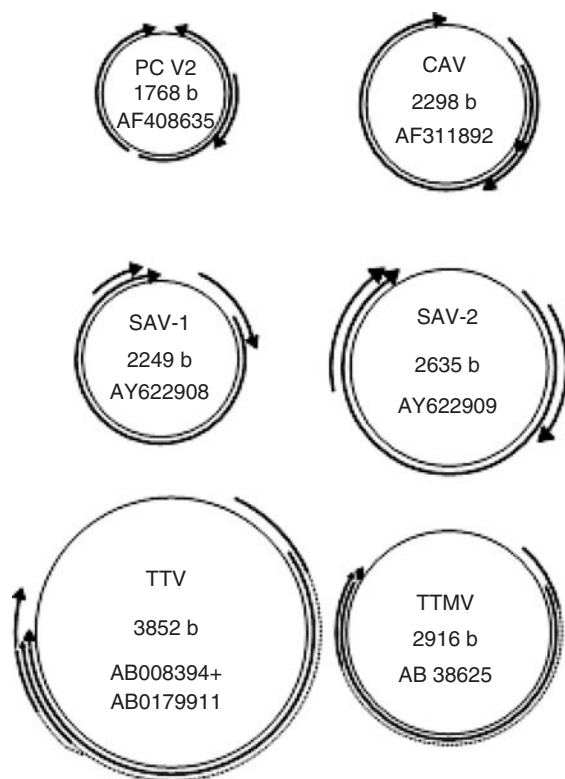

Figure 13.2 Strands of TTV, TTMV and SAVs in comparison to CAV (genus *Gyrovirus*) and porcine circovirus type 2 (PCV-2, genus *Circovirus*). The sizes of the circles correspond to the genome size of each virus. Clockwise arrows, translations on the anti-genomic strand; counter-clockwise arrows, those on the genomic strand.

TTV in Nonhuman Primates

Primates also have TTVs and TTMVs. TTV DNA was detected in most chimpanzees, Japanese macaques, red-bellied tamarins, cotton-top tamarins and owl monkeys examined. In 46% of the 104 chimpanzees, species-specific TTVs in four genetic groups were detected by analysis of the N22 region. Shortened N22 primers detected a diverse spectrum of chimpanzee TTVs, and UTR primers detected TTV/TTMVs in a wide range of apes (gorillas, orangutans, gibbons) and African monkey species (mangabeys, drills, mandrills). (Reviewed in Hino and Miyata, 2007).

TTV is prevalent even in lower primates, such as tupaia (*Tupaia belangeri chinensis*) (Okamoto *et al.*, 2001). Although the genome length of Tbc-TTV14 was short at 2.2 kb, it clustered with TTVs and TTMVs in regard to putative genomic organization and transcription profile. Conserved motifs were commonly observed in coding and

noncoding regions of the Tbc-TTV14 genome and in all TTV and TTMV genomes. Phylogenetic analysis revealed that Tbc-TTV14 is more closely related to TTMVs, as well as those isolated from tamarins and douroucoulis, than to those from humans and chimpanzees.

Viraemia developed in rhesus monkeys 4–7 days and 7–10 days after intravenous and oral inoculation of human TTV, respectively (Luo *et al.*, 2000). The virus was excreted in faeces for over six months. These data imply that TTVs isolated in animals can be of human origin, and that recombination events between human and animal TTVs may take place. TTVs in faeces of wild animals were surveyed in an attempt to test them through noninvasive methods (Barnett *et al.*, 2004). Although TTVs in each host species are more closely related to each other than to those of other host species, the diversity of human TTVs is broad enough to overlap with those of other animals. These patterns suggest interspecies transmission, probably by faeco-oral transmission.

TTV in Lower Animals

TTVs are also found in chickens, pigs, cows, cats, dogs and sheep (Okamoto *et al.*, 2002). Although porcine TTV is not known to be associated with any swine disease,

Figure 13.4 Frames and ORF structures of TTV (AB008394 + AB017911) and TTMV (AB38625). Short vertical lines represent ATG while long vertical lines correspond to stop codons. Fr, reading frame.

there is a potential risk of human infection during xenotransplantation. Porcine TTVs are prevalent in the pig populations of various countries (Table 13.4). These isolates were similar to each other, and the clustering of porcine TTV isolates was independent of the geographic origin. Recently, a novel member of swine TTV was identified using bacteriophage phi29 DNA polymerase to amplify circular DNA molecules through rolling circular amplification with random primers (Niel *et al.*, 2005). Camel TTVs ($n = 23$) were classified in genotype 11 (48%), group 5 (43%) and genotype 16 (9%), which are among the predominant genotypes found in humans in the United Arab Emirates (Al-Moslih, Perkins and Hu, 2007). Bovine isolates, on the basis of NTR sequences, are scattered within the human TTV phylogenetic tree (Figure 13.3b) (Hino and Miyata, 2007). The taxonomic divergence of these animal viruses relative to human TTVs and their pathogenicity are yet to be clarified.

Target Cells of TTV

The concentration of TTV is 10–100 times greater in bile than in peripheral blood, suggesting replication of TTV in the liver. The replicative form of TTV was found in liver and bone marrow. TTV loads in nasal secretion were 10–100 times higher than those in circulating blood, suggesting robust TTV replication in the nasal epithelium. The replication of TTV in respiratory epithelial cells was also suggested by a high concentration of TTV in nasal secretions of 1- to 24-month-old hospitalized

Table 13.4 Prevalence of TTV in pigs (McKeown *et al.*, 2004)

Area	<i>n</i>	Prevalence (%)
Iowa, USA	36	33
Beijing, China	20	80
Thailand	20	40
Korea	20	85
Ontario, Canada	13	46
Quebec, Canada	10	100
Saskatchewan, Canada	15	100
Spain	20	90

children with acute respiratory diseases (ARDs) (Maggi *et al.*, 2003). Low TTV titres in cerebrospinal fluid (CSF) suggested that the central nervous system would be less likely to be a target of TTV replication. (Reviewed in Hino and Miyata, 2007).

Although TTV was originally found in serum, the detection of TTV in stool has suggested that it is transmitted by the faeco-oral route. TTV was detected in water in rivers at a level comparable with those of enteroviruses, rotaviruses and noroviruses (Haramoto *et al.*, 2005; Verani *et al.*, 2006). TTV can be transmitted by mother-to-child infection. The presence of TTV in cord blood is reportedly 0–1% using the N22 PCR (Kazi *et al.*, 2000). Within six months of birth, the prevalence of TTV in children born to TTV-positive mothers was significantly higher than that of children born to TTV-negative mothers. However, at one year of age, the prevalence in children born to TTV-negative mothers caught up with that of children born to TTV-positive mothers and of adults, even without breast-feeding. This implies that a milk-borne transmission of TTV is insignificant.

Clear morphological changes in Chang liver cells have been reported following *in vitro* infection with genotype 1a TTV, and the infectivity is transferable by the culture supernatant (Desai *et al.*, 2005). However, this data contained no quantitative analysis, even if photos suggested the induction of a clear cytopathic effect. Although TTV production in the culture fluid lasted for at least six days, the amount of signalling seen was merely 1/100 that in stimulated PBMCs in which TTV replication aborted within a short period of time.

Figure 13.3 Phylogenetic analysis of TTVs. (A) Phylogenetic tree was constructed on the full genome of TTVs by Peng *et al.* (2002) (with permission of publisher and authors). Group 6 is not shown in the figure. (B) Tree based on NTR of TTVs, including those included in (A) and several newly found bovine sequences (Hino and Miyata, 2007). Strain names starting with 'Bov' are of bovine origin. Numbers in italics indicate branch in groups. Genotypes are indicated in accordance with group markers in (B) (*group 1, †group 2, ‡group 3).

In the bone marrow, TTV may prefer the erythroid series, because the promoter activity of TTV was most significant in K562 cells of the erythroid origin (Kamada *et al.*, 2004), and/or the megakaryocyte series, as thrombocytopenia has been reported in patients infected with TTV. However, TTV replication in PBMC may not be so important, because the highest TTV load in granulocytes was no more than 0.3 copies per cell. Moreover, the TTV-positive signal in PBMCs disappeared after degradation of ssDNA by mung bean nuclease. Transient replication of TTV in PBMCs stimulated with phytohaemagglutinin and Raji cells was reported, but, as elsewhere, quantitative analysis of these observations was lacking. (Reviewed in Hino and Miyata, 2007).

Since most small DNA viruses need cellular factors for initiating DNA replication, the replication of TTVs in PBMC only after stimulation is consistent with the hypothesis that TTV needs a cellular S phase. In this context, higher titres of TTV in nasal secretions of children with ARD may be correlated with the presence of regenerating epithelial cells and/or accumulating inflammatory cells. However, this assumption may be too simple. On the other hand, TTV replication is not sensitive to lamivudine in patients infected with hepatitis B virus (HBV) (Garcia *et al.*, 2003). No sustained responses of TTV can be achieved in any patient after PEG-IFN plus ribavirin treatment of those infected with HCV (Moreno *et al.*, 2004).

Association with Diseases

At present, the pathogenicity of TTV and TTMV remains in question. Most reports have not suggested any associations with significant hepatic diseases. Several reports suggest potential aggravation of underlying hepatic diseases by TTV viraemia. Co-infected patients have been reported with a higher histological score, such as TTV-positive/HCV-positive patients and TTV-positive/HBV-positive children, although there were no significant differences in ALT levels. Among patients with alcoholic liver disease, the improvement rates in ALT, gamma-glutamyl transpeptidase and alkaline phosphatase levels were lower in the TTV-positive group. The same group proposed that a high TTV viral load was a significant risk factor for hepatocellular carcinoma (HCC) in patients infected with HCV. None of these reports has been confirmed by further studies, even by the same groups. (Reviewed in Hino and Miyata, 2007).

Bando *et al.* (2001) found that serum lactate dehydrogenase was significantly higher in the 12/33 (39%) patients with idiopathic pulmonary fibrosis who had been infected with TTV. Additionally, the three-year survival rate was significantly lower in the TTV-positive group. Active TTV replication in ARD in 1- to 24-month-old hospitalized children has been documented (Maggi *et al.*,

2003) but prevalence and viral load of TTV in nasal fluid were similar to those of controls. However, in the children with asthma, three important indices of pulmonary function were inversely correlated with high nasal TTV load. Furthermore, signs of reduced airflow were more frequent in the children with high nasal TTV loads ($\geq 10^6$ DNA copies/ml) (Pifferi *et al.*, 2006). Presence of TTV in the gingival tissue was significantly associated with periodontitis, but it may be derived from the infiltrating inflammatory cells (Rotundo *et al.*, 2004).

Co-infection with other viruses may lead to certain clinical consequences. TTV/TTMV virus loads in both bone marrow and spleen were significantly higher among AIDS patients than among HIV-positive or -negative non-AIDS patients (Thom and Petrik, 2007). TTV/TTMV titre and CD4 T-lymphocyte count had a significant inverse correlation. In the series of Szladek *et al.* (2005), 8/11 (73%) patients with metastasizing or relapsing laryngeal carcinoma were co-infected with genogroup 1 TTV and HPV, in contrast to none of the 14 without tumour progression ($P < 0.001$). Furthermore, 4/5 (80%) papillomatosis patients with malignant transformation were co-infected. Similar studies on the TTV behaviour in patients co-infected with HPV in gynaecology and urology departments would be of interest.

Gergely *et al.* (2005) found that the prevalence of TTV was significantly higher in the patients with severe idiopathic inflammatory myopathy who needed immunosuppressive treatment in addition to corticosteroids than in those with a milder form of this disease. They reported another potentially interesting scenario. Patients with systemic lupus erythematosus produce autoantibodies to HRES-1/p28, an internal protein of human endogenous retrovirus. Computer searching for viral epitopes cross-reactive to the HRES-1/p28 by BLAST yielded ten of them, including four TTV epitopes, two on VP1 and another two on VP2. Prevalence of TTV DNA increased in lupus patients (120/211 (57%)) in comparison with healthy (66/199 (33%); $P < 0.0001$) and rheumatoid arthritis (23/91 (25%); $P < 0.0001$) controls.

Even though the pathogenicity of TTVs is not defined, they might be transmitted with blood transfusions, and possibly by blood products. Oza *et al.* (2004) found no evidence of TTV infections in the commercially-available plasma-derived concentrates of factor IX that are most commonly used for treatment of haemophilia B. Information on the methods needed to inactivate TTV is lacking, but the marked stability of PCV-2 and CAV should be kept in mind. Infectivity of PCV-2 or CAV was almost completely resistant to dry heat up to 120°C for 30 minutes. Their titres were reduced only to 1/20 after pasteurization at 60°C for 24 hours, and to 1/40–1/400 after pasteurization at 70°C for 30 minutes (Welch *et al.*, 2006).

Transcriptional Control

Kamada *et al.* (2004) studied the transcriptional regulation of TTV (group 1) by dual luciferase assays. They found that the region -154/-76 contains the critical regulatory element for the functioning of the TTV promoter (Figure 13.5). Similar results were observed with the SANBAN TTV (group 3). Interestingly, the promoter was more active in HepG2 cells than Huh7 cells for the group 1 TTV, while more active in Huh7 cells than HepG2 cells for the group 3 TTV, possibly suggesting distinct cell tropisms of these two TTVs. (Reviewed in Hino and Miyata, 2007).

Proteins of TTV

On the anti-genomic strand of TTV, three ORFs in each frame are evident with putative initiation codons (Figure 13.6). The largest ORF of TTV in frame 1 resides in association with a TATA box (nt 85–90 of TA278) and a polyA signal (nt 3073–3079). There are additional ORFs on the anti-genomic strand without legitimate initiation codons.

Kamahora *et al.* (2000) constructed a plasmid containing the promoter region through to the polyA signal continuously (nt 2762–3852 connected in tandem with nt 1–3770) to transcribe mRNA in eukaryotic cells. Three mRNA species sized 3.0, 1.2 and 1.0kb, respectively, were expressed in transfected COS1 cells (Figure 13.7). Each mRNA had the 5' terminus at nt 114, adjacent to the TATA box, and the 3' terminus at nt 3087, 6–9 nt downstream of the polyA signal. All three species of mRNA exhibited a common splicing at nt 186–276.

The 3.0kb mRNA has an initiation codon at A⁵⁸⁹TG and codes for the rep protein with 770 aa. The other two mRNA species of 1.2 and 1.0kb have a second splicing, connecting an ORF2 in frame 2 to the other ORF in frames 2 and 3 respectively. The first choice-initiation

Figure 13.6 Comparative arrangement of ORFs expected from the genomes of TTV (AB008394 + AB017911) and CAV (AF372658). SP-1 site (arrow), TATA box (closed triangle), PolyA signal (open triangle) and GC-rich region (closed box) are indicated.

codon for all three mRNAs is common A³⁵³TG. These three mRNAs potentially code for six different proteins (Figure 13.7) (Qiu *et al.*, 2005). The real nature of these proteins has to be elucidated.

The ORF1 protein probably serves as replicase and represents the major structural protein of TTV, because its N-terminus contains a highly basic stretch consistent with other circoviral capsid proteins and several conserved rep protein motifs (FTL and YXXK) (Niagro

Figure 13.5 Enhancer and promoter region of TTV in relation to the tertiary structure in the NCR. Binding sites for transcription factors conserved in various TTVs (open circle, CREB; closed circle, E2F; open square, c-Ets; closed square, USF; hexagon, SP1), and their positions in italics, are shown. Open triangles indicate the boundary of 5' deletion mutants, and closed triangles indicate the boundary of 3' deletion mutants. Their luciferase signals relative to that of the pGL3B (1.2kb NCR) construct are shown on graphs as circles (black for 5' deletions and grey for 3' deletions). The initiation site (nt114) is denoted as +1.

Figure 13.7 Schematic diagram of the TTV genome (AB008394 + AB017911) and its mRNAs. Three reading frames of the genome are shown in the upper panel. The open triangle indicates the position of the cap site while the closed triangle indicates that of the polyA signal. The short and long vertical lines indicate ATGs and stop codons, respectively. Predicted ORFs are indicated by numbers. The shaded area represents the first splicing common to all mRNAs of three different sizes. The lower panel indicates the frames used and configurations of 3.0, 1.2 and 1.0 kb mRNAs. The solid lines indicate exons, the dotted lines represent introns, and the boxes indicate coding regions. Because of the alternative splicing for the 1.0 kb mRNA, the 5' terminal nt 2567 is labelled with an asterisk.

et al., 1998; Takahashi *et al.*, 1998). Post-translational modifications should be investigated further.

Phosphorylation of the ORF 2–4 product on frame 2, derived from the 1.2 kb spliced mRNA using an expression plasmid, has a similarity to NS5A of HCV. Apoptotic ORF3 protein will be discussed later, with CAV protein. A transgenic mouse expressing a TTV product mainly in kidneys and suffering from a nephrotic syndrome has been reported (Reviewed in Hino and Miyata, 2007). It transcribed 1.1 kb mRNA corresponding to the 1.0 kb mRNA, and expressed a 143 aa protein, however the ORF2–5 product derived by the second splicing in the 1.0 kb mRNA species is an artificial protein using A⁵⁸⁹TG instead of A³⁵³TG, and thus is truncated of most N terminus in the ORF2 region (Figure 13.7).

Chicken Anaemia Virus

Although CAV is not a direct subject of this chapter, I would like to refer to it briefly. CAV is currently classified in the family *Circoviridae*, genus *Gyrovirus*. Both CAV and TTV have antisense genomes, not the ambisense genome of *Circovirus*, and lack the 9 nt stem-loop structure common in *Circovirus*. Configurations of ORF in CAV and TTV were similar in spite of the difference in genome size (Figures 13.2 and 13.6). CAV also produces multiple mRNAs (Figure 13.8) (Kamada *et al.*, 2006). A 36 nt stretch in the region at their replication origins has ~80% identity (Miyata *et al.*, 1999). However, no other parts of the genomes show any significant similarities in their nucleotide sequences. The genomic size of CAV, 2.3 kb, is distinctly smaller than that of typical

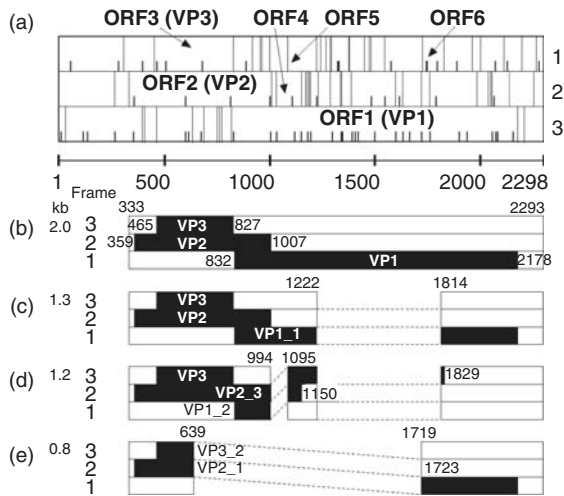

Figure 13.8 Schematic representation of the CAV transcripts and their candidate ORFs. (a) Six open reading frames of the CAV genome. Short and long vertical lines indicate ATG start and stop codons, respectively. Putative ORFs encoded by the transcripts are indicated by arrows. ORFs evident in the 2.0, 1.3, 1.2 and 0.8 kb transcripts are shown in panels b–e, respectively. Dotted lines indicate introns or deleted regions. Black boxes represent putative coding regions. Nucleotide numbers indicate the positions of ORF junctions or boundaries of ORFs.

TTV, 3.8 kb. TTV lacks a unique region of CAV, possessing four or five near-perfect direct repeats of 21 bp (Noteborn *et al.*, 1994). While TTVs are extraordinarily diverse, CAVs are strikingly homogeneous. Considering these features, CAV might be transferred into a new family, *Gyroviridae*, or into *Anelloviridae*, in the future.

In cells infected with CAV, three major proteins, VP1, VP2 and VP3, are expressed, and its capsid contains only the VP1 protein (Noteborn *et al.*, 1998). A single aa change in VP1, Q394H, abrogates the pathogenicity of CAV. Cells expressing either VP1 or VP2 alone are not recognized by neutralization antibody, suggesting that the nonstructural protein VP2 may act as a scaffold in the virion assembly. VP2 and VP3 proteins are probably early proteins, because they appear at 12 hours post-infection, while VP1 appears only after 24 hours (Reviewed in Hino and Miyata, 2007).

VP2, both of CAV and TTV, possesses a common unique feature of both tyrosine and serine/threonine phosphatases. Mutation of the cysteine residue (C95 or C97) in CAV VP2 greatly reduced the virus titre. C95 mutation abrogated both phosphatase activities. However, while C97 mutation slightly reduced the tyrosine phosphatase activity, it significantly increased serine/threonine phosphatase

activity sevenfold. By a number of site-directed mutations introduced into the VP2 genes, discrepancy was observed among virus replication, cytopathogenicity and downregulation of MHC I in infected cells (Peters *et al.*, 2006).

VP3 of CAV, apoptin, induces apoptosis by itself in various transformed and/or tumorigenic cell lines, but not in normal diploid cells. Apoptin is located mainly in the heterochromatic regions of tumour cells, whereas it stays in perinuclear structures of normal cells. Apoptin-induced apoptosis is independent of p53 and Bcl-2. A number of proteins were shown to interact with apoptin in transformed cells (Noteborn, 2004). VP3 of TTV, named TTV-derived apoptosis-inducing protein (TAIP), also has an apoptotic character, but induced only low-level apoptosis in several non-HCC human cancer cell lines (Kooistra *et al.*, 2004). VP3 of CAV is found indispensable in the replication of CAV, and its knockout virus is complemented by VP3 of TTV (Prasetyo *et al.*, 2009).

Problems with the Detection of TTV

In spite of the introduction of TTV as a putative hepatitis virus, there is little evidence for the pathogenicity of TTV. No TTVs may be pathogenic, or else only a limited type of TTV may be pathogenic. While hemi-nested PCR on the N22 region (nt 1914–2185) detects genotype 1–6 TTVs (Okamoto *et al.*, 1998), PCR on the 5' NTR (nt 26–184) detects most genotypes of TTV (Takahashi *et al.*, 1998). Most studies involving NTR PCR are probably less informative in assigning a possible pathogenicity to TTV. This is reminiscent of the history of PCV, where more than 15 years elapsed from the discovery of the original PCV (Tischer *et al.*, 1982) to that of pathogenic PCV-2 (Allan *et al.*, 1998).

INTRODUCTION

Rotaviruses are a major cause of gastroenteritis among children of less than five years of age worldwide (Bern *et al.*, 1992; Parashar *et al.*, 2003, 2006b) and of acute diarrhoea in the young of many other mammalian species (calves, piglets, lambs, rabbits, etc.). They cause more than 600 000 deaths each year, mostly of infants and young children in developing countries (Parashar *et al.*, 2006b). Since the 1960s rotaviruses have been known as the cause of diarrhoeal disease in mice (Adams and Kraft, 1963), monkeys (Malherbe and Harwin, 1963) and calves (Mebus *et al.*, 1969). They were discovered as the cause of the human disease in 1973 (Bishop *et al.*, 1973; Flewett *et al.*, 1973).

ROTAVIRUS STRUCTURE, GENOME AND GENE-PROTEIN ASSIGNMENT

The wheel-like structure of the particle as seen by electron microscopy (EM) is characteristic (Figure 14.1) and has provided the name of the virus (Latin *rota* = wheel). Rotaviruses possess a genome consisting of 11 segments of double-stranded (ds) RNA encoding six structural proteins (VP1–4, 6 and 7) and six nonstructural proteins (NSP1–6) (Figure 14.2a). The genomic RNA segments are between 667 and 3302 bp in size and have short conserved 3' and 5' termini. The structural proteins of the particle constitute an inner layer (VP1–VP3; 'the core') enclosing the genome (Figure 14.2a–c), an intermediate layer (VP6; 'the inner capsid') and an outer layer (VP4, 7; 'the outer

capsid') (Figure 14.2c). Details of the three-dimensional structure have been elucidated in a number of excellent studies by the groups of Prasad, Chiu and Estes (Crawford *et al.*, 2001; Lawton *et al.*, 1997a, 1997b, 1999, 2000; Pesavento *et al.*, 2001; Prasad and Estes, 1997; Prasad *et al.*, 1988, 1990, 1996; Shaw *et al.*, 1993), Yeager (Yeager *et al.*, 1990, 1994) and Cohen and Rey (Lepault *et al.*, 2001; Mathieu *et al.*, 2001; Petitpas *et al.*, 1998). According to their findings, the triple-layered capsid is ordered in 5-, 3- and 2-fold symmetry axes (Figure 14.2b–e) and is perforated by 132 aqueous channels (classes I–III, in three symmetry arrangements; Figure 14.2b). The class I channels have functions in transcription from subviral particles (see below).

Complete gene–protein assignments have been established for several strains; the protein–function correlations are only partially known. Details describing sizes of RNA segments and their products, as well as on post-translational modification and identified or likely functions of the virus-encoded proteins, are summarized in Table 14.1. Functions are reviewed in more detail below.

CLASSIFICATION

A classification scheme for rotaviruses has been derived from the immunological reactivities of three of its components as well as from genomic sequence comparisons and has been established as follows (Estes and Kapikian, 2007):

1. According to the serological cross-reactivity of the inner capsid protein VP6, five groups (A–E) have

▬ DLP; ↗ TLP; ↗ EDLP; ↗ ETLT

Figure 14.1 Electron micrograph of rotavirus particles in the faecal suspension of an infant with acute gastroenteritis, London, 2005. A mixture of triple-layered particles (TLPs = virion, fully-infectious particle), double-layered particles (DLPs containing RNA), empty TLPs (ETLPs, lacking RNA) and empty DLPs (EDLPs, lacking RNA) is seen. (Courtesy of Dr Hazel Appleton and Brian Megson, Health Protection Agency, London.)

been firmly established, and two more groups (F, G) are likely to exist. Within group A rotaviruses there are subgroups (I, II, I + II, nonI, nonII) according to exclusive reactivities with two VP6-specific monoclonal antibodies. More recently, reverse polymerase transcription chain reaction (RT-PCR) was applied to the subgroup classification of human rotaviruses and only two major subgroups were identified (Iturriza-Gómara *et al.*, 2002c).

- Both surface proteins, VP4 and VP7, elicit antibodies which neutralize *in vitro* and *in vivo* (Green and Kapikian, 1992; Offit *et al.*, 1986) and are therefore considered to be involved in protection. In order to characterize strains, a binary classification scheme distinguishing types, similar to that developed for influenza viruses, has been established (so far only for group A rotaviruses). The system differentiates G types (VP7-specific; G for glycoprotein) and P types (VP4-specific; P for protease-sensitive protein). So far, 16 different G types and 27 P types have been detected (and more are likely to be identified), indicating extensive genomic diversity within group A rotaviruses. Whereas the correlation of G serotypes with their genotypes is practically complete, for many P genotypes no serotype has yet been established, due to the lack of P-type-specific monoclonal antibodies and monospecific sera. Thus, it has been agreed to designate the P serotype and genotype individually but jointly, the latter in square brackets; for example,

the human Wa strain is classified as G1P1A[8], the human DS-1 strain as G2 P1B[4], the ovine strain Lp14 as G10P[15] and so on (Estes and Kapikian, 2007).

VP4 and VP7 are coded for by different RNA segments (segment 4 and segment 7, 8 or 9 depending on strain, respectively; see Table 14.1). As rotaviruses were found to reassort readily in doubly-infected cells *in vitro* and *in vivo* (Garbarg-Chenon *et al.*, 1986; Gombold and Ramig, 1986), various combinations of VP4 and VP7 types have been observed in natural rotavirus isolates (Estes and Kapikian, 2007).

REPLICATION

Rotaviruses spread via the faeco-oral route and infect the small intestine after oral ingestion. Viral replication occurs in the mature epithelial cells at the tips of the villi of the small intestine. In the presence of trypsin, rotaviruses grow well in secondary monkey kidney cells, in immortalized monkey kidney cell lines (MA104, BS-C1) and in differentiated human intestinal cell lines (e.g. Caco-2, derived from a colon tumour). Their replication *in vitro* can therefore be studied in detail (Estes and Kapikian, 2007). Triple-layered particles (TLPs) (i.e. the infectious virions) attach to the host cells via the outer-layer protein VP4 (Ludert *et al.*, 1996). Virus entry is by receptor-mediated endocytosis or direct penetration. The cellular receptors of rotaviruses have not been fully characterized. Some animal strains use sialic acid on glycolipids (Ciarlet and Estes, 1999; Ciarlet *et al.*, 2002). Other strains seem to recognize galactose (Jolly *et al.*, 2001). In addition to glycolipids, several integrins have been proposed to mediate internalisation, possibly in a post-attachment step, acting as co-receptors (Coulson *et al.*, 1997; Guerrero *et al.*, 2000; Hewish *et al.*, 2000). The heat shock cognate protein (hsc70) may also be involved as a co-receptor (Guerrero *et al.*, 2002). Human rotavirus strains appear to infect the polarized epithelial cells of the gut via their basolateral membranes (Ciarlet and Estes, 1999).

Replication is exclusively in the cytoplasm. After removal of the outer capsid from TLPs by lysosomal enzymes the viral RNA-dependent RNA polymerase (coded for by RNA 1) is activated in double-layered particles (DLPs), and by use of the VP1/VP3 transcription complex inside the VP2 layer at all fivefold axes of symmetry (Lawton *et al.*, 2000) (Figure 14.2c) large numbers of positive-stranded RNA molecules are transcribed and exit the DLPs via the twelve aqueous class I channels located on the edges of the fivefold axes (Figure 14.2f). This process is adenosine triphosphate (ATP)-dependent. The new RNA molecules (capped, but not polyadenylated) act as

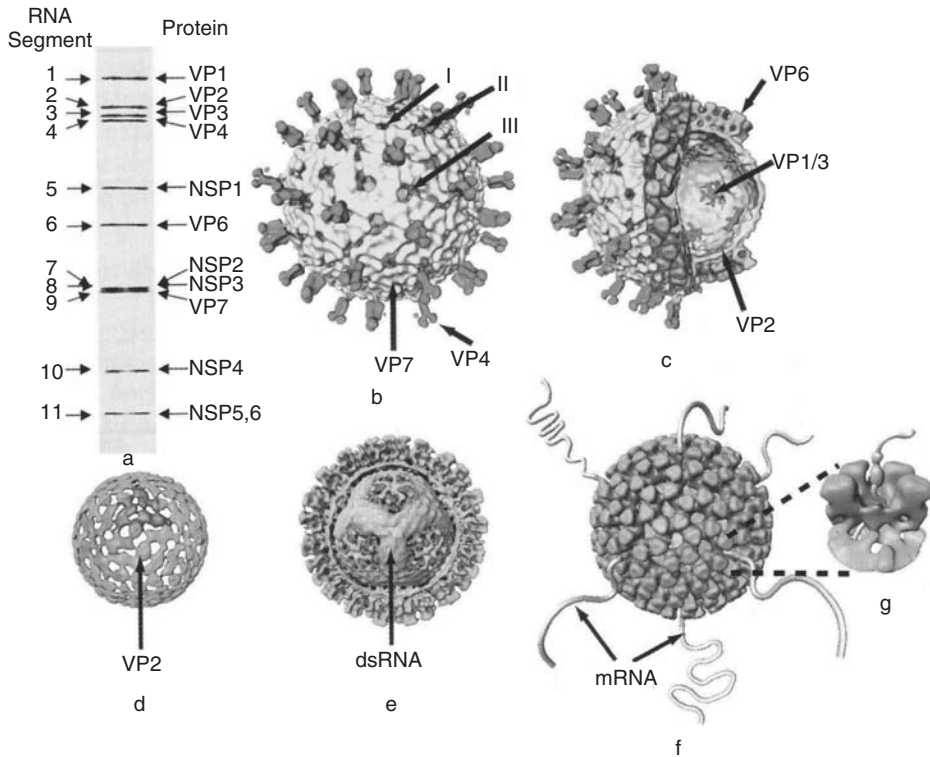

Figure 14.2 Structural organization of rotavirus. (a) Polyacrylamide gel showing rotavirus RNAs 1–11 with gene–protein assignment on the right. (b) Surface representation of rotavirus structure. Channels of classes I–III are indicated. (c) Cut-away of the rotavirus structure showing the intermediate layer (VP6), the core (VP2) and the flower-shaped VP1/VP3 complexes at the inside of VP2 opposite of class I channels. (d) Structural organization of the VP2 layer (60 dimers are shown). (e) Genomic RNA in the rotavirus structure. The VP6 and VP2 layers are partially cut away to expose the RNAs, which at the outside have dodecahedral appearance. (f) Structure of the actively transcribing DLPs with nascent mRNAs exiting through the class I channels. (g) A close-up cut-away view of the exit pathway in one of the channels. The bowling pin-shaped density of the exiting transcript is seen in actively transcribing DLPs. Panels (b) to (g) are delineated from image reconstructions of cryo-electron micrographs. mRNAs, and their translation products start to accumulate in the cytoplasm. NSP3 is intimately involved in translation by binding to the 3' end of mRNA and the eukaryotic translation factor eIF4G (Piron *et al.*, 1998; Vende *et al.*, 2000). However, translation may also occur independent of NSP3 (Montero *et al.*, 2006).

For replication, mRNA molecules may be pulled through VP2 oligomers (the nascent 'core') by means of a complex formation with NSP3, which has NTPase activity and likely acts as a molecular motor (Patton, 2001; Schuck *et al.*, 2001; Taraporewala and Patton, 2001; Taraporewala *et al.*, 1999), and NSP5, a hyperphosphorylated protein in pseudocrystalline aggregates termed 'viroplasm' (intracytoplasmic inclusion bodies). NSP2 and NSP5, when co-expressed in noninfected cells, form viroplasm-like particles (Fabbretti *et al.*, 1999) and have been shown to be essential for RNA replication and

morphogenesis (Campagna *et al.*, 2005; Silvestri *et al.*, 2004; Vascotto *et al.*, 2004). NSP5 interacts with both VP2 (Berois *et al.*, 2003) and VP1 (Arnoldi *et al.*, 2007). The exact order of events in early morphogenesis and the molecular reactions by which the packaging and reassortment of RNA segments into cores (Figure 14.2c,e) are controlled are unknown. Cryo-EM studies have shown the arrangements of dsRNA inside the core as concentric rings (Pesavento *et al.*, 2001, 2003). DLPs form in the viroplasm, consisting of VP1, VP2, VP3 and VP6 and several of the nonstructural proteins, and containing one genome equivalent of packaged single-stranded RNA (which is then replicated to form dsRNA). The DLPs bud through the rough endoplasmic reticulum (RER), with NSP4 (at its C-terminal, cytoplasmic domain) acting as an intracellular receptor for VP6 (Au *et al.*, 1993; Taylor *et al.*, 1993). There, DLPs attract a third,

Table 14.1 Genes, gene-protein assignments and functions of the proteins of group A rotavirus

RNA segment	Protein product							
	No.	Size (bp)	Description	Deduced MW (kDa)	Location (oligomeric state)	No. of molecules per virion	Post-translational modification	Functions
1	3302	VP1		125.0	Inner core	12	–	RNA-dependent RNA polymerase; ssRNA binding; complex with VP3 RNA binding; required for replicase activity of VP1
2	2690	VP2		94.0	Core	120	Myristylation	Guanylyl transferase; methyl transferase; ssRNA binding; complex with VP1
3	2591	VP3		88.0	Inner core	12	–	Haemagglutinin; cell attachment; neutralization antigen (ab protective); fusogenic; protease-enhanced infectivity; virulence (mice, piglets)
4	2362	VP4		86.8	Outer capsid (trimer)	120	Proteolytic cleavage to VP5* and VP8*	RNA binding; virulence (mice); interacting with and degrading IRF-3; non-essential for replication of some strains
5	1611	NSP1 (VP5)		58.7	Nonstructural	NA ^c	–	Group- and subgroup-specific antigen; ab protective (by intracellular neutralization?); required for transcription
6	1356	VP6		44.8	Inner capsid (trimer)	780	Myristylation	

7 ^a	1059	NSP3 (VP9)	34.6	Nonstructural (dimer)	NA	–	RNA binding (3' end); competing with cellular PABP for interaction with EIF4G1 (translation); inhibiting host-cell translation
8 ^a	1104	NSP2 (VP8)	36.7	Nonstructural (octamer)	NA	–	RNA binding; NTPase; helicase; +strand RNA packaging; forms viroplasm with NSP5; virulence (mice)
9 ^a	1062	VP7	37.4 ^b	Outer capsid (trimer)	780	Cleavage of signal sequence; glycosylation	Neutralization antigen (ab protective); Ca ⁺⁺ binding
10	751	NSP4 (VP12)	20.3	Nonstructural	NA	Glycosylation (→VP10, NS28); Trimming	Intracellular receptor for DLPs; role in morphogenesis; interacting with viroplasm; modulating transcription; viral enterotoxin (secreted cleavage product); virulence (mice, piglets)
11	667	NSP5 (VP11)	21.7	Nonstructural (dimer)	NA	0-glycosylation, phosphorylation	RNA binding; protein kinase; forming viroplasm with NSP2; interacting with VP1 and NSP6
		NSP6	12.0	Nonstructural	NA	–	Interacting with NSP5

transient, RER-derived envelope layer, which is shed before complete maturation, and incorporate VP7 and VP4. VP4 may be added late in the process in 'raft'-like structures near the plasma membrane (Delmas *et al.*, 2004). Triple-layered infectious virions are released by the lysis of nonpolarized cells (e.g. MA104), and also from polarized cells before a CPE becomes obvious, probably by other mechanisms. In faecal specimens, TLPs and DLPs (also as 'empty particles'; that is, not containing genomic RNA) may often be observed to occur side by side (Figure 14.1). (For further details of structure–function correlations and replication see Estes and Kapikian, 2007; Lawton *et al.*, 2000; Prasad and Estes, 1997). In immunodeficient hosts and under certain experimental conditions, rotaviruses undergo genome rearrangements (for review see Desselberger, 1996).

PATHOGENESIS

Extensive cellular necrosis of the gut epithelium leads to villous atrophy, loss of digestive enzymes, a reduction of absorption and increased osmotic pressure in the gut lumen, resulting in the onset of diarrhoea. This is followed by a reactive crypt-cell hyperplasia, accompanied by increased fluid secretion, which also contributes to the severity of diarrhoea. Local pathogenesis is shown diagrammatically in Figure 14.3.

Viral factors determining pathogenicity of rotaviruses have been investigated in several animal models (piglets, mice, rabbits; for review see Burke and Desselberger, 1996). The protein product of RNA segment 4, VP4, has been found to be a major determinant of pathogenicity in

several systems, but products of other structural genes (VP3, VP7) and of nonstructural genes (NSP1, NSP2, NSP4) have also been implicated (Broome *et al.*, 1993; Hoshino *et al.*, 1995).

The seminal discovery of NSP4 acting as a viral enterotoxin (Ball *et al.*, 1996; Tian *et al.*, 1994, 1995) has explained the well-known observation that rotavirus-infected animals exhibit profuse diarrhoea prior to the detection of histologic lesions. NSP4 or a peptide thereof (aa 114–135) induces dose- and age-dependent diarrhoea in laboratory animals (mice, rats) *in the absence of histological changes* (Ball *et al.*, 1996). NSP4 produces an increase in intracellular Ca^{++} concentration (Tian *et al.*, 1994), disturbing the cellular electrolyte homeostasis. A peptide of NSP4 which is active as an enterotoxin is secreted from infected cells (Zhang *et al.*, 2000) and is able to induce intracellular Ca^{++} elevation and diarrhoea in mice. It is thought that the secreted protein binds to a (still hypothetical) receptor and thus affects uninfected cells (Tafazoli *et al.*, 2001; Zhang *et al.*, 2000). Silencing of NSP4 expression in rotavirus-infected cells by specific siRNA affects mRNA production and the formation of viroplasms, suggesting a significant involvement of NSP4 in rotavirus replication and morphogenesis as well (Lopez *et al.*, 2005; Silvestri *et al.*, 2005). Immunization of mice with an NSP4-based vaccine, followed by specific antibody production, attenuates the symptoms of rotavirus-induced diarrhoea (Choi *et al.*, 2005). Whether NSP4 antibodies exert a protective function in humans remains to be explored. The enteric nervous system may be involved in rotavirus diarrhoea (and diarrhoea of other causes) as drugs blocking this system were shown to alleviate the diarrhoea (Kordasti *et al.*, 2004; Lundgren *et al.*, 2000; Salazar-Lindo *et al.*, 2000).

Figure 14.4 Rotavirus deaths worldwide (1 dot = 1000 deaths). (Source: Parashar *et al.*, (2003); with permission from Emerging Infectious Diseases.)

Rotavirus RNA and antigen have been detected in the sera of children with acute rotavirus gastroenteritis (Blutt *et al.*, 2003, 2007; Fischer *et al.*, 2005). Whilst viremia in rotavirus infection appears to be relatively frequent, systemic disease is rare (see below), suggesting that spread of rotavirus may be co-incident with systemic disease of different origin (Dormitzer, 2005; Estes and Kapikian, 2007; Ramig, 2007).

IMMUNE RESPONSES AND CORRELATES OF PROTECTION

After neonatal or primary rotavirus infection a mainly serotype-specific humoral immune response is elicited, providing homotypic immunity, but there is also partial protection against subsequent rotavirus infections by other serotypes, and the heterotypic protective capacity increases with the number of re-infections (Velasquez *et al.*, 1996). The exact correlates of protection remain to be determined (Offit, 1994), but levels of rotavirus-specific coproantibodies of the IgA subclass seem to correlate best with protection (Coulson *et al.*, 1992; Feng *et al.*, 1994, 1997; Franco *et al.*, 2006; Yuan *et al.*, 1996), though not in all cases (O'Neal *et al.*, 2000). Humoral antibodies might be neutralizing when directed towards the type-specifying antigens VP7 and VP4, but may also be directed towards the inner capsid proteins VP2 and particularly VP6 (Burns *et al.*, 1996; Feng *et al.*, 1997; Herrmann *et al.*, 1996), possibly interacting with DLPs intracellularly and preventing transcription or maturation ('intracellular neutralization') (Burns *et al.*, 1996; Cortes *et al.*, 2006). There is a rotavirus-specific cytotoxic T-cell response, but its exact role in overcoming an

infection, or in protection against subsequent infections, is not known (Franco and Greenberg, 1995; Franco *et al.*, 2006; Offit, 1994). Natural infection and appropriate vaccination (see below) seem to protect from severe disease in subsequent infections (Coulson *et al.*, 1992; Velasquez *et al.*, 1996), even if the serotype of the challenging virus differs from that of the previous infection or those contained in a vaccine.

ILLNESS, DIAGNOSIS AND TREATMENT

After a short incubation period of one to two days the onset of the illness is sudden, with watery diarrhoea lasting four to seven days, vomiting and rapid dehydration. All degrees of severity of disease are seen, including in apparent infections by so-called 'nursery strains' (frequent) (Gorziglia *et al.*, 1988), central nervous system infections (rare) (Iturriza-Gómara *et al.*, 2002a) and chronic infections and hepatitis in children with immunodeficiencies (rare) (Gilger *et al.*, 1992). In SCID mice, rhesus rotavirus (RRV) causes hepatitis (Riepenhoff-Talty *et al.*, 1987). Respiratory symptoms are not infrequently seen during rotavirus disease, however the question whether rotavirus is actively replicated in the lung and transmitted from there is still unresolved (Ramig, 2007).

Diagnosis of a rotavirus infection is relatively easy as such large numbers of virus particles (up to 10^{11} particles/ml of faeces) are shed. The main techniques are enzyme-linked immunoassays (ELISAs), passive particle agglutination tests and, when searching comprehensively for diarrhoeogenic viruses, EM (Figure 15.1). Serological assays have been used to establish G and P types

of rotavirus isolates, but these depend on the presence of triple-layered virus particles in the clinical specimen, which are often largely outnumbered by bilayered particles. Molecular techniques are therefore increasingly being applied for the purpose of typing, and also of detection. Rotavirus-specific oligonucleotide primers complementary to common and type-specific regions of the VP6, VP7 and VP4 genes allow sensitive detection, subgroup determination and typing for both G and P types, respectively, by RT-PCR (Gentsch *et al.*, 1992; Gouvea *et al.*, 1990; Iturriza-Gómara *et al.*, 2002c, 2003; Simpson *et al.*, 2003).

Treatment of rotavirus disease is by oral, subcutaneous or intravenous rehydration and pain relief as indicated. The formulae of oral rehydration solution (ORS) and reduced osmolarity 'light ORS', recommended by the World Health Organization (WHO), are widely used (Desselberger, 1999) (Table 14.2). Oral immunoglobulins seem to have an effect on the duration of diarrhoea and virus

shedding but are not routinely used (Bass, 2003; Desselberger, 1999; Guarino *et al.*, 1994). Encephalinase inhibitors have been used to dampen the symptoms of severe diarrhoea caused by rotaviruses and other microorganisms (Salazar-Lindo *et al.*, 2000). For immunocompromized children, passive immunization with rotavirus antibodies obtained from eggs or milk has been found to be helpful (Davidson, 1996; Yolken *et al.*, 1985, 1988), but their wider use is not practicable.

EPIDEMIOLOGY

Rotaviruses are spread mainly via the faeco-oral route. Water, fomites and occasionally food may act as vehicles. Rotavirus particles are very resistant to environmental conditions in temperate climates. The high particle number in the faeces of children with acute rotavirus disease and the very small minimum diarrhea-causing dose

Table 14.2 Oral rehydration solutions (ORS) for the treatment of rotavirus-related diarrhoea

Component	Osmolarity (mmol l ⁻¹)	
	WHO ORS	'ORS light'
Sodium	90	60
Potassium	20	20
Chloride	80	50
Citrate	10	10
Glucose	111	84
Total osmolarity	311	224

($1DD_{50} = 10$ plaque-forming units (pfu); Ward *et al.*, 1986) ensure wide and efficient spreading to any susceptible host. Whilst there are marked seasonal peaks (winter/spring) in temperate climates, in tropical regions rotavirus infections and disease occur throughout the year.

The epidemiology of group A rotavirus infections is complex, as at any one time within a geographical location rotaviruses of different G types cocirculate (Desselberger *et al.*, 2001; Gentsch *et al.*, 1996; Ramachandran *et al.*, 1998; Santos and Hoshino, 2005). The relative incidence of G types also changes over time in the same location. Approximately 95% of cocirculating strains are types G1–G4 in most regions of temperate climate, typically G1P1A[8], G2P1B[4], G3P1A[8] and G4P1A[8], but other G types may be represented at high frequencies, particularly in tropical areas (Desselberger *et al.*, 2001; Gentsch *et al.*, 1996; Iturriza-Gómara *et al.*, 2000). Recently, G9 rotaviruses have been isolated as the predominant outbreak strains in several locations in the United States (Ramachandran *et al.*, 1998) and in Europe (Bányai *et al.*, 2005; Iturriza-Gómara *et al.*, 2002b; Marques *et al.*, 2007; Rahman *et al.*, 2005; Reidy *et al.*, 2005; Sanchez-Fauquier *et al.*, 2006; Steyer *et al.*, 2005; Tcheremenskaia *et al.*, 2007; Van Damme *et al.*, 2007). Besides being acquired in the community (Waters *et al.*, 2000), rotavirus infections are increasingly recognized as making up a significant proportion of nosocomial infections (Gleizes *et al.*, 2006). Group B rotaviruses have caused outbreaks of diarrhoea in children and adults in China (Hung, 1988) and have been isolated from sporadic cases of gastroenteritis in Calcutta, India (Kobayashi *et al.*, 2001; Krishnan *et al.*, 1999). Group C rotaviruses are associated with small outbreaks in humans (Caul *et al.*, 1990; Jiang *et al.*, 1995). Besides the accumulation of point mutations (genomic drift) (Iturriza-Gómara *et al.*, 2003), gene reassortment (genomic shift) (Iturriza-Gómara *et al.*, 2001, 2003; Matthjinsens *et al.*, 2006; Maunula and von Bonsdorff, 2002) seems to play a major role in generating the high diversity of rotaviruses. Animals are increasingly recognized as a significant reservoir for human rotavirus infections as animal rotaviruses have been found to infect humans directly and to form reassortants with human rotaviruses (Alfieri *et al.*, 1996; Awachat and Kelkar, 2005; Das *et al.*, 1993; Iturriza-Gómara *et al.*, 2004; Matthjinsens *et al.*, 2006).

VACCINE DEVELOPMENT

Rotavirus infections are recognized as a major viral infection in children (Figure 14.4), and development of vaccines has been in progress since the early 1980s (Vesikari

et al., 1984). Results were mixed for some time, owing to the enormous genomic and antigenic diversity of rotaviruses (for reviews see Angel *et al.*, 2007; Glass *et al.*, 2004, 2006b; Kapikian, 1994a, 1994b). Initially, animal rotaviruses (of simian or bovine origin) were used as live attenuated vaccines for humans. In many cases protection from *infection and/or mild disease* was only modest (40–50%), but 70–80% protection was achieved from *severe disease including dehydration* when a cocktail of different viruses was applied (Joensuu *et al.*, 1997; Pérez-Schael *et al.*, 1997; Rennels *et al.*, 1996). A tetravalent RRV-based reassortant vaccine (developed by Wyeth) received Food and Drug Administration (FDA) approval as a universal vaccine in the United States in August 1998, and recommendations for its usage have been issued (CDC, 1999a). The tetravalent vaccine contained a rhesus monkey rotavirus (RRV) of G3 type and three mono-reassortants individually carrying the VP7 gene of human serotypes G1, G2 and G4 in the RRV genetic background. More than 1.5 million doses were administered in the following 10 months. During that time a number of cases of intussusception were observed in vaccinees, particularly within three to seven days after the first dose, with an odds ratio of 27.9 (95% confidence interval 10.8–72.1) in a case-control analysis of intussusception (Murphy *et al.*, 2001). These observations led the CDC and the American Academy of Pediatrics (CDC, 1999b, 1999c) to withdraw the recommendation for use in infants, and vaccine production ceased. There has been considerable controversy about the vaccine-attributable risk of the occurrence of intussusception, which also occurs spontaneously. Estimates between 1 case per every 4700 and 1 case per every 32000 vaccinated children have been considered (Chang *et al.*, 2001; Kramarz *et al.*, 2001; Murphy *et al.*, 2001; Simonsen *et al.*, 2001). Intussusception was not found to be epidemiologically linked with natural rotavirus infection (Chang *et al.*, 2002; Velazquez *et al.*, 2004), although abnormal gut anatomy has been observed in children with acute rotavirus disease (Robinson *et al.*, 2004). A recent reanalysis of the data indicated that the age of vaccinees is a critical factor for intussusception to occur, as a disproportionately high number (>80%) of children who developed intussusception after the first dose of rotavirus vaccine were older than 90 days (Simonsen *et al.*, 2005). Based on these observations, so-called ‘catch-up vaccinations’ of children older than three months are contraindicated, even when using the more recently developed vaccines (see below).

Despite this major setback, work on alternative live attenuated rotavirus vaccines has continued (Angel *et al.*, 2007; Glass and Parashar, 2006b; Glass *et al.*, 2004, (2006a,b)). In particular, two promising vaccine candidates have emerged. A monovalent vaccine, developed

by GlaxoSmithKline, is derived from an attenuated human rotavirus isolate, 89-12, of the G1P1A[8] type. It has been found to be highly effective in preventing severe rotavirus gastroenteritis and hospitalization (85%) (Bernstein *et al.*, 1998, 1999) and did not present a risk of intussusception above background in over 30 000 vaccinees when compared to the same number of matched, double-blinded placebo controls (Ruiz-Palacios *et al.*, 2006) (Table 14.3). The monovalent vaccine provided good heterologous protection against G3P[8], G4P[8] and G9P[8] strains and was only slightly less efficacious only against infection with G2P[4] strains. The vaccine has now been licensed in Mexico, Brazil, Venezuela and numerous European countries, and has been incorporated into Extended Programme of Immunization (EPI) schemes for universal vaccination of birth cohorts in Mexico, Brazil, Venezuela, Belgium, Luxembourg and Austria.

The other rotavirus vaccine, developed by Merck, is pentavalent and based on the attenuated bovine rotavirus WC3 strain (G6P7[5]) (Clark *et al.*, 1996; Treanor *et al.*, 1995). It consists of a mixture of five mono-reassortants, in which the VP7 gene is individually replaced by the VP7 genes of human G1, G2, G3 and G4 strains, and the VP4 gene by that of a human P[8] strain, all on the background of the other ten genomic RNA segments being contributed by the WC3 strain. This vaccine was also found to be highly efficacious in preventing severe rotavirus gastroenteritis (98%) caused by G1, G2, G3, G4 and G9 strains. No link with intussusception was found in >32 000 vaccinees when compared with the same number of matched, double-blinded placebo controls (Vesikari *et al.*, 2006). The vaccine was licensed for use in the United States, has been recommended for universal use by the Advisory Committee on Immunization Practices (ACIPs) (Parashar *et al.*, 2006a) and has now been licensed in various other countries.

The impact of the new rotavirus vaccines, particularly in countries in which the decision has been made to vaccinate universally on the annual birth cohorts, remains to be seen (Desselberger *et al.*, 2006a). Although one of the vaccines has been tested in some developing countries, the real test of vaccinating populations of infants in the poorest parts of the world is still ongoing (Glass *et al.*, 2006). The risk of undesirable effects of live attenuated vaccines (clinical complications, reversion to virulence, genetic interaction with cocirculating wild-type rotavirus strains, etc.) is considered to be low but is not zero and may only become apparent, or be excluded, once millions of children have been vaccinated. Cases of intussusception may occur in temporal association with vaccination, although the overall background level of intussusception may not be increased (Angel *et al.*, 2007). Thus, intensive post-marketing surveillance is required during the

introduction of the new vaccines in many countries, and is in fact in place. There is a good case for including surveillance of animal rotaviruses in these exercises as well.

A lamb rotavirus strain LLR (G10P[12]) has been licensed as a live attenuated vaccine for human use in China, but no clinical trial data have become available (Glass *et al.*, 2004, 2006a,b). A tetravalent vaccine, based on mono-reassortants of human VP7 genes with the genes of the attenuated bovine UK Compton rotavirus strain, has been proven to be effective and safe (Clements-Mann *et al.*, 2001) and has been expanded into a hexavalent vaccine candidate (Kapikian *et al.*, 2005). Asymptomatic neonatal human rotavirus strains have also been developed as live attenuated candidate vaccines (Glass *et al.*, 2005).

Other rotavirus vaccines under development are: virus-like particles (VLPs) originating from baculovirus recombinants expressing structural proteins (VP2, VP6, VP4 and VP7) (Conner *et al.*, 1996); vaccines with enhancement of rotavirus immunogenicity by microencapsulation (Offit *et al.*, 1994); and DNA-based vaccines (Chen *et al.*, 1997, 1998; Herrmann *et al.*, 1996).

INTRODUCTION

Gastroenteritis in humans can be caused by viruses, bacteria and parasites. The pathogenesis differs considerably depending on the infectious agent. Clinical symptoms, however, are similar and range from mainly upper-gastrointestinal symptoms including vomiting to acute watery or bloody diarrhoea without any vomiting. Globally, viral gastroenteritis is a life-threatening major disease in infants and young children. This chapter presents an overview of gastroenteritis viruses except for rotaviruses, which are reviewed in Chapter 14.

Viruses which are known to cause human gastroenteritis (Figure 15.1) belong to genera of different virus families (Blacklow and Greenberg, 1991; Fauquet *et al.*, 2005):

- rotaviruses (a genus of the *Reoviridae*); see Chapter 14
- noroviruses (NoVs) and sapoviruses (SaVs) (two genera of the *Caliciviridae*)
- astroviruses (*Astroviridae*)
- enteric adenoviruses (species F of the *Adenoviridae*).

In terms of relative frequency of incidence in children, rotaviruses were found to account for 30–60%, caliciviruses for 8–30%, astroviruses for 6–9% and enteric adenoviruses for 3–15% of all cases of viral gastroenteritides (Krajden *et al.*, 1990; Bon *et al.*, 1999; Iturriza Gomara *et al.*, 2008). In adults, caliciviruses are the most

frequent viral cause of diarrhoea. In the Netherlands, between 1994 and 2005, 6707 faecal samples collected from patients involved in 941 outbreaks of gastroenteritis were tested for the presence of NoV, SaV, rotavirus, astrovirus and adenovirus. Viruses were identified as the causative agent in 84.5% of outbreaks, with the aetiological agent of 15.5% still unidentified. NoVs were detected as the causative agent in 78.1% of outbreaks, with rotaviruses, adenoviruses and astroviruses being associated with 4.9, 1.0 and 0.5% of outbreaks, respectively (Svraka *et al.*, 2007). Thus, recently the significance of caliciviruses for gastroenteric disease has been increasingly recognized.

Other viruses that are found in the gastrointestinal tract but are not regularly associated with diarrhoea are: enteroviruses including parechoviruses (*Picornaviridae*), reoviruses (*Reoviridae*), toroviruses (*Coronaviridae*), coronaviruses (CoVs, *Coronaviridae*) and parvoviruses including bocavirus (*Parvoviridae*). Human immunodeficiency virus (HIV; a member of the *Retroviridae* family) can infect the gut directly (Heise *et al.*, 1991). Under conditions of immunosuppression, herpes simplex viruses (*Herpesviridae*), cytomegalovirus (CMV, *Herpesviridae*), and picobirnaviruses (*Picobirnaviridae*) are also found to infect the gut and cause disease.

Many of the obligatory human gastroenteritis viruses do not grow at all, or only very poorly, in cell cultures, and therefore virus isolation is not the diagnostic method of choice. By contrast, electron microscopy (EM)

Figure 15.1 Electron micrographs of (a) adenovirus, (b) astrovirus, (c) sapovirus, (d) norovirus, (e) picornavirus and (f) parvovirus. (Negative staining with 1.5% phosphotungstate, pH 6.5; bar = 100 nm.) (Courtesy of Dr Hazel Appleton and Brian Megson, Virus Reference Department, Centre for Infections, HPA, London.)

permits the differentiation of viruses on the basis of their characteristic morphology (Figure 15.1). However, the sensitivity of detection (approximately 10^6 particles per ml) is low. In general, detection of rotaviruses by EM is easy as this virus is shed in very large numbers (up to 10^{11} particles per ml of faeces) during the peak of the illness. Astroviruses and enteric adenoviruses also occur in large numbers and are readily detected. Other viruses, particularly caliciviruses, are often only detectable by EM very early in clinically-apparent disease. The methods of polymerase chain reaction (PCR) and reverse transcription (RT)-PCR, which have much greater sensitivity (10–100 DNA or 20–100 RNA molecules, respectively, are detectable per reaction), are increasingly being used in diagnostic laboratories. RT-PCR and serological techniques using recombinant antigens have demonstrated the true extent of human infections with caliciviruses and astroviruses, and they are much commoner than previously thought.

Viral gastroenteritis infections follow two distinct epidemiological patterns. In early childhood, diarrhoea occurs as endemic disease, mainly caused by rotaviruses of group A, caliciviruses, astroviruses and adenoviruses of subgroup F. By the age of five years many children have been infected with all these agents, often without apparent symptoms. The main mode of infection is faeco-oral, but infection may possibly also happen by droplet or close

contact. The second pattern is as outbreaks and epidemics, mainly caused by caliciviruses, but sometimes by astroviruses and group B and C rotaviruses. These can affect all ages, and the viruses may be transmitted by infected food (e.g. shellfish) or water (Gray *et al.*, 1997; Hedberg and Osterholm, 1993).

In a community-based study NoV infection was detected by RT-PCR in 871/2422 (36%) cases of gastroenteritis and, remarkably, in 358/2205 (16%) of age-matched asymptomatic controls (Amar *et al.*, 2007). Symptomatic and asymptomatic NoV infections were detected in all age groups but were predominant in children, young adults and the elderly (Amar *et al.*, 2007) (Figure 15.2). Similarly, SaV was detected in 4% of cases and 2% of asymptomatic controls, but in contrast to NoV, symptomatic SaV infections were predominantly in children and asymptomatic infections were found more often in young adults (Figure 15.2). This highlights the lack of long-term immunity to gastroenteric viruses, with infections and re-infections occurring throughout life, particularly at times of frequent contact with children, as a child, as a parent of young children and as a grandparent (Gray *et al.*, 1993).

Treatment largely follows guidelines established since 1985, mainly using oral rehydration fluids containing electrolytes and sugar (Desselberger, 1999). Bismuth subsalicylate has been found to be beneficial in children with

Figure 15.2 Incidence of symptomatic and asymptomatic norovirus and sapovirus infection by age. (Source: Amar *et al.*, 2007.)

acute watery diarrhoea (Figuroa-Quintanilla *et al.*, 1993). Agents used against abdominal cramping such as diphenoxylate or loperamide should be avoided as they can have serious side effects. In severe cases of diarrhoea, rapid fluid replacement by parenteral administration may be required. In developing countries where children are often malnourished, supplementary nutrition is an important component of the therapy. Public health measures to confine outbreaks include frequent hand washing, proper disinfection, removal of infected faeces and contaminated food or water, and exclusion of infected individuals from work. Outbreaks in clinical wards may require temporary closure to new admissions and restrictions on visiting and placements of staff.

Viruses regularly and irregularly causing acute gastroenteritis will be briefly described below (for concise review see Desselberger, 1998; for more extensive information see Chadwick and Goode, 2001; Cohen *et al.*, 2002; Desselberger and Gray, 2003). According to the relative degree of importance of different viruses for clinical human disease, caliciviruses are presented more extensively than the other viruses. Rotaviruses, associated with significant morbidity and mortality worldwide, are reviewed in Chapter 14.

ENTERIC ADENOVIRUSES

Genome and Structure

Adenoviruses are non-enveloped icosahedral viruses of 70–80 nm diameter, possessing a genome of linear ds-DNA of approximately 35 000 bp and a capsid with 240 hexons and 12 pentons at the vertices, which carry

projecting fibres (Berk, 2007). Their three-dimensional structure has been elucidated (Stewart *et al.*, 1991).

Classification

Human adenoviruses occur in 51 distinct serotypes ordered into six different species (A–F, previously called groups or subgroups) within the genus *Mastadenovirus* of the *Adenoviridae* family (Fauquet *et al.*, 2005). The classification is based on immunological, biochemical and biological differences. Within species, serotypes are differentiated by the reactivity of the two major capsid proteins, hexon and fibre. Within each species, DNA sequence homology is greater than 85%. Adenoviruses regularly associated with gastroenteritis are classified in species F, as serotypes 40 and 41 (Wold and Horwitz, 2007).

Replication and Pathogenesis

All adenoviruses grow well in human epithelial cells, with the exception of the fastidious or enteric adenoviruses types 40 and 41. These viruses grow poorly in Graham 293 cells (a human embryonic kidney cell line transformed by adenovirus type 5 DNA; Takiff *et al.*, 1981) or to higher titre in Graham 293 cells expressing the V-protein of the paramyxovirus SV5, which degrades the signal transducer and activation of transcription 1 (STAT1) and therefore prevents the STAT1-mediated interferon response (Sherwood *et al.*, 2007). Adenovirus replication has been studied in detail, mainly with types 2 and 5 of species C. Cell attachment is facilitated by the fibre protein, and uptake is via receptor-mediated endocytosis. Members of the immunoglobulin superfamily have been implicated as receptors, and integrins possibly as co-receptors, with CD46 identified as a receptor

for species B and species D adenoviruses (Gaggar *et al.*, 2005). Following uncoating, viral DNA moves to the nucleus, and a phased early and late gene expression is initiated. The early protein E1A acts as a transcriptional activator and is a potent blocker of apoptosis and interferon (IFN)- α and - β expression. Late gene expression is at the onset of viral DNA replication and is accompanied by blockage of cellular messenger ribonucleic acid (mRNA) expression. Virus assembly is in the cytoplasm. Virus particles are released after cell death, mediated by disruption of the cytoskeleton. Some adenovirus proteins seem to decrease the expression of major histocompatibility complex (MHC) class I antigens on the surface of infected cells, thus hindering susceptibility to adenovirus-specific cytotoxic T lymphocytes, and also to counteract tumour necrosis factor alpha (TNF- α) expression (for details see Berk, 2007).

Adenoviruses replicate in the epithelia of the human respiratory and gastrointestinal tracts, as well as in the conjunctiva and in lymphocytes. Various viral factors contribute to the pathogenesis. Whilst the pentons are directly cytotoxic, early viral proteins counteract TNF and apoptosis, and down-regulate the expression of MHC Class I molecules, thus preventing recognition by cytotoxic T cells. There is persistence of adenovirus-infection in lymphoid cells, the mechanism of which is poorly understood (Berk, 2007).

Diagnosis

Detection of enteric adenoviruses in faecal specimens is mainly by enzyme-linked immunosorbent assays (ELISAs) using species F-specific monoclonal antibodies. EM followed by immune electron microscopy (IEM) can also be used to identify these agents. Adenoviruses are detected in 4–15% of stools from children with gastroenteritis in many hospitals, outpatients clinics and day-care centres (Krajden *et al.*, 1990). PCR techniques have also been applied to the diagnosis of adenovirus infection (Allard *et al.*, 1990, 2001; Avellón *et al.*, 2001). However, of all the adenoviruses detected in faeces, only 30–50% belong to species F (Krajden *et al.*, 1990; Lew *et al.*, 1991), the others being mainly members of species B and D, infecting primarily the respiratory tract. By the age of two years, more than 40% of children possess neutralizing antibodies to adenoviruses types 40 and 41, suggesting that there are likely to be many inapparent infections (Shinozaki *et al.*, 1987).

Clinical Symptoms and Treatment

Clinically, adenovirus-associated diarrhoea does not differ from that caused by other viruses, although the duration of

symptoms may last slightly longer (3–11 days). The stools are watery and non-bloody (in contrast to some bacterial diarrhoeas). Fever and vomiting are common. Usually adenovirus gastroenteritis is a mild disease, and treatment is symptomatic. Cidofovir is active against adenovirus *in vitro* (De Clercq, 1996) and has been used in the treatment of disseminated adenovirus infections in bone marrow transplant recipients (Legrand *et al.*, 2001; Slatter *et al.*, 2005).

Epidemiology

Adenovirus infections occur worldwide as epidemic, endemic or sporadic infections. Enteric adenoviruses are mainly endemic, but outbreaks in hospitals and boarding schools have been reported. Most infections are in infancy and early childhood. The incidence of enteric adenovirus infections is between 4 and 7 per 100 person years in small children (Mistchenko *et al.*, 1992), without a seasonal preference. In immunocompromised persons, adenoviruses can cause severe systemic disease. Different genomic subtypes within types 40 and 41 have been observed (de Jong *et al.*, 1993).

Prevention and Control

At present there is no vaccine candidate for enteric adenoviruses. Control of hospital outbreaks is by cohort nursing of patients, use of gloves, gowns and goggles, and disinfection with sodium hypochlorite.

NOROVIRUSES AND SAPOVIRUSES (HUMAN CALICIVIRUSES)

Introduction

This group of viruses was first recognized from an outbreak of gastroenteritis in an elementary school in Norwalk, Ohio, USA in 1968, affecting half of the students and teachers (for reviews see Cubitt, 1994; Kapikian *et al.*, 1996). The outbreak was not due to a bacterial pathogen, and, finally, using IEM, the causative agent Norwalk virus (NV) was visualized as a 27–35 nm virus particle. Upon cloning and sequencing of the genome (Jiang *et al.*, 1993; Lambden *et al.*, 1993), NV was unequivocally classified as a member of the *Caliciviridae* family. With the advent of molecular diagnostic techniques it has become apparent that NoVs and SaVs are major causes of outbreaks of diarrhoea and vomiting in various population groups, and they are now recognized as the second most important cause of viral gastroenteritis (Fankhauser *et al.*, 1998; Koopmans *et al.*, 2001, 2003).

Structure and Genome

Typically, the surface of the particle carries cup-shaped depressions, which have given the name to this viral family (Latin 'calix' = 'goblet', 'cup'). The morphology of caliciviruses was analysed in more detail using cryoelectron microscopy and image reconstruction, once it became possible to produce recombinants and NoV particles from insect cells which were infected with a baculovirus recombinant expressing the capsid protein (Prasad *et al.*, 1994a, 1994b, 1999). The capsid consists of 90 dimers of a single capsid protein of 58 K molecular weight (monomer), which are arranged in such a way that large hollows are seen at the fivefold and threefold axes. These give the appearance of cup-like structures by EM. Each dimer forms a basal shell (S) domain. This is joined by a flexible hinge to a protruding (P) domain, which is further subdivided into subunits P1 and P2. NoVs recognize human histo-bloodgroup antigens (HBGAs) as receptors (Huang *et al.*, 2005). Human HBGAs are complex glycans found on the surface of red blood cells, on gastrointestinal and respiratory epithelia, and in saliva, milk and intestinal contents. The receptor binding site of the GII-4 strains of NoVs has been mapped to the outermost end of the P domain and forms an extensive hydrogen-bonding network with the saccharide ligand (Cao *et al.*, 2007).

The calicivirus genome consists of single-stranded RNA of positive polarity and approximately 7.7 kb size. The single-stranded RNAs are polyadenylated and have a length of between 7.3 and 7.7 kb (Figure 15.3). The genome composition of the SaVs bears a greater similarity to those of several animal caliciviruses than to human NoVs (Liu *et al.*, 1995; Matson *et al.*, 1995). This justifies their classification as a separate genus. All calicivirus genomes have three open reading frames (ORFs); ORF1 encoding nonstructural proteins, P48, NTPase, P22, VPg, 3CL^{pro} and an RNA-dependent RNA polymerase (RdRp); ORF2 encoding the viral capsid protein (VP1); and ORF3 at the 3' end of the genome encoding a small protein (VP2) of as yet unknown function (Hardy, 2005) (Figure 15.3; Table 15.1). There is a major difference between the genomes of NoVs and SaV; for SaV the ORF2 is in the same reading frame as ORF1 and is thus contiguous with the RdRP gene. For NoV, ORF1 and 2 overlap by a few nucleotides, with a -2 frameshift for ORF2 (Clarke and Lambden, 2001; Liu *et al.*, 1995).

Classification

NoVs and SaVs constitute two of the four genera of the *Caliciviridae* family (the other two being *Vesivirus* and *Lagovirus*, infecting animals). Sequence comparison has allowed the division of human NoVs into two, and

possibly three, genogroups, each containing multiple genetic clusters (Wang *et al.*, 2005; Zheng *et al.*, 2006). A bovine calicivirus (Jena virus) is closely related to genogroup I NoV (Liu *et al.*, 1999), whilst a porcine enteric calicivirus (PEC) is related to SaVs (Vinjé *et al.*, 2000a). Human SaVs are divided into five genogroups, each containing between one and four genotypes (Galimore *et al.*, 2006a). The classification of the *Caliciviridae* family is continually being updated as a result of the mutability of the calicivirus genome, which results from the accumulation of point mutations and genetic recombination.

Replication

As there is no *in vitro* monolayer cell-culture system available for human caliciviruses, their replication has been deduced from that of animal caliciviruses which have a similar genome organization and can be propagated in cell cultures. Feline calicivirus grows in CRFK cells, and an infectious cDNA clone has been constructed (Sosnovtsev and Green, 1995). From this it appears that caliciviruses interact with species-specific receptors. Proteins deduced from ORF1 may arise from appropriate co- and post-translational cleavage of a polyprotein precursor, in a way similar to the cleavage cascade identified for picornaviruses (Estes *et al.*, 1997). Murine NoV type 1 infects macrophage-like cells *in vivo* and replicates in cultured primary dendritic cells and macrophages, and therefore provides important tools, both *in vivo* and *in vitro*, for the investigation of NoV pathogenesis, replication and immunity (Wobus *et al.*, 2004). An infectious cDNA clone of the murine NoV has recently been obtained, allowing a detailed characterization of the viral replication cycle (Ward *et al.*, 2007). Straub *et al.* (2007) reported the culture of human NoV in a highly differentiated 3D cell-culture model of human small-intestinal epithelium. Guix *et al.* (2007) demonstrated that transfection of NoV RNA into human hepatoma cells led to the expression of viral antigens and viral replication, with release of viral particles into the cell-culture medium. Prior treatment of the RNA with proteinase K abolished protein expression after transfection, suggesting that there may be an important role, in infectivity and NoV genome expression, for the covalent linkage of RNA to a virus protein, similar to the role of VPg as a primer for RNA polymerase in picornavirus replication. Transfection of NoV RNA into cultured human hepatoma cells, bypassing receptor binding, internalization and uncoating, results in replication of the viral RNA and the release of virus particles. This contrasts with an inability to infect these cells conventionally, even in the presence of the glycans suspected to be involved in virus attachment. This suggests that attachment is not sufficient to lead to a productive

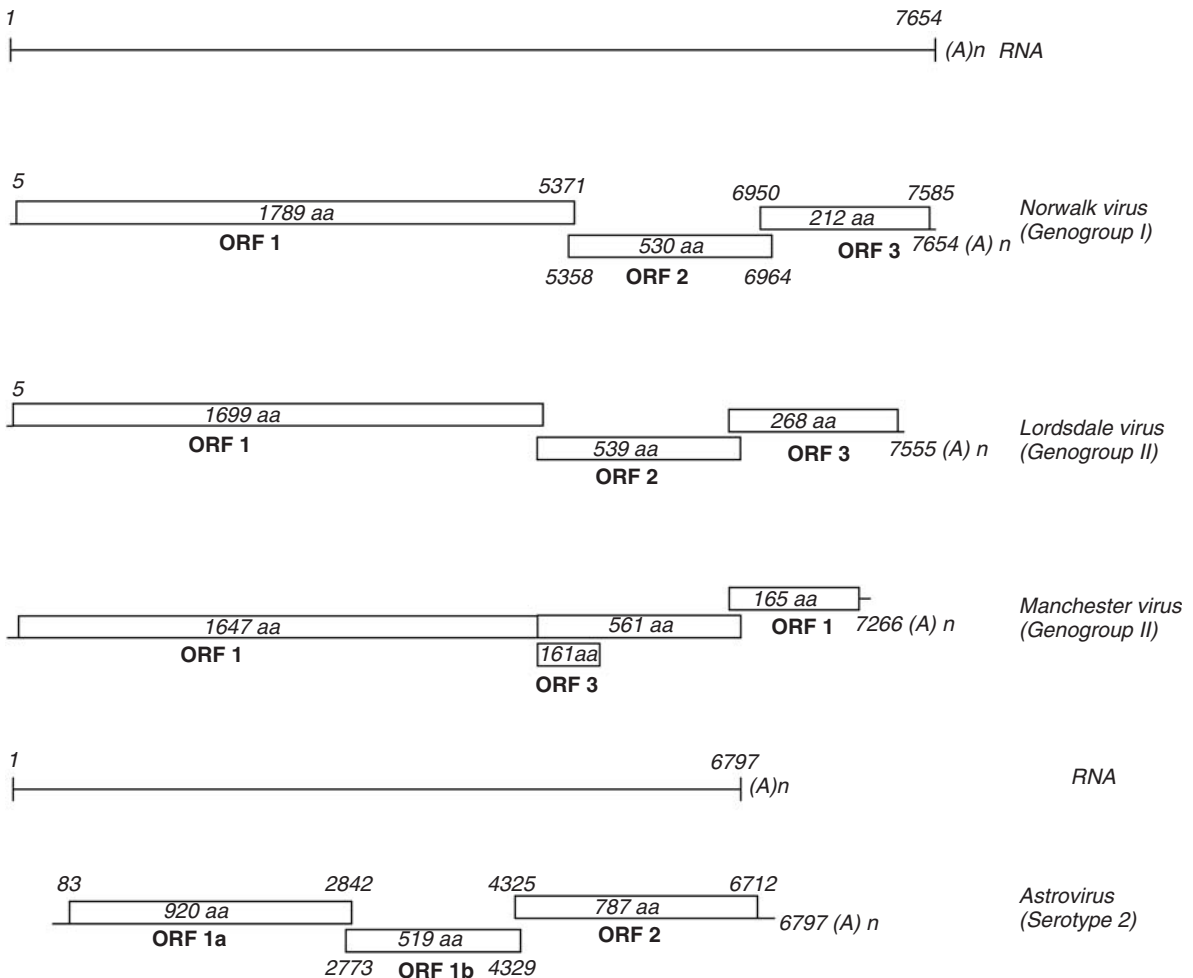

Figure 15.3 Genome organization of Norwalk virus (a norovirus of genogroup I), Lordsdale virus (a norovirus of genogroup II), Manchester virus (a sapovirus) and astrovirus (serotype 2). For nomenclature of noroviruses see Table 15.2. ORF, open reading frame; aa, amino acids; (A)_n, poly(A) tail of RNA. (Source: Estes *et al.*, 1997, slightly modified.)

infection and that other factors are required for entry and uncoating (Guix *et al.*, 2007).

Pathogenesis

The incubation period ranges from 10 to 50 hours, and diarrhoea lasts 24–48 hours. Ileum biopsies from ill volunteers showed that a symptomatic illness correlated with blunting of intestinal villi, crypt hyperplasia, cytoplasmic vacuolization and lymphocytic infiltration of the lamina propria. Small-intestinal brush border enzymes are decreased, and malabsorption and diarrhoea with abdominal cramps, nausea and vomiting result (Green, 2007).

Laboratory Diagnosis

This is mainly by direct EM or IEM, by ELISA (Gray *et al.*, 2007) or by RT-PCR assays (Ando *et al.*, 1995; Moe *et al.*, 1994). For the latter to be successful, broadly reactive primers must be available in order to detect most of the human caliciviruses. Initial use of such primers looked promising (Green *et al.*, 1995). Vinjé *et al.* (2000b) have developed primers with which 90% of outbreaks initially diagnosed by EM could be detected. NoV nucleotide sequence data, accumulated over time, indicate that the most conserved region of the NoV genome is the ORF1/ORF2 junction. Broadly reactive and highly sensitive genogroup-specific real-time quantitative

Table 15.1 Norovirus protein structure and function

Protein	Structural or nonstructural	Function
P48	Nonstructural	May disrupt intracellular protein trafficking
NTPase	Nonstructural	NTPase activity
P22	Nonstructural	May localize replication complexes
VPg	Nonstructural	May recruit translation machinery
3CL ^{pro}	Nonstructural	Protease activity
RdRp	Nonstructural	RNA-dependent RNA polymerase
VP1	Structural	Capsid protein

RT-PCRs have been developed and are used extensively for the detection of NoVs in clinical samples (Kageyama *et al.*, 2003). These techniques have also been applied to detecting caliciviruses in shellfish and other foodstuffs (Atmar *et al.*, 1996; Lees *et al.*, 1995), and on environmental surfaces (Gallimore *et al.*, 2006) from which human infections may originate.

Immune Responses

The immune responses against human calicivirus infections have been examined in adult volunteer studies, using IEM and more recently ELISAs with recombinant antigens. However, volunteers are generally young adults who will have been infected with caliciviruses in childhood and have measurable pre-existing antibodies before challenge. It has not been determined if antibodies are neutralizing, as animal- and cell-culture models do not exist. Interestingly, more than 50% of adult volunteers appear to be susceptible to infection upon challenge (Graham *et al.*, 1994; Gray *et al.*, 1994; Johnson *et al.*, 1990; Parrino *et al.*, 1977).

Volunteer studies have shown that pre-existing NoV-reactive antibodies do not protect from re-infection in the longer run; on the contrary, higher pre-existing antibody levels seem to condition for more severe illness upon re-infection (Gray *et al.*, 1994; Parrino *et al.*, 1977). Some volunteers who fell ill after initial NoV challenge had developed immunity when rechallenged 6–14 weeks later (Parrino *et al.*, 1977). Cellular and humoral immune responses and infection were determined by examining pre- and post-challenge responses in volunteers aged

between 21 and 54 years of age who were challenged with a GII-2 (Snow Mountain) strain of NoV (Lindesmith *et al.*, 2005). Nine of fifteen volunteers were infected, and immune responses were characterized by a ≥ 4 -fold increase in serum immunoglobulin and by significant increases, on day 2 post-challenge, of serum IFN- γ and interleukin-2 (IL-2). No increases in concentrations of IL-6 or IL-10 were detected. PBMCs stimulated with NoV VLPs secreted IFN- γ . Antibody and cellular immune responses were cross-reactive within genogroup but not between genogroups (Lindesmith *et al.*, 2005).

Clinical Course

The clinical symptoms were documented in a study of 50 volunteers and were as follows: 82% (41) became infected, 68% symptomatically and 32% asymptotically. Most common symptoms were nausea, headache and abdominal cramps followed by diarrhoea and vomiting. Severe symptoms lasted for only 12–48 hours (Graham *et al.*, 1994). Persistent infection with caliciviruses and other viruses associated with chronic diarrhoea has been found in children with severe combined immunodeficiency (SCID) (Chrystie *et al.*, 1982) and in patients with acquired immune deficiency syndrome (AIDS) (Grohmann *et al.*, 1993).

Epidemiology

The availability of recombinant proteins expressed from cloned cDNAs has allowed the study of age-dependent antibody prevalence in both developed and developing countries. Epidemic gastroenteritis produced by caliciviruses is relatively mild. There is likely to be a large number of inapparent infections in early childhood, as it has been shown that 50% of three-year-old children already have NoV-specific antibodies, a number that increases to 80% in early adulthood (Gray *et al.*, 1993) (Figure 15.4). In less-developed countries, NoV-specific antibodies are produced after primary infection even earlier in life. In general, children appear to be infected with caliciviruses much more frequently than was recognized previously (Gray *et al.*, 1993; Numata *et al.*, 1994). Two distinct seroepidemiological patterns have been described for SaVs. The first pattern is characterized by high antibody prevalence at birth, reflecting the presence of maternal antibody, followed by a fall in prevalence during the first four months of age, and then a steady increase reaching a prevalence of 100% by the age of four years (Nakata *et al.*, 1988). The second pattern is one of low antibody prevalence in the first three months after birth, followed by a steady increase reaching a prevalence of 80–90% by the age of two to five years. The antibody

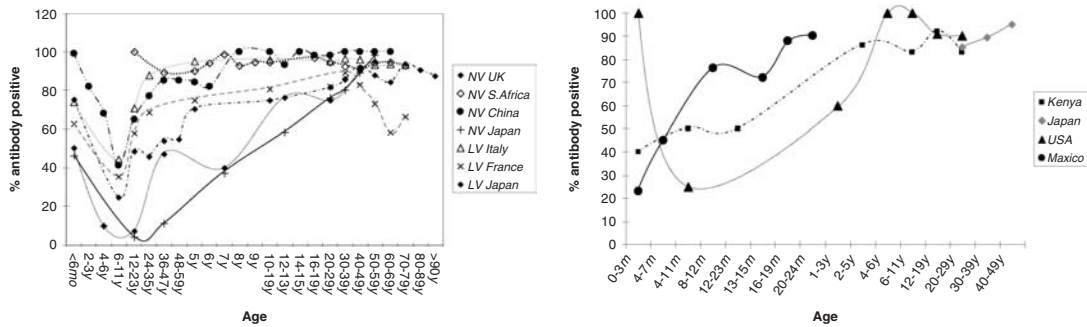

Figure 15.4 Age-related seroprevalence of antibody to (a) norovirus and (b) sapovirus in different countries. NV, Norwalk virus (GI-1); LV, Lordsdale virus (GII-4); MV, Mexico virus (GII-3) (Farkas *et al.*, 2006; Honma *et al.*, 1998; Jing *et al.*, 2000; Nakata *et al.*, 1985, 1988, 1998; Nicollier-Jamot *et al.*, 2003; Numata *et al.*, 1994; Pelosi *et al.*, 1999; Smit *et al.*, 1999).

prevalence in women of childbearing age in these populations is ~90%, but this is apparently not transferred as maternal antibody to offspring in their early months of life (Farkas *et al.*, 2006; Nakata *et al.*, 1998); this phenomenon requires further study.

Outbreaks of acute gastroenteritis that can be related to food or waterborne sources occur frequently in recreational camps, hospitals, schools, cruise ships, nursing homes and so on. (Hedlund *et al.*, 2000; Inouye *et al.*, 2000; Nakata *et al.*, 2000) and are associated with the ingestion of contaminated drinking or recreational water, uncooked shellfish, eggs, salads and cold foods. Mixed infections with caliciviruses of different genogroups have been observed (Gray *et al.*, 1997) and, as a consequence of this, genome recombination was found to occur (Jiang *et al.*, 1999; Phan *et al.*, 2007; Vinjé *et al.*, 2000b). Worldwide, outbreaks occur year round, and nosocomial infections with caliciviruses are common. The viruses are highly infectious and have been found to spread rapidly in volunteer studies. The primary and secondary attack rates are high (above 50%). Transmission is by the faeco-oral route and by projectile vomiting producing an aerosol which scatters these viruses in the environment (Caul, 1994). Viral shedding does not normally persist beyond 100 hours after the initial infection, but can be prolonged for up to two weeks. Shedding has also been detected by RT-PCR in samples collected from volunteers who remained well (Okhuysen *et al.*, 1995).

Diversity and Evolution

Diversity among NoVs is maintained through the accumulation of point mutations associated with the error-prone nature of viral RNA replication and genetic recombination upon dual infection of a single cell (Phan *et al.*, 2007).

The genomic diversity among human NoVs is characterized by three genogroups (GI, GII and GIV), and multiple genetic clusters within genogroups have been described. Genetic lineages made up of variants form the clusters. NoV variants may be associated with epidemics. Between 2002 and 2006, at least six variants (v1–v6) of the GII-4 NoV strain circulated worldwide, and v2 and v4 were responsible for global epidemics of gastroenteritis in 2002 and 2006, respectively (Gallimore *et al.*, 2007).

Host Genetic Resistance to NoV Infection

Carbohydrates of membrane glycoproteins or glycolipids are often associated with virus attachment to cell membranes. The H types 1, 2 or 3 and Lewis^b (Le^b) carbohydrate structures are HBGAs. These antigens are synthesized by the sequential addition of monosaccharides to precursor oligosaccharides that constitute the peripheral region of the glycolipids, as well as of O- and N-linked glycans of glycoproteins. The expression of α 1,2-linked fructose residues on surface epithelial cells of the gut and in body fluids is dependent upon the presence of a wild-type FUT2 allele (secretor gene). The trisaccharide Fuc α 2Gal β 3GlcNAc (H type 1) is recognized by NoV VLPs derived from GI-1 (NV), as are H type 3 and Le^b (Huang *et al.*, 2005) (see above). These oligosaccharides have an α 1, 2-linked fructose in common and are present in the gut on the surface of epithelial cells (Le Pendu *et al.*, 2006).

Although nonsecretors (FUT2^{-/-}), who represent 20% of the European population, are resistant to infection with the majority of NoV strains, and individuals of the B blood group (4–20%) are partly resistant, they are likely to be susceptible to strains that recognize the B blood group antigen or target the Lewis antigens under the control of the FUT3 gene (Tan and Jiang, 2005).

Prevention

The most efficient methods of prevention are measures of good hygiene (hand washing, disinfection and disposal of contaminated faeces and material, hygienic processing of food, withdrawal from work of ill food handlers, etc.) and sometimes closure of facilities (hospitals, nurseries, etc.). A vaccine seems possible, for example derived from VLPs (Jiang *et al.*, 1992) or from transgenic plants ('edible vaccines'; Mason *et al.*, 1996, 2002), but a better understanding of the significance of antibody responses for protective immunity, the duration of protection and the impact of short-term herd immunity is required. Prophylactic surveillance of key personnel in hospitals or food production (including keeping people with vomiting and loose stools off work) and of water sources helps to reduce calicivirus-induced outbreaks.

ASTROVIRUSES

Astroviruses are members of the family *Astroviridae* (Monroe *et al.*, 1993; Fauquet *et al.*, 2005). Virions possess a genome of single-stranded RNA of positive polarity and no envelope, like the *Picornaviridae* and *Caliciviridae* (Mendez and Arias, 2007).

Structure and Genome

Morphologically, astroviruses are 28–30 nm particles with typical five- or six-pointed star patterns on their surface, and sometimes also knob-like structures (Figure 15.1).

The astrovirus genome of approximately 6.8–7.2 kb comprises three ORFs (1a, 1b and 2), coding for a viral protease (ORF1a), an RNA-dependent RNA polymerase (ORF1b) and structural proteins (ORF2) (Willcocks *et al.*, 1994) (Figure 15.3). There is a 70 base overlap in ORFs 1a and 1b, containing sequences directing ribosomal frameshifting (to a –1 frame) for the reading of ORF1b (Brierley and Vidakovic, 2003; Lewis and Matsui, 1994, 1996; Marczinke *et al.*, 1994).

Classification

By 1995, seven serotypes had been distinguished by solid-phase IEM and had been confirmed as different genotypes (Noel *et al.*, 1995). Recently, a genotype 8, which may have arisen through intragenotypic astrovirus recombination, has been identified. Although rare overall, it has had relatively high incidences in Egypt and Spain (Belliot, *et al.*, 1997; Guix *et al.*, 2002; Naficy *et al.*, 2000).

Replication

Astroviruses grow well in human embryonic kidney, monkey kidney or human colon carcinoma cell cultures in the presence of trypsin (Lee and Kurtz, 1981). In all human astroviruses an RGD integrin recognition motif is found in the ORF2, and although experimental data is still lacking, it is postulated that integrin recognition plays a key role in astrovirus cell attachment (van Hemert *et al.*, 2007). After adsorption to and uncoating in cells, astroviruses produce full-length and subgenomic RNAs, the former leading to translation of ORF1a and ORF1a–1b fusion proteins, and the latter directing the production of the ORF2 protein precursor (Geigenmüller *et al.*, 2002, 2003). As mentioned above, the viral RNA polymerase is translated from ORF1b by –1 ribosomal frameshifting at an efficiency of approximately 5%.

Transfection of naked full-length genome RNA of human astrovirus type 1 was shown to lead to the production of infectious virus, allowing a reverse genetics system to be set up from cDNA (Geigenmüller *et al.*, 1997).

Pathogenesis

This is mainly deduced from studies of *in vitro* infected cells and of experimental animals. Adsorption occurs through a cellular receptor, and replication takes place in the cytoplasm. Animals infected with species-specific astroviruses (lambs, calves) show infection of mature enterocytes (at the tip of the villi) of the small intestine at 14–38 hours post infection, and diarrhoea is observed on days 2–4 (Mendez and Arias, 2007).

Clinical Course, Diagnosis, Treatment and Prevention

Clinically, astrovirus disease is similar to that caused by rotaviruses, although often milder.

Diagnosis is by EM, IEM (typing), astrovirus-specific ELISA (detecting all seven types; Herrmann *et al.*, 1990) and generic and type-specific RT-PCR (Noel *et al.*, 1995).

Treatment is symptomatic, and prevention in outbreaks consists of measures to interrupt person-to-person spread (good hygiene, disinfection, surveillance of food sources, etc.). At present, there is no specific antiviral treatment and no vaccine.

Epidemiology

Astroviruses are found in humans, lambs, calves, deer, piglets, mice, dogs and ducks, causing diarrhoea in most cases except for ducks, in which they cause acute hepatitis. Astroviruses are very species-specific. Human astrovirus infections are seen in infants and the elderly as endemic infections and occasionally as the cause of foodborne outbreaks of diarrhoea. The seasonal incidence

Table 15.2 Incidence of astrovirus serotypes in Oxford, UK, 1976–1992, and prevalence of astrovirus type-specific neutralizing antibodies in the Netherlands, 1994–1996

^bFrom Koopmans *et al.* (1998). For astrovirus type 8 see text.

peak is in the winter. Transmission is via the faeco-oral route, person-to-person contact and possibly fomites. The incidence of astrovirus infections in hospital-based and community studies has mostly been $\leq 5\%$ and 1–9% of viral causes of diarrhoea, respectively, but much higher incidence figures ($>10\%$) were recorded in Guatemala and Thailand. The incidence of different serotypes was determined from a collection of isolates in Oxford, UK (Lee and Kurtz, 1994) and has been complemented by an age-stratified study of the prevalence of neutralizing astrovirus antibodies in Utrecht, the Netherlands (Koopmans *et al.*, 1998) (Table 15.2). According to this, serotype 1 is most frequently found, followed by serotypes 2–4 at medium and serotypes 5–7 at low frequencies. The seroprevalence figures suggest that individuals can become infected by more than one serotype. Astrovirus infection is frequent in childhood (often inapparent), and 75% of 10-year-old children have astrovirus antibodies (Koopmans *et al.*, 1998). A high percentage (15%) of cases of diarrhoea in HIV-infected individuals are due to astrovirus infection (Grohmann *et al.*, 1993). Large foodborne outbreaks of astrovirus gastroenteritis have been recorded (Matsui *et al.*, 1994; Mitchell *et al.*, 1995; Oishi *et al.*, 1994).

Cocirculation of multiple astrovirus serotypes was shown by several groups in different locations (Cunliffe *et al.*, 1998; Monroe *et al.*, 2001; Mustafa *et al.*, 2000; Naficy *et al.*, 2000; Noel *et al.*, 1995). The different types cluster in two genogroups (A: types 1–5; B: types 6 and 7; Belliot *et al.*, 1997).

Although enteric astroviruses have been isolated from animals (Koci *et al.*, 2000) there is so far no firm indication that human astroviruses may have arisen from an animal reservoir.

GASTROINTESTINAL VIRUSES NOT REGULARLY ASSOCIATED WITH ACUTE DIARRHOEAL DISEASE

Details of the virology, immunology, diagnosis, clinical symptoms and epidemiology of these viruses are found in other chapters.

Enteroviruses and Parechoviruses

Enteroviruses (polioviruses, coxsackie viruses and echoviruses) and human parechoviruses (HPeVs 1 and 2)—all members of a genus of the *Picornaviridae*—infect humans via the alimentary tract, where they have their first site of replication (lymphoid tissues of the pharynx and the gut). Virus is usually excreted in the stool for several to many weeks and can also be isolated with ease from the pharynx during the first two weeks of infection. Most infections are asymptomatic. The main disease foci are the central nervous system (CNS) (spinal cord, brain, meninges), heart (myocardium and pericardium), skeletal muscles and skin. These are reached after a viraemic phase originating from the gut (Racaniello, 2007).

Diarrhoea is not a regular symptom of primary infection. Some echoviruses (notably types 4, 11, 14, 18, 19 and 22) as well as Coxsackie virus A1 have been documented as associated with outbreaks of diarrhoea (Patel *et al.*, 1985; Townsend *et al.*, 1982), but a consistent association has not been established. The clinical symptoms associated with HPeV1 and 2 infection are predominantly gastrointestinal and respiratory, with fewer CNS symptoms (Ehrnst and Eriksson, 1993).

Aichi virus, a member of the genus *Kobuvirus* of the family *Picornaviridae* (Yamashita *et al.*, 1998), was first isolated in BSC1 (African green monkey kidney) cells from a patient with oyster-associated gastroenteritis in Aichi, Japan. The name *Kobuvirus* is derived from the characteristic morphology of the ~ 30 nm diameter virus particle ('*kobu*' meaning 'bump' in Japanese). The virus has been found to be a consistent cause of sporadic cases and outbreaks of human gastroenteritis in Japan (Yamashita *et al.*, 1991, 1993). It has been a cause of traveller's diarrhoea in South East Asia (Yamashita *et al.*, 1995) and more recently also in Europe and South America (Oh *et al.*, 2006). Symptoms include diarrhoea, abdominal pain, nausea, vomiting and fever with abdominal pain, nausea and fever predominating (Yamashita *et al.*, 2001). The prevalence of neutralizing antibodies to Aichi virus increases significantly with age, from 7.2% in children under 5 years of age to 83.3–87.0% in adults of more than 35 years of age (Yamashita *et al.*, 1993).

Reoviruses

Reovirus, like *Rotavirus* a genus of the *Reoviridae* family, also primarily infects the gut via M cells and has its first round of replication in the Peyer's patches. From there reoviruses are carried in a viraemic step (or by retrograde transport along autonomous nerves) to the CNS, where they have their main disease targets in neuronal or ependymal cells. Reovirus pathogenesis has been studied in detail in mice, and particular pathogenetic factors have been associated with particular gene products (Tyler and Fields, 1996). Reovirus distribution is worldwide and can infect a variety of species, including baboons, bats, birds, cattle, humans, monkeys, sheep, snakes and swine.

At the end of human childhood, antibodies against all three serotypes of reovirus are found, suggesting past infection. No firm association of reovirus infection with any distinct human disease has so far been established, although reoviruses are not infrequently seen in the gut; an association with mild diarrhoea has been suggested (Tyler and Fields, 1996).

Coronaviruses and Toroviruses

These two genera of the *Coronaviridae* (Enjuanes *et al.*, 2000) cause respiratory and gastrointestinal infections in humans. Toroviruses, a well-established cause of diarrhoea in calves (Koopmans and Horzinek, 1994) and of asymptomatic infection in horses, were found to be associated with acute and possibly persistent diarrhoea in children (Koopmans *et al.*, 1997; Waters *et al.*, 2000).

CoVs are a recognized major cause of the common cold in man (Lai *et al.*, 2007). They cause gastroenteritis in animals (Kim *et al.*, 2001) and were found to be associated with cases of human diarrhoea (Gerna *et al.*, 1985). CoV-like particles were also seen in symptomless healthy subjects (Marshall *et al.*, 1989). The true significance of CoV infection for human enteric disease remains to be established (Lai *et al.*, 2007; Siddell *et al.*, 2007; Zhang *et al.*, 1994).

Disease associated with SARS-CoV is biphasic, including a prodromal influenza-like period characterized by myalgia, malaise, chills and fever, followed by the onset of respiratory and gastrointestinal symptoms. The epithelial cells of the mucosa of both the small and large intestines have been shown to be infected with the SARS-CoV, which is consistent with reports of viral shedding in stool samples (Guo *et al.*, 2008). The ability of the SARS-CoV to target cells of the immune system results in targeting of Peyer's patches, with a resulting decrease in both CD20-positive B cells and CD3-positive T cells and excessive atrophy of submucosal lymphoid tissue (Guo *et al.*, 2008).

Parvoviruses

These viruses are well-known pathogens associated with diarrhoea in animals. However, in humans no firm association with diarrhoea has been made, although parvovirus-like particles are not infrequently observed by EM as 'small round viruses' in human faeces.

Human bocavirus (HBoV), a recently-described new virus species belonging to the *Parvoviridae* family, was identified through molecular screening of respiratory tract samples (Allander *et al.*, 2005) and reported to be associated with upper- and lower-respiratory-tract infections (Bastien *et al.*, 2007). More recently, the spectrum of disease associated with HBoV infection has been widened to include gastroenteritis (Lee *et al.*, 2007). HBoV was detected in the stools of 9.1% of subjects in a study of Spanish children with acute gastroenteritis (Vicente *et al.*, 2007). Similarly, HBoV was detected in 2.1% of 1435 samples of faeces collected from children with fever and watery diarrhoea in Hong Kong (Lau *et al.*, 2007). In the absence of case-control studies it has yet to be determined to what extent HBoV is a respiratory and/or enteric pathogen.

Human Immunodeficiency Virus

The clinical virology of this member of the *Retroviridae* family (subfamily *Lentivirinae*) is extensively discussed elsewhere in this book. Here it should be mentioned that there is evidence for primary HIV infection in gut-associated lymphoid tissue and in enterocytes, which may contribute to an enteropathy with chronic diarrhoea in AIDS patients (Aziz *et al.*, 2005; Heise *et al.*, 1991; Kotler *et al.*, 1991; Levinson and Bennets, 1985; Nelson *et al.*, 1988; Rabeneck, 1994).

Cytomegalovirus and Herpes Simplex Virus

These two members of the *Herpesviridae* family are frequent co-infectants/superinfectants in the gut of HIV-infected individuals, causing mainly chronic colitis (Dieterich and Rahmin, 1991; Levinson and Bennets, 1985), but also oesophagitis, gastritis and cholangitis (Theise *et al.*, 1991). There may be interaction between HIV and CMV infections in causing gut disease (Skolnik *et al.*, 1988). With the introduction of highly active antiretroviral therapy (HAART) in 1996, it has become less urgent to initiate or maintain a specific anti-CMV therapy with ganciclovir (Pollok, 2001; Whitcup *et al.*, 1999).

Picobirnaviruses

These bisegmented dsRNA viruses of approximately 35–41 nm in diameter and icosahedral structure were

found in the gut of rats, guinea pigs, pigs and calves, and to be associated with cases of diarrhoea, although not regularly. Recently, besides astroviruses, caliciviruses and adenoviruses, picobirnaviruses were found to be significantly associated with diarrhoea in AIDS patients in case-control studies (Giordano *et al.*, 1999; Grohmann *et al.*, 1993). Similar dsRNA viruses have been demonstrated to infect *Cryptosporidium* spp. but there is little sequence identity between them and the typical picobirnaviruses (Wang and Wang, 1991; Xiao *et al.*, 2001). Reagents derived from the genomic sequence (Rosen *et al.*, 2000) will allow us to unravel the epidemiology of human and related picobirnaviruses. As the picobirnaviruses are much smaller than birnaviruses (infecting exclusively animals) and differ largely from birnaviruses in their nucleotide sequence (Wakuda *et al.*, 2005) and particle structure (F. Rey, personal communication), the proposal to classify them in a separate family, *Picobirnaviridae*, seems to be justified.

INTRODUCTION

Although occasionally occurring as sporadic infections, influenza is more commonly and dramatically seen as local outbreaks or widespread epidemics of respiratory illness; these occur in most parts of the world, in most years (Figure 16.1). Epidemics can be traced anecdotally from the fifth century BC, the Hundred Years War and the court of Mary Tudor, to the more exact records of the last century. Unfortunately, knowledge gained in the last 70 years since isolation and characterization of the influenza virus has done little to prevent epidemics; it is not surprising, therefore, that influenza has been referred to as the 'last plague of mankind'. Epidemics can arise at any time but are usually concentrated in months of high relative humidity; outbreaks occur explosively, often with little or no warning, and the number of people infected can vary from a few hundreds to many hundreds of thousands, causing societal disruption. In addition, history records some nine occasions since 1700 AD when influenza has caused pandemics, and at these times millions were infected. In many years epidemics are short-lived, lasting days or weeks; however, pandemics can continue in successive waves for several months. It is the large number of persons infected during an outbreak of influenza, together with our inability to predict outbreaks, which has focused so much attention on this disease.

Influenza is a short-lived but relatively severe respiratory infection in healthy adults. Individual infection can be life-threatening to the elderly and to those with pre-existing heart, chest or metabolic disease, and infection may result in increased susceptibility to other infectious diseases. Depression and behavioural complications occasionally continue for months after the acute phase

of illness has passed. The seasonal or epidemic nature of influenza is less marked in tropical countries, and the burden of illness much less well defined.

Since the first isolation of an influenza virus in ferrets in 1933, there has been intensive research into the nature and control of the disease. Commissioning of an international network of communicating laboratories, the Global Influenza Surveillance Network (GISN), by the World Health Organization (WHO) to monitor the gradual changes in circulating viruses, occurred in recognition that coordinated global effort is needed to sustain virus-tracking activities (Kitler *et al.*, 2000). Nevertheless, despite intensive scientific and surveillance efforts, many fundamental questions concerning the nature of virus evolution and pathogenicity remain unanswered. Influenza A viruses have a wide host range; this together with a high rate of replication and a segmented viral genome, which allows for genetic reassortment and a mobile global animal reservoir, means that there is a continuing threat of the emergence and adaptation of a new influenza A virus to the human host.

Virus Structure

The influenza A, B and C viruses belong to the genus *Influenzavirus* in the family *Orthomyxoviridae*, within the negative-sense RNA virus order *Mononegavirales*. Influenza viruses grow on embryonated eggs or mammalian cell culture, and when examined in the electron microscope they are seen as approximately spherical particles with a diameter of 80–120 nm. After serial passage in the laboratory, some strains produce filamentous particles, and pleomorphic forms are not uncommon (Stuart-Harris *et al.*, 1985). The electron-microscopic appearance of

influenza virus particles is shown in Figure 16.2a, and a schematic diagram of a viral particle is shown in Figure 16.2b.

Each virus particle is composed of approximately 1% RNA, 70–75% protein, 20–24% lipid and 5–8% carbohydrate. Structurally, the virus consists of a single-strand RNA of negative polarity (Lamb and Krug, 1996) and relative molecular mass (M_r) $4 \times 10^6 - 6 \times 10^6$ segmented into fragments; the M_r s of the fragments range from 3×10^5 to 1×10^6 . The viral RNA is closely associated with the nucleoprotein (NP) to form the ribonucleoprotein (RNP), a helical structure termed the nucleocapsid; the NP has an M_r of approximately 60×10^6 , and there are approximately 1000 molecules in each virus particle. The NP is a type-specific antigen. It occurs in one of three antigenic forms, which provide the basis for the classification of influenza viruses into types A, B and C.

Surrounding the nucleocapsid of influenza A is a second protein referred to as the matrix protein (M1) which contributes 35–45% of the mass of the virus particle. The M_r of the M1 protein is 23×10^6 , and there are approximately 3000 molecules in each virus particle. A second M protein, termed M2 and coded by the same segment as the M1 protein, is important in virus replication; there are relatively few copies of M2 present in each virus particle, 14–68 molecules, which are inserted into the viral membrane external to the M1 protein; this is a lipid bilayer derived from the host cell which constitutes approximately 20–24% of the virus.

Two virus glycoproteins are inserted into the membrane; these are rod-shaped structures projecting out from the virus particle to give the spiky appearance of the surface (Figure 16.2a and b). The first of these glycoproteins is the haemagglutinin (HA), which is composed of two separate fragments, termed HA1 and HA2, joined together by a disulphide bond (Skehel *et al.*, 1984). The complete HA molecule is composed of a trimer of these subunits, each of M_r $75-80 \times 10^6$, and 20% carbohydrate, to give a total M_r of approximately 225×10^6 . There are approximately 1000 HA molecules on each virus particle; each HA particle is 14–16 nm in length and 4 nm in diameter, and is inserted in the lipid membrane by a hydrophobic tip. The HA forms 25–30% of the protein of the virus. The function of the HA is the attachment of the virus to the surface of host cells during the initial stages of virus infection; the HA also attaches to receptors on erythrocytes, causing haemagglutination, a property which forms the basis of several *in vitro* tests for the detection of virus and virus-induced antibody. The subtype classification of influenza A viruses is based on the different antigenic forms of the HA molecule, H1–H16.

The second glycoprotein extending from the surface of the virus particle is the neuraminidase (NA). There are 100–200 NA molecules on the surface of each virus particle; they are 10 nm long and 4 nm in diameter, and composed of four identical subunits, each of M_r approximately 60×10^6 , and an unknown amount of carbohydrate; these structures account for some 7% of the total viral protein. The NA molecules are attached to the viral membrane by a

stalk terminating in a hydrophobic tip; the complete structure has a mushroom appearance (Laver *et al.*, 1984) and a total M_r of approximately $200\text{--}250 \times 10^6$. Suggested functions of the NA include the removal of sialic acid residues from cell surfaces to promote virus absorption, and the removal of virus receptors on the infected cell surface, to facilitate release of newly-formed virus particles (Colman, 1998). The NA glycoprotein is antigenically variable, and differences are used in the subtype classification of the viruses: N1–N9.

Influenza virus particles also contain an RNA-dependent RNA polymerase complex; this consists of three proteins, termed polymerase basic protein 1 (PB1), polymerase basic protein 2 (PB2) and polymerase acid (PA) protein; the M_r s vary (range $80\text{--}90 \times 10^6$) and there are approximately 50 molecules of each species in each virus particle, which are closely associated with the nucleocapsid. These proteins have a complex role in virus-specific RNA synthesis during virus replication. A recent finding is the presence of a second small

nonstructural protein in infected cells synthesized from the PB1 gene, termed PB1-F2, which appears to have a mitochondrial localization and a role in the induction of cell death (Chen *et al.*, 2001). Viral RNA codes for two further nonstructural proteins, termed NS1 and NS2. These are expressed in infected cells; NS1 is synthesized early after infection, while NS2, now termed nuclear export protein (NEP), appears late and is found in virus particles (Paragas *et al.*, 2001). These viral proteins are multifunctional and have roles in RNA binding and interaction with host-cell responses (reviewed by Palese, 2005).

Most studies on the structure of influenza virus particles have been carried out on influenza A viruses; however, sufficient work has been done with influenza B viruses to suggest general similarity in size, composition and structure. Some differences in the genetic organization of influenza B have been found, most notably in the coding arrangements for the accessory protein BM2, and the presence of NB protein coded on gene 6, which does not have a homologue in influenza A viruses. The significance of these differences for virus natural history and epidemiology is not known. The influenza B virus also differs from influenza A viruses by the presence of an antigenically-distinct NP, and this, together with the antigenic specificity of other virus proteins, underlies differences in epidemiological behaviour. Antigenic variants occur less frequently, there are no antigenic subtypes or animal reservoirs for influenza B, and epidemics tend to occur less frequently than do influenza A epidemics. As a result, children tend to be older when experiencing their first influenza B infection.

The size, composition and structure of influenza C viruses are similar to those of influenza A; the main difference is an antigenically-distinct NP, and the presence of a Haemagglutinin-Esterase protein, which combines the function of the HA and NA of influenza A and B, with a different substrate specificity of 9-*O*-acetyl-*N*-acetylneuraminic acid (Rogers *et al.*, 1986). These differences characterize a virus which has clinical and epidemiological properties distinct from those of both influenza viruses A and B, since it causes a much milder illness.

Host Range

Influenza B and C are viruses of humans, with very few reports of sporadic infections occurring in nonhuman mammalian hosts (seals, pigs and dogs). In contrast, influenza A viruses are primarily viruses of avian water-based birds, with all subtypes H1–H16 and N1–N9 being found in this natural reservoir in a variety of H and N combinations (Figure 16.3). Restricted subtype combinations have established and adapted to mammalian hosts (humans: H1N1, H3N2; pigs: H1N1, H3N2; and horses: H3N8, H7N7). However, there is enormous potential for zoonotic infection of humans with different subtypes, either from pigs or avians, and for cross-species transmission from water birds to aquatic mammals which share an ecological niche (seals and whales); from water birds to gallinaceous birds (domestic poultry), which may in turn infect mammalian hosts such as felines (cats and tigers), canines (mink) or humans; from horses to dogs (Figure 16.4); and from humans to susceptible animals,

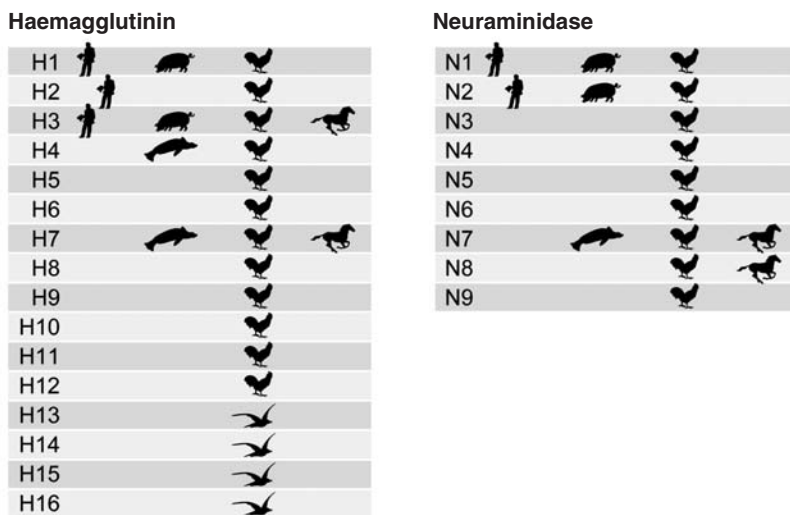

Figure 16.3 HA and NA subtype distribution in different animal species.

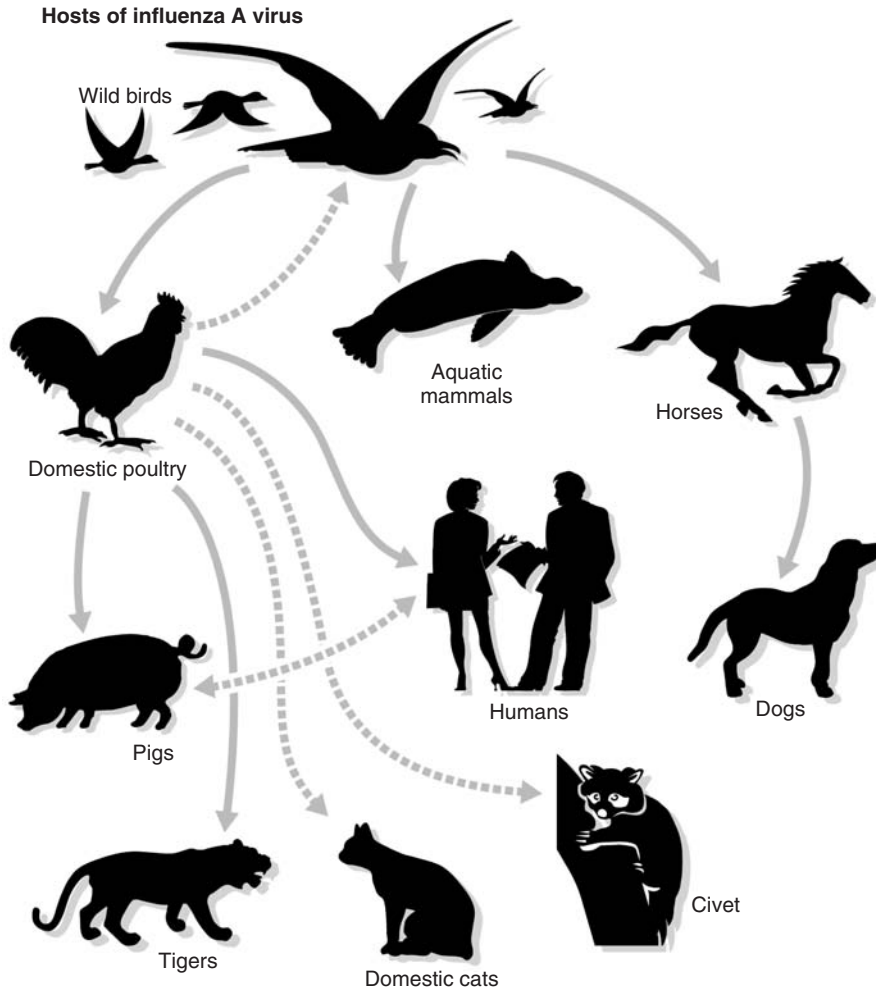

Figure 16.4 The ecology of influenza A. Dotted lines represent routes of transmission which are less well documented.

as in the original identification of influenza virus from a ferret infected by a human.

Replication

Most studies on the replication of influenza viruses have been carried out using influenza A strains, but the limited studies with influenza B virus have not indicated major differences in the mechanism of replication of this virus type. When an influenza A virus is inoculated on to cell cultures, there are three possible outcomes. First, the virus may fail to initiate infection, commonly because the cells do not possess the receptor essential for virus binding to cells. Second, the virus may undergo an incomplete growth cycle, known as abortive infection; this occurs in a variety of cell lines, including HeLa cells, L cells

and human diploid fibroblast cells. There is no accepted explanation for abortive replication, but because of a block at some stage of the normal replication cycle large numbers of virus particles are produced which are deficient in RNA content and are non-infective. Abortive infection is also seen when excessive amounts of virus are inoculated on to permissive cells, such as amniotic cells of the embryonated hen's egg, where the effect is described as the Von Magnus phenomenon. Third, infection may be permissive and result in the production of infectious virus; the various stages of replication are shown in Figure 16.5.

Receptor Binding

Permissive infection by influenza virus occurs in a range of cultured mammalian cells; typically dog, baboon and

Figure 16.5 Schematic diagram of influenza A or B replication.

monkey kidney are preferred cell lines, as well as other continuous cell lines of human origin. These generally require that trypsin is added to the medium, since proteolytic cleavage of the HA into HA1 and HA2 by host enzymes is essential for virus infectivity and multicycle replication. Cells lining the amniotic and allantoic cavities of the embryonated hen's egg also support viral replication. Infection is initiated by adsorption of the virus to the cell surface. Adsorption requires the interaction of two molecules; these are the sialic acid-containing receptors on the surface of the cell, and the virus HA. Some 28 species of sialic acid receptors, together with sugar chains, are known (Suzuki *et al.*, 2001), and the specificity is important as there is selective binding of both avian and human strains to different sialic acid residues. Avian strains preferentially bind to $\alpha 2,3$ sialic acid, and human strains preferentially bind to $\alpha 2,6$ linked sialic acid (Rogers *et al.*, 1983) (Figure 16.6); neither preference is absolute, although receptor characteristics are important in determining virus–host range (Matrosovich *et al.*, 1997). Pathogenicity is also affected by genetic determinants. Some viruses can cross species barriers via other receptors (Stray *et al.*, 2000). The role of HA in virus binding is demonstrated in studies which show inhibition of virus binding with antibody to HA. Viral adsorption to cells provokes receptor-mediated endocytosis of virus particles via clathrin-coated pits, which can be seen by electron microscopy to appear approximately 20 minutes after infection. Virus internalization is followed by fusion of the viral envelope with endosomal membranes, a procedure

which requires the acidic environment at pH 5.0–6.0 in the endosomes, and the separate availability of HA1 and HA2 fragments of HA to allow insertion of the viral membrane into that of the host membranes. An acidic environment within the virus particle is achieved via the M2 protein in the virus membrane, which acts as an ion channel to allow hydrogen (H^+) ions into the virion. The low pH also frees the M1 protein from RNP, thus allowing the 'uncoated' RNA complex to migrate to the cell nucleus (Wang *et al.*, 1997).

Nucleic Acid Replication

The events of virus replication in the cell nucleus are complex and remain to be fully understood (Lamb and Krug, 1996). Information to date suggests that transcription of the messenger ribonucleic acid (mRNA) from all RNA fragments takes place immediately after entry into the cell nucleus. Initially, similar amounts of each mRNA are produced; however, this is followed by a regulatory phase in which the synthesis of mRNA coding for the NP and the NS1 predominate; it is clear that mRNA synthesis is regulated at all stages, and that this regulation is controlled by virus proteins, particularly P proteins NP and NS1 (Portela *et al.*, 1999). Synthesis of mRNA involves, sequentially, cap recognition and binding, endonuclease activity, initiation and then elongation, to produce an mRNA species which is a shorter and polyadenylated complementary copy of virion(v) RNA. First, the polymerase complex binds to a methylated-cap structure present on heterologous, cellular RNA; this cap recognition is a function

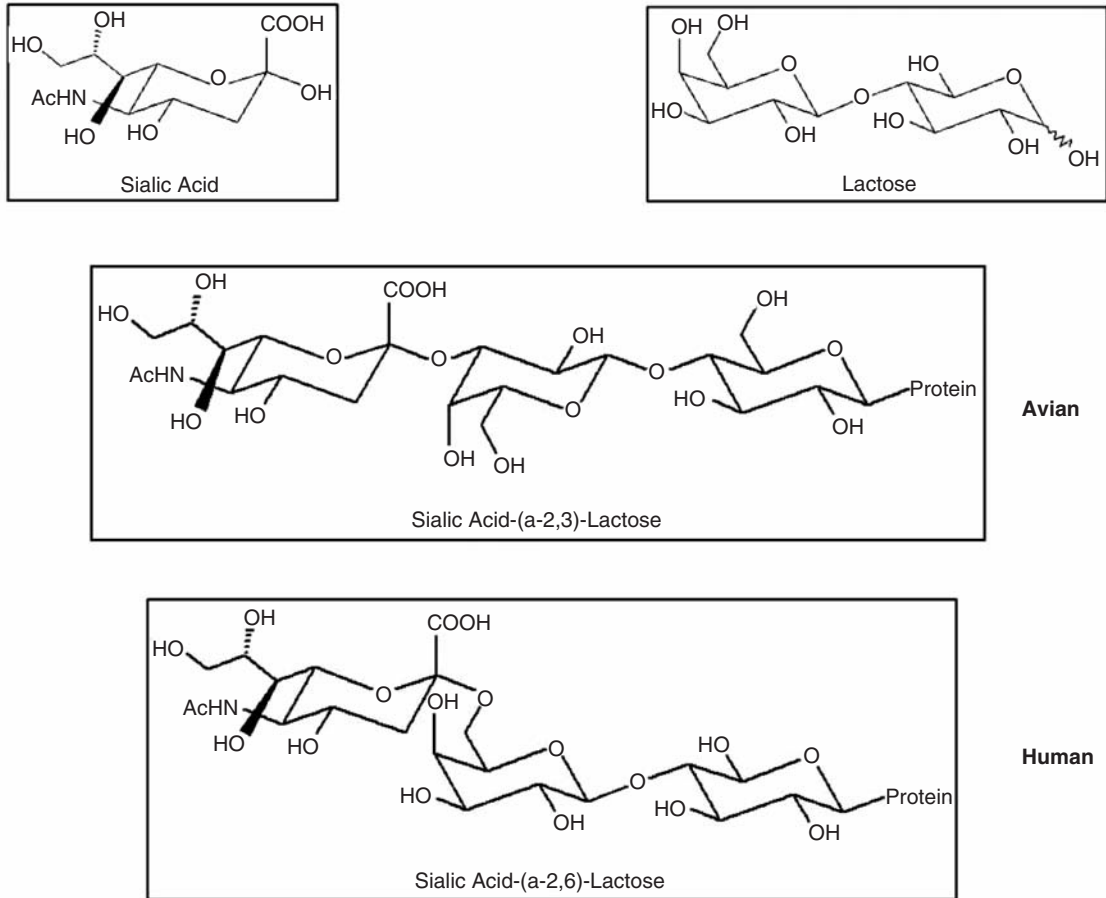

Figure 16.6 Linkage of sialic acid receptors for avian and human influenza viruses.

of PB2 protein. Second, a nucleotide sequence of 10–30 bases is cleaved from the cap structure by endonuclease activity, termed ‘cap snatching’. This structure forms the starter molecule for viral mRNA synthesis; it has been suggested that this cleavage is one of the functions of PB1 or PB2 proteins (Blok *et al.*, 1996). The cap sequence incorporates a G complementary to the penultimate C of the vRNA to complete the initiation step, and this is a function of the PB1 protein. Finally, elongation takes place to produce complete mRNAs; this step requires binding to NP, and elongation is thought to be controlled by the PA protein. Cap snatching from the host RNA requires active host RNA synthesis, and virus replication is dependent on this process; for this reason, inhibitors such as α -amanitin inhibit influenza virus replication.

Although interaction occurs between PB1 and PB2, and PB1 and PA, no direct interaction between PB2 and PA has been demonstrated to date; the exact role of these interactions in viral replication remains to be determined.

The mRNAs leave the cell nucleus and bind ribosomes, and translation of viral proteins is initiated.

The synthesis of a complementary, full-length, positive-sense RNA replication intermediate (A^- RNA), which is neither capped nor polyadenylated and does not require primer initiation and then subsequent production of negative-sense progeny virion(v) RNA, occurs after the time of peak production of mRNA and protein synthesis. Full-length vRNAs are produced in approximately equimolar amounts throughout infection, and are synthesized in the infected cell nucleus. The process requires the RNA polymerase to switch to a replicase mode and requires NP function, although how this is carried out is poorly understood. The time sequence for the appearance of the various viral proteins has been studied extensively: the presence of NP can be detected approximately two hours after virus infection, and the concentration rises to a maximum at five to six hours; the NP1 protein appears five hours after infection,

and has been identified in the cytoplasm and, to a lesser extent, the nucleus of infected cells; the HA and NA appear approximately four hours after infection.

The processes described above interfere with normal host-cell functions; specifically, there is a preferential synthesis of viral components at the expense of host-cell components. One of the chief mediators of the above is the NS1 protein, which is one of the most abundantly produced proteins synthesized in infected cells (Liu *et al.*, 1997). The NS1 protein inhibits the processing of cellular RNA by a number of mechanisms; the result of this is the cessation of cellular gene expression, and in particular their nuclear export. An important consequence of the activity of NS1 is to antagonize interferon production and thus interfere with the cellular response to virus infection (García-Sastre, 2001); indeed, this may be the most important role of NS1, since it is not essential for viral replication, as seen in studies in which NS1 mutants replicate in interferon-negative cells. Alteration of NS1 may be an important means of attenuating viruses for vaccine purposes

Virus Assembly

Assembly of new virions within infected cells begins with the binding of NP to newly-synthesized vRNAs to form RNP (Elton *et al.*, 1999). RNPs exit the nucleus in association with M1 and NEP proteins, and at the cell membrane they are enclosed by an envelope which contains HA, NA and M2 proteins; it is proposed that the M1 protein is the major driving force in this process (Gómez-Puertas *et al.*, 2000). Virus escapes by budding from lipid rafts in the plasma membrane; the process of virus release is detectable as early as five to six hours after infection, and is maximal seven to eight hours after infection. An important element in this process is believed

to be the NA, which prevents aggregation of virus at the host membrane by hydrolysis of sialic acid residues from the viral envelope at the cell membrane.

VIRAL VARIATION

Historical Aspects

Annual epidemics of influenza are associated with attack rates of 5–30% of the population, a significant increase in rates of hospitalization and death, predominantly among elderly and the very young. Nine pandemics have been recorded since 1700, which began at a focal point and spread rapidly through the world to infect hundreds of millions of individuals (Figure 16.7). Accurate documentation of pandemics was first seen in the 1889–1892 pandemic, which spread from Russia into Europe and the United States; infection presented as an upper-respiratory-tract infection of sudden onset and short duration; the total number of cases was high; and deaths were most numerous amongst infants and the elderly, but occurred in a relatively small percentage (0.05%) of the 25–30% of the world population infected. The pandemic 1918–1920 is known as the Spanish influenza. This pandemic spread worldwide for some six to eight months, and gave rise to an infection of unusual virulence which commonly caused a severe pneumonia; some 40–50 million deaths occurred, principally among young adults (Potter, 1998). The effects of the pandemic caused international panic. The number of deaths recorded is probably only a fraction of the true number: many countries did not record figures. India was said to have lost a generation, and 1.5 million deaths occurred in sub-Saharan Africa. The propaganda surrounding the World War of

Figure 16.7 Schematic of influenza pandemic, based on historical accounts from 1700. Gives years of pandemics, estimated numbers of deaths in each pandemic and causal virus. NK, not known.

1914–1918 undermined the accuracy of data from Europe, and the Bolshevik revolution in Russia resulted in ignorance of the effects of the pandemic in that country (Crosby, 1976).

The definition of a pandemic of influenza is an outbreak of infection arising in a specific geographical region, spreading worldwide and infecting a high percentage of people. A pandemic is caused by a strain of influenza virus which could not have arisen by mutation from strains previously circulating. The influenza outbreaks of 1932–1933 and 1947–1948 were caused by viruses related to each other and to the virus that caused the pandemic of 1918–1920; thus, by the above definition, the widespread outbreaks of 1932 and 1947 were not pandemics. However, a pandemic did occur in 1957, which originated in China and spread throughout the world, infecting 40–50% of people and causing over 1 million deaths, mainly in the elderly population; however, fatalities among the younger victims were more conspicuous in the early months of the epidemic than later, and this is of note in other pandemics (Simonsen *et al.*, 1998). Pandemic infection occurred again in 1968, and the event was similar to that of 1957 (Figure 16.7). Pandemic infection broke out in 1976, due to an influenza virus very closely related to a virus strain which disappeared in 1947. This pandemic was therefore limited to the young,

since many persons born before 1947 had retained immunity to infection. Prior to 1976, the appearance of a new pandemic virus had been accompanied by the disappearance of the virus subtype previously causing infections in man; however, from 1976 the old and new subtypes co-circulated, and this continues to the present day (Figure 16.8).

No discernible pattern for predicting pandemics can be seen; however, the largest gap between pandemics over the last 150 years has been 40 years. In conclusion, the historical record of influenza indicates almost annual occurrences of epidemics, punctuated at intervals of 10–40 years by pandemics: there is little evidence to suggest that this situation will not continue into the future (Potter, 2001).

Antigenic Shift

Since 1933, the viruses which cause pandemic and epidemic outbreaks have been isolated and compared. Viruses isolated from patients infected in the epidemic years 1933–1946 and 1947–1956 show wide variations, but antiserum from ferrets experimentally infected with these viruses show serological cross-reactivity. Sequence data confirmed that the two groups of virus, represented by A/PR/8/34 and A/FM/1/47, were related and belonged

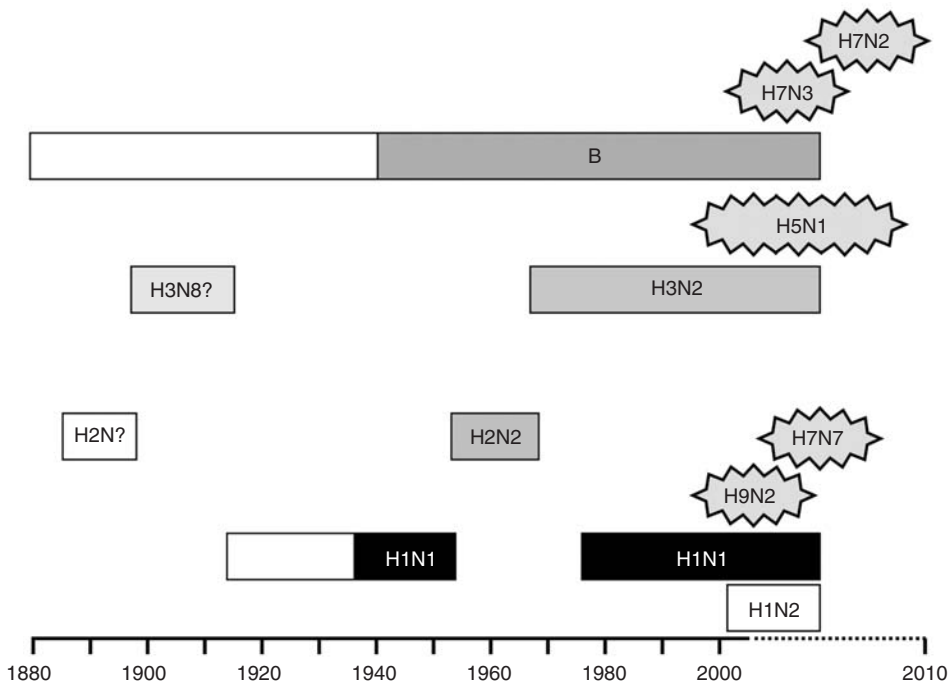

Figure 16.8 Circulation of influenza types and subtypes in humans since 1900. The jagged symbols represent limited transmission of avian viruses to humans.

to the H1 subtype. RNA sequences recovered and amplified by the polymerase chain reaction (PCR) from post-mortem lung tissue from two US soldiers who died in 1918 also confirmed that the Spanish influenza pandemic was caused by an influenza A (H1N1) virus (Taubenberger *et al.*, 1997). In contrast, the virus subtypes which emerged to cause the pandemics of 1957 and 1968 were unrelated to each other or to the H1N1 subtype, and could not have arisen by mutation from the preceding subtypes. This demonstrates that when pandemic infections are recorded, new influenza virus subtypes have emerged in a population that has no immunity; a phenomenon known as antigenic shift. The historical pattern for pandemic influenza is for a new virus subtype to emerge and spread rapidly, causing explosive outbreaks in many countries. Population immunity to the new subtype is built up over a period of years, and further outbreaks are more limited. However, after 10–40 years a new virus subtype emerges, with an HA which does not cross-react with antibody generated to the HA of the previous virus subtype, and to which the population is therefore largely susceptible. This initiates a new cycle of influenza pandemic and subsequent epidemics. Sudden changes in antigenicity can also occur in the virus NA molecule, although the impact is not as great as a change in the HA.

Although the HA antigens of different influenza A virus subtypes show no cross-reactivity in serological haemagglutination inhibition (HI) tests (Table 16.1), a degree of heterosubtypic immunity may exist, as evidenced in the phenomenon known as ‘original antigenic sin’, first reported by Francis *et al.* (1953). This term describes the observation that infection by an influenza virus induces antibody to the other virus subtypes that the individual has been infected with previously; indeed, the titre of antibody to the earlier-infected subtype can be several-fold greater than to the current infecting virus. This is probably due to B memory cells, which persist after infection, being stimulated by new virus serotype,

and suggests a relatedness in the HA antigens of different virus serotypes not detected in HI and other serological tests.

The importance of antigenic shift in producing new antigenic subtypes which spread to cause pandemic infection is evident, but despite some 100 years of intensive research, the origin of pandemic viruses is uncertain. The most widely held theory for the origin of human pandemic influenza viruses is that new virus subtypes are reassortant viruses arising during double infection of a single host. As influenza A viruses have a wide host range, dual infection with mammalian-adapted and animal virus in a species permissive for replication of both could result in a reassortant virus with surface antigen(s) from the nonhuman virus and other genes from a mammalian-adapted virus. Reassortant viruses can be produced experimentally from human and animal parents and may occur naturally. Viruses with segments derived from humans, pigs and avians have emerged to cause disease in pigs in North America since 2000 (Webby *et al.*, 2004). This, together with the emergence and spread of H1N2 derived from circulating human H1N1 and H3N2 (Gregory *et al.*, 2002), indicates that reassortment does occur both between species and within species. Close studies of avian species in South East Asia confirms the enormous genetic diversity which can be generated through segment exchanges within aquatic and land-based birds (Webby *et al.*, 2007). It has been suggested that reassortment of the whole HA molecule from an avian influenza virus into a new pandemic strain is not essential, and that only some of the sequences from avian virus may be necessary to produce an HA of radically different antigenic form, although there is no evidence to support this so far. Influenza B viruses do not occur in animals and do not exhibit antigenic shift; this is also indirect evidence for reassortment as the mechanism for the emergence of new influenza A virus subtypes.

Table 16.1 Antigenic shift in the haemagglutinin of influenza A viruses

Virus subtype	Virus strain	Serum HI antibody titre to influenza virus ^a			
		A/PR/8/34	A/FM/1/47	A/Sing/1/57	A/HK/1/68
H1N1	A/South Carolina/1/18	NK	NK	NK	NK

H3N2	A/HK/1/68	<10	<10	<10	1280

NK, not known; <10, limit of detection of HI antibody.

^aInfluenza A viruses grown in eggs were tested in HI tests with antisera from ferret infected intranasally with live virus and bled three to four weeks later. The serum HI antibody titre against eight HA units of virus is listed. The titres in bold represent reactivity of a virus with homologous antisera.

The pandemics in the years 1889, 1900, 1918, 1957, 1968 and 1976 were due to influenza A virus subtypes H2, H3, H1, H2, H3 and H1, respectively (Figure 16.7). Thus of the 16 HA types identified in nature, only influenza viruses A (H1, H2 and H3) have caused human pandemics; and over the observation period of approximately 100 years, they have occurred sequentially. From these observations it has been suggested that only these subtypes can cause pandemics and that they exist cryptically in nature, and can emerge when the antibody state of the population has fallen to levels which allow pandemics to occur. Although serological studies have detected the presence of antibodies to influenza virus A (H3), which was first seen in 1968 in serum from aged persons collected before the pandemic, no reservoir for the virus in humans before this date has been found. The evidence supporting this theory remains fragile.

Concern about the emergence of the next pandemic has been demonstrated by the epizootic of influenza A (H5N1) virus infection in chickens in South East Asia, which first came to attention in 1997. Zoonotic infection of 18 humans was associated with 6 case fatalities (de Jong *et al.*, 1997). Although stringent control measures involving chicken slaughter and improved hygiene suppressed further human infections for a few years, Hong Kong experienced further human cases in 2003, with H5N1 viruses which had evolved significantly from those seen in 1997 (Shinya *et al.*, 2005). Since this time there has been infection of humans with H5N1 in at least 10 countries in South East Asia, Europe and the Middle East through direct exposure to poultry or wild birds, with a case fatality of approximately 50%. Zoonotic infections with influenza H7, H9 and H10 emphasize the necessity for concern with respect to the continuing pandemic threat posed by viruses in an animal reservoir with close proximity to humans, leading to intensified surveillance in humans and animals, and heightened preparedness for a potential pandemic (WHO, www.who.int/csr/disease/avian_influenza/ai_timeline/en/index.html).

Antigenic Drift

When the viruses of the same subtype from various epidemic seasons between pandemics are compared in cross-HI tests, they exhibit strain differences. Although all viruses belong to the same subtype they are not identical; these changes are termed 'antigenic drift'. Table 16.2 shows the major HA variants found in viruses isolated in 1968–1979. All belong to the H3N2 subtype associated with the epidemic of 1968. A/HK/1/68 virus reacts most strongly with homologous antiserum, and cross-reactions are seen with other viruses in the series; the degree of cross-reactivity decreases as the time difference increases. Similar drift can be seen in the strains isolated from 1979 to the present day (not shown). The practical effects of antigenic drift are that infection by one strain may induce some cross-reactive antibody and partial immunity to viruses of the same subtype, but as time passes and virus diversity increases, this immunity is likely to be less and less effective. In this way viruses alter from year to year, giving rise to new strains that cause fresh epidemics.

It is considered that virus variants occurring naturally by mutation are selected by antibody pressure in an immune or partially-immune population. New viruses are not neutralized completely by antibody to pre-existing virus strains, and are therefore capable of causing new epidemics. Virus strains with antigenic changes detected by serology and biochemical techniques can be recovered by growth in low concentration of antibody. Antigenic drift also occurs in the NA antigen. Epidemics due to new virus strains exhibiting antigenic drift do not have such a great clinical impact as those due to viruses showing antigenic shifts, since partial immunity is present due to previous infection. Antigenic drift has been shown for influenza subtypes H1, H2 and H3, and also for influenza B, and is widely accepted to account for the inter-pandemic seasonal outbreaks. Recent work on the global circulation of H3N2 viruses examined the emergence of new antigenic drift strains, and indicated

the importance of particular global regions in South East Asia as the source of new antigenic-drift variants (Russell *et al.*, 2008)

VIRUS CLASSIFICATION

The antigenic differences of the HA and NA antigens of influenza A viruses provide the basis of their classification into subtypes. This classification is of practical importance as the antigenic differences are critical for the understanding of virus epidemiology and for vaccine production. At the present time the agreed classification is shown in Table 16.3. Previously, the results of serology studies suggested that the HA of the influenza virus strain which affects swine, termed H_{sw}, was similar to that which caused the pandemic of 1918–1920, and this has been confirmed by sequence data from the two viruses. Strains occurring in the years 1933–1948 were classified as a subtype termed HO, and those occurring in 1947–1957 were termed H1. Recent studies have shown that the HA of all these viruses are related, and the classification shown in Table 16.3 groups these viruses into a single subtype, termed H1. The HA of human subtype H3 cross-reacts with the HA of equine influenza virus Heq2 and avian influenza virus Hav7, and these three are now grouped together into a single subtype, H3. Further subtype classification shown in Table 16.3 gives the new and old designations. Recent structural studies on the virus HA have refined the understanding of subtype classification and indicated some structural features distinguishing subtypes (Ha *et al.*, 2002).

Antigenic differences also occur in the NA antigen of the influenza A viruses. The antigenic form designated N1 is found in all human influenza A viruses isolated prior to 1957, and the form designated N2 has been found in all human isolates recovered since that time. Strains having the N1 NA recurred in 1976, and have persisted since that date. The other antigenic variants of the NA occur in viruses isolated from birds and horses (Figure 16.3).

Using the above classification it is possible to describe any influenza virus in terms of its subtype specification. Every influenza virus is referred to as A or B, followed consecutively by the place of isolation, the laboratory number and the year of isolation. Following this designation, the subtype designation is given in parenthesis. Thus, influenza virus A/Hong Kong/1/68 (H3N2) signifies an influenza A virus isolated from a patient in Hong Kong in 1968, and of subtype H3N2. Within any subtype as described above, a number of strains can occur as a result of antigenic drift, and these are important in epidemiology and in vaccine design, since antibody against one strain does not completely neutralize viruses of other strains; thus, minor variations need to be identified and, where necessary, alterations to vaccine composition made accordingly. Virus strains of different subtype can be distinguished by a variety of tests, including serological tests using homologous and heterologous polyclonal and monoclonal sera, and genetic analysis focussing on the genes for viral HA and NA. In this way, large numbers of differing strains are identified and distinguished within any one influenza A subtype. Tracking the antigenic drift which gives rise to strain variation is of crucial importance in influenza research and surveillance.

PATHOGENESIS

Evaluation of disease spectrum and case fatality in different pandemics and epidemics demonstrates that there are significant differences in disease severity caused by different influenza virus strains, most notably the severity of 1918 influenza, and more recently the high case fatality caused by H5N1 zoonotic infection in man. Unusual disease syndromes may also occur in certain populations, for example the high rates of influenza-associated

encephalopathy seen in Japan, which indicate the potential for contribution of host factors in infection outcome.

There is no agreed explanation for the pathogenesis of human influenza. However, historical and virological investigations have broadly defined the effects of virus infection. Infection is the result of inhaling respiratory droplets from infected persons; these droplets containing virus are deposited on the mucus blanket lining the respiratory tract (Figure 16.9a and b). Much virus is destroyed by nonspecific immune barriers, such as mucus binding,

which is functional at this site, or inactivated by natural inhibitors containing sialic acid present in serum or mucosal fluids, which can bind virus HA and competitively inhibit virus binding to cells (Matrosovich and Klenk, 2002). However, some virus escapes these inhibitors, release from mucus being assisted by the action of virus NA allowing attachment by the virus HA to receptors on the cells of the respiratory epithelium; epithelial cells of both the upper and lower respiratory airways are rich in sialic acid receptors. Following viral attachment, replication proceeds; virus can be isolated following acute infection from 1 to 7 days, with peak titres usually occurring at 48–72 hours after the onset of symptoms. Histological studies on nasal exudate cells and tracheal biopsies have indicated that the major site of virus infection is the ciliated columnar epithelial cells. Following infection, these cells become progressively rounded and swollen, and the nucleus appears shrunken and pyknotic; the cytoplasm becomes vacuolated, the nucleus degenerates and ciliation is lost, and eventually cells slough off their basement membranes.

The progression of changes in the cells of the respiratory epithelium suggests the tracheal bronchial epithelium is an early site of infection. Thus, early lesions in the tracheobronchial mucosa have been described in uncomplicated influenza, clinically evident as bronchitis and tracheitis; the tissues show increased permeability of vascular capillary walls, oedema, polymorphonuclear infiltration and phagocytosis of degenerate epithelial cells. The basement membrane is not affected.

Because of the generalized symptoms present in uncomplicated seasonal human influenza, viraemic spread from the respiratory tract has been suggested. Influenza has been associated with electrocardiogram (ECG) and electroencephalogram (EEG) changes; some unconfirmed reports of virus antigen in brain and heart have been recorded; and influenza has been temporally associated with cases of virus encephalitis, particularly among children. However, demonstration of viraemia has not been conclusive; blood samples from children infected with influenza were not found to contain virus when tested by PCR (Mori *et al.*, 1997). In addition, the failure to prove viraemia at least in some cases leaves unexplained the myalgia and malaise which are commonly seen in influenza, and the sudden and marked temperature rise which follows infection. Clearer understanding of the relationship of innate immune response to infection, and of viral gene expression, are likely to provide explanations of these host responses to infection.

Zoonotic Infections

Zoonotic influenza infections with nonhuman subtypes of influenza A demonstrate a different disease spectrum and

pathogenicity profile (Table 16.4). H5N1 infections are associated with a disseminated viral infection, with virus being recovered from a number of anatomical sites, including brain and gastrointestinal (GI) tract, with evidence of viraemia (Beigel *et al.*, 2005; de Jong *et al.*, 2005). Infection is thought to initiate lower in the respiratory tract, as a consequence of the receptor preference of avian influenza strains for $\alpha 2,3$ sialic acid receptors, which occur much more frequently in cells of the lower airway, giving rise to an initial lower-respiratory-tract infection or pneumonia (Shinya *et al.*, 2006). Limited autopsy evidence from cases of H5N1 is consistent with respiratory failure and interstitial pneumonia, but also evidence of multisystem failure. Whilst there is some evidence of extra-respiratory spread of virus in a few cases, this may not account for all the pathogenic features. Immune dysregulation is considered an important contributor to pathogenesis as there is autopsy evidence for haemophagocytic syndrome (reviewed by Gambotto *et al.*, 2008; To *et al.*, 2001). H7 infections are particularly associated with unilateral or bilateral conjunctivitis, which is not commonly seen in seasonal influenza or H5N1 infections

Animal Models

One of the key differences between highly-pathogenic and low-pathogenic strains in an avian host is the restriction of replication to cells of the avian GI tract in a low-pathogenic strain. Disseminated infection is a hallmark of high-pathogenicity avian influenza infection, with a wide range of tissues supporting viral replication. Pathogenesis studies of avian influenza viruses in avian hosts clearly identify molecular determinants of virulence being directly associated with the cleavability of the HA into HA1 and HA2. H5 and H7 subtypes of influenza exist in highly-pathogenic and low-pathogenic forms, the difference between these strains being the amino acids present at the cleavage site between HA1 and HA2. The highly-pathogenic forms of avian influenza contain a series of basic amino acids, usually generated through insertional mutation at the carboxyl terminal of HA1. These basic amino acids increase the size of a protein loop in the stalk region of the HA protein, making the site more accessible to a wider range of host proteolytic enzymes, enhancing the ability of the virus to replicate in a wider range of tissues (Steinhauer, 1999) (Figure 16.10).

Molecular determinants of pathogenicity in an avian host may play a role in mammalian hosts, but may not be necessary or sufficient to account for high pathogenicity in a mammalian host. The 1918 influenza is known to have high virulence for humans. This virus lacks a polybasic HA cleavage site, yet retains virulence in ferret and monkey models. Additional virulence determinants in viral

Table 16.4 Zoonotic infections with influenza A

Subtype and country	Spectrum of illness	Case no.	Fatality

genes are likely to include mutations in viral nonstructural genes and genes associated with viral replication, implicated in adaptation to mammalian hosts. The entire sequence of influenza viruses has been known since the late 1970s, but the molecular basis of virulence in mammalian hosts is still not understood. It is not known why encephalitis syndromes occur at high frequency following influenza infection in children in Japan (Morishima *et al.*, 2002), why H5N1 viruses are associated with such lethal

infection in humans and animals, or why unusual clusters of fatalities accompany occasional drift variants of human influenza (Bhat *et al.*, 2005). Linking viral gene analysis with analysis of host response to infection should be a final step towards understanding influenza pathogenesis in humans and eventually determining predictive markers for clinical outcome and therapeutic intervention. Consideration of zoonotic influenza infection requires a broader diagnostic approach, looking at different body fluids

including blood and faeces, and samples from lower in the respiratory tract. The ability to analyse viruses recovered from different compartments offers a tantalizing prospect of looking in detail at 'within host' variation, and what clues this may yield for better understanding of pathogenesis.

CLINICAL FEATURES

Uncomplicated Infection

Influenza has been described as an unchanging disease due to a changing virus, and this description underlines the relative constancy of the clinical presentation of the infection. Detailed analysis of the symptoms seen in the groups of patients studied in the years 1937–1941, 1947 and 1957 indicate some differences in the relative incidence of some symptoms; however, these are probably due to the variable recording of different observers. Although the clinical presentation of uncomplicated influenza in any one age group is generally agreed (Figure 16.11), variation in the incidence of certain symptoms does occur for different ages; vomiting and convulsions are rarely seen except in infants; croup is more a feature of infection in young children; sore throats and myalgia are seen more commonly in adults.

Following droplet infection from infected individuals, the incubation period is approximately 48 hours, but may vary from 24 to 96 hours; the variation may depend on the size of the infecting dose. The onset of the illness is

usually abrupt, and many patients can pinpoint the hour of onset. The symptoms in adults commonly include a marked fever, headache, photophobia, shivering, a dry cough, malaise, aching muscles and a dry tickling throat or other features of laryngeal irritation, which can lead to the voice becoming husky and even lost. The fever is usually continuous and classically lasts three days, at which point the temperature falls and the symptoms abate (Gentile *et al.*, 1998; Hayden *et al.*, 1998) (Figure 16.12). In a percentage of cases, a second fever spike may occur after this time; it will be smaller than the first one but will give the common biphasic fever curve. Of the acute symptoms listed, the cough may persist for several days; the eyes are often watery, burning and painful in movement; the nose can be blocked or may have a purulent discharge; cervical adenopathy is unusual but has been described; and myalgia is more severe in the leg muscles, but also may involve the extremities. Although the infection usually resolves within seven days, listlessness and depression are common residual complaints.

Studies of the clinical illness resulting from infection by influenza B virus show close similarity to that caused by influenza A virus. Some authors have suggested that influenza B infections are milder than those caused by influenza A, with less myalgia and higher incidence of nasal symptoms, and differences have been reported in the incidence of sweating and other symptoms; however, these differences are small. In contrast, influenza C infection is generally accepted as a relatively mild respiratory infection of young children and a mild upper-respiratory-tract infection of adults that is rarely diagnosed.

Figure 16.11 Symptoms and signs of seasonal and avian influenza based on Fig 19, Nicholson (1998), and Beigel *et al.* (2005). Overall incidence and highest and lowest incidence of symptoms recorded during several studies of individuals with virologically-confirmed seasonal influenza A or H5 avian influenza.

Gentile *et al.*, 1998

Figure 16.12 Relationship between virus shedding and systemic and nasal symptoms of influenza A H1N1. (Source: Gentile *et al.*, 1998, with permission.) Dark line represents virus shedding.

Tracheobronchitis and Bronchitis

All series of patients studied have included a small proportion in which the respiratory symptoms were more severe. These patients have a productive cough, chest tightness and substernal soreness. Rales and rhonchi are commonly heard but the lungs are radiologically clear. These symptoms are most commonly seen in patients with chronic obstructive bronchitis and in older persons, and it is evident that age and chronic pulmonary disease predispose to severe bronchitis, which can result in death.

Pneumonia

Pneumonia in patients with influenza virus infection can be primary viral pneumonia or secondary bacterial infection. In viral pneumonia, patients develop persistent fever with leukocytosis, dyspnoea, hypoxia and cyanosis following the acute symptoms described above. Sputum specimens will show no clear bacteriological cause, and a proportion of these patients will die of diffuse haemorrhagic pneumonia. Autopsies show congested, dark-red lungs, and the mucosa of the trachea and bronchi will be hyperaemic. Microscopic examination of lungs section has consistently revealed tracheitis and bronchiolitis with

haemorrhage, hyperaemia, a small cellular infiltrate and loss of ciliated epithelium. An alveolar exudate containing both neutrophils and mononuclear cells in haemorrhage is common. Cases of influenza viral pneumonia are relatively uncommon but are demonstrated in most influenza epidemics; pneumonia can occur in previously young and healthy persons, but it is more commonly associated with patients with pre-existing cardiovascular disease, such as rheumatic heart disease. The pathology of the viral pneumonia which killed many relatively young and previously healthy people during 1918–1920 was unique to that epidemic, and contained pathological features not described before or since (Crosby, 1976). Thus, following the acute symptoms of influenza described above, some patients showed increasing tracheobronchitis and bronchiolitis, shortage of breath and the appearance of mahogany spots around the mouth, which would extend and coalesce into a violaceous cyanosis until ‘a white man could not be distinguished from a coloured’. With increasing cyanosis, blood-stained fluid would froth from the mouth and death would follow from suffocation. The time from onset of infection to death varied from a few hours to 2–3 days. Post-mortem examination would not show the signs of secondary bacterial pneumonia; rather, the lungs con-

tained up to a litre of blood-stained, frothy and fibrin-free fluid; petechial and confluent haemorrhages were seen in the lining of the trachea and bronchi; and the lung tissue exhibited intense inflammatory changes with marked adenopathy.

Secondary bacterial pneumonia may be more common than primary viral pneumonia, and usually occurs late in the course of the disease. It usually ensues after a period of improvement from the acute symptoms of infection. The symptoms and signs are those of typical bacterial pneumonia and of the organisms involved, commonly *Staphylococcus aureus* and *Haemophilus influenzae*, although other bacteria may also be found. The association of *S. aureus* with secondary bacterial pneumonia following influenza is much more common than might be anticipated, and there appears to be a good reason for this: cleavage of the virus HA by bacterial proteases (Tashiro *et al.*, 1987). The incidence of secondary bacterial pneumonia is most common in the elderly and those with underlying disease, such as congestive heart failure and chronic bronchitis; in addition, patients with diabetes mellitus, renal disease, alcoholism and those who are pregnant may also have increased susceptibility to secondary bacterial infection.

Myositis and Myoglobinuria

In addition to myalgia, which is a characteristic feature of acute influenza infection, clinical myositis and myoglobinuria can occur. Symptoms usually develop soon after subsidence of the acute upper-respiratory-tract symptoms; the muscles are painful and tender to touch, but neurological symptoms are not evident. Changes in serum transaminases and creatinine phosphokinase levels accompany these symptoms, and histological examination of muscle biopsies has revealed necrosis of the muscle fibres and a mononuclear cell infiltration.

Reye's Syndrome

A syndrome characterized by encephalopathy and fatty liver degeneration was originally described in 1929, and more fully characterized by Reye *et al.* (1963). Later observers noted an association of recent viral infection with this syndrome, now termed Reye's syndrome. Typically, a previously normal child has a virus-type prodromal illness, followed in a few days by vomiting, altered consciousness and occasionally convulsions; the liver may be enlarged, and there is evidence of hepatic dysfunction, with raised transaminases and blood ammonia levels. Forty to fifty percent of patients admitted to hospital for Reye's syndrome die. At autopsy, an enlarged, pale and fatty liver is usually seen, and histological examination shows diffuse panlobar microvesicular fatty infiltration. The brain shows evidence of encephalitis with

cerebral oedema. Outbreaks of Reye's syndrome have been recorded in conjunction with influenza A and influenza B epidemics, and there is clustering of cases in the winter months.

An experimental disease similar to Reye's syndrome can be induced in mice by intravenous inoculation with influenza B virus; other studies have suggested that acute viral infection in conjunction with cofactors may be responsible for initiating the pathology of the disease. In particular, the use of high concentrations of aspirin during an acute virus infection has been suggested as a possible precondition for development of Reye's syndrome. There is epidemiological data to support this association, because Reye's syndrome is now rare, following widespread advice to give paracetamol, not aspirin, to febrile children.

Otitis Media

Although considered by many to be a bacterial infection, or a bacterial infection secondary to viral disease, it has been increasingly recognized that otitis media could be the result of influenza infection. Diagnosis of this in young children is associated with influenza epidemics, and in many cases bacterial causes of infection cannot be demonstrated. Association of influenza with otitis media is now recognized epidemiologically, but there is a need for detailed virological examination of patients presenting with otitis media, particularly in the age group zero to four years (Fleming, 2000).

Influenza in Pregnancy

The literature contains a number of reports of an increased incidence of congenital malformations (Conover and Rossmann, 1990) and neural-tube defects (Lynberg *et al.*, 1994) following influenza virus infection during pregnancy. In contrast, transplacental passage of the virus has not been demonstrated satisfactorily (Irvine *et al.*, 2000), and prospective studies of congenital abnormalities following epidemics of influenza have failed to establish a relationship between influenza-virus infection and these abnormalities. Reports of the association of maternal influenza with schizophrenia and Parkinson's disease in the offspring exist, but evidence of association is both fragile and contradictory. Earlier retrospective studies of small groups of patients infected during influenza epidemics suggested an increased risk of schizophrenia where infection took place in the second trimester of pregnancy (O'Callaghan, 1991); however, other similar studies have failed to confirm these results. There are methodological difficulties, particularly in the early studies, which relied on small numbers of patients asked to recall events 20 years or more in the past and on questionable evidence for past influenza infection. Three

larger studies published in 1999 found no evidence of an association between influenza-virus infection in pregnancy and later schizophrenia in the offspring (Bradbury and Miller, 2000). Follow-up studies of influenza during pregnancy have indicated increased severity of influenza illness among pregnant women, but no evidence of increased medical problems among the offspring. The recommendation for immunization of pregnant women is a recognition of the severity of this infection in this group, particularly from the pandemics of 1898 and 1918, when the death rates in pregnancy were considerable.

Other Complications

Although influenza in healthy adults is normally severe but of short duration, resolving in three to five days, complications can occur, particularly in elderly patients and in those with predisposing conditions, as outlined above. In addition, virus infection can result in a number of other less well understood complications. Influenza can cause ketoacidosis in diabetic patients, even in relatively mild cases of infection. Acute viral encephalopathy can occur and Guillian–Barré syndrome is a rare but recognized complication; both can lead to death. Histological examination of brain tissue has shown no gross abnormalities, but small changes consistent with virus encephalitis have been shown. The pathogenesis of the neurological complications is unknown, since virus recovery from the brain has rarely been documented.

Epidemiological studies have associated influenza A with sudden unexplained death and sudden infant death syndrome (SIDS), sometimes called ‘cot death syndrome’ (Zink *et al.*, 1987). Firm population data associating acute influenza infection with SIDS have been sought by many but are difficult to obtain, and the association is made on circumstantial evidence. Studies evaluating the burden of mortality due to influenza in young children have demonstrated that the importance of influenza as a serious pathogen may be significantly underestimated in this age group. The emergence of new antigenic-drift variants may be associated with unusual mortality in children experiencing a primary influenza infection, as occurred in the winter of 2003/2004 with A H3N2 Fujian-like antigenic variants (Bhat *et al.*, 2005). Factors underlying the severity of infection in young children and host predisposition to fatal outcome remain to be determined.

Zoonotic Infections

There is a spectrum of illness associated with the presentation of zoonotic avian influenza infection, which is associated with the infecting subtype (Table 16.4). However, in the early stages of infection it may be difficult to

distinguish zoonotic influenza infection from seasonal influenza infection as many presenting features are shared. H5N1 infections are associated with illness onset up to seven days post exposure, with predominant clinical features of high temperature, cough and shortness of breath (Figure 16.11). A high proportion of cases experience either transient or lasting respiratory failure during the course of a severe illness, which often involves multi-system failure. Although the majority of cases have been respiratory in presentation, a handful have been documented with atypical presentation involving fever, GI disturbance and diarrhoea, without obvious disease of the respiratory tract. Early clinical signs include disturbances in liver-function tests, lymphopenia and the presence of interstitial pneumonia on X-ray, which are not typically seen in seasonal influenza (Figure 16.11). Progression of disease typically involves respiratory failure and acute respiratory-distress syndrome, with death most frequently being due to respiratory failure. Recovery will begin to occur 7–10 days after illness onset, and tends to coincide with development of neutralizing antibodies. H7 infection is most likely to lead to unilateral or bilateral conjunctivitis. Of 83 people infected with H7N7, approximately 40% had evidence of virus in the upper respiratory tract, with 10% having a mild respiratory illness (Koopmans *et al.*, 2004). A single case fatality due to acute respiratory failure was recorded in an adult male.

DIAGNOSIS OF INFECTION

During seasonal epidemics of influenza, large numbers of patients are seen with similar influenza symptoms, increasing the probability of a correct clinical diagnosis. Concordance between clinical diagnosis and laboratory-proven cases of influenza are good, with correlations of 70% at the peak of the epidemic (Zambon *et al.*, 2001). However, influenza A and B can co-circulate, and mixed infections of influenza and other viruses have been reported; under these circumstances clinical diagnosis can be misleading and a diagnosis on clinical grounds cannot be confidently made. It may be considered that clinical diagnoses at the time of an epidemic are relatively easy and possibly of limited value. In contrast, laboratory diagnosis of isolated sporadic cases of suspected influenza should be carried out wherever possible, since the predictive value of clinical assessment is much lower, and infection may represent the first case of an impending epidemic or infection by a new virus strain, as has been seen with zoonotic H5, H7 and H9 infections of humans.

Laboratory diagnosis of influenza infection during the acute phase of illness in humans relies on isolation or

Figure 16.13 Diagnosis of influenza infection. Broken line indicates seasonal influenza virus shedding, compared with delayed shedding peak of avian H5 influenza.

detection of viral components during the period of viral replication, using a variety of techniques (reviewed by Zambon, 1998) (Figure 16.13). For seasonal human influenza A (H1N1, H3N2 and B), viral shedding peaks within several days of the onset of illness, and is readily detectable in the upper respiratory tract for up to five to seven days. In contrast, the peak of virus shedding following zoonotic infection may occur longer after illness onset and may be prolonged. Throat or nasopharyngeal swabs can be taken into a suitable transport medium, or nasal washing can be collected; comparative studies have shown that virus can more commonly be isolated from nasal washing than from other specimens. In all cases, the rapid transfer of specimens, or proper maintenance of specimens where delay may occur, is important for virus isolation.

Influenza viruses A and B, present in pathological specimens and collected into transport medium, can be cultured by inoculation on to mammalian cells or by amniotic inoculation of embryonated hens' eggs. Continuous cultures of kidney cells from dogs, rhesus monkeys, baboons or chicks are the preferred cell substrate. The addition of trypsin to ensure the cleavage of virus HA and HA1 and HA2 is usually necessary for virus infectivity in cell culture. After adsorption and incubation of virus-infected

cells, newly-produced virus can be detected by a number of methods. Free virus released into the maintenance medium of the cell culture can be detected by haemagglutination with erythrocytes, as described for amniotic fluid (Figure 16.14). Virus HA is inserted into the membranes of infected cells during replication and erythrocytes will adhere directly to these infected cells; this phenomenon is termed haemadsorption and can be observed under the microscope. Finally, viral protein can be detected in infected cells by fixation and staining by immunofluorescence (IF) (Figure 16.15). If specimens are inoculated into embryonated eggs, the virus is adsorbed from the fluid of the amniotic cavity on to cells of the amniotic membrane, where multiplication occurs, releasing newly-formed virus back into the amniotic fluids. After two to three days of incubation, virus can be present in high titres in the amniotic fluid and can be detected by adding aliquots of harvested amniotic fluid to chick, turkey, guinea pig or human erythrocytes and observing haemagglutination. Egg fluids negative for virus can be passed to further embryonated eggs and retested; specimens which do not reveal virus after two passages are recorded as negative in eggs. In recent years, there has been alteration in the receptor of circulating seasonal influenza viruses, which makes the use of embryonated eggs less favourable for the primary

Figure 16.14 Haemagglutination and haemagglutination inhibition. (a) Demonstrates haemagglutination in tissue-culture supernatant in the presence of virus. As virus is diluted out, erythrocytes settle out to form a button. (b) Demonstrates haemagglutination inhibition (HI). Row G demonstrates serum with an HI antibody titre of 160, and row H serum with an antibody titre of 320 (HI titre is measured as the last well in which there is complete inhibition of haemagglutination reaction).

isolation of human strains of influenza (Thompson *et al.*, 2006), although this is the culture medium of choice if there is a suspected avian influenza strain in a zoonotic infection.

Virus Recognition

Influenza viruses isolated from embryonated hens' eggs or cell culture can be identified by serological methods. First, influenza virus can be recognized as A, B or C by complement fixation (CF) tests using extracts of infected cells or embryonic membranes, which contain high titres of NP antigen, and standard antisera against influenza A, B or C viruses.

Further classification of influenza isolates into subtypes and strains is a highly specialized activity. Each virus

isolated is tested by HI test in comparison with a range of virus subtypes and strains with appropriate reference antisera. Virus strains are standardized to contain a fixed amount of HA activity by titration against erythrocytes, and then reacted against a range of dilutions of each antiserum. By observing the patterns of HI against the various antisera, the virus subtype and strain is identified. Should the virus isolate not be inhibited by any of the sera to the same titre known for the reference virus, the clinical isolate may be a new subtype or strain; homologous serum against the strain is then prepared in animals, and more extensive cross-HI tests are performed. These tests require the addition of new antisera to update the battery of sera used. In addition, the NA of the virus strain may also be typed serologically. This is done by identifying which antisera prepared against the various influenza NAs inhibit the NA of unknown virus to the same titre as against homologous virus; the indicator system in this test is an NA substrate, such as fetuin.

Virus Shedding

Viral replication outside the respiratory tract or viraemia is not a feature of human seasonal influenza, and conjunctival infection is rare. In contrast, in zoonotic influenza H5N1 infection virus can be detected in respiratory-tract samples, blood and faeces, indicating a systemic illness during the acute illness phase (Beigel *et al.*, 2005). The highest viral shedding occurs lower in the respiratory tract, reflecting the cell tropism of H5N1 virus and the distribution of appropriate receptors in the lower respiratory tract (Shinya *et al.*, 2006; van Riel *et al.*, 2007). Although H5N1 viral shedding may be prolonged and viral replication may be higher than in seasonal human influenza infection, the concentration of viral protein or nucleic acid in accessible upper-respiratory-tract secretions is lower. Zoonotic influenza A H7 infection is associated with virus shedding in conjunctival fluid, but only in a minority of cases is virus recovered from elsewhere in the respiratory tract (Koopmans *et al.*, 2004). Virus-shedding patterns in zoonotic influenza A virus infection therefore bring additional diagnostic opportunities to detect virus in different body compartments, but they also bring significant challenges. The experiences of avian influenza A infection in humans in the last few years (H5N1, H7N7, H9N2, H7N3), with serious illness presenting unexpectedly, underlines the difficulties of rapid influenza diagnosis. Initially, H5N1 illness may be indistinguishable from seasonal influenza, or worse still, in rare cases, it may bear no resemblance to human influenza, as has occurred in Thailand and Vietnam (de Jong and Hien, 2006). Detection of highly-conserved viral internal protein or genes (NP, M or NS) in respiratory secretions is sufficient to determine whether infection is due to influenza

A rather than influenza B or C (type-specific diagnosis), but does not inform which influenza A subtype (H1–H16) is present. Subtype-specific diagnosis requires analysis of the surface proteins or their gene segments. The HA and NA genes are subject to rapid genetic drift, leading to amino acid substitution on the surface of these proteins. Detection diagnostics based on these genes or proteins require frequent updating to take account of rapid evolution. Hitherto, the precise diagnosis of influenza A subtype (H1–H16; N1–N9) has not been considered relevant for clinical management of human influenza, although it is important for surveillance purposes (Zambon, 1998).

There are important clinical and public-health advantages that accrue from more rapid laboratory confirmation of subtype-specific diagnosis during the acute phase of illness. There is now a clear shift towards nucleic acid amplification (NAA) techniques for clinical virology diagnosis generally. Increasing use of automation facilitates high-throughput, real-time PCR to provide sensitive, specific, quantitative detection of virus nucleic acids, including influenza A, in different body fluids within hours of sample taking. Reverse-transcription polymerase chain reaction (RT-PCR) shows a high concordance with results obtained from slower culture and serological methods (Ellis and Zambon, 2002; Weinberg *et al.*, 2004; Zambon, 1998). Ensuring that influenza diagnostic techniques based on NAA techniques such as PCR are both sensitive and specific requires accurate knowledge of sequence diversity. Portions of gene segments which are highly conserved are chosen as detection targets, for example NP, MP (matrix protein and NS1 for type-specific diagnosis (A, B or C). Subtype-specific diagnosis (H1–16; N1–9) requires targeting of the highly-variable viral HA and NA genes. All strategies based on detection of HA of any subtype require frequent verification that single-base mutations found in newly-emerging drift variants do not affect test performance. It is essential to regularly update reagents to take account of sequence diversity and different genetic lineages detected in circulating viruses. Thus, efficient and effective subtype-HA-specific nucleic-acid-based diagnosis, either for human or zoonotic influenza infection, requires coordination between surveillance laboratories generating HA or NA sequence data from newly-emerging strains, and diagnostic end users, if subtype-specific diagnostics are to be applied in clinical laboratories.

Pinpointing the emergence of antigenic variants of human influenza requires growth of influenza viruses from clinical material. It takes a few days to obtain virus particles in adequate concentrations (approximately 10^7 – 10^8 particles per ml of culture fluid) to provide sufficient HA protein for analysis. Innovations, including the use of engineered mammalian cell lines such as MDCK cells

expressing enhanced levels of 2,6 sialic acid virus receptor (Matrosovich *et al.*, 2003), may enhance sensitivity for detection of human viruses, but have not reduced the time taken for virus to grow. The rapidity of viral evolution, the difficulty of working with highly-pathogenic viruses, the diversity of circulating strains, the limited access to original clinical material containing influenza virus and the delay in availability of sequence data from contemporaneous strains all make it difficult for the medical-devices industry to validate tests designed for human diagnosis. The predictive value of any diagnostic test, even one with 99% sensitivity and 99% specificity, is less than 70% when disease frequency is low, indicating the necessity for sensitive tests and confirmation strategies when trying to diagnose rare infections such as H5N1. Viral detection microarrays on a bite-sized chip could be one way forward for specific subtype diagnosis, but it may be a decade or more before this technology can be deployed in a low-skill format.

Rapid point-of-care tests (PoCTs) for influenza were developed alongside drugs for treatment of human influenza in the 1990s, to assist individual patient management ‘Test and Treat’. These tests require limited skill and equipment to provide a result in 10–30 minutes, in time to influence prescription in a physician’s office or at the bedside. Current PoCT formats use antibodies to detect conserved type-specific viral NP or M protein present in respiratory secretions. This allows detection of influenza A or B, but it may not always distinguish between them and does not indicate which subtype of influenza A is involved. A diversity of technologies can be applied to this task (reviewed in Nicholson *et al.*, 2003), including lateral-flow immunochromatography, solid-phase capture ELISA with optical or colorimetric read-outs, and activation of viral NA enzyme activity with substrate detection. Although influenza PoCT devices are widely used in some countries, for example Japan, in conjunction with antiviral drug prescription for seasonal influenza, the global uptake has been limited due to the costs of such tests, although they are useful in outbreak settings. Early data from clinical cases of H5N1 indicate that existing PoCT tests perform poorly in comparison to H5 virus-culture investigation (Beigel *et al.*, 2005), partly because the concentration of H5 virus protein in respiratory secretions from the upper airways is limited and partly because of the inherent sensitivity limitations of the tests.

Direct PCR sequencing of clinical material containing influenza virus does not require virus cultivation. This approach has been successfully applied to fresh, frozen and archived human tissue, and has provided important diagnostic information, for example the viroarchaeology of 1918 influenza in exhumed cadavers and frozen sections (Taubenberger *et al.*, 1997). Although the influenza virus

genome is relatively small, consisting of approximately 15,000 nucleotides, the technologies for whole-genome sequencing have not been applied to any great extent to investigate variation in influenza virus strains. Recently, however, whole-genome sequencing of a library of animal viruses (Obenauer *et al.*, 2006) has indicated the wealth of information that can be obtained from this approach. Similar analysis of human influenza A strains collected from a single locality over several years has also revealed a greater degree of diversity and reassortment than had been expected (Holmes *et al.*, 2005). Exploring the relationship between sequence diversity, antigenic variation and virus evolution allows the development of mathematical models for virus evolution (Smith *et al.*, 2004). Useful mathematical models would increase the ability to anticipate the emergence of significant antigenic variants and prediction of virus variation, rather than the reactive observational analysis of circulating strains currently undertaken.

Diagnostic challenges may ultimately become research opportunities, if the technical solution to providing better diagnosis at the point of patient care can be married to the technical achievements of recovery of nucleic acid, sequence reconstruction of viral genomes and information capture about outcomes of infection.

Immunological Diagnosis of Influenza Infection

Infection with influenza viruses creates a symphony of innate immune responses in the individual, rapid analysis of which could be used to differentiate H5 infection from human influenza infections or other viral or bacterial infections. The concept of using detection of a host immune signature based on innate immune responses to diagnose a specific viral infection is a very attractive area for microarray development, but these efforts have yet to translate into simple, cheap devices for patient diagnosis or disease-severity prediction. This approach has been used to try to tease apart the immune-response events occurring following infection with highly-pathogenic viruses in animal models (Kobasa *et al.*, 2007) and is likely to be a very active area for development in the next decade. Results in humans with H5N1 point to events early post infection determining outcome of infection, in particular high pharyngeal viral load, viral RNA in blood and host response with high levels of immunocytes and cytokines (de Jong and Hien, 2006). However, available data do not provide any pragmatic markers that can be used to predict outcome or provide specific diagnosis. Immunological diagnosis of influenza will rest for the foreseeable future on the detection of specific antibody responses.

Infection with influenza virus results in the development of antibody to the viral envelope glycoproteins HA and NA, as well as to internal proteins M, M2 and NP.

Serum immunoglobulin M (IgM), IgA and IgG to HA appear within two weeks of infection. Peak antibody responses occur within two months and decline thereafter (Murphy and Clements, 1989). Serological tests provide the most sensitive and practical alternative for diagnosis in the absence of virus isolation or detection but, since they require a convalescent serum specimen, the diagnosis is retrospective. However, a diagnosis may be made on a single serum sample by demonstrating the presence of a virus-specific IgM response; such responses may be present for about eight weeks, occasionally longer, following influenza infection, although this is not a widely used technique as it lacks specificity in adults.

The demonstration of a fourfold or greater increase in antibody titre in the convalescent serum as compared to the acute serum is considered diagnostic of infection. A traditional method of measuring antibody titre is by CF: soluble antigen is extracted from embryonic membranes of infected cells and is reacted against a range of dilutions of the acute and convalescent sera. A more specific test for antibody to influenza virus is the HI test. For this, paired sera are treated to remove nonspecific inhibitors, a series of dilutions are added to a standard quantity of intact virus and, after incubation, erythrocytes are added. The presence of antibody is indicated by inhibition of haemagglutination, and the highest serum dilution that inhibits haemagglutination is recorded as the titre of HI antibody in the serum specimen (Figure 16.14).

Infection by influenza virus results in a rise of serum antibody titre, but the requirements for an equal to or greater than fourfold rise in titre of HI or CF antibody reflects the inaccuracy of these tests for detecting increases in antibody. A more precise method of measuring antibody is by the single radial haemolysis (SRH) technique. Here, influenza virus is coated onto sheep red cells, and after suspension in melted agar with complement the agar is poured into dishes or on to glass slides. After setting, wells are cut in the agar and inoculated with dilutions of test sera. The presence of antibody in the sera is detected by lysis of the red cells, as antibody combines with complement and antigen on the red-cell surface. This lysis can be seen with the naked eye, and the amount of antibody present is directly related to the area of haemolysis. The procedure is more sensitive than CF or HI antibody and has a greater degree of precision: a 50% increase in zone area of haemolysis reflects a rise in antibody and is evidence of recent infection. Sera do not require pre-treatment to remove the nonspecific inhibitors which plague the HI test, although the difficulty in standardizing this test has precluded its widespread use.

Measurement of serum HI titres in convalescent sera has been used as a surrogate measure for neutralizing antibodies, and has been recognized as a correlate of immune

protection for many years. It remains the mainstay of serological diagnosis of influenza and assessment of an individual's exposure to different strains of influenza. ELISA assays using antibody/antigen sandwich and capture immobilization on sophisticated chemically-derivatized solid surfaces, microparticles and beads have substantially enhanced detection of specific antibodies in body fluids to nano- or picogram quantities, improving the sensitive, accurate detection of many viral infections. Unfortunately, ELISA antibody titres do not readily measure functionality of antibody and may not distinguish between recent and past infection. It is therefore difficult to relate ELISA detection of influenza IgG antibody to definitive diagnosis of recent infection or to any known serological correlates of protection.

Zoonotic infection with influenza A subtypes (H5 and H7) presents further serological challenges. The classical techniques of HI antibody detection have proved to be insensitive for detection of antibodies to these subtypes, either following natural infection or vaccination, which has necessitated the development of modified serological tests that are restricted to a handful of laboratories globally (Stephenson *et al.*, 2003a). The limited serological data from accumulated field studies investigating community transmission of H5 influenza do not suggest that there is appreciable subclinical H5 disease in parts of the world where H5 is endemic in poultry (Ortiz *et al.*, 2007). However, because of the severity and, often, the geographical remoteness of the human cases so far, relatively few serological investigations have been carried out, in part because there is a lack of easily-portable, low-technology serological tests. Recombinant protein expression and the capability arising from reverse-genetic techniques has not yet impacted on human influenza serological diagnosis to deliver serological techniques which give clues about early subtype-specific antibody response to infection, or to provide a substitute for assays which give information about correlates of protection but require the use of live virus. These gaps serve to emphasize the difficulty of translating technical innovations into practical diagnostics for a rapidly-evolving virus that causes poorly-differentiated clinical disease.

TREATMENT AND PREVENTION

The clinical severity of influenza, with high temperatures, respiratory symptoms, myalgia and severe prostration, requires most patients to seek bed rest during the acute phase of illness; the exhaustion and depression which follow may require further convalescence. It is clearly desirable that adequate means of treatment and prevention should be developed. Progress has been relatively slow,

although significant leaps forward in antiviral therapy and vaccine effectiveness have been achieved in the last 10 years.

Treatment

At the present time, the treatment of seasonal influenza is usually symptomatic. Most adult patients are advised to rest for two to three days until the acute symptoms have subsided. In view of the evidence that a combination of salicylates and acute influenza infection underlies the pathogenesis of Reye's syndrome in children, paracetamol is given in place of salicylates to treat common symptoms of headache and malaise. Codeine linctus may relieve cough and antibiotics are indicated where chest complications are present or suspected. The use of prophylactic antibiotics in patients with chronic chest disease who thus have a higher risk of developing post-influenzal pneumonia is contentious; some advocate this practice, but the incidence of secondary bacterial pneumonia is not reduced and infection may be by antibiotic-resistant organisms.

Since the earliest conception of antiviral chemotherapy, influenza has been one of the target diseases against which suitable antiviral compounds should be developed. The search for such compounds has used three methods. First there is a rational approach, which predicts a substance that would interfere with virus replication; this requires an exact knowledge of the molecular events of virus infection and multiplication, and such information is rarely complete; however, this approach identified ribavirin. The second method involves serendipity, and requires the random screening of chemical compounds in the hope that an active compound will be found by chance; this method identified amantadine. Lastly, there is the structural approach: the three-dimensional structures of the HA and NA of influenza virus have been elucidated and the identification of the active sites in these structures of virus replication predicts the structure of compounds which may interfere with their function; this strategy led to the development of the neuraminidase inhibitor (NI) drugs (reviewed by Hayden and Pavia, 2006) (Figure 16.16).

Amantadine, Rimantadine

Amantadine and rimantadine are synthetic, water-soluble primary amines with a symmetrical structure; they consist of a stable base with an active amino group (Figure 16.16). In experimental studies, the compounds inhibit the growth of influenza virus in cell culture and limit virus replication in mice, ferrets and other experimental animals. They also reduce tissue damage by influenza virus in infant rats and protect hamsters from infection from virus-infected animals placed in the same cage (Potter and Oxford,

Neuraminidase Inhibitors

Figure 16.16 Antiviral drugs used against influenza A and B. Shaded areas of neuraminidase-inhibitor molecules represent the areas in contact with substrate binding site.

1977). On the other hand, the compounds are not equally active against all influenza A viruses and do not work against influenza B. Studies on the mode of action of amantadine have indicated two features of the antiviral activity. First, the compound acts at the level of virus uncoating by lysosomal enzymes; this process requires a functional ion channel formed by the M2 protein and a fall in pH within the virus particle for optimal fusion of the viral membrane with host membrane, but amantadine blocks the viral ion channel and thus uncoating and subsequent virus replication is limited. Second, the action of amantadine on the M2 ion channel actively inhibits the transport of HA and other viral subunits to the cell surface and actively inhibits the viral assembly process (Lin *et al.*, 1997).

Clinical studies with amantadine have shown that the compound can occasionally induce mild neurological symptoms; these include insomnia, loss of concentration and mental disorientation. The symptoms are quickly shown by susceptible individuals, and cease when treatment is stopped. If these symptoms do not occur within 24 hours of initiation of amantadine treatment, they are unlikely to occur at all. Both prophylactic and therapeutic studies have been carried out. Prophylactic studies in schools or universities have demonstrated approximately 60% protection for those taking amantadine prophylactically. In therapy trials, amantadine significantly reduced the duration of fever (51 hours as opposed to 74 hours in the placebo group), and illness (2.5 days as opposed to 3.5 days). Rimantadine is the preferred compound, since, although not as effective as amantadine, it is less toxic (Arruda and Hayden, 1996), but it is not licensed in many parts of the world, including Europe.

Resistance to Amantadine/Rimantadine

Resistant strains arise readily *in vitro* and during treatment and are transmitted without loss of fitness. Resistance to both drugs is conferred by mutations at key residues in the transmembrane region of the M2 protein, particularly at residues 26, 27, 30, 31 and 34. The most commonly occurring mutation is S31N. In the last five years it has become apparent that the majority of circulating seasonal influenza A H3N2 strains are naturally resistant to amantadine (Bright *et al.*, 2005), as are avian H5N1 influenza strains, which limits the usefulness of these drugs when applied without knowledge of viral subtype.

Ribavirin

The structure of the synthetic nucleoside analogue 1B-D-ribofuranosyl-1,2,4-triazole carboxymide (ribavirin) is shown in Figure 16.16. The compound inhibits the replication of a wide range of RNA and DNA viruses *in*

vitro, including both influenza A and influenza B, and limits influenza virus replication in mice and ferrets. The compound probably acts by inhibition of virus nucleic acid synthesis, through alteration to cell metabolism. Antiviral compounds which act through alteration to cell metabolism have broad antiviral activity and do not generate resistant viruses; these two properties are true for ribavirin. Ribavirin is well tolerated in concentration 200-fold greater than that necessary to inhibit virus replication; however, the compound has been reported to have immunosuppressive effects, although these are completely reversible once treatment is stopped. Clinical studies have demonstrated a significant therapeutic effect on symptoms of both influenza A and B (Stein *et al.*, 1987), and the compound is very effective in animal studies when given by aerosol combined with rimantadine or amantadine (Hayden, 1996).

Neuraminidase Inhibitors

The activity of the NA enzyme, situated on the outer surface of the influenza virus particle, is important in the replication of both influenza A and B viruses. The three-dimensional crystalline structure of this glycoprotein has been established (Laver *et al.*, 1984), and although the structure can vary between influenza strains, X-ray crystallography and site-directed mutagenesis indicate that the active site is conserved (Laver *et al.*, 1999). It is apparent therefore that drugs that combine with the active site would have antiviral activity. The first active antineuraminidase compound, 4-guanidino-Neu5Ac2en (zanamivir, Relenza), was shown to have good antiviral activity against influenza A and B *in vitro* and, given as an aerosol, was safe and effective in animal models and in clinical studies (Monto *et al.*, 1999). The structure of this compound is shown in Figure 16.16. The second compound, with similar structure and properties (3R, 4R, 44)-4 acetoamido-5-amino-3-(1-ethyl[*rp*][*pxy*])-1 cyclohexane-1 carboxylic acid (oseltamivir, Tamiflu), given orally as a prodrug, shows similar antiviral activity in volunteer studies (Nicholson *et al.*, 2000) and is also licensed for treatment. Several other similar compounds are in development, for example peramivir (Sidwell and Smee, 2002).

Treatment of adults with seasonal influenza with these compounds is demonstrably effective: the incidence, severity and duration of illness can be reduced. The effect of the drugs is maximized when given early in infection, in the first 48 hours of illness onset, but they may still be effective when given later in infection when illness is severe (McGeer *et al.*, 2007). NIs can be given prophylactically to family members of an index case, and as part of seasonal prophylaxis in institutional settings so as to interrupt transmission of influenza. The

two licensed drugs oseltamivir and zanamivir both act on the enzyme active site; the former is an oral drug, given twice a day; the latter is a topical drug, given by inhalation because of poor oral bioavailability.

The WHO advises the use of oseltamivir for treatment of human H5N1 cases, and oseltamivir or zanamivir for prophylaxis (Schunemann *et al.*, 2007). Early treatment with drug, within five days, substantially improves case fatality (Gambotto *et al.*, 2008) compared with individuals receiving drug late into illness presentation, a situation reminiscent of data obtained with human seasonal influenza, where early treatment substantially reduces viral replication and provides a better clinical outcome. However, several factors may limit the efficacy of oseltamivir in treatment of H5N1. These include late presentation of illness, substantial irreversible pathological tissue damage at the time of treatment initiation, high replication capacity of the H5N1 viruses and emergence of resistant viruses. Together these factors may affect the efficacy of treatment of H5N1 infections, but in view of the severity of infection, antiviral treatment should not be withheld even in those presenting late.

Resistance to Neuraminidase Inhibitors

Resistance to NI drugs has been difficult to generate *in vitro*, requiring multiple passages, and resistant viruses are generally compromised in fitness, because mutations conferring resistance reduce the stability of the protein and/or enzymatic activity. Surveillance of natural isolates prior to the licensure of NI drugs in 1999 did not demonstrate the existence of naturally-occurring resistance (McKimm-Breschkin *et al.*, 2003). Since the time of licensure, the usage of oseltamivir has far exceeded that of zanamivir, probably for reason of ease of application. Surveillance studies since the introduction of NI drugs indicate that the level of resistance to oseltamivir in unselected viral isolates is detectable, with approximately 0.1–1% even in regions with high drug use, such as Japan. Studies of viral isolates recovered from individuals post treatment indicate that approximately 4% of adults and approximately 18% of children may have resistant viruses, although these resistant viruses may not necessarily be transmitted to others. Taken together, the data are suggestive of low-level spread of drug-resistant viruses in the community following the introduction of this class of drugs (Monto *et al.*, 2006; NISN WER, 2007). The genetic mutability of influenza viruses is clearly demonstrated by the emergence of drug-resistant H1N1 influenza in the winter of 2007/2008, as a consequence of spontaneous mutation at position 274 (Histidine to Tyrosine H274Y) in the absence of drug pressure (Lackenby *et al.*, 2008). Such viruses are clearly transmissible and able to compete with other circulating H1N1 strains, although

their long-term persistence is not yet demonstrated. The development of NI drug resistance is to a certain extent subtype dependent, as the exact conformation of each NA subtype active site varies in detail, which affects the nature of drug binding and the potential for generating virus that is drug resistant (McKimm-Breschkin *et al.*, 2003; Russell *et al.*, 2006) (Table 16.5). The landscape of resistance in the NI drugs has altered substantially following the emergence of drug-resistant viruses in the absence of drug pressure. The impact of antiviral resistance on the usefulness of these drugs will require close monitoring in the coming years, particularly in light of the emergence of drug resistance in H5N1 infections and of natural variation in susceptibility found amongst these viruses (de Jong *et al.*, 2005; McKimm-Breschkin *et al.*, 2007).

Clinical experiences of the use of the existing antiviral drugs for treatment of influenza indicate that a search for new targets for antiviral therapy or for immune modulation is urgently required. Although immune modulation is an attractive approach to severe influenza infection, particularly avian influenza H5N1 infections, a much clearer rationale is required for understanding the nature of immediate/innate immune responses. Sixteen of nineteen patients with H5N1 who received corticosteroids did not survive, indicating lack of benefit from empirical adjunct steroid treatment (Gambotto *et al.*, 2008).

Prevention

Vaccines are the mainstay of control and prevention of seasonal influenza, and have been used since the 1940s, with gradual incremental improvement in the accuracy of strain composition, formulation for vaccine potency and reduction of side effects. The majority of vaccines used globally are inactivated killed-virus vaccines, which are administered annually to ‘at-risk populations’ at the beginning of the winter season in developed countries in the Northern or Southern Hemisphere. There has been a long-standing tradition of the use of live-attenuated vaccines in Russia, and since 2000 the use of live-attenuated vaccine using well-characterized cold-adapted attenuated influenza strains has been recommended and introduced for children in the United States. Despite these developments, the search for improved vaccines continues. Recent innovations include the shift towards the use of mammalian cell culture as the substrate for growth of vaccine viruses. This substrate reduces the dependency of vaccine production on the availability of embryonated eggs and improves the flexibility and scaleability of bulk production. The gradual introduction of reverse-genetics technology (Fodor *et al.*, 1999; Neumann *et al.*, 1999) will serve to improve the yield of vaccine strains and the speed at which vaccine candidate strains can be made available to manufacturers.

Table 16.5 Neuraminidase inhibitor resistance profile

NA mutation	NA type/subtype	Fold decrease in neuraminidase enzyme susceptibility			
		Oseltamivir	Zanamivir	Peramivir	A-315675
E119V	A/N2	R (>50)	S (1)	S (1)	S (1)
R292K	A/N2	R (>1000)	S (4–25)	R (40–80)	S (8)
H274Y	A/N1	R (>700)	S (1)	R (40–100)	S (3)
R152K	B	R (>30–750)	R (10–100)	R (>400)	R (150)

R, resistant; S, sensitive.

Correlates of Immunity to Influenza

The antigens of the influenza virus particle which stimulate immunity to subsequent infections have been identified. The results of challenge studies indicate that immunity is induced by the host immune responses to the virus HA and, to a lesser extent, to the NA. Some evidence suggests that the immune response to the M2 and NP proteins may also contribute to immunity.

Studies to determine which immune responses correlate with protection against infection indicate that the serum antibody titre against the viral HA is the most important; thus susceptibility to influenza virus infection is inversely related to the titre of serum HI antibody. This is true for both experimental challenge with attenuated virus and natural infection with virulent virus, and a serum HI antibody titre of approximately 30–40 and 20–30 represents a 50% protective level of antibody against infection by homologous influenza A and B virus, respectively (Potter and Oxford, 1979). Further, the degree of cross-immunity for viruses of different subtypes of strain is directly related to the degree of cross-reactivity of the HA antigens: immunization with an influenza-virus vaccine confers no protection against challenge with virus of different subtype, since there is no cross-reactivity of the HA of the two viruses. In addition to conferring relative protection against infection, the serum HI antibody is reported to both reduce the severity of infection and decrease virus spreading from infected persons. Similar studies have shown that serum NI antibody also confers protection against influenza virus infection; this has been shown in studies with experimental animals and in observations of natural infection in humans. Thus, anti-NA antibody has been shown to confer protection against the clinical effects of influenza virus infection, not infection *per se*, and in the presence of an NI antibody, infection will induce protective HI antibody, whilst clinical symptoms are considerably reduced and may not occur. A generally-held view is that the serum HI antibody is more important in determining immunity than the serum NI antibody, as indicated

by several studies. The importance of cellular immune responses in immunity to infection remains to be established (McMichael *et al.*, 1983), although the role of cellular immunity in assisting clearance of infection is well established; however, cellular immunity is an important prerequisite for humoral antibody response in clinical disease.

From the above it is clear that an influenza vaccine must contain the surface HA and NA antigens of the virus in a form which will stimulate serum HI and NI antibody, local IgA antibody and possibly cellular immunity. It is essential that the vaccine contains the antigens of recently-isolated virus strains; although some cross-reactivity and corresponding cross-immunity are seen between viruses of the same subtype, the most solid immunity is found following immunization with virus homologous to the infection strain. Thus, whatever the type of vaccine used, it is necessary to review virus-strain composition and ensure regular updating to match new antigenic drift variants as they occur.

Inactivated-virus Vaccines

At the present time and for the last two decades, strains of influenza A (H3N2) and (H1N1) and influenza B have been circulating in any one year (Figure 16.8); thus, the currently-infecting strains of each of the three viruses are grown in parallel for vaccine production. Inactivated virus vaccines are prepared by inoculating the currently-circulating strain of influenza virus into embryonated hens' eggs or mammalian cell culture; culture fluids are harvested after two to three days of incubation and centrifuged by zonal centrifugation in order to concentrate and purify the virus particles, which are inactivated with formalin or β -propiolactone. Vaccines are standardized by HA content for intramuscular inoculation. The three viruses are mixed to contain 15 μ g HA of each virus in each dose, to constitute a trivalent vaccine. Inactivated vaccines may be either whole-virus vaccines, prepared as described here, or split-product or subunit vaccines, where further purification steps are undertaken after virus inactivation (Figure 16.17).

Figure 16.17 Electron micrographs of different types of inactivated influenza vaccines. (Source: Wood, 1987.)

Whole-virus Vaccines

Clinical studies with whole vaccines prepared in this manner have recorded some local pain in approximately 20–30% of vaccinees, and symptomatic reactions, such as fever, headache and muscle pain, in about 5% of persons; however, these responses are usually mild and ephemeral. The vaccine induces serum HI and NI antibody responses, which confer protection on 60–90% of volunteers against challenge virus infection and significant prevention of hospitalization and deaths in the elderly (Nichol and Treanor, 2006). The vaccine may be given annually to the young or elderly, and higher doses may be given to the elderly, who give relatively poor immune responses to conventional vaccine (Keitel *et al.*, 1996). The serum antibody response persists at a protective level for one to five years, depending on the vaccine virus strain and the age of the vaccinees; however, subsequent infecting virus strains may show antigenic drift and the vaccine-induced antibody will be less effective in protecting against these new strains. In contrast, the antibody response to a vaccine containing virus of the new subtype against which the vaccinees have had no past experience is relatively short-lived, and 60–80% of the antibody may have disappeared by 12 months after immunization.

Split-virus Vaccines

Because of the relatively high incidence of reactions seen in vaccines given as inactivated whole-virus vaccine, at-

tempts have been made to reduce reactogenicity while preserving the ability to induce satisfactory titres of serum antibody (immunogenicity). For this, virus pools grown, purified and inactivated as described above are treated with detergents to disrupt the virus particles; inoculation of virus produced in this way induces fewer reactions in volunteers than whole-virus vaccines and the serum antibody responses and protection afforded against subsequent challenge are similar. For these reasons, there has been a gradual shift to split vaccines from whole-virus vaccines, to the extent that probably over 80% of inactivated vaccines given from 2000 have been either split or subunit vaccines.

Subunit-virus Vaccines

Since only virus HA and NA antigens are required to induce immunity, vaccines containing purified surface antigens and free of virus RNA and core proteins have been investigated; these are conventionally given as aqueous suspension, but may be administered with carrier compounds to enhance the immune response (O'Hagan *et al.*, 2007). Volunteers given aqueous subunit vaccines intramuscularly experience fewer reactions than those given whole-virus vaccines. In years of antigenic drift, when the population is primed, serum HI antibody responses to whole and subunit saline vaccines are similar, and since aqueous vaccines are less reactogenic, these are preferred.

However, when vaccinees are not primed by previous exposure to viruses of the same subtype, the serum HI antibody response to whole vaccine is significantly greater than for subunit vaccine; in order to achieve protective levels of antibody, two doses of subunit vaccine may be necessary, and the search for an acceptable adjuvant to overcome this need is an important research activity. The choice of vaccine formulation may therefore be dependent on the immune status of the population being vaccinated. In the event of antigenic shift and the emergence of a novel virus subtype to which the population has no prior exposure, the choice of vaccine may depend on which is most immunogenic at lowest antigen dose in different age groups. In general, in this situation it is accepted that two doses of vaccine may be needed to generate a sufficiently protective immune response.

Vaccine Adjuvants

Subunit vaccines, though demonstrating improved reactogenicity profiles, remain short of ideal in protection against influenza, and experimental studies to find a suitable carrier/adjuvant to enhance antibody reproduction have been pursued vigorously for some years. A large number of adjuvants are known but few are suitable for intramuscular injection: ISCOMS and MF59 enhance serum antibody responses, but there is a modest increase in the incidence of side-effect reactions; and immune modulators such as interleukin 2 (IL-2), which enhance antibody responses in mice, have not been investigated in human volunteers. Subunit trivalent influenza vaccines adjuvanted with MF59 have now been licensed for seasonal influenza and are beginning to be used; however, the real advantage of adjuvants may be demonstrated in populations naïve to a particular influenza subtype, as has been demonstrated in clinical vaccine trials of H5N3 and H5N1 influenza vaccines (Leroux-Roels *et al.*, 2007; Nicholson *et al.*, 2001; Stephenson *et al.*, 2003b). As the threat of pandemic influenza remains, the field of pandemic vaccine development is actively investigating the use of different adjuvants to enhance the immunogenicity of vaccines and produce dose-sparing vaccines.

Live-virus Vaccines

Inactivated influenza vaccines induce serum HI and NI antibodies to protective levels in the majority of vaccinees; however, the local IgA antibody and cellular immune responses are disappointing. In contrast, there is evidence that immunization with live-attenuated influenza vaccine induces a full range of immune responses and a more solid immunity than inactivated vaccines. The preference for vaccine delivered noninvasively and the

reactogenicity profile of inactivated vaccine have continued to encourage the development of live vaccines against influenza. Influenza viruses can be attenuated by serial passage in embryonated hens' eggs, by chemical mutation or by laboratory passage at reduced temperatures (cold adaptation). Using these techniques, viruses can be produced which infect and immunize volunteers without producing appreciable clinical illness. Attenuated viruses produced by one of the above methods have been mixed with wild-type viruses causing current infections to produce reassortants, which contain the RNA fragments coding for the wild-type HA and NA surface antigens and all the other genetic material (internal genes) from the attenuated strain. These reassortants can be produced relatively quickly in the laboratory and, when inoculated intranasally into volunteers, produce few and mild symptoms, and induce both serum and local HI and NI antibody against the wild-type virus and immunity to challenge virus infection (Beare, 1982). Two strains, A/Ann Arbor/6/60 (H2N2) and B/Ann Arbor/1/66, have been used to produce attenuated influenza A and B vaccine reassortants for over three decades (Maassab and DeBorde, 1985); in all studies, the selected reassortants have been shown to be safe and effective, easily administered and suitable for all ages.

The development of a suitable influenza-virus vaccine initially requires the production and purification of a suitable reassortant from an established, suitable and attenuated virus and the wild-type virus. Vaccine virus must be attenuated for various groups of volunteers of different ages and susceptibility, must induce antibody responses and must protect against challenge virus infection. This has been demonstrated for the Ann Arbor cold-adapted vaccine strains, in a series of large randomized controlled trials over a number of years, resulting in licensure in the United States for use in children older than five years (Belshe *et al.*, 2007). The superiority of these vaccines in an elderly population has not yet been demonstrated, and remains in some doubt, since the existence of antibody in elderly adults as a result of lifetime exposure to influenza may preclude sufficient replication of an attenuated influenza to achieve a boosting of immunity.

Other Approaches to Vaccine Development

In addition to the above influenza vaccines, several other approaches are possible and under investigation. Large quantities of influenza-virus antigens can be made by cloning the relevant genes into a variety of vehicles for expression; this would make vaccines more available, since quantity would not be limited by the availability of embryonated hens' eggs. An example of such an approach is the use of recombinant protein HA vaccine produced by baculovirus expression, which produces an extremely

pure product but requires large quantities of protein to establish immunogenicity (Treanor *et al.*, 2007). Reverse genetics has been developed, which allows virus to be produced from susceptible cells transfected with plasmids coding for each of the eight gene segments of the virus RNA (Fodor *et al.*, 1999; Neumann *et al.*, 1999); this opens the possibility of laboratory-designed live and inactivated influenza vaccines. Clinical vaccine studies with H5N1 have shown that vaccines developed in this way are both safe and immunogenic (Bresson *et al.*, 2006; Treanor *et al.*, 2006), and this technology, together with the use of mammalian cell culture, is likely to revolutionize the field of influenza vaccines in the years to come.

One of the limitations of influenza-vaccine usage is the requirement to inoculate intramuscularly; to obviate this, inactivated vaccines have been tested intranasally. Inactivated vaccines given intranasally are generally poor immunogens: these vaccines need to be combined with adjuvant/carrier to be effectively immunogenic. Licensure in Switzerland of inactivated virosomal vaccine adjuvanted with a powerful mucosal adjuvant, LTK, was unexpectedly followed by an increased incidence of Bell's palsy (Mutsch *et al.*, 2004), which has reinforced caution in the development of intranasal delivery of inactivated vaccines. DNA vaccines coding for virus HA have been used successfully in animal models (Wong *et al.*, 2001)

and have demonstrated immunogenicity in human clinical studies (Drape *et al.*, 2006), and represent an exciting new development for influenza vaccines.

Vaccine Recommendations

At the present time, live-attenuated influenza-virus vaccine is available for use in the United States and Russia (although different strains are used), but not in Europe, and the novel methods of producing vaccine outlined above remain in their infancy. The majority of currently-available vaccines are inactivated split or subunit vaccines mainly produced from virus grown in hens' eggs with a clearly-defined annual production schedule (Figure 16.18), although this is likely to shift to mammalian-cell production over the next 10 years, improving the scalability and flexibility of production of inactivated vaccines. Of these, the most popular are the aqueous subunit vaccines, which have replaced the earlier whole- and split-virus vaccines in many countries. These vaccines produce relatively few reactions, and such reactions are usually mild and of relatively short duration; they produce serum antibody in the large majority of subjects, and immunity to infection in 60–90% of vaccines. Early fears that these vaccines may be unsuitable in certain patient groups, such as those with multiple sclerosis, acquired immunodeficiency syndrome

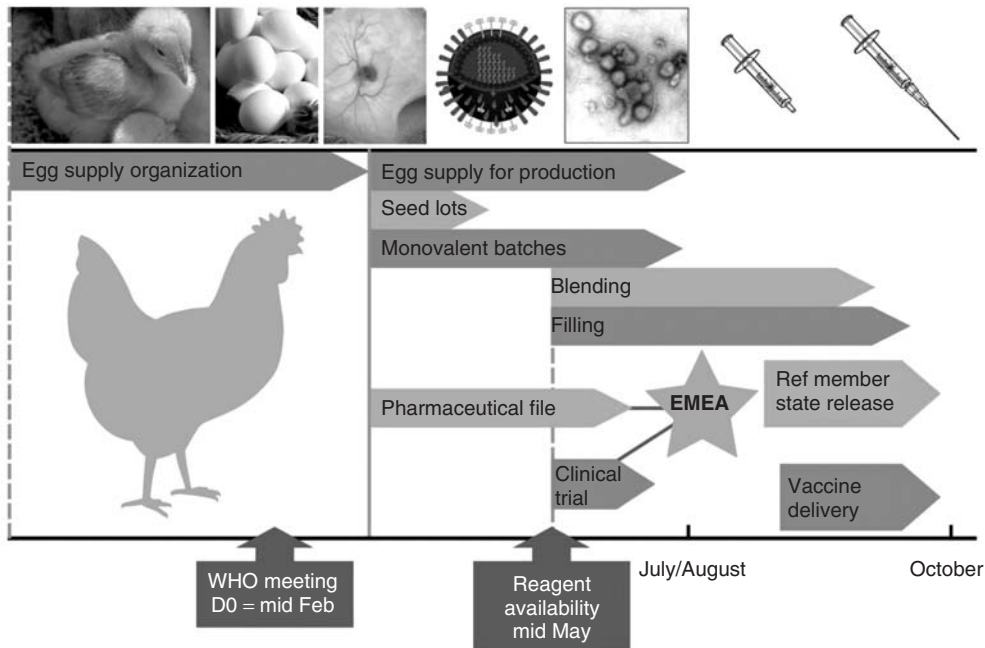

Figure 16.18 Annual production schedule of inactivated influenza vaccine produced from embryonated eggs. EMEA, European Medicines Agency.

(AIDS) or diabetes, have been largely discounted by more recent and larger studies.

A substantial literature assembled over the past three decades attests to the safety and the efficacy of inactivated influenza vaccine; these studies were carried out in children, in healthy adults and in the elderly. Meta-analysis of collected studies from the literature in both healthy young and elderly people indicates that immunization is both safe and effective in producing immunity, and in the elderly can prevent approximately one in five cases of influenza illness and one in four deaths, where there is a good match between the influenza strains in the vaccine and those in circulation (Nichol and Treanor, 2006; Ohmit *et al.*, 2006; Vu *et al.*, 2002). With this information it is difficult to understand the reluctance of some health-care workers to receive vaccine themselves; immunization rates for health-care workers in many Western countries are less than 20%. Finally, although inactivated influenza vaccines are effective in the elderly population, they are less effective than in younger people, since the immune response is impaired by age; however, recent clinical studies suggest that a combination of inactivated vaccine given intramuscularly and live vaccine given intranasally can be more effective than killed vaccine on its own. The use of live vaccines could result in this strategy being used to further protect the vulnerable and aged population.

Vaccine is recommended in most Western countries for all aged over 65 years, for patients with chronic lung or heart disease, for patients with metabolic disorders such as diabetes, renal disease or immunodeficiencies, including children, for whom influenza is life-threatening, and for residents of institutions for the elderly or disabled; other groups, such as household contacts of high-risk persons and health-care workers, should be considered for immunization, together with pregnant women after the first trimester. Recently there has been considerable impetus to extend use of vaccine to young children, for whom influenza is a more serious clinical disease and in whom the virus replicates to higher titres, thus identifying them as a focus of infection for others (Neuzil, 2004). For the remainder of the population, immunization against influenza is a debatable subject; some authorities hold that vaccines should be available for all and used according to the wishes of doctors and patients, while other protest that the further widespread use of vaccine is not justified (Abramson *et al.*, 2006).

A particularly active field of vaccine research currently is that of pandemic vaccine development (vaccines for nonhuman subtypes of influenza), which is serving to highlight the limitations of existing vaccines and also pioneering new approaches to vaccination, including new vaccines, methods of formulation and antigen-sparing strategies (Stephenson *et al.*, 2004). Vaccines will be

in very short supply in the event of a new influenza pandemic, and continuing effort is urgently needed to ensure effective use of both vaccines and drugs should one emerge.

INTRODUCTION

Human parainfluenza viruses (HPIVs) are a leading cause of hospitalization for acute respiratory-tract disease (ARD) in young children. Although the characteristic HPIV-mediated illness is laryngotracheobronchitis (croup), their repertoire in the paediatric population also includes upper-respiratory-tract infection, as well as bronchiolitis, pneumonia and lower-respiratory-tract pathology. Parainfluenza viruses are also able to trigger community-acquired ARD, requiring hospitalization in adults, as well as morbidity and mortality in immunodeficient patients and transplant recipients.

Despite the considerable progress that has been made during the past five years, vaccination against HPIV is not yet available. However, vaccines based on cold-adapted viruses have been tested in phase II trials and recently-established reverse-genetics systems manipulating infectious HPIV cDNAs allow for the development of promising vaccine candidates. In addition, results from reverse-genetics-based genome-modification studies, as well as detailed analysis regarding the binding of those viruses to cellular receptors and the concomitant regulation of fusion between viral envelope and cellular membranes leading to viral internalization and release, shed light on the complex pattern of infection and replication of, and immunity against, HPIVs. Large epidemiological studies continuously underline the important contribution of HPIV infections, including the less well studied HPIV type 4 serotypes, in paediatric and adult hospitalizations, which is often underestimated, partly due to

the attention on other viral pathogens. Unravelling of the molecular, cellular and epidemiological aspects of HPIV infection, aided also by efficient nucleic-acid-based detection methods, was of great benefit in the battle against these pathogens. For instance, elucidation of mechanisms used by HPIVs to infect and replicate within hosts, and in addition to escape interferon (IFN)-driven host antiviral immune surveillance has already led to the application of effective intervening strategies. Agents targeting particular events of the viral replication cycle (e.g. attachment to and replication in target cells) are promising. Comprehensive reviews regarding epidemiological studies and molecular mechanisms regulating HPIV infection, propagation and treatment continuously appear, and the reader is encouraged to refer to them for further information (Henrickson, 2003; Moscona, 2005).

TAXONOMY

Parainfluenza viruses are single-stranded negative-sense enveloped RNA viruses belonging to the order *Mononegavirales*. Four major HPIVs have been genetically and antigenically identified (HPIV1–4). Furthermore, there are two subtypes of HPIV4 (A and B), as well as some subgroups/genotypes of HPIV1 and HPIV3. All HPIVs are members of the *Paramyxovirinae* subfamily in the large *Paramyxoviridae* family, and classified into different genera (Figure 17.1). Thus, human and animal PIV1s and PIV3s belong to the *Respirovirus* (former *Paramyxovirus*) genus, whereas PIV2s and PIV4s are members of the

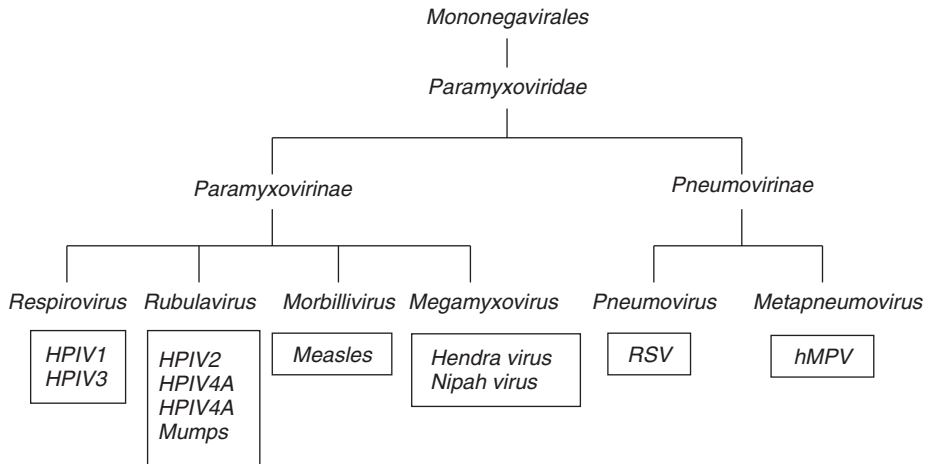

Figure 17.1 Classification of human parainfluenza and related viruses. From top to bottom: order, family, subfamily and genus—the viruses are listed in blue. For abbreviations, see text.

Rubulavirus genus. The human pathogen mumps virus is also a member of the *Rubulavirus* genus. These two genera, together with the *Megamyxovirus* genus (to which the recently-identified Hendra and Nipah viruses belong) (Mounts *et al.*, 2001; Nichol *et al.*, 2000) and the *Morbillivirus* genus (which includes measles virus), form part of the *Paramyxovirinae* subfamily (Figure 17.1). The *Pneumovirinae* subfamily contains the *Pneumovirus* genus, the most important member being human respiratory syncytial virus (RSV), as well as the *Metapneumovirus* genus, to which human metapneumoviruses (hMPV) belong (van den Hoogen *et al.*, 2002).

Sendai virus (SeV), simian virus 5 (SV5) and bovine PIV3 (BPIV3) are well-studied animal counterparts of HPIV1, HPIV2 and HPIV3, respectively. In particular, SeV was originally isolated from the lung of a fatal case of newborn pneumonitis in Sendai, Japan in 1953, but is considered a murine virus (referred to also as murine PIV1, MPIV1) since it readily infects and causes disease in mice, and there have been no reported further outbreaks of the human disease (see ‘Receptors, Virus Entry and Host Range’). Notably, SV5s isolated from different species, including humans, show impressive similarities in sequences and infection properties, suggesting that SV5 may be able to persistently infect humans. Accordingly, its designation as HPIV5 has been proposed (Chatziandreu *et al.*, 2004). The related avian Newcastle disease virus (NDV) belongs to the *Avulavirus* genus of the *Paramyxovirinae* subfamily. Several additional PIVs able to infect and propagate in various animal species have been identified (listed in Henrickson, 2003).

STRUCTURE AND PHYSICAL PROPERTIES

The nonsegmented, negative-stranded RNA species of PIV form genomes approximately 15–16 kb long, encoding at least six mRNAs. They also contain short (less than 100 nt long) untranslated regions at their 3′ and 5′ ends, named leader and trailer respectively, which contain important replication and transcription promoter elements (see ‘Replication’). The gene order starting from the 3′ end is: N-P-M-F-HN-L. These combine to form the nucleocapsid and the envelope of the virion (Figure 17.2). Whereas HN and F proteins mediate binding of HPIVs to target cells and subsequent fusion to cellular membranes, the matrix protein is necessary for viral assembly and budding. Shifts in reading frame, as well as read-through and RNA-editing events, allow the encoding of additional protein species by the P, M and F parts of the genome (see ‘Replication’). These species, designated V, C and D, are characteristic of each HPIV subtype, playing important roles in replication, assembly, maturation and virulence. Some of them may be expressed only in infected cells and are involved in modulation of host immune responses.

With the exception of phosphoprotein P, each of those proteins has a characteristic molecular weight (MW) that does not essentially differ among the different HPIVs (N: 66–70 kDa; M: 28–40 kDa; F: 60–66 kDa; HN: 69–82 kDa; L: 175–251 kDa) (Henrickson, 2003). In contrast, P proteins from HPIV1 and HPIV3 are smaller (49–53 kDa) than those of HPIV2 and HPIV4 (83–90 kDa). MW patterns of the HPIV proteins when run in electrophoresis gels may differ from those predicted,

Figure 17.2 The parainfluenza life cycle. Upon binding to sialic acid receptors, viral envelope fuses to plasma membranes, PIV enters the target cell and (-)RNA genome is released into the cytoplasm. Following transcription and replication, L, NP and P proteins are produced and form the newly-produced genomes. M protein is transferred to the plasma membrane, where together with glycosylated HN and F produced through cellular organelles (rough endoplasmic reticulum (RER) and Golgi apparatus), it enriches the plasma membrane regions that allow budding of newly-formed infectious virions. (Source: Moscona, 2005, with permission.)

due to post-translational modifications (glycosylation or phosphorylation).

Viral RNA is encapsidated within multiple copies of the N protein, resulting in helical nucleocapsids. These are further associated with P and L proteins to form the ribonucleoprotein (RNP) complex (Figure 17.2). Accordingly, N is present in abundance in the RNP of the virion to perform its encapsidation function (2600 molecules), whereas the proportions of the L and P proteins are lower (30 and 300 molecules, respectively).

The resulting virions are pleomorphic, roughly-spherical, lipid-containing enveloped particles, 120–300 nm in total diameter (Figure 17.3). The nucleocapsid strands are 12–17 nm in diameter, with cross-striations at intervals of 4 nm. Their total MW is at least 500×10^6 Da and

their density in sucrose is $1.18\text{--}1.20 \text{ g ml}^{-1}$. HPIV virions can be morphologically distinguished from influenza viruses by their thicker and nonsegmented nucleocapsids and from other paramyxoviruses by either morphological (e.g. thinner nucleocapsid than that of *Pneumovirinae* RSV and hMPV) or enzymatic criteria (e.g. absence of neuraminidase activity by morbilliviruses) (Henrickson, 2003).

RECEPTORS, VIRUS ENTRY AND HOST RANGE

Infection of target cells by PIVs is initiated by attachment of virus through interaction of the HN glycoprotein with a cell-surface receptor containing sialic acid (*N*-acetyl

Figure 17.3 The parainfluenza virion. Electron microscopy appearance showing surface glycoproteins. Magnification $\times 275\,000$. (Source: Henrickson, 2003, with permission.)

neuraminic acid, Neu5Ac). F and HN envelope proteins then regulate the process that allows the fusion of the virus envelope with the plasma membrane. Following penetration, the virion gets uncoated and the viral nucleocapsid material is released into the cytoplasm, serving as template for both transcription and replication. Next the replica genomic RNA is packaged into progeny virions that are generated through budding out of plasma membrane areas rich in HN, F and M proteins (Figure 17.2). The M protein triggers budding by interacting with the nucleocapsid and the cytoplasmic components of HN and F proteins, thus mediating the alignment of the former with viral-protein-rich areas of plasma membrane.

HPIV3 infection of airway epithelial cells is polarized and restricted to ciliated cells, as also shown by the use of recombinant HPIV3 engineered to express enhanced green fluorescent protein (EGFP) (Zhang *et al.*, 2005). Characteristically, PIV3 enters and can be released by type II alveolar polarized epithelial cells, preferentially from the apical surface (Bose *et al.*, 2001) with microtubules actively regulating the release process. F-protein trafficking also seems to be restricted to the apical surface of ciliated cells, suggesting that budding may occur from cilia (Zhang *et al.*, 2005).

Both sialoglycoproteins (e.g. glucophorin) (Suzuki *et al.*, 1984; Wybenga *et al.*, 1996) and gangliosides can

serve as specific viral receptors for PIVs (Holmgren *et al.*, 1980; Suzuki *et al.*, 1985; Umeda *et al.*, 1984). It has been shown that SeV is able to bind to both ganglio-series and neolacto-series gangliosides, with a terminal *N*-acetylneuraminic acid (NeuAc) linked to galactose (Gal) by an $\alpha 2-3$ linkage (NeuAc $\alpha 2-3$ Gal) as isoreceptor. HPIV1 and HPIV3 subtypes bind to neolacto-series gangliosides of $\alpha 2-3$ linkage with different binding specificity (Suzuki *et al.*, 2001). Glycoarray-based analysis comprising 285 oligosaccharides demonstrated that HPIV1 and HPIV3 bind only to a subset of glycans that contain $\alpha 2-3$ -linked sialic acids (Amonsén *et al.*, 2007), in contrast to influenza viruses, which use the $\alpha 2-6$ linkage. Differences among HPIV serotypes do exist: HPIV1 binding requires a minimal motif (Neu5Ac $\alpha 2-3$ Gal $\beta 1-4$ GlcNAc), while a longer oligosaccharide is normally needed for HPIV3. Moreover, additional molecules such as heparin sulphate may regulate binding and entry of HPIV3 (Bose and Banerjee, 2002). Finally, cell-surface-expressed nucleolin seems to be required for virus internalization during infection of human lung epithelial cells (Bose *et al.*, 2004).

HN not only mediates HPIV binding to sialic acid containing cellular receptors, but has two additional important properties: it uses its neuraminidase activity

to cleave sialic-acid-containing receptors and undergoes conformational changes which activate the fusion activity of the HPIV F protein. The crystal structure of HPIV3 HN was resolved, indicating that its tertiary structure is a six-sheeted β -propeller (Figure 17.4) and that the sialic acid binding and cleaving functions contained in the globular head of the molecule are not separated (Lawrence *et al.*, 2004). Accordingly, both functions are inhibited by zanamivir (4-GU-DANA, Relenza), a sialic acid analogue. On NDV HN two different active sites appear to exist: site I, showing both receptor binding and neuraminidase activities, and site II, involved only in receptor binding; the latter has a higher avidity for sialic acid receptors than site I and is resistant to zanamivir inhibition (Murrell *et al.*, 2003).

Upon binding to sialic acid receptors HN undergoes a conformational change, which in turn triggers a conformational change in F protein that makes it assume its fusogenic function. Recently, a second zanamivir-resistant active site was also found in HPIV3 HN, which mediates both binding to sialic acid and triggering of the fusion function of F protein (Porotto *et al.*, 2007). N-terminal heptad repeats and C-terminal heptad repeats (N-HR and C-HR) contained within the latter confer a trimeric core coiled-coil formation, and proteolytic cleavage by endoproteases, such as furin and Kex2, into two subunits (membrane distal F₂ and membrane proximal F₁) is required for the exposure of the hydrophobic fusion peptide contained in the new N-terminus of the F₁ subunit. The fusion peptide contains 25 hydrophobic residues highly conserved among the paramyxovirus species. Upon F-protein activation it inserts itself into the target membrane in a transient intermediate, anchoring to both viral

and cell membranes. Then N-HR and C-HR associate into a tight coiled-coil-containing complex, and subsequent re-folding brings together the viral and cell membranes and leads to their fusion, using the free energy generated by the coiled-coil-formation step (Moscona, 2005).

By cleaving sialic acid HN can promote the release of newly-formed virions from the cell surface, allowing them to penetrate additional cells (Huberman *et al.*, 1995). Surprisingly, inhibition of HPIV HN activity by 4-GU-DANA while blocking receptor binding and thus fusion and viral entry, actually aids in the release of newly-formed virions from the infected cells by blocking the interaction between them and their receptors (Porotto *et al.*, 2001). However, this is not the only mode of PIV propagation. PIV envelope proteins accumulating in the cell surface of the infected cells can fuse with neighbouring cells, leading to syncytium formation. Again, neuraminidase activity of HN controls the process by modulating the number of available receptors on the adjacent cells (Moscona and Peluso, 1992). In particular, it has been reported that syncytium formation by HPIV3 is reduced when the target cells are infected at high multiplicity of infection (MOI). The absence of cytopathic effect (CPE) from these ‘persistently-infected’ cells is due to sialic acid cleavage by the HN neuraminidase in a manner proportional to viral loading (Moscona and Peluso, 1993). This phenomenon can be reproduced at low MOI by addition of exogenous (bacterial or viral) neuraminidase. On the other hand, infection with HPIV1 and 2 at high MOI fails to inhibit syncytial formation *in vitro*, as appears to be the case also for infection of ciliated epithelial cells by recombinant HPIV3 (Zhang *et al.*, 2005). Interestingly, the observed CPE cannot be

Figure 17.4 Structure of HN dimer of HPIV3. The N- and C-termini of each monomer are shown in dark and lighter grey, respectively, with the rest of the polypeptide in other shades. Interaction with sialic acid (ball and stick representation) is also depicted. (Source: Adapted from Lawrence *et al.*, 2004, with permission.)

blocked by bacterial or NDV neuraminidase treatment, but it is significantly reduced by HPIV3 neuraminidase, suggesting different cleavage specificities of PIVs' neuraminidases (Ah-Tye *et al.*, 1999). Nevertheless, these data show that in addition to the differences in binding specificities, CPE formation is also differentially regulated by the individual HPIV serotypes, a fact that might have particular impact on their pathogenesis pattern.

Viral interference, a state whereby cells infected by a specific virus are refractory to subsequent infections by the challenge virus, is induced by several mechanisms, including attachment interference. For example, expression of NDV HN inhibits infection of the target cells by NDV (Morrison and McGinnes, 1989). Furthermore, it seems that the neuraminidase activity of HPIV3 depletes the cells of appropriate receptors and protects them from re-infection not only by HPIV3 but also by HPIV2 (Horga *et al.*, 2000). This heterologous interference pattern suggests additional regulatory mechanisms of PIV infection and propagation.

It is plausible that the binding specificities of parainfluenza viruses would determine host range of the particular subtypes. Indeed, sialoglycoproteins localized on erythrocyte membranes mediate the well-studied PIV-mediated agglutination of these cells (haemadsorption activity). In addition, blood-group-I-type gangliosides able to bind HPIVs have been detected in the cell surface from human and bovine, but not equine, erythrocytes. Accordingly, HPIV1 and HPIV3 are unable to induce agglutination of horse erythrocytes, but succeed in agglutinating human- and bovine-derived ones (Suzuki *et al.*, 2001).

However, receptor specificity is not the only determinant of PIVs' host range. Cell-specific replication patterns, as well as cell-specific escape from immune-regulatory mechanisms of the virus, seem to play more important roles in this issue, as described in the following sections.

Finally, it should be noted here that the host range for some PIV species has not been conclusively defined. For instance, SV5, originally isolated from monkey tissue, seems to be a canine virus, but it has also been proposed to be a human pathogen (Chatziandreou *et al.*, 2004). Similarly, SeV, considered to be mainly a murine virus, has been reported to propagate equally well as its homologue HPIV1 in the respiratory tract of primates (Skiadopoulos *et al.*, 2002a).

REPLICATION

Following viral entry and release of the viral RNP into the cytoplasm, transcription is the first event initiating the viral replication cycle. Transcription is thought to start at the 3' end of viral RNA and generates the six canonical

mRNAs by a sequential start–stop mechanism. Conserved sequences flanking the 3' and 5' termini of each PIV gene, termed gene start (GS) and gene end (GE), mediate transcription initiation and termination/polyadenylation, respectively.

Following this initial transcription phase, sequences located in the leader of the 3' end of PIV RNA promote the replication of the nascent RNA, so that the entire genome is copied into a positive-sense replica called the antigenome. A prerequisite for this synthesis is the ability for read-through transcription ignoring the GS and GE signals of each particular mRNA. Subsequently, promoter sequences found in the 3' end (trailer) of the PIV antigenome drive the synthesis of genomic RNA, leading to the replication of the entire PIV genetic material (Figure 17.5).

The whole transcription and replication procedure is thought to be mediated by the RNA-dependent RNA polymerase complex of P and L proteins, and the nucleocapsid N protein. Indeed, efficient HPIV3 transcription and replication has been demonstrated by a minireplicon (i.e. an otherwise 'empty' recombinant viral genome containing only the promoter elements for transcription and replication), when these three proteins were provided in trans by cotransfection (Durbin *et al.*, 1997). Using a similar approach, HPIV2 infection could be achieved using the full-length HPIV2 cDNA (Kawano *et al.*, 2001). It seems that P acts as transactivator of L, which is the catalytic subunit of the polymerase complex. Moreover, the L protein is not able to bind by itself to the N-RNA complex to initiate RNA synthesis, but requires the formation of the L–P complex. Interestingly, N–P and P–P complexes have also been observed in the infected cells. The N–P complex seems to play an important role in encapsidation of the nascent RNA chains during genome replication. The N-terminus of the P protein is responsible for the formation of the soluble N–P complex, whereas the C-terminus mediates P binding to the N-RNA template, as well as the formation of the stable L–P complex (De *et al.*, 2000). According to a recently-proposed model, the polymerase enters the template at approximately the location of the N GS but then scans the template bidirectionally to find a GS signal and initiate transcription (Hoffman *et al.*, 2006). In addition to the role of viral proteins, cellular actin microfilaments seem to play an important role in HPIV3 RNA synthesis and replication (Gupta *et al.*, 1998). Importantly, the actin-binding β -catenin interacts with HPIV3 RNP at the periphery of infected cells and can be packaged in HPIV3 virions, and functions as transcriptional activator of HPIV3 (Bose and Banerjee, 2004).

The promoter elements for SeV and HPIV3 replication have been mapped (Hoffman and Banerjee, 2000;

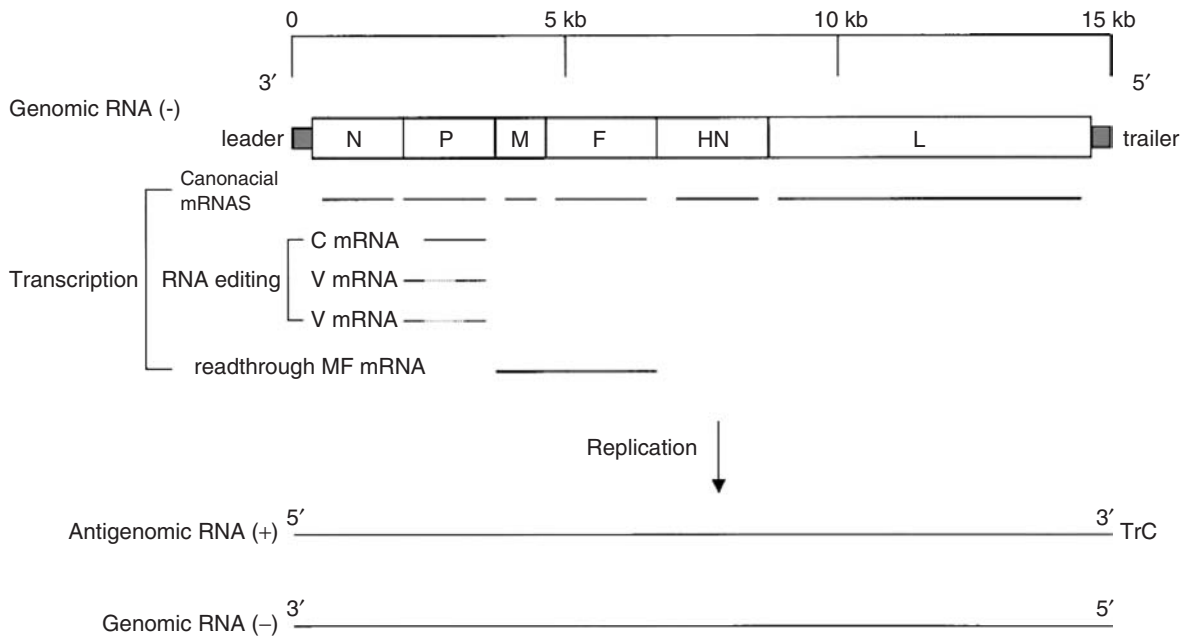

Figure 17.5 The genomic organization and main transcriptional and replication events of parainfluenza viruses. The genomic organization of the PIV genome (3' to 5' direction) as found in the RNP complex of the virion is shown in the upper part of the scheme. Cistron sizes were designed to roughly correspond to the original sequence length, depicting thus relative sizes (in thousands of RNA bases, kb). Upon RNP release into the cytoplasm of a target cell, canonical, as well as alternative, transcriptional events produce the six main mRNAs and additional species (for their role in virus life, see text). Dashed lines within V and D products represent sequences not included in the fusion mRNAs and indicate inclusion of the second ORF. Promoter sequences found in the 3' (leader) of the genome drive not only the transcription but also a round of replication ignoring gene initiation and stop signals, thus producing the antigenomic RNA (depicted in 5' to 3' direction). Promoter elements (TrC) found in the 3' of the latter trigger a second round of replication, generating negative-sense original PIV RNA.

Tapparel and Roux, 1996). The first 12 nucleotides of the 3' leader are essential for HPIV3 replication driven by the leader (Le) promoter. Similarly, the respective region 1–12 of the 3' terminus of the antigenome is critical for the synthesis of genomic DNA driven by the so-called trailer complementary (TrC) promoter (Hoffman and Banerjee, 2000). In addition, cis-elements found within regions 13–28 and 79–96 promote replication, whereas the intergenic region and the start sequence of N gene (49–61) promote transcription (Hoffman *et al.*, 2006).

Replication of most paramyxoviruses, with the remarkable exception of RSV (Samal and Collins, 1996), obeys the so-called 'rule of six' (Calain and Roux, 1993): it is efficient only if the nucleotide length of the genome is a multiple of six. This special feature, thought to reflect an association of the NP protein strictly with six nucleotides in the nucleocapsid, is an absolute prerequisite in SeV, but can be partially circumvented in HPIV2 or HPIV3 (Durbin *et al.*, 1997; Kawano *et al.*, 2001).

Apart from the 'canonical' N, P, M, F, HN and L proteins, a number of alternative transcriptional and translational events have generated additional gene products by PIVs (Figure 17.5). Many of these proteins modulate the transcription and/or replication processes of these viruses.

In particular, an overlapping open reading frame (ORF) located within the P region encodes the nonstructural C protein found in HPIV1, 2 and 3. The C protein of SeV has been reported to inhibit RNA replication by down-regulating the promoter of genomic RNA (Cadd *et al.*, 1996). It also contributes to the SeV pathogenicity for mice (Kurotani *et al.*, 1998). Similarly, the C protein of HPIV3 inhibits viral transcription, and the elements responsible for this inhibition have been localized within a coiled-coil region of the molecule (Malur *et al.*, 2004).

A polymerase slippage on a cis-acting sequence motif in the template P gene leads to the addition of nontemplate nucleotides during mRNA synthesis. Transcription of these elements leads to reading-frame shifts

and internal ORFs are expressed as chimeras fused to the amino-terminus of the P protein. This RNA editing leads to the translation of an additional V protein by the HPIV3 genome. In HPIV2, however, which lacks the above-mentioned C ORF, it is actually the insertion of two G residues that produces the mRNA encoding the P protein, whereas the unedited mRNA (which is actually the exact copy of the P gene) encodes the V protein (Kawano *et al.*, 2001). The differences between the PIV subtypes do not stop here: the V protein is a structural protein detected in the HPIV2 virion (Ohgimoto *et al.*, 2001), but is a non-structural component of SeV (Lamb and Choppin, 1977), whereas the HPIV1 genome does not encode V protein at all (Matsuoka *et al.*, 1991). Recovery of infectious virions from an HPIV2 cDNA modified to lack V-protein expression [HPIV 2V(-)] was successful using the usual reverse-genetics protocols, but the titres obtained were 10–100 times lower than those of unmodified HPIV2, although RNA synthesis was not impaired in the former. Furthermore, HPIV2V(-) virions were anomalous in size, consisting of heterogenous populations and being of larger mean diameter (220 nm vs. 165 nm) (Kawano *et al.*, 2001). The regulation of virus growth by V protein seems to be mediated by a complex formed between V protein, the viral NP complex and proteins provided by the host (i.e. AIP (ALG-2 interacting protein)/Alix). Inhibition of the latter by the small-interference RNA (siRNA) methodology is able to suppress virus growth in cell cultures (Nishio *et al.*, 2007). In addition, the V protein is involved in HPIV-mediated STAT (signal transducers and activators of transcription) degradation, an event essential for HPIV propagation through evasion from the host's immune response (see sections below).

Finally, RNA editing of the P region in HPIV3 and BPIV3 results in the generation of a unique protein named D, not encountered in other paramyxoviruses, which is the fusion product of the N-terminus of P protein and a second internal ORF (Galinski *et al.*, 1992; Pelet *et al.*, 1991).

In addition to synthesizing monocistronic mRNA, the viral polymerase in some cases ignores the termination GE and initiation GS signals. Accordingly, bicistronic M–F read-through transcripts are abundant in cells infected by HPIV1 or HPIV3, but not by SeV (Bousse *et al.*, 1997; Spriggs and Collins, 1986). This capacity to read through was due to cis-elements contained in the long noncoding region of the HPIV1 F gene, and when these sequences were introduced in the SeV M–F boundary they conferred M–F read-through transcription in the modified *Respirovirus* (Bousse *et al.*, 2002). This modification was further shown to reduce the levels of F protein and virus propagation in the infected cells, resulting in reduced pathogenicity of the virus for mice. Thus, failure of transcriptional termination in specific gene boundaries

of the PIV genome may form an additional regulatory mechanism of replication and pathogenesis associated with the parainfluenza viruses.

The mechanisms regulating PIV replication may also contribute to determination of tissue tropism by these viruses. For instance, although Madin–Darby bovine kidney (MDBK) epithelial line cells are refractory to HPIV1, the virus is able to infect them and its genetic material is transcriptionally active in this environment. However, replication seems to be severely impaired, since only trace amounts of genomic RNA and no nucleocapsid formation are detectable following infection, rendering these cells nonpermissive for HPIV1 infection (Tao and Ryan, 1996). Amino acid differences observed at given positions in the otherwise highly homologous BPIV3 and HPIV3 proteins are host-range specific and consistent with the ability of each strain to preferentially propagate in either bovine or primate tissues (Bailly *et al.*, 2000).

During PIV replication the nascent RNA associates with the N–P complex to form the helical nucleocapsid, with matrix protein M playing a central role in this encapsidation procedure (Coronel *et al.*, 2001). Lastly, the nucleocapsids associate with the viral-envelope proteins (M, HN and F) at the plasma membrane and new infectious virions are released from the cell surface, further propagating infection (Figure 17.2).

VIRAL TRANSMISSION, INCUBATION AND SHEDDING

Although transmission has not been extensively studied, it is believed that close-contact transmission and surface contamination may be more important than small-particle aerosol spread or direct hand contact in HPIV transmission (Henrickson, 2003). Similar to RSV, HPIVs live for long periods on skin and cloth (e.g. survive for up to 4 hours on porous surfaces and 10 hours on nonporous surfaces) (Brady *et al.*, 1990). Thus, prevention is particularly important within hospitals and clinics. Common detergents, antiseptics and disinfectants readily remove HPIVs from such surfaces.

Mucous membranes of the nose and throat are the primary sites of infection. After an incubation period of two to eight days, viral replication occurs in the nasopharyngeal epithelium, and one to three days later it is spread throughout the tracheobronchial tree, including the lower respiratory tract. The virus is normally not propagated beyond the respiratory tract, but HPIV has been isolated from cerebrospinal fluid, pericardial and myocardial material, white blood cells and liver in several cases of immunocompromised as well as immunocompetent patients (Reviewed in Henrickson, 2003).

Recurrent infections are a common event and seem to occur more than once, even during adulthood (Marx *et al.*, 1999). However, symptoms become progressively more restricted to the upper respiratory tract.

Shedding of HPIV3 at four to six weeks after onset of respiratory-tract infection (RTI) was observed in a paediatric population (Frank *et al.*, 1981). Increased shedding has also been correlated with more severe RTI symptoms in HPIV1-infected children (Hall *et al.*, 1977). In a remote community model (an isolated population in an Antarctic station), HPIVs could be isolated throughout a period of complete social isolation of greater than eight months (Muchmore *et al.*, 1981). Persistent infection has been demonstrated *in vitro*, where the levels of viral neuraminidase activity and sialic acid receptors or genetic alterations of host cells seem to modulate the process; HPIV2 may use different mechanisms than the other serotypes to achieve this (Ah-Tye *et al.*, 1999). Altered or compromised immunity seems to be responsible for cases of persistent HPIV infection in patients (Henrickson, 2003).

PATHOGENESIS

HPIV infection and illness is associated with both upper and lower-respiratory-tract symptoms. Furthermore, HPIVs have been clearly associated with the development of croup, pneumonia and bronchiolitis in susceptible individuals, mainly children (see 'Epidemiology' and 'Clinical Features'). Pathologic features of these conditions, such as airway inflammation, necrosis and sloughing of the epithelium, oedema, excessive mucus production, alveolar filling and interstitial infiltration of the lungs, should therefore be considered consequences of HPIV-associated airway lesions (Marx *et al.*, 1999).

HPIV infections are also associated with the accumulation of ions and fluid in the respiratory tract. This may at least partly be due to a direct effect on ion transport by the respiratory epithelium (activation of Cl^- secretion and inhibition of Na^+ absorption), as shown in a model of SeV infection of tracheal epithelium (Kunzelmann *et al.*, 2004). The effect seems to be mediated by binding of SeV to a HN-resistant glycolipid, possibly asialo-GM1.

CPEs, mainly syncytium formation, are thought to be of crucial importance for HPIV pathogenesis. Thus, HPIV1 and HPIV2 have been shown to readily infect and propagate in cultured human tracheal epithelial cells (Stark *et al.*, 1991). CPE including early syncytium formation has also been demonstrated in this system. The role of HN-receptor interaction in the process has been demonstrated in experiments using variants of HPIV3

that contain single amino acid changes in HN. These altered HN molecules show increased avidity for sialic acid receptors, and as a result the respective variants are highly fusogenic and destroy a cell monolayer more rapidly than wild-type (wt) HPIV3. More importantly, they cause alveolitis and more severe interstitial pneumonitis than wt HPIV3 in a reliable cotton-rat model for PIV infection (Prince *et al.*, 2001). The enhanced inflammatory response caused by HN variants is dissociated from viral replication or infectivity and is thought to be caused by HN-directed alterations in chemokine expression of the host (Moscona, 2005).

The main body of evidence concerning HPIV-mediated airway inflammation comes from animal studies, since early experimental infection protocols of human volunteers (Kapikian *et al.*, 1961; Lefkowitz and Jackson, 1966; Smith *et al.*, 1967; Tremonti *et al.*, 1968) have not been continued and HPIV inoculation was poorly infectious (Clements *et al.*, 1991).

Rats and mice develop bronchiolitis and pneumonia following PIV infection, with characteristics similar to the human pathology (Mo *et al.*, 1995; Porter *et al.*, 1991; Sorden and Castleman, 1991). Although the respiratory epithelium is the major site of infection in such models, olfactory infection with SeV has been demonstrated in mice. Respiratory inflammation (IFN- γ , IL-2, IL-6, TNF- α (tumour necrosis factor- α) secretion) is evident in the bronchoalveolar (BAL) fluid of C57BL/6J mice inoculated with nonfatal doses of SeV, peaking between day 7 and day 10, the time point at which the virus is cleared from the lungs (Mo *et al.*, 1995). Infiltration of BAL fluid and bronchioles by inflammatory cells (neutrophils, lymphocytes, macrophages and mast cells) has been reported in an SeV-infected rat (Sorden and Castleman, 1991). Eosinophils, macrophages and neutrophils accumulated in the BAL fluid of guinea pigs four days post-PIV3 infection and this was associated with airway hyperreactivity (Toward *et al.*, 2005). In addition, the expression of chemokines such as MCP-1 (monocyte chemoattractant protein-1), RANTES (regulated-on-activation normal-T-cell-expressed-and-secreted protein), GRO- α (growth-related oncogene- α) and IL-8 is induced by SeV in human cells (Hua *et al.*, 1996; Le Goffic *et al.*, 2002). Infection of epithelial cells by HPIV4 enhanced epithelial IL-8 and IL-6 production by both NF- κ B- and AP (activator protein)-1-mediated transcriptional up-regulation, as well as by inhibition of their mRNA degradation (Roger *et al.*, 2004). Moreover, the chemokines RANTES and MIP-1 α (macrophage inflammatory protein-1 α) have been also found elevated in nasal secretions of paediatric patients with acute upper-respiratory illness attributed to a number of respiratory viruses, including HPIV (Bonville *et al.*, 1999).

Airway inflammation and hyperresponsiveness are also induced by HPIV3 in guinea pigs, characterized by increased release of and response to histamine, and BAL enrichment with eosinophils, neutrophils and monocytes (Folkerts *et al.*, 1993; Graziano *et al.*, 1989; van Oosterhout *et al.*, 1995). Eosinophil accumulation is well correlated with the degree of airway responsiveness, as well as with the significantly-elevated eotaxin levels following HPIV3 inoculation (Scheerens *et al.*, 1999). Interestingly, the viral content detected in the lungs of inoculated animals presensitized with ovalbumin (i.e. eosinophil enriched) was considerably reduced (80%) compared to the nonsensitized ones (Adamko *et al.*, 1999). Treatment with an antibody to IL-5, a known eosinophil chemoattractant, reversed the ovalbumin effect and inhibited viral clearance. Thus, similarly to what has been previously reported for RSV (Domachowske *et al.*, 1998), eosinophils, when activated by the HPIV virus, apart from mediating inflammatory activity, may also exert antiviral action.

In accordance with the increased airway hyperresponsiveness and the HPIV-mediated eosinophilia established in the animal models, naturally-occurring HPIV3 infection has been associated with mild exacerbation of asthma (Matsuse *et al.*, 2005). However, no correlation could be found between HPIV3 and sputum cytokine (IL-5, IL-10 and IL-12) and eosinophil marker (eosinophilic cationic protein) levels. In contrast, cysteinyl leukotrienes were significantly increased during HPIV3-associated mild asthma exacerbation (Matsuse *et al.*, 2005).

Finally, both HPIV2 and HPIV3 have been reported to induce expression of intercellular adhesion molecule-1 (ICAM-1) in tracheal and other human epithelial cells (Gao *et al.*, 2000; Tosi *et al.*, 1992a). Notably, ICAM-1 also serves as receptor for the majority of rhinoviruses, another important group of respiratory pathogens. This increase may induce adhesion of inflammatory cells in airway epithelium, further augmenting local inflammation, as has been shown for neutrophils in *in vitro* systems (Tosi *et al.*, 1992a, 1992b). Indeed, from the limited human studies available, HPIV3 infection has been associated with BAL neutrophilia in a patient experiencing unilateral bronchiolitis obliterans (Peramaki *et al.*, 1991), whereas bronchial neutrophils and eosinophils were found significantly increased in otherwise healthy individuals during common colds caused by respiratory viruses including HPIV (Trigg *et al.*, 1996).

The above data clearly indicate an inflammatory impact of PIV infection, consistent with an early report showing increased nasal secretion of IFN in children infected by PIVs (Hall *et al.*, 1978); however, further human studies would be required to establish its clinical impact.

ANTIGENICITY AND IMMUNITY

Almost all children by the age of three years demonstrate serologic evidence of HPIV infection (Henrickson, 2003). Sera obtained from subjects one to two weeks following HPIV infection contain antibodies able to inhibit HPIV-induced adsorption of erythrocytes to cultured cells. These so-called haemagglutination inhibition (HI) antibodies persist in the host for several years, whereas complement-fixing antibodies against the whole virion (V-CF) appear one to two weeks later and tend to persist only for approximately one year. Neutralizing antibodies are detected at the same time as HI antibodies. Although IgG1 constitutes the majority of the antibody response against HPIV, one third of adults show increased IgG3, IgG4, serum IgA and IgM levels.

Antibodies can be elicited against the HN, N, P, F and M proteins. However, HN seems to possess the greater antigenicity. Twenty-one epitopes have been mapped in HPIV1 HN (Henrickson and Savatski, 1997). They are organized in five non-overlapping antigenic sites (I–V) and a sixth site connecting sites I, II and III. By examining clinical isolates collected during a period of 35 years and from different geographic regions, evidence was provided showing that only 33% of these epitopes were conserved among isolates. Two sites were found in all isolates, but another one was missing from isolates collected in the last 15 years. Similarly, some monoclonal antibodies against HN and N of HPIV1 strains generated in the 1990s did not react with isolates obtained in the 1970s and 1980s (Komada *et al.*, 1992), in contrast to an earlier report suggesting HN homogeneity by finding a single change in the HPIV1 HN antigenic pattern in a limited number of isolates obtained between 1981 and 1989 (Hetherington *et al.*, 1994). Monoclonal antibodies raised against HPIV3 allowed the mapping of 5, 2, 6 and 6 epitopes in HN, F, N and M proteins, respectively (Rydbeck *et al.*, 1987); this analysis also revealed antigenic variation among isolates obtained throughout a six-year period. Similarly, considerable antigenic variation has been found among clinical HPIV2 isolates, as well as HPIV4A and HPIV4B. In general, analyses of all HPIV serotypes indicate higher antigenic and genetic heterogeneity than initially believed, suggestive of antigenic changes that, although slow, are reminiscent of the evolutionary pattern of influenza B (Henrickson, 2003). Accordingly, some of the standard sera raised against HPIVs in the previous decades fail to detect the virus in serologic tests imposing the use of more recent materials as antigenic sources.

At least 20 epitopes have been located in the F protein of HPIV3 (van Wyke Coeling and Tierney, 1989). From

those, only 14, organized in three non-overlapping antigenic sites, induce the production of neutralizing antibodies. In addition, HPIV3 frequently accumulates mutations producing F epitopes that efficiently bind to antibodies but are resistant to neutralization. Similarly, antibodies against HPIV4 (of both subtypes) can be divided into three groups: those showing high neutralizing, HI and hemolysis inhibition activities, those neutralizing the virus but unable to inhibit haemagglutination, and those exhibiting low neutralizing and HI activity (Komada *et al.*, 1989). The F protein seems to possess neutralizing-related epitopes in this case.

The antigenic capacity of HPIV proteins is complex and often unpredictable. The HN glycoproteins of related PIV subtypes for instance may be antigenically dissimilar even if they share common epitopes, as is the case for HPIV3 (Ray and Compans, 1986). However, even when the amino acid identity between HN proteins of closely-related viruses is high (e.g. between HPIV1 and SeV) there may be a limited conservation of epitopes and high-antigenic diversity (Komada *et al.*, 1992). In the case of the HPIV4 subtypes (4A and 4B), antigenicity of the N protein is highly conserved between them, but monoclonal antibodies raised against F or HN proteins show low cross-reactivity with the heterologous subtype viruses, although there is a high degree of amino acid identity between the respective glycoproteins (Komada *et al.*, 1989). By constructing HPIV4B cDNAs with putative N-glycosylation sites identical to those of 4A, it could be shown that the mutant 4B subtype was antigenically closer to 4A than to the wt HPIV4B (Komada *et al.*, 2000), suggesting that N-glycosylation pattern determines, at least partially, the limited cross-reactivity observed between PIV species.

The severity of respiratory illness and the duration of virus shedding seem to be reduced in the presence of high titres of neutralizing antibodies (Chanock *et al.*, 1961). However, the fact that HPIV3, for instance, can re-infect an individual within a short time interval, and even in the presence of neutralizing antibodies (Bloom *et al.*, 1961; Glezen *et al.*, 1984; Welliver *et al.*, 1982), and may cause infection of a persistent nature (Gross *et al.*, 1973; Muchmore *et al.*, 1981) suggests that the virus fails to induce a state of long-lasting immunity. These events cannot be explained by the relatively stable antigenic determinants. On the other hand, the fact that the most severe symptoms develop in subjects with defects in cell-mediated immunity or severe immunodeficiency syndromes (Dorman *et al.*, 1999; Taylor *et al.*, 1998) indicates that the interaction of PIVs with the T-cellular compartment of the host's immune response may be of crucial importance for the fate of both the virus and the infected host.

Cytotoxic responses preferentially mediated by $\alpha\beta$ T cells (although $\gamma\delta$ T cells and natural killer (NK) cells are also involved) are elicited against HN, P and NP proteins, and regulate clearance of the HPIVs from the lower airways. Cytokine induction in response to HPIV3 has been shown to inhibit both T-cell proliferation and cytotoxicity *in vitro* (Sieg *et al.*, 1994, 1995). In particular, HPIV3 induced IL-10-inhibited proliferation of CD3⁺ peripheral blood mononuclear cells (PBMCs) derived from healthy human donors and infected *in vitro* by the virus (Sieg *et al.*, 1996). In addition, the HPIV3-infected lymphocytes failed to respond to IL-2, suggesting that IL-10-inhibition of T-cell function may support enhanced virus survival. HPIV3 infects and replicates poorly in human monocytes, simultaneously increasing their survival by induction of granulocyte macrophage colony forming factor (GM-CSF) expression (Plotnicky-Gilquin *et al.*, 2001). In addition, the virus replicates extensively in human dendritic cells (DCs), accelerating their apoptosis. The surviving DCs seem to undergo maturation via increased production of IL-12 following HPIV3 treatment, but mature DCs were poor stimulators of allogeneic T-cell proliferation (Plotnicky-Gilquin *et al.*, 2001). Recent evidence suggests that the neuraminidase activity of HN of HPIV3 may be responsible for the induction of DC maturation and the production of a characteristic pattern of cytokines (Horga *et al.*, 2005). Thus, HPIV3 infects and differentially regulates the growth and response of these two professional antigen-presenting cell populations. Infected DCs may actually contribute to the active dissemination of the virus, whereas only small numbers of surviving pulmonary DCs should be able to reach the draining lymph nodes; however, these cells would have low stimulatory properties, thus aiding survival of the virus. The infected monocytes might also constitute a reservoir for HPIV3.

HPIV3 induces the expression of major histocompatibility complex (MHC) class I and class II molecules in human alveolar epithelial cells (Gao *et al.*, 1999). Although IFN- β is also induced and acts as an intermediate in this process, viral antigens also contribute to MHC induction. MHC class I induction is virus-replication-independent, whereas infectious virions are required for induced expression of MHC class II molecules. Such an induction pattern could contribute to HPIV3 infection immunopathology by increasing cytotoxic T-lymphocyte (CTL)-mediated lysis of respiratory epithelium.

PIVs are able to escape IFN-mediated antiviral immune responses. Type I IFN (IFN- α and IFN- β) responses are mediated by both STAT1 and STAT2 transcription factors, whereas type II (IFN- γ) uses only STAT1. It has been shown that the V protein of SV5 is responsible for blocking IFN antiviral responses in human cells by

targeting STAT1 for degradation by the proteasome (Didcock *et al.*, 1999). Degradation is independent of IFN signalling and targets both phosphorylated and unphosphorylated STAT1. Although practically all PIVs seem to resist IFN responses (Young *et al.*, 2000), there are differences in the mechanisms used by the individual members of the subfamily to achieve this. In particular, HPIV3 and SeV have been shown to block both type I and type II IFN pathways, whereas HPIV2 is able to block only type I, by down-regulating STAT2 (Young *et al.*, 2000). Accordingly, HPIV2 replication is severely impaired in IFN- γ pretreated cells (Andrejeva *et al.*, 2002). The inability of HPIV2 to block IFN- γ -mediated defense could suggest why HPIV2 infections are generally less severe than HPIV3-mediated ones (see 'Clinical Features'). In addition, human STAT2 transfected into mouse cells confers on SV5 the ability to mediate STAT1 degradation and to escape from type I response in an otherwise refractory environment (Parisien *et al.*, 2002), suggesting that STATs may serve as intracellular determinants of PIV host range by affecting each other's degradation. There is also species specificity since, besides STAT2 degradation, HPIV2 V protein can also abolish STAT1 in an *in vitro* system, depending on whether the host cells are of mouse or human origin (Precious *et al.*, 2005). Interaction of V protein with partners such as the UV damaged DNA binding protein (DDB) and Cullin4A (Cul4 α), which associate with the E3 ubiquitin ligase complex, is crucial for this process. Although HPIV4 is able to associate with STAT1, STAT2, DDB and Cul4 α , it is unable to induce STAT degradation and thus escapes antiviral IFN responses (Nishio *et al.*, 2005), a fact that may explain the more modest symptoms observed with HPIV4 infection. Recent *in vitro* studies indicate that in addition to V protein, the C protein of HPIV3 may also mediate suppression of antiviral responses using a somewhat different mechanism, namely by inhibiting STAT1 phosphorylation (Malur *et al.*, 2005). On the other hand, the C protein of HPIV1 inhibits both activation of IFN regulatory factor 3 and IFN production in A549 airway epithelial cells (Van Cleve *et al.*, 2006). Nevertheless, examination of V and C proteins from several PIV species suggests that V proteins may use different mechanisms than C proteins to suppress double RNA-induced IFN- β production targeting particular signalling molecules, such as melanoma differentiation-associated protein 5 (MDA-5) (Komatsu *et al.*, 2007). In addition, the highly homologous HPIV1 and SeV (murine PIV1) or their C proteins both block the IFN Jak/STAT pathway in human cells. However, when human cells are pretreated with IFN, although the replication of both viruses is initially inhibited, it is subsequently recovered only for the human PIV1. Conversely, SeV overcomes suppression in IFN-pretreated murine cells,

again emphasising that PIV-mediated anti-IFN activity is species-specific (Bousse *et al.*, 2006).

Finally, HPIV3 has been shown to induce type I IFN expression in human epithelial cells (Gao *et al.*, 2001), consistent with the reported elevated IFN levels following parainfluenza infection in children (Hall *et al.*, 1978). HPIV3-induced IFN- α/β inhibits signals downstream of class II, major histocompatibility complex, transactivator (CIITA) mRNA accumulation, a transcription factor regulating IFN- γ -induced MHC class II expression. On the other hand, HPIV3 antigens directly inhibit CIITA mRNA accumulation (Gao *et al.*, 2001), the overall effect being an inhibition of IFN- γ -induced MHC class II expression in epithelial cells; that is, the primary target of respiratory virus replication (Gao *et al.*, 2001). This may result in regulation of CD4⁺ cell activation, in addition to PIV-mediated regulation of macrophages, B cells and DCs.

EPIDEMIOLOGY

HPIVs are one of the leading causes of hospitalization for ARD in young children. It has been estimated that they can account for 9–30% of hospitalizations for paediatric acute respiratory illnesses (Henrickson, 2003). Studies with paediatric populations across the United States revealed that during 1970s–1990s HPIV infections were responsible for approximately 65% of croup, 20–40% of upper-respiratory-tract infections (URTIs) and 20% of lower-respiratory-tract infections (LRTIs) (Weinberg, 2006). However, the high prevalence of HPIV infections may have been underestimated (at least 1.5 times), since most large cohort studies were based on less sensitive detection methods (cell culture, serology) than the conventional and real-time reverse transcriptase PCRs (RT-PCRs) that are currently being applied. Real-time RT-PCR-based diagnosis of respiratory viruses including HPIVs increased the calculated incidence of infection by a viral respiratory pathogen from 24 to 43% in infants and from 3.6 to 36% in adults hospitalized for respiratory illness (van de Pol *et al.*, 2007).

Similarly to RSV, HPIV transmission is likely to take place by aerosolization of large droplets rather than by aerosol (small-droplet) spread (Hall, 2001; Henrickson, 2003). Virus-laden droplets expelled from lower-respiratory or nasal secretions of infected individuals primarily infect mucous membranes of the nose and throat, where, after a two-to-eight-day incubation period, HPIVs are replicated and eventually spread into the lower respiratory tract. Viral pneumonia, otitis media, bronchiolitis, fever of unknown etiology and nonspecific URTI are often encountered among HPIV patients (Weinberg, 2006). Among serotypes, HPIV1 and HPIV2 are

generally more associated with croup, URTI and pharyngitis (Knott *et al.*, 1994), whereas HPIV3 is in addition a major cause of infant bronchiolitis and is also associated with the development of pneumonia in susceptible subjects (Hall, 2001). HPIV3 seems to infect younger children than HPIV1 and HPIV2 (50–67% are infected by one year of age (Weinberg, 2006)). HPIV4 subtypes cause a rather mild illness; however, lower-respiratory-tract symptoms have been documented (Lindquist *et al.*, 1997). In an HPIV4 outbreak in a developmental-disabilities unit a portion of the paediatric patients infected by HPIV4 showed LTRIs, including respiratory failure requiring mechanical ventilation (Lau *et al.*, 2005). Although less studied, HPIV4 may cause more severe pathology than previously believed; HPIV1 and HPIV3 are generally thought to confer the more symptomatic phenotypes, followed by HPIV2 and the less symptomatic HPIV4s.

Serological evidence suggests that almost 50% of infants have been infected by HPIV3 by the time they reach their first birthday (Parrot *et al.*, 1962). In contrast, HPIV1 and 2 are encountered more frequently in toddlers and preschool children. Although HPIVs mainly affect the paediatric population, adult infection is not uncommon, and is usually associated with mild URTI and common cold (Makela *et al.*, 1998). Nevertheless, a portion of community-acquired pneumonia in adults may be associated with HPIV infection (Marx *et al.*, 1999). By collecting data from England and Wales for the period 1975–1997, Laurichesse *et al.* (1999) were able to illustrate the different age-distribution patterns of all four HPIV subtypes (Figure 17.6). In contrast, they could not find any significant gender-dependent differences.

The relative circulation rates differ among the individual HPIV serotypes. A US national prospective study analysed over 40 000 reported positive test results covering a 15-year period (1990–2004) (Fry *et al.*, 2006) and found that more than half of HPIV infections were due to HPIV3 (52%), followed by HPIV1 (26%), HPIV2 (12%) and HPIV4 (2%). These results were in accordance with a previous study that followed successive cohorts formed over a period of 20 years (1974–1993) in Nashville by 1429 otherwise healthy infants and young children of less than five years of age; that study identified HPIV3 as the most common HPIV pathogen isolated from LRTI specimens (59%), followed by HPIV1 (29%) and HPIV2 (12%) (Reed *et al.*, 1997). In all, HPIV isolates represented 17.4% of all viral cultures that yielded a virus in that study, with 10% of the children having a symptomatic HPIV3 LRT infection. The higher incidence of HPIV3 infections was consistent with the annual epidemic pattern of HPIV3 isolation during this period, in contrast to the biennial outbreaks of HPIV1 and HPIV2. In addition, Laurichesse *et al.* (1999) reported finding HPIV3 more frequently isolated from children aged 3–12 months, whereas the other two species were more common in the second year of life.

HPIV1 outbreaks are correlated with well-defined biennial rises in croup outbreaks usually recorded in the autumn (Hall, 2001). HPIV1 outbreaks occur biennially between late September and December, with an outbreak duration of 13–15 weeks (Fry *et al.*, 2006). HPIV2 outbreaks have been thought to follow those of type 1, being generally less predictable, though simultaneous incidence has also been recorded (Hall, 2001). More-recent data, however, suggest an annual occurrence from October to

Figure 17.6 Age distribution of HPIV laboratory reports in England and Wales, 1985–1987. (Source: adapted from Laurichesse *et al.*, 1999.)

December (Figure 17.7), with outbreak duration varying between 1 and 18 weeks (Fry *et al.*, 2006).

As mentioned, HPIV3 infections seem to be considerably more frequent (Fry *et al.*, 2006; Laurichesse *et al.*, 1999) and to occur annually, with peaks recorded during spring and summer. Outbreaks of this virus last longer than those of the other members of the family (Hall, 2001). Importantly, Fry *et al.* demonstrated recently that in the years with no HPIV1 activity, HPIV3 incidence (occurring annually between April and June; Figure 17.7) seemed to be significantly more prevalent, characterized by either an elongated spring outbreak or a second smaller outbreak in the fall (Fry *et al.*, 2006). The study used the cumulative-sum method, which determines periods of peak viral incidence, relying on the presence of significantly more positive tests than those observed in the preceding weeks. The emerging interaction between HPIV1 and HPIV3 may be of particular importance for designing preventive strategies.

HPIV4 isolates are rare (Figure 17.7) and accordingly their seasonal pattern is less well characterized (Fry *et al.*, 2006); however, HPIV4 diagnosis is probably underestimated and previously-undetected cases can be identified with more sensitive methods, such as real-time RT-PCR (Templeton *et al.*, 2005). Although the majority of HPIV4 clinical isolates are of subtype B, as many as 95% of adults have antibodies against HPIV4A, compared to 75% that have antibodies against HPIV4B.

Croup incidence is associated more with HPIV1 epidemiology than with the other HPIV subtypes. In a study conducted between winter and spring of three consecutive years in Canadian patients with croup, HPIV1 was isolated in 30.3% of cases and HPIV3 in 3.5%. Peak monthly HPIV1 isolation occurred in November in this study and in January in another study of similar design (McLean, 2000). By analyzing croup hospitalization collective data from the United States, Marx *et al.* (1997) confirmed the unique pattern of HPIV1 epidemics: HPIV1 has produced national epidemics of acute RTI in the United States in the odd-numbered years between 1979 and 1993, whereas it has rarely been isolated in between the peaks. Notably, HPIV1 was calculated to be responsible for ~18% of all cases of croup recorded and ~37% of all cases with determined aetiology, indicating the leading role of this HPIV subtype in the disease. While the major peaks of croup occurred biennially during October in odd-numbered years, minor peaks were produced annually around February (Figure 17.8). Interestingly, these trends were also age-dependent, with epidemics of children under five years closely following the biennial pattern, whereas for older children the annual winter peak was equally as high as that of the autumn, and moreover there were no apparent differences between odd- and even-numbered years in the magnitude of the autumn peak. The pattern of the autumn peaks coincided well with

Figure 17.7 Seasonal trends in HPIV incidence. Distribution of positive tests for all HPIVs in the United States during 1990–2004, based on weekly reports to the National Respiratory and Enteric Viruses Surveillance System (NREVS). (Source: adapted from Fry *et al.*, 2006.)

Figure 17.8 Collective data from croup hospitalizations (children <15 years of age) in the United States, 1979–1993. 22.5% of all croup hospitalizations per biennium, and 36.7% in odd-numbered years, can be attributed to HPIV1. (Source: Marx *et al.*, 1997, with permission.)

peaks of HPIV1 isolation across the United States (Marx *et al.*, 1997).

Another population-based prospective study suggested that during their respective epidemic seasons, HPIV1 and HPIV3, but not HPIV2, were among the most commonly detected infectious agents in adult patients hospitalized for LRTI (together with RSV and influenza A and B) (Marx *et al.*, 1999). Importantly, no HPIV1 and very few HPIV3 infections could be documented in between the epidemic seasons. Although similar rates of incidence were observed for HPIV1 and HPIV3 in this adult population in the epidemic seasons (2.5% and 3.2% of hospitalized patients, respectively), the likelihood of clinically-serious disease was greater for HPIV3 infection. In contrast, the role of HPIV2 was emphasized in a study among hospitalized children with LRTI, where it was suggested that HPIV2 predominantly associates with inspiratory difficulties, as compared with HPIV1 and HPIV3 (Korppi *et al.*, 1988).

CLINICAL FEATURES

Acute laryngotracheobronchitis (croup) is the major clinical manifestation, and the hallmark of HPIV (especially HPIV1) infection in children. The syndrome is characterized by croupy cough, inspiratory stridor, cry or hoarse voice, difficulty during inspiration and in-drawing of the chest wall in the subcostal, intercostal or supraclavicular areas (McLean, 2000). There are frequent rhonchi in the lungs and air entry into the chest is inhibited. Accordingly, diminished inflation of the lungs is revealed in some cases by radiology. In some cases there is also severe airway obstruction due to swelling of the epiglottis or the aryepiglottic folds of the larynx, which may

require emergency tracheotomy to reestablish inspiration. Upon hospitalization (usually 3–24 hours after the onset of the clinical syndrome) the symptoms usually subside relatively quickly (one to two days). Influenza, measles and chickenpox may also induce croup in paediatric patients.

Parainfluenza viruses have also been involved in LRTI and other complications of upper URTI. About 30–50% of patients developing URTI due to parainfluenza infection may experience otitis media (Knott *et al.*, 1994). About 15% of HPIV infections also involve the lower respiratory tract, with some 2.8% of patients requiring hospitalization (Reed *et al.*, 1997). A study analyzing the prevalence of HPIV1 and HPIV2 in US children under six years of age receiving emergency treatment and/or requiring admission due to LRTI during the fall of 1991 reported that PIVs were associated with croup (48%), bronchiolitis (10%), pneumonia (12%), cough with fever (29%) and wheeze with fever (19%) (Henrickson *et al.*, 1994). HPIV association with bronchiolitis has also been clearly documented (Hall, 2001; Welliver *et al.*, 1986). Pneumonia and bronchiolitis due to HPIV3 infection occur mainly in the first six months of life, as is also the case for RSV (Reed *et al.*, 1997). HPIV3 infection has also been associated with mild exacerbation of asthma (Matsuse *et al.*, 2005).

A report examining data collected over a period of 20 years concerning immunocompetent children aged under five years with a clinically significant ARD revealed the absence of significant differences among clinical signs and symptoms between the three main HPIV serotypes. The most common symptoms comprised coryza and cough, with fewer than 10% of cases experiencing high body temperatures (Reed *et al.*, 1997). There were no significant differences between upper and lower RTI among the subtypes, with LRTI being more rare than

expected. In contrast, HPIV3 was more often associated with acute otitis than HPIV1 and HPIV2 combined (Reed *et al.*, 1997). In a recent outbreak of the less well studied HPIV4 in a developmental disabilities unit, affecting 38 children 3 three staff members, URIs were the major symptoms, but LRTIs occurred in 7% of the children. A case of respiratory failure requiring ventilation support was also reported in the same outbreak. Genetic analysis suggested that the outbreak was probably of the HPIV4A serotype (Lau *et al.*, 2005).

Although HPIV infection is thought to concern mainly paediatric patients, it has also been associated with LRTI in adults. Association of HPIV3 with adult croup has recently been documented, providing evidence suggesting that the disease may be severe in adults as well as in the paediatric population (Woo *et al.*, 2000). Furthermore, in a prospective study among adults hospitalized during 1991–1992, HPIV1-mediated symptoms and disease included wheezing, rhonchi and one case of lobar pneumonia (Marx *et al.*, 1999). Wheezing and rhonchi were also recorded among HPIV3-infected patients, at rates significantly higher than those reported among patients experiencing a bacterial pneumonia (*C. pneumoniae*, *M. pneumoniae*, etc). 27% of HPIV3-infected hospitalized patients developed lobar pneumonia.

Nosocomial spread of community-acquired parainfluenza viruses transported into transplantation units by employees or visitors may cause severe infection of patients receiving immunosuppressive treatment following bone marrow transplantation. The severity depends on the degree of immunosuppression, the virus subtype, the presence of other infections and the timing of the infection (before or after engraftment) (Wendt and Hertz, 1995). A high mortality rate due to pneumonia, reaching even 37%, has been reported for HPIV infections in cases of children and adults receiving bone marrow transplantation, as well as of infants with combined immunodeficiency (Frank *et al.*, 1983; Wendt *et al.*, 1992); however, lower mortality rates have also been documented (Dignan *et al.*, 2006). In a recent outbreak within a haematology unit, nine deaths occurred among haematopoietic stem cell transplant recipients after community-acquired HPIV3 was introduced into the clinic by a patient. Another patient became chronically infected by the same strain of HPIV3 and passed the virus over to other patients, which in combination with a later RSV outbreak ended up with the disastrous outcome of 9 deaths among 27 infected patients (Jalal *et al.*, 2007). In patients with severe combined immunodeficiency syndrome or acute myelomonocytic leukemia, HPIV infection may be associated with the development of persisting, severe and sometimes fatal LRTI, including giant-cell pneumonia (reviewed in Henrickson,

2003). IFN- γ -deficient patients are also more susceptible to HPIV3 infection (Dorman *et al.*, 1999). Moreover, patients undergoing lung transplantation are significantly susceptible to HPIV infection (Vilchez *et al.*, 2003). Infections occurred in 1.6–11.9% of the recipients among several studies, most probably almost a year after transplantation, and were highly associated with allograft rejection. As many as 32% of HPIV-infected recipients developed active bronchiolitis obliterans six months after infection, severely impairing long-term survival of lung transplants. Notably, HPIV3 has been associated with rejection of renal and liver transplants. On the other hand, HPIV infection may be asymptomatic in patients undergoing hemopoietic cell transplantation, in contrast to RSV and influenza infections (Peck *et al.*, 2007).

In immunocompromised patients, infection of HPIV is not restricted to the respiratory tract, but may affect diverse tissues, including myocardium. Characteristically, in a retrospective study samples obtained from a small group of patients with congenital immunodeficiency who died following HPIV infection were examined for signs of HPIV presence (immunohistochemistry) and related cytopathology (e.g. presence of giant cells). As well as lung and bronchi, in most of the cases HPIV infection and cytopathic events were documented in additional tissues, including pancreas, kidneys, bladder, gastrointestinal tract, spleen, thymus and/or lymph nodes and small blood vessels in various organs (Madden *et al.*, 2004). Furthermore, *in vitro* studies suggested that HPIV3 is able to infect epithelial cells of pancreatic, bladder, colon and thymus origin, suggesting that HPIV infection may be spread to other organs, at least under immunocompromised conditions, thus increasing its morbidity and mortality.

Rarely, parainfluenza infection has been also shown to affect the central nervous system and brain, even in immunocompetent subjects associated with acute and chronic neurological disease, suggesting a potential neurotropism in certain hosts. Thus, PIV has been isolated from children and adults with meningitis (Arguedas *et al.*, 1990; Arisoy *et al.*, 1993; Vreede *et al.*, 1992). Furthermore, the presence of PIV has also been documented in syndromes such as Guillain–Barre and Reye's (Powell *et al.*, 1973; Roman *et al.*, 1978). A particular problem has been the development of febrile seizures in children hospitalized for HPIV infection: in that case HPIV4B seems to be more aggressive (up to 62% association) than the other serotypes (17% for HPIV3 and 7% for HPIV1). Hendra and Nipah viruses have been reported to cause severe encephalitis, and are associated with mortality in children and adults (Mounts *et al.*, 2001; Nichol *et al.*, 2000). In addition, HPIV1, HPIV2 and HPIV3 have been identified in the airways of children with acute encephalitis.

Finally, HPIV infections have been documented in several syndromes in the absence of other pathogens, including acute respiratory-distress syndrome in children, parotitis, hepatitis, gastroenteritis, as well cardiovascular (myocarditis and pericarditis) and muscular disorders (rhabdomyolysis) (reviewed in Henrickson, 2003).

DIAGNOSIS

As for all respiratory viruses, identification of parainfluenza viruses in clinical specimens can be achieved by detecting whole virus, viral proteins and viral RNA in clinical samples, as well as by investigating host antibody responses. Methods include: identification of the virion or viral proteins by electron microscopy or immunofluorescence, respectively; virus culture and identification based on CPEs in cultured cells; a variety of serology techniques to detect antibody responses; and detection of PIV genetic material with the aid of the RT-PCR method. The latter has proved to be a very reliable, rapid and sensitive method in a number of applications (either in its conventional or in the real-time format), allowing the simultaneous detection of other respiratory viruses in the same specimen, and it is being used in current large epidemiological cohort studies.

Nasopharyngeal secretions or throat swabs constitute the preferred specimens for all PIV detection methods, with the latter in general giving less satisfactory results (McLean, 2000).

Whole-virus Detection

Viral-particle identification can be achieved by electron microscopy either in nasopharyngeal aspirates and lavages or in lung biopsies. Microdrops of secretion or garglings are placed on electron-microscope grids (McLean, 2000). Negative-staining electron-microscopic examination can be performed immediately, and virions morphologically identified as paramyxoviruses (~140 nm total diameter, roughly spherical, see 'Structure'). Concentration by centrifugation or use of antisera may be necessary in cases of very low levels of viral particles within particular specimens. In addition, discrimination between orthomyxoviruses and paramyxoviruses is difficult since they have similar electron-microscopic appearance. Although quick, this method would additionally require immunofluorescence for HPIV subtyping.

Protein-based Methods

Protocols for immunofluorescent-based subtyping require the centrifugation of nasopharyngeal secretions. Throat swabs can also be directly smeared on to slides,

which are then dried and fixed in acetone. HPIV-specific antibodies can then be applied for direct or indirect immunofluorescence-based detection. This can be also conducted in combination with antibodies against other respiratory viruses. In a relevant protocol the RSV-specific antibody used was rhodamine-labelled, whereas antibodies against HPIV1–3, influenza A and B and adenovirus were labelled with fluorescein. Following RSV test in one spot, a second reaction in another spot determines which of the other viruses is present. The sensitivity of this very rapid method was ranked as higher than enzyme-linked immunoassay (EIA), but lower than cell culture (Landry and Ferguson, 2003).

Whole-virus intranasal inoculation in hamsters or guinea pigs produces hyperimmune sera used in HPIV serologic tests. Monoclonal antibodies to all four serotypes of HPIV have also been produced, which show minimal cross-reactivity, in contrast to commercially-available antisera (Henrickson, 2003). Immunofluorescent foci in the cytoplasm of cells exposed to an antibody specific for a given subtype, which are absent when the specimen is incubated with antisera against another subtype (or virus), document serotype-specific HPIV infection of the patient. This method, when used in combination with electron microscopy, allows same-day confirmation of HPIV infection. It is also the most rapid and sensitive method available for HPIV detection and subtyping in tissue culture (Henrickson, 2003). However, the timing of sampling is of crucial importance since acute infection, during which viral shedding is greatest, may have occurred before hospitalization. Moreover, the detection of antigen in nasal specimens of immunocompromised and elderly patients has been claimed to be a rather insensitive method (Englund *et al.*, 1997; Sable and Hayden, 1995; Whimbley and Ghosh, 2000). Finally, direct immunofluorescence staining of HPIVs in clinical material shows considerable variability in sensitivity, although specificity is universally high (reviewed in Henrickson, 2003). The best results were obtained with HPIV3.

In addition to conventional immunofluorescence microscopy, flow-cytometry analysis with or without PCR can also be used for the detection of PIVs (Lee *et al.*, 2007). EIA, radioimmunoassay (RIA) and fluoroimmunoassay (FIA) techniques have been applied to PIV detection, showing sensitivities between 75 and 95% with polyclonal sera (Henrickson, 2003).

Virus Culture

For the virus to be recovered by tissue-culture techniques, the nasopharyngeal secretions or throat swabs are typically resuspended in 2 ml cell-culture medium containing 10% fetal bovine serum (FBS). Viral suspensions retain viability in this medium and can be kept, if necessary, for

24 hours at 4°C before being transferred to tissue culture. For longer delays, freezing at -70°C is recommended. Susceptible cultures are primary human fibroblast or primary monkey kidney (PMK) cell cultures and several continuous cell lines (e.g. the monkey-kidney-derived LLC-MK₂, CV-1, Vero, HMV-II, HEp-2, MDCK, L929, HeLa cells, etc.) (Henrickson, 2003). The infection protocol should be performed both at 37°C and at 33°C, since some strains seem to prefer the lower temperature conditions prevailing in the upper respiratory tract. Most HPIV clinical isolates can be detected 10 days after initial inoculation. However, this period may be unacceptably slow in emergency cases in the clinic. Recently, mixtures of cell lines have shown improved viral detection abilities: co-cultures of the influenza-susceptible mink-lung-derived Mv1Lu cells and the human adenocarcinoma A549 cell line (R-mix) have been shown to synergistically detect respiratory viruses with greater sensitivity than single cultures. A relevant protocol consists of the inoculation of R-mix monolayers with a clinical sample on coverslips; 24 hours later a coverslip is stained with a panel of antisera against different respiratory viruses, and, given a positive result, cells from parallel coverslips are further examined for the presence of individual viruses with monoclonal antibodies. HPIV, influenza and RSV have been detected with this method up to four days earlier than the conventional cell-culture technique and with equal sensitivity (Barenfanger *et al.*, 2001).

Upon propagation in cell culture, haemagglutinin-containing viruses such as HPIVs can be identified by their ability to induce erythrocyte haemadsorption by infected cells. For this the supernatants should be removed and the cell monolayer exposed to 0.1% suspension of guinea pig or avian erythrocytes in saline. Haemadsorption is then observed under a light microscope. By adding 0.5% suspensions of guinea pig or avian erythrocytes to cells plated in 96-well plates and inoculated by twofold serial dilution of viral preparations, the titre of specimens can be determined with precision (McLean, 2000). Since the same effect can be mediated by all HPIVs, as well as by the influenza viruses, serotyping (haemadsorption inhibition test, HA_I) of the viral isolate is then necessary for confirmation of the patient's virus type or subtype. To that end, 250 µl suspensions containing 10 antibody units of antisera raised against each PIV and influenza serotype are mixed with the fresh, titrated viral isolate, diluted so that the latter contains four haemagglutinating doses. Since even in normal sera activities inhibiting PIV-mediated haemagglutination are present, an inactivation step should be performed before the haemadsorption test. Such nonspecific activities are sensitive to heat or periodate treatment or incubation with receptor-destroying enzyme (RDE); the latter

binds to and inactivates serum-derived HPIV-binding activities (Canchola *et al.*, 1965; Smith *et al.*, 1975). After 10 minutes incubation at room temperature, 0.5% suspensions of erythrocytes are added and the serotype against which the specific antiserum inhibits haemadsorption will coincide with the serotype of the viral isolate. Alternatively, cells inoculated with specimen and showing haemadsorption can be placed on slides and incubated with anti-PIV antibodies for immunofluorescent detection, as described above. Although both procedures can be completed within 2–3 hours, the rate-limiting step is the previously-conducted tissue-culture isolation, rendering the method a complex and time-consuming process.

Serological Techniques

The prerequisite for serological identification of PIV infection is the collection of both acute-phase and convalescent blood samples. The former should be collected as soon as possible after onset of the symptoms, whereas the latter is obtained later, usually after two to six weeks. The paired sera should then be treated with heat and periodate or receptor-destroying enzyme to inactivate inhibitory substances and should be applied as serial twofold dilutions in HI tests against four haemagglutinating doses of each parainfluenza serotype (McLean, 2000). Virus infection is considered to be confirmed if antibody conversion from negative to positive can be documented. Alternatively, if both sera are positive, a fourfold difference in antibody titre is considered confirmation of serological evidence of infection with the respective PIV serotype. Again, although the final step of this method is quick (two hours), the requirement of the specimen obtained during convalescence limits its usefulness to retrospective diagnosis of acute illness. Furthermore, this method is not that sensitive for young infants, where antibody may be detected only after recurrent infections in some cases (McLean, 2000).

Apart from HI antibodies, neutralizing and complement-fixing antibodies can also be detected in patients' paired sera, although the latter method is thought not such a useful test for clinical diagnosis (McLean, 2000). For neutralization tests, cultured cells should be inoculated with 100 tissue culture infective doses of PIV subtypes mixed with twofold serial dilutions of patients' sera. Three days later haemadsorption assays should be inhibited by positive sera. RIA and enzyme-linked immunosorbent enzyme (ELISA) tests are also available for detection of antibody responses to HPIV infection, though they are not widely used.

An inherent problem in serologic diagnosis of acute HPIV is that ELISA and HI tests are not able to discriminate between HPIV1 and HPIV3, whereas mumps

antibodies can cross-react (Henrickson, 2003). Complement fixation may serve as an alternative method since it is characterized by minimal heterologous cross-reactivity; however, it is the least sensitive of the serologic assays.

RNA-based Diagnosis

RT-PCR protocols allow the specific detection of HPIV genetic material (RNA) in clinical specimens (Karron *et al.*, 1994). Total RNA is extracted from nasopharyngeal secretions or throat swabs previously kept at -70°C in appropriate virus transport medium (VTM) (e.g. Hanks balanced salt solution enriched with 0.5% bovine serum albumin (Corne *et al.*, 1999)) to avoid deterioration of genetic material. Throat swabs can be broken directly into a denaturing solution to inactivate all RNase activity and then stored or transported at room temperature (Carman *et al.*, 2000). Extracted RNA is reverse transcribed into cDNA and the HPIV cDNA is then subjected to conventional PCR (single-round or nested), multiplex PCR (simultaneously detecting more than one pathogens) or real-time PCR (can be also multiplex) with HPIV-specific primers. In such protocols, serotype-specific primers have been designed, usually against the HN or P coding regions of HPIV1–4, exploiting the differences in nucleotide sequence occurring between these species (Aguilar *et al.*, 2000; Corne *et al.*, 1999). Nucleotide diversity observed within each serotype (e.g. Henrickson and Savatski, 1992; van Wyke Coelingh *et al.*, 1988) should also be taken into account and areas of low homology should be selected for serotype-specific primer-pair design (Corne *et al.*, 1999). This method can be readily accomplished within one working day, a fact of obvious importance for the effective treatment of patients. PCR products (amplicons) can also be sequenced and the diversity of individual serotypes within characteristic genes such as HN can be studied, providing valuable epidemiological information concerning particular HPIV outbreaks (Echevarria *et al.*, 2000; Jalal *et al.*, 2007).

Conventional, nested and multiplex RT-PCRs are available for simultaneous determination of HPIV serotypes alone (Aguilar *et al.*, 2000; Corne *et al.*, 1999; Echevarria *et al.*, 1998) or other respiratory viruses (Fan *et al.*, 1998; Freymuth *et al.*, 1997; Grondahl *et al.*, 1999; Hindiyeh *et al.*, 2001; Kehl *et al.*, 2001; Liolios *et al.*, 2001) from clinical samples.

The well-known Hexplex (Prodesse, Waukesha, WI) formulation is a multiplex method allowing the simultaneous detection of HPIV1–3 and other respiratory viruses (e.g. influenzas A and B, as well as RSV A and B) that has achieved high sensitivity and specificity scores in clinical samples (Kehl *et al.*, 2001). Such highly-sensitive protocols allow the detection of HPIVs in samples with low virus copy numbers, or of viral RNA without presence of

live virus, both of which may be missed by conventional cell-culture techniques (Fan *et al.*, 1998). The detection limits of multiplex RT-PCR protocols can go down to 1 tissue culture infectious dose (TCID₅₀) for cultured PIV viruses (Corne *et al.*, 1999) or 100–140 copies per ml, depending on the serotype (Fan *et al.*, 1998). The sensitivity of this highly-specific and fast method is generally at least as high as combined tissue culture and immunofluorescence (Corne *et al.*, 1999), and sometimes even more sensitive (Aguilar *et al.*, 2000; Fan *et al.*, 1998). Multiplex real-time PCR methods for HPIV detection are also available (Hu *et al.*, 2005). In a relevant study a two-tube multiplex reaction in combination with molecular beacons was used to discriminate all four HPIVs, RSV and influenza viruses (Templeton *et al.*, 2004). The minimal amount of detectable HPIV1, HPIV2, HPIV3 and HPIV4 RNA was 0.01, 0.001, 0.1 and 0.0001 of the TCID₅₀, respectively. When applied to clinical samples this proved more sensitive than cell culture and, importantly, considerably less time-consuming (it can provide results within six hours). In addition, real-time PCR protocols applied for the detection of panels of respiratory viruses including HPIVs show increased diagnostic efficiency in comparison to cell culture and direct immunofluorescence-based diagnosis (van de Pol *et al.*, 2007).

A combination of RT-PCR with enzyme immunoassay techniques (RT-PCR-EIA), consisting of hybridization of the HPIV amplicon with biotinylated RNA probes generated against amplicon internal sequences, has also been used (Karron *et al.*, 1994). In addition, new emerging techniques achieve high sensitivity scores by probe hybridization and electroluminescence, or by molecular beacons (Hibbitts *et al.*, 2003). Finally, methods combining multiplex RT-PCR and microsphere flow cytometry (MultiCode-PLx system; Eragen Biosciences) have been reported to rapidly and efficiently detect multiple respiratory pathogens, including PIVs (Lee *et al.*, 2007; Nolte *et al.*, 2007).

The fast-developing array technology has been also employed to detect viral pathogens. Microarrays containing 1600 oligonucleotides targeting viral genomes were used to identify up to 140 distinct viral prototypes including HPIVs (Wang *et al.*, 2002). A recently-developed commercial custom-designed resequencing respiratory pathogen microarray by Affymetrix needs further validation, but initial promising results have been reported (Lin *et al.*, 2006). Provided it is able to achieve high sensitivity scores, such methodology may replace current detection protocols in the future, mainly due to its ability to handle large amounts of data and to provide more composite information concerning the pathogens than the other methods.

PREVENTION

There are no established anti-HPIV vaccines available for clinical use. Early attempts with formalin-inactivated whole HPIV1, 2 or 3 viruses failed, probably due to inadequate neutralizing activity against the native HPIVs and/or failure to induce mucosal immunity against HPIV HN and F proteins. Currently, vaccination strategies include immunization against particular proteins of HPIVs (i.e. HN and F), the use of attenuated strains (e.g. animal strains or strains obtained *in vitro* by cold-adaptation) and engineered approaches (i.e. recombinant animal/human viruses or constructs containing genetic material of multiple viruses generated by reverse genetics).

BPIV3 is a promising vaccine candidate against HPIV3, with which it shares sequence and antigenic similarities (Clements *et al.*, 1991). The bovine subtype is characterized by attenuated replication in the respiratory tract of primates; however, it is immunogenic and protective against HPIV3 challenge. The antibody responses to BPIV3 vaccination have been evaluated in phase 2 clinical trials in infants (Lee *et al.*, 2001). Bovine-attenuated PIV3 induced antibody production in seronegative children (Karron *et al.*, 1995a). The safety characteristics of BPIV3 vaccine were evaluated in a phase II trial, where vaccinees of two groups received doses of either 1×10^5 or 1×10^6 TCID₅₀ (Greenberg *et al.*, 2005). Both groups showed similarly good seroconversion rates and minimal BPIV3 isolation after the fourth dose, suggesting the vaccine efficiently immunizes and is being well tolerated by children.

Another attenuated, serially-passaged (passage 45), cold-adapted human PIV3 (Hall *et al.*, 1992) gave promising results in both seronegative and seropositive children and infants aged from 6 months to 10 years (Karron *et al.*, 1995b). In addition, the cold-adapted HPIV3 cp45 was stable and did not revert to wild-type as reported with previous early-passage HPIV3 approaches, whereas it is more immunogenic than BPIV3. A phase II trial examined the properties of HPIV3 cp45 on a vaccination protocol in 380 children (226 seronegative for HPIV3) aged 6–18 months (Belshe *et al.*, 2004b). No adverse effects were reported for the 15-day period following immunization and the vaccine appeared both safe and efficient for seronegative children, 84% of which developed more than fourfold increase in antibody titres. Furthermore, the HPIV3 cp45 has a low risk of transmission, as revealed by a protocol following the infection characteristics of seronegative children who were in close contact (play-groups) with infected vaccinees (Madhi *et al.*, 2006). In addition, this HPIV3 cp45 was used in combination with an RSV-attenuated strain in a phase I double-vaccination protocol (Belshe *et al.*, 2004a) and promising results were

obtained, showing that the combination did not affect the vaccine properties of the monovalent formulations.

In contrast to attenuated type 3 viruses, the type 1 SeV, although considered as a murine subtype, has been shown to replicate equally as well as human PIV1 in the upper and lower respiratory tract of primates (Skiadopoulos *et al.*, 2002a). This, together with the fact that this serotype was originally isolated from humans, has so far excluded its use as a vaccine in humans.

Recently, by using powerful reverse-genetics methodology, a recombinant infectious PIV virus was produced expressing the HN and F proteins of HPIV1 on the cold-adapted HPIV3 backbone mentioned above (Skiadopoulos *et al.*, 1999). This construct was proven to protect against HPIV1 challenge in primates (Skiadopoulos *et al.*, 2002b), while retaining its attenuated phenotype. In addition, by replacing the HPIV3 HN and F sequences with chimeric ORFs, encoding the HPIV2 ectodomains fused with the transmembrane and cytoplasmic domains of HPIV2, Skiadopoulos *et al.* (2002b) succeeded in generating a vaccine candidate against HPIV2.

This methodology allows inclusion of more than one antigenic viral glycoprotein in the attenuated backbone. Thus, a recombinant HPIV3 was generated that additionally expressed HN of HPIV1 and HPIV2; the emerging infectious virions conferred immunity against all three HPIVs in hamsters, while retaining the attenuated pattern of infection (Skiadopoulos *et al.*, 2002b). Further extension of the repertoire could include vaccination against other respiratory pathogens, such as RSV types A and B (Schmidt *et al.*, 2002). Conversely, reverse genetics was also used for the development of an attenuated influenza virus that, instead of HN of influenza, expresses that of HPIV. Mice immunized with this vaccine developed immunity against both viruses, which allowed them to survive lethal doses (Maeda *et al.*, 2005).

Additional strategies include the insertion of point mutations associated with temperature-sensitive or non-temperature-sensitive attenuation of HPIV strains. Using a combination of such mutations comprising the P/C, L and HN genes of HPIV1, Skiadopoulos and his group were able to identify a combination of the five examined genetic alterations that rendered the HPIV1 strain attenuated and stable (Bartlett *et al.*, 2005). The resulting recombinant HPIV1 rC(R84G/F170S)L(Y942A/L992C) was efficient as vaccine in African green monkeys. However, single mutations have been shown to allow reversion to wt HPIVs and larger deletions of two to six nucleotides have been employed to confer attenuation properties that are stable, while retaining immunogenicity. The attenuated phenotype seems to be due to disruption of C-mediated inhibition of IFN production and signalling (Van Cleve *et al.*, 2006). Individual deletions confer attenuation in

hamsters but not in African green monkeys, and vice versa, whereas by examining combinations, researchers end up with HPIV mutants that are stable, attenuated in both animal systems of experimental infection, and able to provide high immunogenicity and protection against native HPIV challenge. One such combination of mutations and deletions in C and HN proteins showed good characteristics and will be evaluated clinically as a live intranasal HPIV1 vaccine (Bartlett *et al.*, 2006), suggesting that this technique may be valuable for the establishment of candidate vaccines for clinical trials. Finally, insertion of mutations from heterologous paramyxoviruses into the L gene of HPIV2 generated mutants with attenuated phenotype when used in hamsters, which are candidates for HPIV2 vaccine development (Nolan *et al.*, 2005).

Additional viruses may be also used in such combinations, for instance RNA replicons based on an attenuated alphavirus backbone. Such constructs were engineered to express PIV3 HN and were able to elicit HN-directed immunogenicity in mice and hamsters, as well as to protect hamsters against PIV3 challenge (Greer *et al.*, 2007). Clinical studies evaluating the clinical efficacy of such elegant recombinant vaccine candidates in humans are awaited with particular interest.

TREATMENT

A major problem limiting development and use of efficient therapeutic treatments is that many clinicians do not count HPIV infections among the common pathogens in adult respiratory infections (Hall, 2001). The major clinical need is in young children with croup. Current therapy includes supportive care and steroid therapy if needed.

Studies investigating the action of steroids in mild to severe croup have been reviewed and analyzed (Moss *et al.*, 2002). Although smaller studies may bias results showing larger effects, it has been confirmed that nebulized steroids are effective in significantly reducing the severity of croup (e.g. improvement of croup scores by five hours) in children attending the emergency departments of hospitals. Notably, administration of immune-response stimulants or cytokines improved host defense to PIV challenge in *in vitro* systems and animal models (reviewed in Henrickson, 2003).

Croup is not the only manifestation of HPIV-mediated disease. Patients may develop tracheobronchitis, bronchiolitis, pneumonia or otitis media, each one requiring specific treatment. In extreme cases, excessive secretions may require emergency removal by bronchoscopic aspiration, whereas bacterially-complicated HPIV-triggered pneumonia requires antibiotics.

HPIV replication and pathology are currently targeted for the development of inhibitor drugs, synthetically

generated or derived from natural sources (Jiang *et al.*, 2001). The broad-spectrum antiviral agent ribavirin and its analogues are known to bind and inhibit HPIVs (Gabrielsen *et al.*, 1992; Ghose *et al.*, 1989). Aerosolized ribavirin has been used in immunocompromised patients for parainfluenza virus infections where the use of corticosteroids may lead to HPIV infection and pneumonia, both associated with mortality (Elizaga *et al.*, 2001; Englund *et al.*, 1997; Nichols *et al.*, 2001); however, the results were rather disappointing since ribavirin did not affect either the duration of viral shedding or mortality rates associated with HPIV3 infection (Nichols *et al.*, 2001). Nevertheless, it is still considered a potential therapeutic intervention in cases of immune deficiency where alternatives are not obvious (Stankova *et al.*, 2007).

Stages in the viral replicative cycle that are targeted for antiviral drugs include virus entry (HN binding to sialic receptors) and HN-mediated activation of F protein (reviewed in Moscona, 2005). A hydrophobic pocket in the C-terminus of the N-HR trimer, one of the heptad-repeat-containing peptides that are essential for fusion by F protein, may interfere with the stability of a hairpin intermediate. Accordingly, small molecules that bind to the hydrophobic pocket probably impair the fusion of both RSV and SV5. Sialic acid analogues, such as the 4-Guanidino-Neu5Ac2en (GU-DANA; zanamivir) originally designed to inhibit influenza infections (Greengard *et al.*, 2000), inhibit HN neuraminidase action and thus indirectly inhibit the triggering of fusion activity of F protein and syncytial formation by HPIV3 (Porotto *et al.*, 2001). These could therefore be potential candidates as inhibitory agents of viral entry and cytopathology. However, PIV variants (HN mutants) with increased receptor-binding avidity can escape the inhibitory effect of this agent (Murrell *et al.*, 2003), partly due to reduced affinity of the HN receptor-binding site for this compound, in parallel with increased avidity of the HN mutant for the original receptor (Porotto *et al.*, 2004). In addition, analogues designed to block neuraminidase function of NDV *in vitro* failed to block virus binding and entry, indicating that the differences among PIV members require that treatment of each one should be considered individually (Porotto *et al.*, 2004). Moreover, by interfering with HN-receptor interaction 4-GU-DANA enhances the release of newly-formed virions (Porotto *et al.*, 2001). Oseltamivir, another inhibitor of influenza neuraminidase, is less similar to the natural substrate than zanamivir but triggers more drug-resistant viral strains to be developed, in accordance with the notion that the less modifications the analogue contains in comparison to HN, the more efficient for clinical use it may be (Moscona, 2005). Several relevant analogues are currently being tested in members of the HPIV family (e.g. Ikeda *et al.*, 2004, 2006)), as

well as in combinations of HPIV and bacterial infections (Alymova *et al.*, 2005).

Synthetically-modified pyrimidine bases of uracil have been shown to specifically inhibit SeV replication (Saladino *et al.*, 2001). Further approaches include benzothiazole derivatives, carbocyclic 3-deazaadenosine (Cc3Ado), calcium elenolate, ascorbic acid, protein-synthesis inhibitors (puromycin) and nucleic-acid-synthesis inhibitors (reviewed in Henrickson, 2003). Endoplasmic reticulum α -glucosidase inhibitors (castanospermine and 1-deoxynojirimycin) known to block the trimming of N-linked glycosylation have recently been used and were shown to reduce the infectivity of newly-released HPIV3 particles, probably by inhibiting the first steps of HPIV3 envelope glycoprotein processing (Tanaka *et al.*, 2006). It is hoped that some of these innovative approaches may lead to effective strategies against HPIV infections in the future.

Respiratory Syncytial Virus

Caroline Breese Hall

University of Rochester School of Medicine, Rochester, NY, USA

INTRODUCTION

*On the barely born
the Gods bestow
the most potential,
the greatest woe.*

C.B.H.

Respiratory syncytial virus (RSV) infections are a common and concerning conundrum. This ubiquitous agent is the major respiratory pathogen of young children, with life-threatening illness occurring most frequently in the first few months of life, and is commonly followed by the sequelae of recurrent wheezing. Worldwide acute respiratory disease is the leading cause of morbidity and mortality in young children, causing an estimated 4 million deaths each year in children within the first five years of life (Selwyn, 1990). Viruses are the most frequent cause, and RSV is the leading viral agent. Much about this virus, however, we do not understand—its immunity, its ‘inner soul’ and its control.

RSV was first isolated in 1956 (Morris *et al.*, 1956) from a colony of chimpanzees suffering from the common cold, and thus was initially called chimpanzee coryza agent (CCA). The human source of the pathogen was subsequently recognized by an identical agent being recovered from the respiratory secretions of an infant with pneumonia (long strain) and from a child with laryngotracheobronchitis (Chanock *et al.*, 1957).

The virus has now been recognized throughout the world as causing annual outbreaks of pneumonia and bronchiolitis in infants, and both upper- and lower-respiratory-tract infections in older children and adults.

In temperate climates peak periods of RSV activity generally occur in the winter and spring (Stensballe *et al.*, 2003). The predictability of its pattern of activity is singular among respiratory viruses.

THE VIRUS

RSV belongs to the order *Mononegavirales*, family *Paramyxoviridae*, subfamily *Pneumovirinae* and in the genus *Pneumovirus*. In size, RSV lies between the larger paramyxoviruses and the smaller influenza viruses. The genome of the A2 strain of RSV is composed of 15 222 nucleotides, and the complete sequence of the A2 strain gene has now been delineated. RSV is an enveloped RNA virus with nonsegmented, single-stranded, negative-sense RNA genome, which encodes for 11 proteins. Each messenger RNA (mRNA) encodes for one major protein, except for M2 mRNA which encodes for two different proteins, M2 and M1. Eight are structural proteins (L, G, F, N, P, M, M2-1 and SH), two are nonstructural (NS1 and NS2) and M2-2 is a regulatory protein (Collins *et al.*, 2006). Of the structural proteins, three compose the viral capsid, N (nucleoprotein), P (phosphoprotein) and L (polymerase), and two are associated with the matrix membrane, the nonglycosylated M and M2 proteins. The other three structural proteins, the glycosylated F (fusion), the G (attachment) proteins and the small nonglycosylated hydrophobic protein, SH, are transmembrane surface proteins.

These two large glycoproteins, F and G, projecting from the surface give the envelope the appearance of a thistle (Figure 18.1) and make them integral to the immunity and pathogenicity of the virus. The G protein

Figure 18.1 Negative contrast electron micrograph of RSV. The fringed envelope is variable in shape. The surface projections are about 15 nm long and the envelope contains a helical nucleocapsid which may occasionally be visible (negative contrast, 3% potassium phosphotungstate, pH 7.0; 6200 000). (Courtesy of Professor C.R. Madeley.)

is involved in initial attachment of the virus to the host cell and the F protein mediates penetration into the host cell by fusing the viral and host cell membranes. The G and SH proteins, however, augment this fusion process.

Neutralizing antibodies are produced to the F and G proteins, and fusion-inhibiting antibodies to the F protein. Antibody to the F protein also provides heterologous immunity to both strain groups, whereas antibody to G affords little protection against heterologous strains. Infants are able to produce both F and G antibody after initial RSV infection, but the response to the G protein is more variable. In young infants, the heavily glycosylated G protein is a poor immunogen, and pre-existing maternal antibody results in a greater degree of dampening of the infant's own antibody response.

Antigenic variation among strains of RSV has resulted in the two major strain groups, designated A and B, which have been delineated on the basis of their reactions with monoclonal and polyclonal antisera. The major antigenic differences between these two strain groups have been linked to the G protein (Collins *et al.*, 2006). The amino acid sequence of the G protein differs by about 50% between the two strain groups, and the antigenic relatedness is only 3–7%. The amino acid sequence of the F protein, on the other hand, is relatively conserved, allowing neutralizing antibody to the F protein to be cross-reactive. The F proteins of the prototype A and B strains exhibit greater than 90% amino acid homology and high antigenic relatedness. Intragroup variations also occur, with

an amino acid diversity for the G protein within the group varying from about 12% for group B to about 20% for group A (Cane, 2001; Cane and Pringle, 1995). In tissue culture, RSV produces a characteristic syncytial appearance with eosinophilic cytoplasmic inclusions. RSV has a growth cycle which, after inoculation, consists of a period of adsorption, with about 50% of the inoculum being absorbed in 2 hours, followed by an eclipse period of 12 hours. The subsequent log phase of replication of the new virus occurs over about 10 hours. At the time when maximal quantities of virus are obtained, about 50–90% of the virus remains cell-associated on the surface of the cell. Non-infectious incomplete virions comprise most of the cell-associated virus. Peak titres with the laboratory prototype group A virus (long strain) usually occur in 48 hours. Generally 10 plaque-forming units are produced for each infected cell. Under certain conditions, such as repeated high passage, continuous infection may develop, which is associated with a diminished amount of cell-free virus and a loss of the characteristic cytopathic effect.

EPIDEMIOLOGY

RSV is characteristically epidemic and global in distribution. Its seasonal pattern (Figure 18.2) is distinctive in that it predictably produces a sizeable outbreak of infections each year (Hall, 2001a; Kim *et al.*, 1973a). However, the timing and length of the outbreaks of RSV vary according to the geography (Mullins *et al.*, 2003; Stensballe *et al.*, 2003). Areas with warm or tropical climates tend to have more prolonged outbreaks, and some may detect the presence of RSV infections throughout the year. Nevertheless, certain months tend to have more pronounced swells of RSV activity. In the United Kingdom and the temperate parts of the United States, the peak period of RSV activity generally occurs from January through March, and in the USA the overall RSV activity is usually 20 or more weeks, stretching from the end of October to May.

The role of strain variation in the epidemiology, severity and clinical impact of an RSV outbreak remains unclear (Brandenburg *et al.*, 2000; Gilca *et al.*, 2006; Moore and Peebles, 2006; Papadopoulos *et al.*, 2004). Strains from both groups appear to circulate concurrently, although the proportion from each group may vary by year and locale (Cane, 2001; Hall *et al.*, 1990; Kim *et al.*, 2007b). In most areas in which this has been examined, A strains tend to dominate, and outbreaks composed almost entirely of B strains are uncommon. Studies of strains from cities across the United States have shown substantial annual differences, suggesting that the more influencing factors may be local rather than national (Anderson *et al.*, 1991). Homotypic immunity to previous strains

Figure 18.2 The number of cases of bronchiolitis and the number of isolates of respiratory syncytial virus from children under five years of age evaluated in private offices and outpatient facilities from 1998 to 2005, identified by a community surveillance programme in Monroe County, NY.

may also play a role, as several distinct, but varying, genotypes within a strain group appear to predominate each year in a community (Cane, 2001; Peret *et al.*, 1998). Some studies have suggested that the magnitude of an outbreak and the severity of clinical illness are greater with A-strain infections, while others have not. This indicates the difficulty in separating out the roles of strain variation from the collage of other environmental and host factors that contribute to the severity associated with RSV infections (Hall *et al.*, 1990; McConnochie *et al.*, 1990; Papadopoulos *et al.*, 2004; Toms, 1990).

In most places the size of the annual RSV outbreak will fluctuate. Nevertheless, over 11 consecutive years the number of hospital admissions for children with RSV lower-respiratory-tract disease in Washington, DC, did not vary more than 2.7-fold, demonstrating the consistent and persistent impact of this virus (Kim *et al.*, 1973b). During the period of peak activity, RSV is the dominant cause of lower respiratory illness in young children, despite the overlapping seasons of the other viral respiratory pathogens of young children, such as influenza, the parainfluenza viruses and human metapneumovirus (hMPV) (Hall *et al.*, 2005; Iwane *et al.*, 2004; Nicholson *et al.*, 2006; Wolf *et al.*, 2006).

The striking characteristics of RSV's epidemiology from the clinical aspects are first, it is highly contagious. Second, lower-respiratory-tract disease associated with primary infection is almost entirely confined to the child less than three years of age, and is most common and severe during the first six months of life. Third, re-infections occur throughout life and often within short

intervals (Glezen *et al.*, 1986; Hall *et al.*, 1991; Henderson *et al.*, 1979). Fifty per cent or more of infants have been estimated to acquire RSV infection during their first year of exposure to RSV, and approximately 40% of these infections will result in lower-respiratory-tract disease.

Essentially all children have been infected with RSV during the first three years of life. In a prospective longitudinal study of families in Houston, TX, Glezen *et al.* (1986) showed that 69% of infants in the first year of life were infected with RSV, and one third of those infections were associated with lower-respiratory-tract disease. In the second year of life, 83% of the infants acquired RSV infection, and 16% had lower-respiratory-tract disease. Even during the third and fourth years of life, one third to one half of the children were infected with RSV, and about one quarter had lower respiratory tract involvement (Glezen *et al.*, 1986). The attack rate in day-care centres is even higher, with 65–98% of the children becoming infected during each of the first three years of life and up to one half of the infections being manifest as lower-respiratory-tract disease (Henderson *et al.*, 1979). Recurrent infections, therefore, are not only common but may occur within a single season.

Transmission

Nosocomial Infection

RSV appears to spread with equal facility and alacrity on hospital wards housing young children (Berner *et al.*, 2001; Goldmann, 2001; Halasa *et al.*, 2005; Hall, 2000a; Hall *et al.*, 1979). The epidemiologic, immunologic and

clinical characteristics of RSV explain its propensity for becoming a major nosocomial hazard on paediatric wards. Epidemics occur yearly, resulting in the admission of a large number of young infants with primary infection, who tend to shed virus in high titres and sometimes for prolonged periods. Individuals of any age in contact with these infants compose a large susceptible population, as immunity is not durable. Most of these cross-infections result in symptomatic illness, and about half will involve the lower respiratory tract. The morbidity and cost are considerable, and the mortality may be high among young children with underlying prematurity, cardiopulmonary and immunodeficiency diseases (Berner *et al.*, 2001; Hall, 2000a; Hall *et al.*, 1979, 1986; Meissner, 2003; Weisman, 2003). Early recognition that RSV activity is present in the community and institution of appropriate infection control measures have been effective in reducing nosocomial infection rates as high as 40–45% among contact infants (Goldmann, 2001; Greenough, 2001; Hall, 1983).

RSV nosocomial infections may commonly involve both staff and adult patients. Among immunocompromised patients, especially transplant recipients, RSV infection tends to be serious and difficult to control (Champlin and Whimbey, 2001; Goldmann, 2001; Kim *et al.*, 2007a; Whimbey and Ghosh, 2000). Visiting children with mild colds are often the source. In compromised patients, nosocomially-acquired RSV infection frequently is not recognized as being caused by RSV but is thought to be one of the opportunistic infections to which such patients are prone, which may be clinically similar. The outcome, however, may be as devastating and even fatal.

Hospital personnel may also have a high rate of RSV infection, acquired nosocomially or in the community. This may appear insignificant since cases are frequently mild upper-respiratory-tract illnesses not requiring absence from work (Hall, 2000a, 2001b). These unnoticed illnesses of hospital personnel, nevertheless, may initiate and be integral to the continued spread of RSV on wards housing children or adults.

Modes of RSV Transmission

The spread of RSV appears to require close contact with infectious secretions, either by large particle aerosols or by fomites (Hall, 2000a; Hall and Douglas, 1981). Small particle aerosols, which can traverse greater distances, appear to be an infrequent mode of transmission for RSV. Hospital staff are apt to spread the virus by touching contaminated secretions or objects while caring for an infected patient. Self-inoculation may then occur by the inadvertent rubbing of their eyes or nose, the major portals of entry for RSV.

How long RSV remains infectious on inanimate objects varies according to the environmental conditions,

especially the dew point, and the type of contaminated surface. Generally, hard, nonporous surfaces allow longer duration of viable virus. During the winter months of the usual RSV outbreak, RSV in freshly-obtained secretions from hospitalized infants was recovered from countertops for up to 6 hours, from contaminated gloves for 1.5 hours, from cloth gowns and paper tissue for 30–45 minutes, and from the hands of hospital personnel for 20 minutes. Furthermore, infectious virus could be transferred to the hands of hospital personnel touching these contaminated surfaces and could be recovered from their hands for up to 25 minutes, thus allowing self-inoculation to occur and also transmission to other individuals via contaminated hands (Hall *et al.*, 1980). This underscores the observation that good hand washing is the single most effective means of controlling the spread of RSV (Hall, 2007a). Effective hand washing may be accomplished by traditional methods with soap or with other cleaners and water, or by the more recently preferred alcohol-based hand sanitizers, which provide extended protection (Centers for Disease Control and Prevention, 2002).

PATHOGENESIS

The incubation period for RSV is usually three to six days, but can range from two to eight days. Inoculation of the virus occurs through the upper respiratory tract, primarily the eyes or nose (Hall *et al.*, 1981). The virus subsequently spreads along the epithelium of the respiratory tract, mostly by cell-to-cell transfer along intracytoplasmic bridges. As the virus spreads to the lower respiratory tract it may produce bronchiolitis and/or pneumonia.

Pathology

Early in bronchiolitis a peribronchiolar inflammation with lymphocytes occurs, and the walls, submucosa and adventitial tissue appear oedematous (Hall, 2000b; Openshaw, 2005) (Figure 18.3). This progresses to the characteristic necrosis and sloughing of the bronchiolar epithelium, which may also be associated with a proliferative response of the epithelium. Plugging of these small airways results from the sloughed, necrotic material leading to obstruction of the flow of air, the hallmark of bronchiolitis. The tiny lumina of an infant's airways are particularly prone to obstruction from such inflammatory exudate and increased secretion of mucus.

If the bronchiolar lumina are incompletely obstructed, air trapping will occur distal to the sites of partial occlusion. Similar to a ball-and-valve mechanism, airflow is less impeded during the negative pressure of the infant's inspiration, but with the increased pressure of expiration,

Figure 18.3 Pathological findings of an infant dying with RSV bronchiolitis. The wall of the bronchiole appears inflamed and oedematous, and sloughed, necrotic material fills the lumen in the small airway.

the airway lumen narrows, causing greater or complete obstruction to the flow of air. The trapped air causes the characteristic hyperinflation of bronchiolitis, which, when adsorbed, results in multiple areas of focal atelectasis.

Resolution of these pathologic changes may take weeks. Although the bronchiolar epithelium may show signs of regeneration in three to four days, ciliated cells rarely are present within the first two weeks. Other changes in the submucosal glands and types of cell in the airway may persist for even longer periods.

The pathologic findings of bronchiolitis may progress or coexist with those of pneumonia during RSV infection. In the latter, infiltration of the interstitial tissue with mononuclear filling and collapse of the alveoli are observed.

IMMUNITY

Immunity to RSV continues to be a major area of interest and research. Much progress has been achieved recently, but many of the complexities and conundrums remain unresolved. Multiple factors contribute to the variability of the immune response among different individuals. These include the host's epidemiologic and clinical experience, their genetic background and the characteristics of the virus (Openshaw, 2005; Openshaw and Tregoning, 2005; Moore and Peebles, 2006).

Innate Immunity

Innate immunity is evoked when RSV first infects the respiratory epithelial tissue and antigen-processing cells. The innate response is characterized by the synthesis of chemokines and pro-inflammatory cytokines and the

presence of inflammatory cells. The release of chemoattractant chemokines results in the trafficking of polymorphonuclear cells, eosinophils and interferon- γ (IFN- γ) secreting natural killer (NK) cells to the respiratory tract.

Toll-like receptors (TLRs) on alveolar and mononuclear cells appear to be important in mediating and characterizing the initial response. The viral-TLR interaction produces a cascade of immune-modifying and antiviral mediators. In animal-model experiments the components of TLR-mediated immune responses vary according to the TLRs involved. The effectiveness of the infant's innate immune response in modifying the initial and subsequent infection is unclear. However, this is likely affected by RSV's ability to evade certain antiviral components of the immune response, such as the IFNs (Johnson *et al.*, 2005).

Humoral Immunity

Specific maternal antibody is present in the cord blood of essentially all infants. Although the presence of this passive antibody has been suggested as playing a role in the pathogenesis of immune-mediated disease among infants with RSV, evidence has accumulated over the past two decades, indicating that maternally-derived antibody provides early protection for the infant. The level of passive neutralizing antibody in the cord blood has been correlated with an older age of first infection (Glezen *et al.*, 1986). This has been corroborated by experiments in animal models showing protection against RSV infection by passive administration of high-titred neutralizing antibody to RSV. The subsequent successful use of intravenous immunoglobulin with enhanced levels of RSV-neutralizing antibody for protecting high-risk infants against serious disease confirmed the beneficial effect of specific humoral antibody. This led to the current use of prophylaxis against RSV infection with monoclonal antibody for premature and other high-risk infants (American Academy of Pediatrics (AAP), 2006).

Primary RSV infection produces a specific, but transitory, serum IgM antibody response, followed by detection of IgG antibody during the second week after infection, which declines after one to two months. The neutralizing antibody response of young infants is generally blunted, with diminished responses to the F and G proteins. These proteins are glycosylated, especially the G protein, and thus are poor immunogens in infants. Maternal antibody also interferes with the antibody response, especially to the G protein. An IgA serum antibody response in young infants may not be detectable. After repeated infection an anamnestic response generally occurs in all three immunoglobulin classes. The serum antibody response to the F protein is broadly cross-reactive between the two strain groups, as the neutralizing epitopes are well conserved

among RSV A and RSV B strains. In contrast, antibody to the G protein is poorly cross-reactive and specific according to the group and genotype.

During the first six months of life, when the serum antibody responses are generally suboptimal, the infant's innate immunity is bolstered primarily by mucosal IgA (Welliver, 2003). IgA, IgG, IgM and IgE RSV-specific antibodies bound to epithelial cells and free in nasal secretions have been identified during the course of RSV infection in infants.

Cellular Immunity

Systemic and local cell-mediated immune responses appear to be key to the severity and recovery from RSV infection. This is supported by the observation that children and adults who have deficient cell-mediated responses with or without concurrent deficits in humoral antibody production tend to have prolonged, severe and sometimes fatal infection with RSV (Champlin and Whimbey, 2001; Hall *et al.*, 1986; Jarvis *et al.*, 1983; Whimbey and Ghosh, 2000). Recognition that the immune response to RSV may be integral in the pathogenesis of disease, indeed more important than the cytopathology engendered by direct viral invasion, came initially from studies aimed at explaining the experience with the first RSV vaccine, the formalin-inactivated vaccine, developed in the 1960s. In the trials of this first vaccine for RSV, those infants who received the vaccine developed more severe disease when subsequently exposed to the wild virus than did those children who had not received it; 80% were hospitalized compared to 5% of the control children (Chin *et al.*, 1969; Fulginiti *et al.*, 1969; Kapikian *et al.*, 1969; Kim *et al.*, 1969, 1976). Serologic studies demonstrated that the high levels of circulating antibody to the F and G proteins in the vaccinees were deficient in neutralizing and fusion-inhibiting capacity. In the lungs of fatal vaccinee cases peribronchiolar infiltration and increased levels of eosinophils were observed (Chin *et al.*, 1969; Murphy *et al.*, 1986).

Subsequent studies have suggested that integral to the pathogenesis of disease associated with both the formalin-inactivated vaccine and with primary infection is the T-cell response (Graham *et al.*, 1991, 1993; Moore and Peebles, 2006; Openshaw, 2005; Openshaw and Tregoning, 2005). These studies, primarily those using the Balb/c mouse model, demonstrated that the immune response during RSV infection varied according to whether it was elicited predominately by Th1 cells or by Th2 cells. Th1-dominant responses have been associated with viral clearance and control of the severity of clinical disease, and are characterized by induction of IFN-secreting CD4⁺ and CD8⁺ cytotoxic lymphocytes with production of IL-2, IFN- γ and IFN- α . In contrast, Th2-dominant responses are

primarily characterized by CD4⁺ cells producing IL-4, IL-5 and IL-13, pulmonary eosinophilic infiltration and IgE antibody, and are associated with the clinical manifestations of hyper-reactive airways and increased severity of disease (Openshaw and Tregoning, 2005; Openshaw *et al.*, 2003; Welliver, 2003;).

A fine balance of both Th1 and Th2 responses appears necessary for optimal clinical outcome. The multiple factors that affect this balance are only partially delineated, but include the infant's age, genetic background and the type of antigen provoking the immune response. Live virus and the F protein induce Th1-dominant responses, whereas inactivated virus, as in the formalin-inactivated RSV vaccine, and the G protein result in Th2-dominant responses. Although the experimental data have generally indicated a central role of Th1 versus Th2 cellular responses in determining the type and severity of disease associated with RSV, other studies have not confirmed this (Anderson *et al.*, 1994; Welliver *et al.*, 2002).

Information concerning the immune response remains incomplete, confusing and at times contradictory. However, several conclusions appear warranted: (i) the immune response to RSV is affected by multiple host and viral factors which currently prohibit predicting the clinical outcome of a child infected with RSV. (ii) The importance of the pathogenic role of the immune response in producing RSV disease is supported by the observation that *in vivo* the direct cytopathology produced by replicating RSV is only moderate and not necessarily concordant with the clinical manifestations. (iii) Innate immunity is important in the initial protection of the infant against primary infection, but also may quickly be altered by acquired immunity from T- and B-cell responses elicited during the characteristically high levels of viral replication which occur during primary infection (Openshaw, 2005). (iv) The acquired cellular immune response is integral in the clinical expression of RSV infection. Animal-model experiments suggest that the balance between the Th1 and the Th2 responses is critical in determining the immunologic and clinical outcome. These responses may be of prime importance during the first several months of life, when RSV infection most frequently results in hospitalization. During this period, the relatively weak Th1 responses may unfavourably tip the precarious balance of immunity and result in more severe disease in some infants.

CLINICAL FEATURES

Infection in Infants and Young Children

The importance of RSV as a cause of lower-respiratory-tract disease in the young is illustrated by the observation that the periods of peak occurrence of pneumonia

and bronchiolitis in young children signal the presence of RSV in the community. RSV has been reported in various studies as causing up to 10% of croup cases, 5–40% of the pneumonias and bronchitis in young children and 50–90% of the cases of bronchiolitis in infants. In the United States bronchiolitis has been shown to be the leading cause of all infant hospitalizations (Leader and Kohlhasse, 2003). The annual estimated number of hospitalizations for bronchiolitis attributed to RSV from 1994 to 1996 was 51 000–82 000 children within the first year of life and 62 000–100 000 children within the first five years of life (Shay *et al.*, 1999). RSV pneumonia was estimated to contribute another 11 000–44 000 hospitalizations for children under one year of age. In emergency departments, 22 visits attributed to RSV per 1000 infants have been estimated to occur each year (Leader and Kohlhasse, 2003). Worldwide, RSV is estimated to cause 600 000–1 million deaths among children less than five years of age (Simoes, 1999). In the United Kingdom approximately 3% of each year's birth cohort, approximately 20 000 infants, are admitted for bronchiolitis every winter, and 3% of these children need assisted ventilation (Sharland and Bedford-Russell, 2001). Similar admission rates for bronchiolitis have been estimated for Europe, Australia and North America. However, children with high-risk conditions may have substantially greater rates of admission (Carbonell-Estrany, 2003; Meissner, 2003; Nicholson *et al.*, 2006; Weisman, 2003). In the United Kingdom and North America, readmission rates for RSV bronchiolitis of premature infants (<32 weeks gestation) have been reported as about 6–8%, and 12–17% for infants with chronic lung disease. The mortality from RSV bronchiolitis, nevertheless, has been significantly reduced in recent years to an estimated 0.13% (PREVENT-Study-Group, 1997; Sharland and Bedford-Russell, 2001).

Primary RSV Infection

The first RSV infection is almost always symptomatic, but may be as mild as a common cold or as severe as a life-threatening lower-respiratory-tract infection. The manifestations of RSV infection initially observed in infants are usually those of a febrile upper-respiratory-tract infection. Lower-respiratory-tract involvement commonly becomes evident within several days. Although fever is common during the early phase of the illness, the infant may be afebrile by the time the lower-respiratory-tract disease becomes prominent and hospitalization is undertaken.

The harbinger of the lower-respiratory-tract disease is often a worsening cough. As the disease progresses, tachypnoea and dyspnoea develop, overtly marked by retractions of the chest wall. The hallmarks of bronchiolitis are wheezing and hyperinflation, often associated with a

strikingly elevated respiratory rate and sometimes with diffuse crackles. In pneumonia, the crackles may be localized or diffuse and may be accompanied intermittently by wheezes. Indeed, bronchiolitis and pneumonia often appear to represent a continuum and may be difficult to differentiate clinically. The variability in auscultatory findings and in the respiratory rate within short periods of time is common enough in infants with lower-respiratory-tract infection due to RSV to be considered characteristic. The course of the illness similarly may be variable, lasting from one to several weeks, but most infants will show clinical improvement within three to four days of the onset of the lower-respiratory-tract disease, and most children hospitalized with RSV are discharged within three to seven days, with an average of three to four days (Iwane *et al.*, 2004; Purcell and Fergie, 2004).

Evaluation of the severity of the lower-respiratory-tract disease in these young infants is often problematic. Multiple factors present during the initial evaluation have been associated with an increased risk of severe disease (American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis, 2006). Among these are atelectasis on chest roentgenogram, an oxygen saturation by pulse oximetry of <95%, an appearance of clinical toxicity, and tachypnoea with a respiratory rate of ≥ 70 breaths per minute. An increased respiratory rate may result not only from RSV-induced compromised pulmonary function, but also from the concurrent presence of fever. Fever and the localization or extent of the wheezing or crackles generally do not correlate with the severity of illness.

The clinical assessment of hypoxaemia is difficult as clinically-important degrees of hypoxaemia may exist without the presence of cyanosis. The hypoxaemia results from diffuse involvement of the lung parenchyma, which may not be evident on chest roentgenogram, but causes an abnormally low ratio of ventilation to perfusion. Alveolar hypoventilation and progressive hypercarbia may develop but are rare in infants given good supportive care and supplemental oxygen if required.

The roentgenographic picture of infants with lower-respiratory-tract disease due to RSV may vary from a virtually normal appearance to one that mimics bacterial pneumonia. The severity of the infant's illness generally is not mirrored by the roentgenographic changes. Infants with the typical findings of bronchiolitis, hyperinflation and minimal peribronchial increased markings nevertheless may be severely ill and hypoxaemic. The most characteristic findings on the chest radiograph with RSV lower-respiratory-tract disease are hyperinflation, interstitial infiltrates—which are often perihilar, involving more than one lobe—and atelectasis, especially of the right-middle or right-upper lobes (Friis *et al.*, 1990;

Simpson *et al.*, 1974; Wildin *et al.*, 1988). This latter finding is commonly mistaken as resulting from bacterial pneumonia.

In the Newcastle upon Tyne (UK) studies of infants hospitalized with RSV lower-respiratory-tract disease, hyperinflation was present in over half the children and increased peribronchial markings in 39% (Simpson *et al.*, 1974). Hyperlucency, which occurred as the sole abnormality in 15% of the cases, was particularly associated with RSV infection. Consolidation was present in approximately one quarter of the cases and was usually subsegmental in distribution. The roentgenographic abnormalities, and sometimes the hypoxaemia, tend to persist beyond the time of clinical improvement.

RSV infection during the newborn period occurs less frequently than during the subsequent several months, but is not rare (Mlinaric-Galinovic and Varda-Brkic, 2000; Heerens *et al.*, 2002). The manifestations of the disease in the newly-born, however, may be atypical and missed clinically (Hall *et al.*, 1979). Neonates, especially in the first two to three weeks of life, commonly do not have the typical clinical findings of lower-respiratory-tract disease. More often RSV is initially manifested by such nonspecific signs as lethargy and poor feeding. Upper-respiratory-tract signs may be present in only about half. Premature infants appear to be more susceptible to infection, and the mortality may be high among those in neonatal intensive care units.

Primary infections may also be manifested only as upper-respiratory-tract disease or tracheobronchitis, especially in older infants and children. Ear infection associated with RSV infection is common, and 20–30% of infants hospitalized with RSV infection manifest otitis media. RSV may be recovered from 0 to 60% of middle ear aspirates of children with otitis media. It may be detected as the sole pathogen or in conjunction with bacterial agents. Epidemiologic and laboratory studies have indicated that RSV is a major cause of otitis media among infants and during the first years of life, and may have a more complicated course (Anderson, 2001; Chonmaitree *et al.*, 1992). In general, upper-respiratory-tract infections associated with RSV, whether primary or recurrent, tend to be more prolonged and severe than the usual cold (Hall, 2001b).

Acute Complications of RSV Infections

Apnoea is a frequent complication of RSV infection in young infants, occurring in up to 20% of hospitalized cases (Church *et al.*, 1984; Openshaw *et al.*, 2003). Apnoea may be the initial sign of RSV infection, preceding overt respiratory signs, and is non-obstructive. Apnoea is most likely to occur in premature infants with a gestation of 32 weeks or less and in those of young

postnatal age, less than 44 weeks postconceptional age. A history of apnoea of prematurity has also been identified as a significant risk factor for the development of apnoea with RSV infection. Although the prognosis for such infants has not been defined accurately, it does not appear to place the infant at increased risk of subsequent apnoea (Church *et al.*, 1984).

Infants with RSV bronchiolitis appear to be particularly predisposed to aspirate, which may be clinically manifest as airway hyper-reactivity (Hernandez *et al.*, 2002). One study conducted over a 12 month follow-up period showed that 83% of infants who had been hospitalized with RSV bronchiolitis developed reactive airway disease if given no ribavirin nor therapy for aspiration. However, among the infants who were given thickened feedings along with early ribavirin therapy, the proportion with episodes of reactive-airway disease was reduced to 45% (Khoshoo *et al.*, 2001). The reduction was greater with both ribavirin and thickened feedings than with either therapy alone.

In developed countries, secondary pulmonary bacterial infection or sepsis is an unusual complication (<1% of cases) (Hall *et al.*, 1988; Purcell and Fergie, 2004; Titus and Wright, 2003). In support of this are studies showing that antibiotic therapy did not result in an improved rate of recovery of infants with RSV lower-respiratory-tract disease (National Guideline Clearinghouse, 1998). The most frequent concurrent bacterial infection detected among children with bronchiolitis or RSV infection is urinary-tract infection (Levine *et al.*, 2004; Purcell and Fergie, 2004). The most likely reason for their coexistence is epidemiologic rather than RSV infection predisposing the infant to bacterial urinary-tract infection. RSV infections among hospitalized infants and the initial detection of urinary-tract abnormalities signalled by a urinary-tract infection commonly occur at the same age. In developing countries, however, concurrent pulmonary bacterial infection is more common and may be a major factor leading to the high mortality rate among infants in these countries.

More frequently co-infections which occur among young children with RSV infection are from other viruses (Glezen, 2004; Legg *et al.*, 2005). Usually these concurrent viral infections are from other respiratory viruses, which tend to circulate during the same season as RSV, such as influenza, parainfluenza viruses, hMPV, adenoviruses, rhinoviruses and bocaviruses. Whether children with these dual infections are more likely to have severe infection is unclear, but this may be affected by which virus is concurrently present and whether the virus is being detected during the acute phase of the infection or during a period of prolonged shedding from past illness.

Children at Increased Risk from RSV Infection

Certain groups of children appear to be at risk of developing complicated, severe or even fatal RSV infection (Meissner, 2003; Weisman, 2003). Among these the highest risk groups are those with chronic lung, cardiac and immunosuppressive conditions. In addition, acute or chronic conditions which affect a child's ability to handle respiratory secretions may augment the severity of the RSV infections. In children with nephrotic syndrome, cystic fibrosis and other chronic illnesses, RSV may also cause exacerbations and complications of their underlying disease. Among hospitalized infants with RSV infection the most frequent of the underlying conditions are those with pulmonary disease, especially chronic lung disease following prematurity. These children comprise about 10–15% of the infants hospitalized with RSV infection. Their risk of developing prolonged and complicated infection with RSV extends into the second year of life for those who continue to require medical therapy (Groothuis and Nishida, 2002; Meissner, 2003; Weisman, 2003). Infants of very low birth weight, <1500 g, and of gestational ages ≤ 28 weeks have the highest risk of severe and fatal illness (Holman *et al.*, 2003).

Although immunocompromised children are a smaller proportion of the high-risk children hospitalized with RSV infections, they are particularly important because of the severity of their infection and their susceptibility to nosocomial RSV infection. The degree of immunosuppression correlates with the risk of complicated infection. Thus, those with congenital immunodeficiency diseases and recipients of bone marrow or solid organ transplantation are at highest risk, and may develop lower-respiratory-tract disease at any age, which may be severe or even fatal (Whimbey and Ghosh, 2000; Champlin and Whimbey, 2001; Kim *et al.*, 2007a).

Young children with compromised cellular immune function during an acute or recurrent RSV infection may have higher viral loads than immunocompetent children of similar age, but not than young infants with primary infection. More notable is the prolonged and often intermittent shedding that frequently occurs in children with deficient cellular immunity. In the more compromised children, RSV may be detected for weeks to months in secretions from the lower respiratory tract, which may not be concurrently identified in the upper-respiratory-tract secretions. The viral loads and duration of shedding in these children is highly related to the diagnostic techniques. The rapid antigen tests applied to upper-respiratory-tract secretions are particularly variable in their sensitivity and reliability for diagnosis of these children. On the other hand, reverse transcriptase polymerase chain reaction (RT-PCR) assays are highly sensitive and specific, resulting in the

detection of more prolonged shedding among both immunocompromised and immunocompetent children. However, the clinical correlation with detection and quantitation of shedding by RT-PCR assays requires further study.

The risk of more complicated RSV illness among patients with human immunodeficiency virus (HIV) infection is less clear, but appears to vary according to the stage of their disease, the presence of concurrent viral and bacterial illnesses, and therapy. A limited number of children with RSV infection who are in different stages of HIV infection have been studied, but generally their illness appears less severe than among those who are severely immunosuppressed from transplantation and congenital immune-deficiency diseases (Chandwani *et al.*, 1990; King, 1997; Madhi *et al.*, 2000, 2001, 2002). In some studies the clinical outcome after viral respiratory infections, including influenza, has not differed appreciably between children with and without HIV infection (Madhi *et al.*, 2002).

Infants hospitalized in the first few months of life with uncorrected cyanotic congenital heart disease are potentially at particular peril (Meissner, 2003). Although all the factors or types of cardiac condition associated with a poor prognosis have not been defined, pulmonary hypertension accompanying congenital heart disease may increase the risk appreciably. Recent surgical and technical advances and early correction have substantially reduced the mortality and morbidity in infants with congenital heart disease. Nevertheless, their risk for fatal RSV disease still appears to be more than three- or fourfold greater than that estimated for other infants hospitalized with RSV infection (Fixler, 1996; MacDonald *et al.*, 1982; Meissner, 2003; Navas *et al.*, 1992).

Sequelae Associated with RSV Infections

The most frequent sequelae following RSV lower-respiratory-tract disease in early infancy is recurrent wheezing, sometimes associated with prolonged alterations in pulmonary function. The potential link between RSV bronchiolitis in early infancy and the later development of hyper-reactive-airway disease or asthma is an area of much interest, research and controversy (Douvillat *et al.*, 2007; Henderson *et al.*, 2005; Martinez, 2003, 2005; Openshaw *et al.*, 2003; Sigurs *et al.*, 2005; Stensballe *et al.*, 2006; Taussig *et al.*, 2003). Studies have reported rates of subsequent reactive-airway disease of approximately 30–50%, but most of these involved children who were hospitalized and thus had more severe bronchiolitis (Wennergren and Kristjansson, 2001). These episodes of recurrent wheezing tend to occur most frequently during the first couple of years after hospitalization and improve with age, lasting for several years or

up to adolescence. However, the link between reactive airway disease and RSV is not clearly defined. Whether RSV lower-respiratory-tract infection early in life is truly causal of these later sequelae is controversial.

Much of the current research has shown that the components of the cellular immune response elicited by RSV during bronchiolitis are those associated with asthma, predominately Th2, and the eosinophilic response observed in the lungs of animals with a Th2 response to RSV is similar to that seen in the secretions of children with an allergic response. Despite this, atopy does not appear to be the major factor in predicting which children will develop such long-term pulmonary abnormalities (Martinez, 2003). In a subgroup of children, however, atopy does appear to be a factor in increasing their risk of more severe RSV disease and the subsequent complication of recurrent wheezing (Welliver, 2000; Welliver and Duffy, 1993; Welliver *et al.*, 2002).

Multiple environmental, anatomic and other host factors appear to interact in both predisposing an infant to developing bronchiolitis with primary RSV infection and in augmenting the risk of recurrent wheezing. The importance of the genetic background in determining the variation in the clinical and immune response to RSV has been suggested by the increasing number of studies suggesting that certain gene variants (polymorphisms) correlate with a risk of more severe disease. Among these are certain variants of the genes encoding IL-4 and the IL-4 receptor α -chain, genes for IL-8, IL-10 and chemokine receptor (CCR) (Goetghebuer *et al.*, 2004; Hoebee *et al.*, 2003, 2004).

Infection in Older Children and Adults

Repeated RSV infections occur throughout life, and the interval between infections may be only weeks or months (Hall *et al.*, 1991). In older children and adults these repeated infections are usually manifest as upper-respiratory-tract infections or sometimes as tracheobronchitis. In a minority of adults, usually less than 15%, the infection may be asymptomatic (Hall, 2001a, 2001b). Even in young healthy working adults, and in military recruits, RSV infection causes considerable morbidity and work absenteeism, similar to that resulting from influenza (Hall, 2001b; O'Shea *et al.*, 2005). RSV infection has been shown to produce in young healthy adults hyper-reactivity of the airways to cholinergic stimulus, which may last for eight weeks after infection.

RSV infection in the elderly may be more severe and have some similarities to infection at the other end of the age spectrum (Falsey and Walsh, 2000; Falsey *et al.*, 2005; Nicholson *et al.*, 1997). In older individuals, RSV has been associated with pneumonia, exacerbations of chronic bronchitis and underlying cardiac disease, and can

produce a flu-like syndrome indistinguishable from that of influenza. RSV infection in older adults occurs more frequently than is generally recognized and has been shown to have an impact equal to that of nonpandemic influenza. Although the rates of RSV infection in this population vary from year to year and according to the general health of the individual, about 5–10% of those in assisted-living or long-term-care facilities will acquire RSV infection each year, and 2–5% will succumb. A large prospective study of viral respiratory infections among healthy elderly patients, high-risk adults and hospitalized adults showed that among those who were followed prospectively over four years, the incidence of RSV infection was 5.5% each year, which was nearly double that observed for influenza (Falsey *et al.*, 2005). Furthermore, the clinical manifestations and severity of the disease associated with RSV infection were similar to those from influenza. The morbidity from RSV infection was 8% and from influenza 7%.

DIAGNOSIS

The diagnosis of RSV lower-respiratory-tract illness is often made on the basis of typical clinical and epidemiologic findings (American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis, 2006). Laboratory-confirmed diagnosis of RSV infection may be made by identification of the viral antigen by rapid diagnostic or molecular techniques, viral isolation or serology (Henrickson and Hall, 2007).

Viral isolation has been the standard upon which other diagnostic methods have been judged, but molecular techniques such as RT-PCR are increasingly becoming the gold standard. Viral isolation is dependent on the quality of the laboratory tissue-culture techniques, the specimen and the age of the patient. For infants, viral isolation can be sensitive and specific, but for older individuals tissue-culture diagnosis may be less sensitive, as individuals with a recurrent infection shed smaller quantities of virus and for shorter periods.

Nasal washes or tracheal secretions are generally the best specimens for isolation, but they are not as readily obtained as swabs of the upper respiratory tract. An acceptable alternative to nasal washes and lower-respiratory-tract aspirates is the combination of two swabs, one from the nasopharynx and one from the throat, placed together in one vial of viral transport media. The specimen should be inoculated on to tissue culture promptly and without subjecting it to major temperature changes. RSV is a relatively labile virus and withstands freezing and thawing poorly. Specific cytopathic changes usually appear within three to five days in sensitive continuous cell lines, such

as Hep-2. The use of shell vials allows earlier diagnosis (Figure 18.4).

The disadvantages of viral isolation include the required technical expertise, the number of days for identification (three to seven), the necessity to monitor consistently the sensitivity and quality of the cell lines used, and the expense. The major advantages of isolation techniques are the detection of concurrent viruses and having the virus available to freeze for future research.

Many rapid assays are commercially available for detecting RSV antigens, primarily immunosorbent assays (EIAs) and optical immunoassays (OIAs). They offer the advantages of ease of performance, rapidity and low cost. The sensitivity and specificity of these kits, however, may be highly variable and they should only be used during the peak periods of RSV activity. During periods of low prevalence, as at the beginning and end of the RSV season, the sensitivity and specificity fall markedly. These tests are also less sensitive in certain populations, such as the elderly and immunocompromised patients (Henrickson and Hall, 2007).

Both direct and indirect immunofluorescent reagents, utilizing either polyclonal or monoclonal antibodies, are available. They possess a high degree of specificity and sensitivity, about 95% if performed by experienced laboratory personnel (Figure 18.5). The reliability of these immunofluorescent techniques over the rapid EIA and

OIA assays is an advantage, but the required experience and time, along with the variable patterns produced by different antibodies utilized among vendors, are disadvantages.

Of the currently available methods, PCR assays are generally the most sensitive and specific and allow simultaneous detection of multiple viruses. The use of nested PCR assays augments the sensitivity, and RT-PCR assays offer additional benefits of a diminished number of procedural steps and, therefore, less time and chance for contamination. The major advantage these assays have offered for diagnosing RSV infection in children is illustrated by comparison of the use of RT-PCR to tissue culture. Of 983 nasal/pharyngeal specimens from children in Rochester, NY, 496 were determined to be positive for RSV, which was defined as the detection of RSV by RT-PCR two or more times and/or by isolation of RSV in tissue culture (Henrickson and Hall, 2007). Of these, 99% were positive by the RT-PCR assay, 51% by tissue culture and 49% by both methods. RSV was detected by viral isolation alone in only 1% of the specimens. The RT-PCR assays were equally sensitive for group A and B RSV strains. The advantages and continued improvements in these assays predict that they will become more widely available for clinical laboratories.

Multiple serologic tests are available, mostly in research laboratories. Neutralization assays and EIA, using

Figure 18.4 Positive indirect immunofluorescent antibody test on nasal secretions from an infant with lower-respiratory-tract disease due to RSV.

Figure 18.5 Stained preparations of uninfected HeLa cells (left) and cells infected with RSV (right). Syncytial formation is well illustrated by the infected monolayer.

the purified major RSV glycoproteins F and G, are most frequently used, and they offer the possibility of detecting specific antibody classes. Assays for IgM antibodies to RSV are of limited usefulness, as IgM antibodies are commonly not detectable in patients with proven infection and, if present, may appear anywhere from 6 to 40 days from the onset of the illness (Dowell *et al.*, 1996; Vikerfors *et al.*, 1988).
