Serologic diagnosis by detecting antibody rises in acute and convalescent sera is rarely of help in the acute management of the patient since seroconversion usually does not occur for at least two weeks and may require four to six weeks. Furthermore, among 10–30% of patients some serologic assays may be falsely negative (Falsey *et al.*, 2005; Henrickson, 2004). Young infants in particular may have poor antibody responses which are not detectable by some antibody assays.

MANAGEMENT

Most infants do well with their RSV infection with just the usual care given for fever, maintenance of adequate hydration and clearing of the nasal passages by gentle bulb suction as necessary. For the more severely affected infants with lower-respiratory-tract disease, the quality of the supportive care is most important (Panitch, 2003). Documentation of the blood gases in the more severely ill hospitalized infant is essential to determine the need

for supplemental oxygen. Most infants respond well to relatively low concentrations of oxygen, since the major parenchymal abnormality is an unequal ratio of ventilation to perfusion. In the severely-ill infant, frequent assessment of the blood gases may be required to monitor for hypercarbia, and if progressive this may indicate the need for airway intervention. Hypercarbia and recurrent apnoea are the most frequent reasons for assisted ventilation. Hypoxaemia, unresponsive to oxygen therapy, is less common.

The antiviral agent, ribavirin (1-*b*-D-ribofuranosyl-1,2,4-triazole-3-carboxamide), is the only agent currently approved for specific treatment of RSV infection (Jafri, 2003). Ribavirin is a synthetic nucleoside which appears to interfere with the expression of mRNA and has an unusually broad spectrum of antiviral activity, affecting a variety of both RNA and DNA viruses *in vivo* and *in vitro*. No toxicity has been shown with ribavirin therapy (Krillov, 2002) and development of resistance to ribavirin by RSV strains or other viruses has not been observed. Ribavirin is administered by small-particle aerosol, usually for 12 or more hours per day, but may be in shorter or intermittent periods until clinical improvement, which is usually in two to five days. Analysis of eleven randomized trials of the use of ribavirin showed seven demonstrated benefit, and four did not (American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis, 2006; King *et al.*, 2004). Studies examining the effect of ribavirin therapy on the long-term pulmonary sequelae have given mixed results. Because of the

heterogeneity of the studies and the relatively low numbers of patients studied, the use of ribavirin is variable and controversial. It is expensive and its relative cost to benefit is unclear. For these reasons the drug is not recommended for routine management of infants with RSV infection. Its use may be considered for those patients at high risk for severe disease, and the decision made according to the individual circumstances (American Academy of Pediatrics (AAP), 2006; American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis, 2006).

Bronchodilators, glucocorticosteroids and antibiotics are commonly used for the treatment of RSV bronchiolitis (Behrendt *et al.*, 1998). Among hospitalized infants, 75–80% are administered bronchodilating agents and 10–40% receive glucocorticoids, yet neither of these is routinely recommended (American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis, 2006). The multiple trials that have evaluated α -adrenergic bronchodilators have been variable in design, agents used, patients included and measured outcomes. Systematic reviews of their use for children with bronchiolitis have concluded that insufficient evidence exists to recommend their use routinely in children with their first episode of wheezing (AHRQ, 2003; American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis, 2006). However, these guidelines do allow the option for a carefully monitored trial of inhaled bronchodilating agents for some cases. They further stress that such a trial should be carefully and objectively evaluated, and that bronchodilator therapy should be continued only if benefit is demonstrated.

The studies examining the use of glucocorticosteroids for bronchiolitis also have been generally of varied design, making comparisons difficult. However, several reviews analysing the randomized and controlled trials concluded the evidence was not sufficient for a recommendation of routine use (AHRQ, 2003; American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis, 2006). Although two controlled studies evaluating oral glucocorticosteroid therapy for bronchiolitis showed benefit, a more recent and larger study involving 20 emergency departments did not (Corneli *et al.*, 2007). This placebo-controlled trial examined the outcome of 608 children 2–12 months of age who presented with their first episode of bronchiolitis. No significant difference in the rate of hospitalization or in the assessment of the respiratory status existed between those children who were administered one dose of oral dexamethasone (1 mg kg^{-1}) and those who received placebos. Also of note was that no significant benefit was observed among the subgroup of children with asthma or an atopic family history. This large, well-designed study supports the

current recommendations against the use of glucocorticosteroids for this defined population of first-time wheezers (American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis, 2006; Hall, 2007b).

Antibiotics are commonly administered to young infants with RSV lower-respiratory-tract disease, even among children with laboratory-confirmed RSV infection. In part, this may relate to the concern that infiltrates from atelectasis represent bacterial pneumonia or secondary pulmonary bacterial infection, both of which are rare. Prophylactic use of antibiotics has not been shown to be effective and is not warranted among children with RSV infection. Antibiotics should be used only when specific indications of a bacterial infection are present.

Chest physiotherapy, cool-mist therapy, aerosolized therapy with saline and chest percussion are not recommended for the routine management of children with bronchiolitis (National Guideline Clearinghouse, 1998; Perlstein *et al.*, 1999).

PREVENTION

For decades now, research has been directed towards the development of a safe and effective vaccine for RSV (Domachowske and Rosenberg, 2005; Greenberg and Piedra, 2004; Moore and Peebles, 2006; Piedra *et al.*, 2003). Immunization for RSV, however, poses singular problems. A vaccine for RSV would need to be administered within the first few weeks of life, when maternal antibody is consistently present and when the repertoire of both T-cell and B-cell responses is limited, especially among high-risk premature infants, for whom the vaccine is most needed. For these same reasons determining the correlates of the immunogenicity and effectiveness of a vaccine in this age group is particularly problematic. Furthermore, since repetitive infections are the mien of RSV, an RSV vaccine ideally should be able to produce more durable immunity than that observed after natural infection.

Following the experience with the initial formalin-inactivated vaccine, subunit and especially live-attenuated vaccines have been sought. The advantages of live-attenuated vaccines over subunit vaccines are the potential induction of both local mucosal and systemic humoral immunity, better and cellular responses and intranasal administration.

Live-vaccine candidates have been developed by cold-adaptation (cold-passage, cp) and chemical mutagenesis to produce temperature-sensitive (ts) mutants that will replicate at the low temperatures (32–35 °C) of the upper respiratory tract, but not at the higher temperatures in the lower respiratory tract (Collins and Murphy, 2005). The

initial 'cp' and 'ts' vaccine candidates proved to be too reactive or overly attenuated, and some were associated with prolonged shedding of virus. The mutations produced by these methods tended to be genetically unstable, variable and unpredictable.

The development of reverse genetics, which allows the recovery of infectious RSV from c-DNA clones, has now allowed the development of specifically-defined mutations, to be incorporated into candidate vaccines. Multiple 'cp/ts' mutations generated by reverse genetics have been introduced singularly or in combination into recombinant wild-type RSV, and their level of attenuation evaluated in animal models. Further 'designer gene' candidate vaccines have been generated by reverse genetics of RSV mutant strains with single or multiple gene delineations. These appear promising and are currently considered among the prime candidates for immunization (Karron *et al.*, 2005).

Multiple subunit RSV vaccines have been developed, and several have progressed into clinical trials in adults and children. These vaccines have primarily focused on the major RSV surface glycoproteins, F and/or G, which are the major targets of neutralizing antibody. Several generations of the F subunit vaccines have been evaluated in trials of healthy and elderly adults, pregnant women, and healthy and high-risk children beyond a year of age. Some have been administered with carriers and adjuvants which can augment and modulate the type of immune response, such as liposomes, biodegradable microspheres and vesicles of immunostimulating complexes. While these vaccines have appeared safe and well-tolerated, they are not sufficiently immunogenic in seronegative infants, and the neutralizing antibody response is frequently suboptimal. The RSV F subunit vaccines are able to reduce the overall occurrence of RSV infection, but not the incidence of lower-respiratory-tract disease if infection of the upper respiratory tract has already been established (Simoes *et al.*, 2001). Higher levels of neutralizing antibody have been induced in adults by a subunit vaccine containing purified F, G and M proteins from an RSV A strain, but the antibody levels obtained were not durable.

The hurdles currently existing for the development of an effective vaccine for RSV indicate that immunization for RSV in infants is unlikely to be available soon. Some of these candidate vaccines, however, could become available in the interim and provide some protection for groups of older individuals who are at high risk for RSV infection, such as the elderly and children with chronic underlying conditions, and could result in considerable progress toward the goal of controlling, if not eliminating, RSV infections.

Alternative means of protection against RSV infection have focused on diminishing the severity of RSV disease

in high-risk infants. The use of passively-administered humanized monoclonal antibodies became possible with the licensure of palivizumab, a humanized RSV monoclonal antibody, in 1998. Palivizumab was developed from a mouse monoclonal antibody that recognizes a protective epitope of the F protein. Two large randomized and placebo-controlled trials were integral in the licensure of palivizumab (Impact-RSV-Study-Group, 1998; PREVENT-Study-Group, 1997). These studies demonstrated that the rate of hospitalization for RSV illness was reduced over 50% among those infants who received prophylaxis, compared to those who received placebo. Among the different subgroups the hospitalization rates were reduced from 39 to 78%. Post-licensure studies have continued to show a significant reduction in the necessity for hospitalization among high-risk infants with RSV infection. The American Academy of Pediatrics currently recommends palivizumab prophylaxis for selected groups of children less than two years of age with chronic lung disease, prematurity and functionally-important congenital heart disease. Palivizumab is recommended in the United States to be administered in five-monthly doses to span the major months of RSV circulation. Because the potential benefit compared to the expense will vary according to the child's risk factors, such as gestational and postnatal age and presence of underlying conditions, the recommendations are subject to variable interpretation and often the decision must be based on individual circumstances.

Palivizumab is not currently recommended to diminish the risk of subsequent wheezing, as this use has not been well studied. However, a cohort study of premature infants who did and who did not receive palivizumab were prospectively followed for two years for the occurrence of recurrent wheezing. Those who had received prophylaxis had a significantly greater reduction in subsequent wheezing, suggesting palivizumab prophylaxis may have later beneficial effects in preterm infants (Simoes *et al.*, 2007).

Despite the proven efficacy of palivizumab in reducing hospitalization from RSV infection in high-risk infants, its use remains controversial. The economic analyses have varied, but most have not demonstrated an overall saving in health-care costs when the majority of high-risk children receive prophylaxis. Palivizumab has not been shown to be effective in the treatment of RSV disease, nor has it been demonstrated to diminish significantly the rate of mortality for infants with RSV. However, the mortality rate currently from RSV infections is extremely low. Further generations of humanized recombinant monoclonal antibodies derived from palivizumab have been developed. One of these, motavizumab, which has a binding affinity 70 times greater than that of palivizumab, was

Table 18.1 Infection control procedures, both standard precautions and contact precautions, for prevention of respiratory syncytial virus (RSV) infection. Recommended by Centers for Disease Control and Prevention

Recommendation category, procedure	Comment(s)
Category 1-B recommendations ^a	
Hand washing	Water with soap or antibacterial agent or waterless antiseptic hand rub
Wearing gloves	Combined with hand washing before and after each glove change; may diminish self-inoculation
Wearing gowns	When direct contact with patient or patient secretions is likely
Wearing masks plus eye protection	Eyes and nose are major sites for inoculation
Housing patient in private room or in a cohort isolated from other patients	Patients with documented infection can be grouped and isolated from other patients; beds should be separated by >0.9 m
Use of dedicated patient-care equipment. Sometimes recommended with less or no supporting evidence	Equipment, including toys, assigned to specific patients
Staff assigned according to patient's RSV status	Specific staff care only for patients with RSV infection
Visitor restrictions during RSV season	Some qualify by restricting young children only
Screening visitors for illness during RSV season	Visitor assessed by trained personnel and/or advised by use of an educational patient-information list

^aCenters for Disease Control and Prevention 1-B recommendations based on 'strong rationale and suggestive evidence', strongly recommended for all hospitals and 'reviewed as effective by experts in the field'. Reprinted from Hall, 2000a; see also Centers for Disease Control and Prevention, 2003; Gardner, 1996.

recently demonstrated in a large phase 3 trial to result in a significantly greater reduction in hospitalization for RSV infection than that following palvizumab prophylaxis.

The prevention of RSV infection in normal infants, however, currently is not possible because of the ubiquitous and contagious nature of the virus. Infection-control procedures may be effective in limiting nosocomial spread of RSV, but are of limited effectiveness and feasibility in the home. Of the infection-control procedures employed to limit the nosocomial spread of RSV, annual education of staff and good hand washing are most important (Hall, 2000a) (Table 18.1). The use of gloves may be of benefit when compliance with consistent and careful hand washing is less than optimal. The routine use of gowns and masks has not been shown to be of additional benefit. The use of gowns, however, may be advisable during periods of close contact, during which an infant's secretions are apt to contaminate clothing. Since RSV primarily infects via the eyes and nose, surgical masks which cover the nose and mouth are of limited value, but eye-nose goggles have been shown to be beneficial (Hall, 2000a).

Other procedures of potential, but less well proven, benefit include isolation or cohorting of RSV-infected infants and assignment of nursing personnel to care for either infected or uninfected infants, but not both simultaneously. During epidemic periods the number of patient contacts and visitors should be limited. Cleaning of objects and surfaces contaminated with infant secretions is

also advisable. RSV is a relatively labile virus and can be eradicated from surfaces by most any cleaning agent and certainly by those that are routinely used in hospitals, including soap and water, detergent and chemical disinfectants. Elective admissions of infants with high-risk conditions should be avoided during the epidemic periods of RSV. For those infants who must be admitted, particular care must be employed to prevent such cross-infections.

Adenoviruses

Marcela Echavarría

Clinical Virology Laboratory, Department of Clinical Analysis, Centro de Educación Médica e Investigaciones Clínicas, 'Norberto Quirno', CEMIC, University Hospital, Buenos Aires, Argentina

INTRODUCTION

Adenoviruses were discovered in the early 1950s from a military recruit with atypical pneumonia. Epidemiologic studies soon identified these viruses to be the major cause of acute respiratory disease (ARD) in military recruits. Later, these viruses were described as proven agents of infant gastroenteritis and conjunctivitis. Adenoviruses are also associated with pharyngitis, pharyngoconjunctival fever (PCF), pertussis-like syndrome, keratoconjunctivitis, bronchiolitis, pneumonia, acute haemorrhagic cystitis (HC), hepatitis, meningitis, encephalitis, myocarditis, pericarditis, genital infections, pancreatitis and disseminated disease. Clinical manifestations vary with the host, the site of pathology, and the serotype involved. In recent years, adenoviruses have been increasingly recognized as significant viral pathogens with high morbidity and mortality, especially among immunocompromised patients. In addition, increasing attention is being given to their utility as vectors for gene therapy.

Adenovirus infections are common, have worldwide distribution and occur throughout the whole year. These infections are frequent during childhood, where they tend to be self-limited and induce serotype-specific immunity. Adenoviruses are endemic in the paediatric population; epidemics and outbreaks with higher morbidity and mortality can occur in children and adults.

Human adenoviruses belong to the *Adenoviridae* family and the *Mastadenovirus* genus. They are divided into six species, designated A through F. To date, 52 adenovirus

serotypes have been described. The recently-described serotype 52 has a pending species classification into species G, as proposed by Jones *et al.* (2007). About half of the known serotypes have been recognized as causing illness. Most of the higher numbers for serotypes have been isolated from immunocompromised individuals but not necessarily associated with disease.

Adenoviruses are medium-sized, non-enveloped icosahedral viruses with a single linear, double-stranded DNA molecule. They are highly resistant to inactivation and readily spread in closed populations.

Adenovirus diagnosis is mostly carried out using direct methods, including virus isolation in cell culture, antigen detection by immunofluorescence (IF), immunohistochemistry, genome detection with or without amplification and, to a lesser extent, electron microscopy (EM). Molecular methods using DNA amplification by polymerase chain reaction (PCR) have increased the sensitivity and rapidity of diagnosis. More recently, the use of 'real-time' PCR assays has permitted even faster results and the quantification of the virus, allowing therapeutic intervention, prognosis and the follow-up of patients with severe disease.

Although no specific treatment for adenoviruses is available, there is evidence that some antiviral agents such as cidofovir and ribavirin are useful in treating some infections.

Sensitive, rapid and early diagnosis is important, given the disease severity and high mortality rates in some patient populations.

DESCRIPTION AND CHARACTERISTICS OF THE VIRUS

History

Hilleman and Werner (1954) described the recovery of a new virus from throat washings obtained from a military recruit with primary atypical pneumonia during a respiratory epidemic in 1952–1953 at Fort Wood. Rowe *et al.* (1953) described the spontaneous degeneration of cultures of adenoidal tissue obtained by routine adenoidectomies in children by an ‘adenoid-degeneration agent’. Tests performed by both groups gave evidence of an immunological relationship between the two agents. These viruses were initially called ‘adenoid-degeneration agent’ (Rowe *et al.*, 1953) and ‘RI-67’ (respiratory infection from recruit #67) (Hilleman and Werner, 1954) but in 1956 the term adenovirus was adopted as viruses were first recovered from adenoid tissues (Enders *et al.*, 1956). Retrospective serological procedures demonstrated that adenoviruses were present and associated with ARD in soldiers at Fort Bragg during World War II.

Taxonomy

Adenoviruses are widespread in nature and have been isolated from human and many animal species. The family *Adenoviridae* has been subdivided into four genera: *Mastadenovirus*, *Aviadenovirus*, *Atadenovirus* and *Siadenovirus* (Mayo, 2002).

The *Aviadenovirus* genus, from the Latin ‘*avi*’, meaning ‘bird’, is limited to viruses of birds.

The *Mastadenovirus* genus, from the Greek ‘*mastos*’, meaning ‘breast’, infects mammals and includes human, simian, bovine, equine, porcine, ovine, canine and opossum viruses (Benko *et al.*, 2005).

The *Atadenovirus* genus, named in recognition of the high A+T content in the genome, has been recovered from reptiles, birds, marsupials and ruminants.

The *Siadenovirus* genus, from ‘*Si*’ for ‘sialidase’, was named in recognition of the presence of a putative sialidase homologue gene and infects amphibians and birds.

The regions E1A and E1B, E3 and E4 are present only in the *Mastadenovirus* genus. In the other genera, the location and organization of these three early regions is very different.

Basic Virology

Six of the approximately nineteen *Mastadenovirus* species (formerly called subgenera) infect humans and are designated A through F, with species B further subdivided into subspecies B1 and B2. Species G has been proposed as a new species. Species classification is defined by immunological, biological and biochemical characteristics, specifically on the basis of oncogenicity in rodents, the differential haemagglutination patterns with erythrocytes from different species, the lengths of their fibres and the percentage of G+C in the genome (Table 19.1). Transformation occurs primarily in rodent cells infected with species A serotypes, which integrate into the host genome and induce cellular replication without producing infectious virus. Although all adenoviruses can transform cells in tissue culture, there is no clear evidence that they cause cancer in humans.

Different adenovirus serotypes are described within one species. A serotype is defined on the basis of its immunological distinctiveness, as determined by quantitative neutralization with animal antisera. Initially only 24 antigenically-distinct adenoviruses were described. In 1960, serotypes 25–33 were recovered from stool samples and were not associated with known diseases. Types 40

Table 19.1 Classification of the 52 human adenovirus serotypes by species characteristics

Species	Serotypes	Oncogenic potential	% G+C	Haemagglutination		Fibre length (nm)
				Rhesus	Rat	
A	12, 18, 31	High	48–49	–	+ /–	28–31
B1	3, 7, 16, 21, 50	Weak	50–52	+	–	9–11
B2	11, 14, 34, 35	Weak	50–52	+	–	9–11
C	1, 2, 5, 6	None	57–59	–	+ /–	23–31
D	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51	None	58	+ /–	+	12–13
E	4	None	57–61	–	+ /–	17
F	40, 41	None	57–59	–	+ /–	~29
G (proposed)	52	Nd	Nd	Nd	Nd	Nd

Nd: not determined yet.

and 41 were associated with gastroenteritis, and the last nine serotypes (43–51) were isolated from AIDS patients (de Jong *et al.*, 1999). In 2007, the new strain postulated as adenovirus 52 was identified in an outbreak of gastroenteritis (Jones *et al.*, 2007). Within one serotype there may be different genotypes, which suggest changes of the genomic DNA not associated with serological changes. Genome typing can be done by restriction endonuclease analysis of full-length viral DNA, by PCR or by sequencing. Forty genotypes for adenovirus 2, twelve for adenoviruses 7 and eleven for adenovirus 11 are some of the examples obtained by restriction enzyme analysis (Adrian *et al.*, 1986). The prototype strain is named with the letter 'p', and the subsequent genotypes with letters 'a', 'b', 'c', 'd' and so on. Most of the prototype strains are not currently circulating, probably due to a continuous

evolutionary process. Although adenoviruses are DNA viruses with a DNA polymerase, giving high fidelity due to proofreading capability, the emergence of new serotypes and genotypes is well known, especially among species D. The appearance of multiple serotypes or genotypes among adenoviruses and papilloma viruses (another DNA virus) suggests an evolutionary mechanism. Beside homologous recombination as a primary mechanism for evolution, it has been proposed that illegitimate recombination can occur among adenoviruses (Crawford-Miksza and Schnurr, 1996).

Structure

Adenoviruses are medium-sized, non-enveloped icosahedral viruses 70–90 nm in diameter (Figure 19.1). Each particle contains a single linear, double-stranded DNA

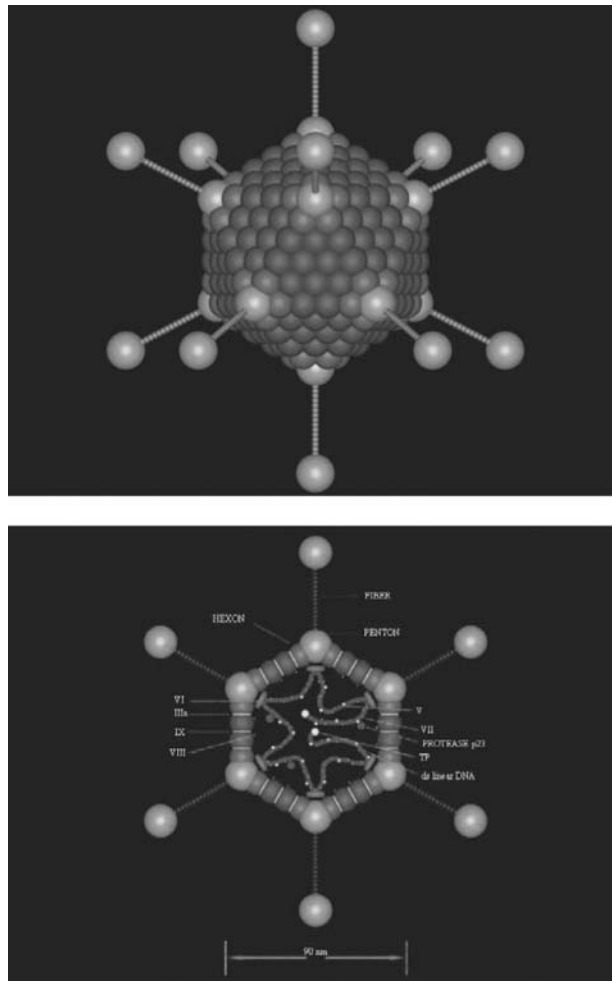

Figure 19.1 Schematic graphic of adenovirus particle. Location of proteins and genome.

molecule of about 36 kb, encoding approximately 40 genes (Davison *et al.*, 2003). Major transcription units include early genes E1A, E1B, E2, E3 and E4, genes expressed later in the early phase (IX and IVa2), and late genes (L1–L5.) One or more (depending on the serotype) virus-associated (VA) non-translated genes are also described.

The protein capsid is formed by 252 capsomeres. The 240 hexons are grouped into 20 triangular faces, with 1 penton at each of the 12 vertices. Each penton consists of a base and the fibre, a rod-like projection of variable length with a terminal knob that interacts with cellular receptors.

The polypeptides are named with Roman numerals (I–X) and some of their functions are still unknown (Table 19.2). The hexon, penton and fibre (polypeptides II, III and IV, respectively) are the major components of the capsid and the principal antigenic determinants of the virus (Figure 19.1).

The hexon has antigenic sites common to all human adenoviruses. Neutralizing antibodies are directed against the ϵ epitope of the hexon. Hexons also contains type-specific sites which induce neutralizing antibodies. Fibres have type-specific and some species-specific antigenic determinants, and are responsible for haemagglutination *in vitro*.

Adenoviruses have a linear, nonsegmented, double-stranded DNA of about 36 kb. The terminal nucleotide sequences are inverted repetitions and there is a protein of 55 kDa covalently attached to the 5' end of each strand. Both of these features are related to viral DNA replication, which contains two identical origins.

Resistance to Physico-chemical Agents

As non-enveloped viruses, adenoviruses are highly resistant to physical and chemical agents and are resistant

to inactivation at room temperature. They remain infectious at room temperature for prolonged periods in certain fomites, giving them a high potential for spread. Some serotypes, especially those associated with epidemic keratoconjunctivitis (EKC) have the ability to survive on nonporous surfaces for 35 days (Nauheim *et al.*, 1990). Transmission is person-to-person but they can also spread through water, fomites and instruments. Nosocomial infections and severe outbreaks have been reported.

They are stable at low pH and resistant to gastric and biliary secretions, thus allowing the virus to replicate and achieve a high viral load in the gut. They are resistant to ether and isopropyl alcohol. Sodium hypochlorite (500 ppm) for 10 minutes, or immersion in water bath at 75°C for 30 seconds, at 60°C for 2 minutes or at 56°C for 30 minutes can be used to inactivate. Effective surface disinfections include ~1900 ppm available free-chlorine, 70% ethanol, 65% ethanol with 0.63% quaternary ammonium compound, and 79.6% ethanol with 0.1% quaternary ammonium compound. These disinfectants should be allowed to contact all environmental surfaces for at least a minute (Rutala *et al.*, 2006). Hand hygiene with an antimicrobial soap and water should be used when adenoviral contamination may have occurred. Adenoviruses survive freezing with minimal loss of infectivity.

Replication

Replication begins by attachment of the fibre knobs to cell-surface receptors. Most human adenoviruses species A, C, D, E and F use the coxsackie adenovirus receptor (CAR) protein, which is a member of the immunoglobulin superfamily, as the initial receptor (Roelvink *et al.*, 1998).

The species B attachment receptor has not been identified, although recent studies have proposed a species B adenovirus receptor (sBAR) for species B1 and B2, and a specific receptor sB2AR exclusively for species

Table 19.2 Adenovirus proteins

Proteins from the capsid		
Name	Name	Known functions
II	Hexon monomer	Structural
III	Penton base	Penetration
IIIa	Associated to penton base	Penetration
IV	Fibre	Receptor attachment, Haemagglutination
V	Core: associated to DNA and penton base	Histone-like; Packaging?
VI	Hexon minor polypeptide	Stability/particle assembly?
VII	Core	Histone-like
VIII	Hexon minor polypeptide	Stability/particle assembly?
IX	Hexon minor polypeptide	Stability/particle assembly?
TP	Genome–Terminal Protein	Genomic replication

B2 (Segerman *et al.*, 2003). Other receptors include sialic acid saccharides, mostly used by adenovirus serotypes 8, 19 and 37 (species D) (Arnberg *et al.*, 2002).

After attachment, the virus migrates to clathrin-coated pits and is internalized in endosomes. Interaction between the penton base protein of the viral capsid and integrins ($\alpha_v\beta_3$ and $\alpha_v\beta_5$) is needed for efficient internalization. The interaction occurs through an arg-gly-asp (RGD) sequence present in the penton base. Since not all cell types produce α_v integrins, attachment can occur but no efficient replication is achieved.

Uncoating of the virus occurs and transport of the genome to the host nucleus is microtubule-mediated. The intracellular trafficking is different for species B and C. While adenovirus 5 (species C) rapidly translocates to the nucleus within one hour after infection, adenoviruses 7 (species B) is widely distributed in the cytoplasm. It has been suggested that the fibres do not only mediate the binding to the cell surface but also modulate intracellular trafficking (Miyazawa *et al.*, 1999).

Viral proteins are expressed, and viral DNA replication which occurs in the nucleus starts 12 hours post-infection in tissue culture. Structural proteins synthesized in the cytoplasm then move to the nucleus and form capsids, which encase the DNA and aggregate into crystalline arrays. After maturation, viruses remain localized in the nucleus (Figure 19.3). During a lytic

infection the cells die and the virus particles are liberated.

Virus DNA Replication

The replication cycle is divided into three phases: an immediate-early phase, a delayed-early phase, which precedes viral DNA replication, and a late phase, which follows DNA replication and is characterized by the expression of the structural proteins of the viral capsid. The five early transcription units are E1A, E1B, E2, E3 and E4. E1A and E1B stimulate the infected cell to transcribe and replicate adenovirus genes (Russell, 2000). E1A blocks interferon (IFN)-induced gene expression and the ability of the p53 and Rb growth-suppressor genes to suppress cell division. E1B proteins inhibit apoptosis in the stimulated cell. The E2 region codes for proteins necessary for viral DNA replication. Several E3 products prevent death due to receptor-mediated apoptosis. E3/14.7K seems to interfere with the cytolytic and pro-inflammatory activities of tumor necrosis factor (TNF), while E3/10.4K and 14.5K proteins remove Fas and TRAIL receptors from the cell surface by inducing their degradation in lysosomes. These and other functions that may affect granule-mediated cell death might drastically limit lysis by natural killer (NK) cells and cytotoxic T cells. In general, E3 gene products appear to facilitate immune evasion. E4 gene products are

Figure 19.3 Electronic microscopy micrograph of adenovirus in a thin section of the infected cell (magnification $\times 108,000$) (Kindly provided by Dr Ludmila Asher.)

diverse and some are required for efficient tripartite splicing, used in the transcription of the late genes. The two delayed early units are IX and IVa2. One late unit is processed to generate five families of late mRNA (L1, L2, L3, L4 and L5). Not all the late genes are structural; there are also VA genes transcribed by the RNA polymerase III. The VA RNA is a short, highly-structured RNA that interferes with the cell's ability to produce IFN.

Almost all transcription units generate a complex set of alternately-spliced mRNAs that encode for multiple proteins. Interestingly, important molecular and cell biological processes such as RNA splicing and cell cycle regulation were discovered while studying adenovirus gene expression.

Assembly of the virion particles occurs in the nucleus, where they form crystalline aggregates like nuclear inclusion bodies (Figure 19.3). The replication cycle takes approximately 30 hours. From 10 000 to over 1 000 000

viral particles are produced per cell; only 1–5% are infectious.

Adenoviruses may cause at least three different types of infection. Productive lytic infection occurs mostly in epithelial cells. Latent or persistent infections occur primarily in the lymphoid mucosal tissue at sites such as the tonsils and adenoids, where they are maintained by unknown mechanisms and infrequently produce virus (Garnett *et al.*, 2002). Transformation occurs primarily in rodent cells infected with species A serotypes, which integrate into the host genome and induce cellular replication without producing infectious virus.

PATHOGENESIS

In cell culture, adenoviruses cause cell rounding, aggregation and accumulation of basophilic nuclear inclusions. Pentons have a toxin-like activity and isolated

penton bases produce the detachment of monolayers in cell culture after two hours of incubation. Adenoviruses have the capability to shut down host mRNA and synthesize adenovirus structural proteins, which accumulate in the nucleus, giving the characteristic histopathological intranuclear inclusions.

The reasons for the different organ tropisms and the production of such diverse diseases by adenoviruses serotypes have not been completely elucidated. Studies of the pathophysiology are limited by the lack of animal models that faithfully reproduce the diseases seen in humans. Studies on pathogenesis have been carried out in the cotton rat (*Sigmodon hispidus*) as it is susceptible to intranasal infection with adenovirus serotype 5 and develop pulmonary histopathology similar to that seen in humans, although the virus is not truly adapted to this animal.

In the cotton rat, the virus replicates in bronchiolar epithelial cells. *In situ* hybridization also shows early gene expression in macrophages/monocytes in alveoli and hilar lymph nodes (Ginsberg and Prince, 1994). The histopathological response consists of two phases. The early one is a mild-to-moderate damage of bronchiolar epithelial cells (including cytoplasmic vacuolation and loss of cilia) and diffuse infiltration of the peribronchiolar and alveolar regions with monocytes/macrophages, neutrophils and lymphocytes. The late phase consists of a peribronchiolar and perivascular infiltration composed almost entirely of lymphocytes. The predominant process is the response of the host to infection, rather than direct viral damage to cells.

Only early genes seem to be required to induce pathological changes in cotton rats. It seems that for complete viral replication it is essential only to infect a sufficient number of cells to yield an adequate expression of early gene functions. However, results from the cotton rat should be cautiously extrapolated to humans.

Whether or not adenoviruses causes a lytic infection still remains controversial. Earlier studies on the mechanism of adenovirus pathogenesis in cell cultures led to the hypothesis that the basis of cell killing is the intranuclear accumulation of viral proteins. Studies in mice and cotton rats showed that neither adenovirus 2- nor adenovirus 5-infected epithelial cells are lysed, although they are severely injured and probably die, because early adenovirus genes shut off DNA and protein synthesis in infected cells.

Studies on pathogenesis in children with fatal adenovirus infection have shown that TNF- α , interleukin (IL)-6 and IL-8 were detected in the serum, while these cytokines were not found in patients with moderate diseases (Mistchenko *et al.*, 1994).

Whether the cell-damaging effects of adenovirus infection or the host immune responses are responsible for the tissue pathology and clinical manifestations remains unclear.

Latency/Persistence

Adenoviruses devote a significant portion of their genome to gene products whose sole function seems to be the modulation of host immune responses. These mechanisms might play a role in maintaining the virus in a persistent state. Adenoviruses mount an apparently effective defense against the host immune response, as evidenced by the ability of the virus to persist at low levels in the host for long periods of time with periodic shedding of infectious virus in faeces and into respiratory secretions. Adenoviruses 1, 2, and 5 persist in tonsils for years through a low-grade replication.

Although the establishment of persistent infections is well documented in several epidemiological studies, the tissue site of replication during asymptomatic periods is enigmatic. In 1973 van der Veen *et al.* isolated adenovirus types 1, 2, 5 and 6 with a low frequency from tonsil- and adenoid-derived lymphocytes. One group reported the presence of adenovirus nucleic acid sequences in peripheral lymphocytes of healthy adults by *in situ* hybridization (Horvath *et al.*, 1986). However, amplification studies using PCR have demonstrated zero or low (1.7%) presence of adenovirus DNA in peripheral blood from healthy adult volunteers (Flomenberg *et al.*, 1997; Villamea *et al.*, 2002). Adenovirus species C persists in mucosal lymphoid tissues from tonsils and adenoids (Garnett *et al.*, 2002). Virus shedding in stool also supports a mucosal association of the virus. Thus, the virus may be strictly associated with the mucosal-lymphocyte compartment and rarely be found in circulation.

The gp 19kDa and protein 14.7kDa play a central role in the ability of subgroup C to produce persistent infections. Gp 19 prevents transport of the class I MHC to the surface of infected cells, reducing cytotoxic T-cell attack of the infected cells.

IMMUNE RESPONSE

The host has a range of efficient and well-orchestrated strategies to respond to adenovirus infections. Innate defenses, including recruitment of macrophages, activation of complement and NKs, the production of a range of pro-inflammatory cytokines and the orchestration of other signalling pathways, play a significant role in clearing adenovirus infection. The host also produces IFN, and the cell can redirect its metabolism to apoptotic circuits.

From the viral side, adenoviruses develop a number of mechanisms to evade the host immune response (see 'Immune Evasion').

In addition, cellular and humoral responses are critical in controlling adenovirus infections. T cells are effective defenses via both CD8 and CD4. CD4+ T-helper cells stimulate proliferation of B cells to synthesized immunoglobulins for the humoral response. It was suggested that CD4 T cells recognize conserved antigens among different serotypes and that the majority of individuals develop long-lived CD4+ T-cell responses to adenoviruses (Flomenberg *et al.*, 1995). This may play a role in modulating infections with a range of serotypes.

The humoral response is a major component in the control of adenovirus infections. After infection, most patients develop group- and type-specific antibodies to the infecting serotype. Group-specific antibodies do not neutralize viral infectivity but are useful for diagnosis. Type-specific antibodies are measured by neutralization or inhibition of haemagglutination. Adenovirus-neutralizing antibodies are directed against epitopes of the capsid, including the penton, the fibre and the hexon. These antibodies may protect against re-infection with the same serotype. This observation led to the development of effective vaccines for military recruits.

Immune Evasion

Adenoviruses have the capability to evade the immune system through several different mechanisms: (i) Inhibition of IFN functions by viral-associated (VA) RNA and E1A. IFNs are often the earliest host response to viral infection. dsRNA produced during viral infection induces antiviral cytokines. The dsRNA-dependent protein kinase (PKR) phosphorylates the translation factor eIF2 alpha. Adenoviruses encode VA RNAs that are transcribed by RNA polymerase III. Synthesis of VA RNA begins early in infection. This binds and inhibits PKR, preventing the induction of IFN type I. In addition, E1-A proteins also have the property to inhibit the function of IFN type I. (ii) Inhibition of TNF and Fas-mediated apoptosis. TNF is a pro-inflammatory cytokine secreted by activated macrophages and T cells. It can induce cell death. Adenoviruses encode four proteins (E1B19K, E314.7, E310.4K/14.5K) that protect adenovirus-infected cells from TNF and/or Fas-mediated apoptosis. (iii) Downregulation of surface class I MHC. Antiviral immune effector mechanisms rely on cytotoxic T lymphocytes (CTLs) to clear viral infected cells. CD8+CTL are triggered to lyse viral infected cells through recognition of viral peptides bound to class I MHC molecules on the cell surface. Adenoviruses encode proteins that inhibit class I presentation. E3 gp 19 and E1 A from adenovirus type 12 bind MHC class I and retain them in the endoplasmic reticulum, thus

reducing the transport of class I MHC to the cell surface (Mahr and Gooding, 1999).

Oncogenicity

Adenoviruses of species A are highly oncogenic, while those of species B are weakly oncogenic, in newborn hamsters. Despite extensive efforts, no evidence has been found concerning the aetiologic role of adenoviruses in human malignancies.

EPIDEMIOLOGY

Adenovirus infections are transmitted by direct contact, small-droplet aerosols, the faeco-oral route, water, ocular instruments and fomites. The mode of transmission in early life is thought to be primarily faeco-oral.

A child born in a family with relatives harbouring the virus in the intestine will eventually become an excretor. An infected child may excrete the virus initially from the respiratory tract and later from the gastrointestinal tract. Intermittent excretion in stools can be as prolonged as 906 days (Brandt *et al.*, 1969).

Adenovirus infections occur worldwide as epidemic, endemic and sporadic infections. The most common adenovirus serotypes causing respiratory infections are serotypes 1, 2 and 5 (species C) and serotypes 3 and 7 (species B). Adenovirus types 1, 2, 5 and 6 are mostly endemic, whereas 4, 7, 14 and 21 cause small epidemics. Respiratory outbreaks have been described in closed communities such as boarding schools, day-care centres and military training facilities. For respiratory epidemics (serotypes 4 and 7), spread by direct contact and aerosols are important.

The epidemiological pattern of adenovirus respiratory infection in civilian populations is different from the military. Recent publications described serotypes 4, 7 and 21 as the most prevalent types related to respiratory outbreaks among military recruits in the United States (Kolavic-Gray *et al.*, 2002).

Adenoviruses can cause ocular infections such as PCF and epidemics of keratoconjunctivitis (KC). PCF has been mostly associated with serotypes 1–7 and less frequently with serotypes 11–17, 19–21 and 29. Serotypes 3, 4 and 7 are commonly associated with swimming-pool outbreaks (Turner *et al.*, 1987). Adenovirus serotype 4 commonly causes ocular infections in Asia, but this is uncommon in Western countries.

Large epidemics of KC have been associated with serotypes 8, 9 and 37 (Keenlyside *et al.*, 1983). They spread by contact, through contaminated fingers or ophthalmologic instruments. These serotypes are often

endemic in poor hygienic conditions in developing countries, but in Western countries occur mostly in epidemics, which are sometimes nosocomial.

Infant gastroenteritis has mostly been associated with serotypes 40 and 41, which are therefore named 'enteric adenoviruses'. Adenovirus species A, B, C and D can also cause acute gastroenteritis. Serotypes 2 and 31 are more frequently followed by serotypes 1, 3, 5, 7, 12 and 18 (Filho *et al.*, 2007; Yolken *et al.*, 1982). Enteric types 40 and 41 spread via the faeco-oral route, and gastroenteritis occurs endemically throughout the world.

CLINICAL FEATURES

Adenovirus infections are widely distributed and common. Infections occur most frequently during childhood, where they tend to be self-limited and induce type-specific immunity following recovery. Adenovirus serotypes have different cell tropisms and cause distinct clinical manifestations (Table 19.3). In addition, some genotypes (e.g. 7h) appear to be more virulent, causing unusually severe respiratory manifestations and higher mortality rates (Kajon *et al.*, 1996).

Although adenovirus infections were traditionally associated only with respiratory, ocular and gastrointestinal diseases, many other clinical manifestations have now been associated with infection, especially in immunocompromized patients.

Clinical manifestations depend on the host and the serotype involved and include pharyngitis, PCF, conjunctivitis, pertussis-like syndrome, KC, bronchiolitis, pneumonia, acute HC and gastroenteritis (Ambinder *et al.*, 1986; Kajon *et al.*, 1996; Turner *et al.*, 1987; Yolken *et al.*, 1982). Less frequent clinical syndromes are hepatitis, meningitis, encephalitis, myocarditis, pericarditis, genital infections, pancreatitis and fatal disseminated disease (Davis *et al.*, 1988; Munoz *et al.*, 1998; Swenson *et al.*, 1995).

RESPIRATORY INFECTIONS

In Children

Most children become infected with one or more adenovirus serotype early in life. These infections are usually self-limited and mild. When symptomatic, usual signs and symptoms are fever, nasal congestion, coryza, pharyngitis and cough with or without otitis media. Adenoviruses may cause an exudative tonsillitis that is clinically indistinguishable from group A streptococcus. If conjunctivitis accompanies the syndrome, the disease is called PCF.

Upper-respiratory illnesses are mostly associated with species C (serotypes 1, 2, 5), while species B infections prevail in children with acute lower-respiratory disease from adenovirus (Kajon *et al.*, 1996). The frequency of adenoviruses in nasal-swab specimens from outpatient children with upper-respiratory infection showed 9% positivity using a generic PCR (Echavarría *et al.*, 2006). Interestingly, simultaneous infection with two different adenovirus species was observed in 19% of the cases.

After the onset of symptoms, adenovirus excretion in stools may be prolonged for months and this feature may account for the endemic presence of the virus in paediatric populations (Brandt *et al.*, 1969). On the other hand, adenovirus detection in nasal-swab samples by PCR showed a clearance of the virus within one to twelve weeks (Figure 19.4).

Lower-respiratory infections may be severe and require hospitalization. In children less than four years old, between 2 and 7% of acute respiratory infections and 10% of respiratory infections that require hospitalization are caused by adenoviruses. A higher prevalence has been documented in Argentina, which was dependent on the complexity of the hospital (Carballal *et al.*, 2001; Videla *et al.*, 1998). The syndromes include bronchitis, bronchiolitis, croup and pneumonia. Severe and even fatal pneumonia with a fatality rate around 16% or higher, which is primarily associated with adenoviruses types 3 and 7, can occur in infants and children (Murtagh *et al.*, 1993). In particular, genotype 7h, initially described in Argentina, was associated with a fatal outcome in 34% of cases during the acute stage of the disease (Murtagh *et al.*, 1993). Among survivors, residual lung damage secondary to bronchiolitis obliterans has been reported. Children less than two years old are more susceptible to severe primary infections, with occasionally fatal outcomes and long-term sequelae. In general, extra-pulmonary manifestations such as gastroenteritis, renal involvement, hepatosplenomegaly, meningoencephalitis and disseminated disease have been associated with a higher mortality rate. In bronchiolitis cases, intense air trapping with parahilar and peribronchiolar infiltrates with segmental or lobar atelectasis is observed. When multifocal pneumonia develops, fluffy or patchy and dense parenchymal infiltrates indicating alveolar consolidation scattered throughout both lungs with ill-defined margins are observed. With progression of the disease, hazy to totally opaque lungs can be observed. Air leaks can produce pneumothorax or pneumomediastinum (Murtagh *et al.*, 1993). Of those who recovered, most had residual chronic pulmonary sequelae. It was postulated that adenovirus genotype 7h may have increased virulence compared to other types (Kajon and Wadell, 1994). During 1984–1985, the predominant genotype in Argentina was 7c, but in 1986 it switched to 7h

Table 19.3 Adenovirus diseases, associated serotypes, hosts and clinical specimens for diagnosis

Diseases	Associated serotypes		Frequent hosts	Specimens
	Frequent	Infrequent		
Upper-respiratory illness	1-3, 5, 7	4,6,11,14,15, 18,21,29,31	Infants, children	NP ^a aspirate or swab
Lower-respiratory illness	3,4,7,21	1,2,5,7,8,11,35	Infants, children, IC ^b	NP aspirate or swab, BAL, lung tissue
Pertussis syndrome	5	1,2,3,12,19	Children	Throat swab
Acute respiratory disease	4,7	2,3,5,8,11,14,21,35	Military recruits	Throat swab, BAL, lung tissue, NP aspirate or swab
Acute conjunctivitis	1-4,7	6,9,10,11,15-17, 19,20,22,37	Children	Conjunctival swab or scraping
Acute haemorrhagic conjunctivitis	11	2-8,14,15,19,37	Children	Conjunctival swab or scraping
Pharyngoconjunctival fever	3,4,7	1,2,5,6,8,11-17, 19-21, 29,37	Children	NP aspirate or swab, throat swab, conjunctival swab or scraping
Epidemic keratoconjunctivitis	8,9,37	2,3,4,5,7,10,11, 13-17,19,21, 23,29	Any age	Conjunctival swab or scraping
Gastroenteritis	40,41	1,2,3,5,7,12-18, 21,25,26,29, 31, 52	Children	Stool
Haemorrhagic cystitis	11	7,21,34,35	Children, IC	Urine
Hepatitis	1-3, 5,7	4,31	Infants, children, IC	Liver tissue, blood
Myocarditis	7,21		Children	Heart tissue, blood
Meningoencephalitis	2,7	1,3, 5,6,11,12,32	Children, IC	Brain tissue, CSF
Veneral disease	2,37	1,5,7,11,18,19,31	Teens, adults	Lesion swab

Figure 19.4 Longitudinal observation of adenovirus (AdV) detection by PCR in 11 patients with upper-respiratory infection and in several tested nasal-swab samples obtained during winter and spring.

(Carballal *et al.*, 2002). In Japan, the first report on 7h occurred in 1996 (Hashido *et al.*, 1999). In the United States, Australia and countries from Europe, the most prevalent genotype has been 7b, although the appearance of 7d2 and 7h in North America represents introduction of these viruses from previously geographically-restricted areas (Erdman *et al.*, 2002). A recent study evaluating the adenovirus prevalence in the United States from samples obtained in 2004–2006 using a molecular typing technique did not show a strong association between serotype 7 and higher morbidity compared to other serotypes. This could be due to the stabilization of circulating adenovirus serotype 7, with subsequent increases in herd immunity and reduction in these infections (Gray *et al.*, 2007).

Adenoviruses can be recovered throughout the year, although a higher frequency is observed in winter and spring.

Severe lung disease after measles infections has also been described. It is suggested that secondary infection with adenoviruses is responsible in some patients. Measles virus may render children more susceptible to serious complications from adenovirus infection. The many deaths from ‘measles pneumonia’ in developing countries and the occasional occurrence of post-measles bronchiec-

tasis in some countries may be due to secondary adenovirus infections (Warner and Marshall, 1976).

Pertussis-like Syndrome

Pertussis syndrome is usually caused by *Bordetella pertussis*. However, adenoviruses have frequently been isolated in patients with this syndrome. The rate of adenovirus infection was statistically significant in patients with pertussis syndrome (23%) versus control subjects (5%). The frequent association of adenoviruses with pertussis syndrome suggests that they may play a role in the pathogenesis of this disease. Adenovirus type 5 has been isolated from patients with severe whooping cough that ended fatally. However, it is not known whether adenoviruses co-infect with *B. pertussis* or whether that infection causes conditions favourable to reactivation of latent adenoviruses.

Acute Respiratory Disease in Military Recruits

Adenoviruses were first associated with respiratory outbreaks among military recruits undergoing basic training in 1953 (Hilleman and Werner, 1954). During the 1950s through the 1960s, adenovirus-associated ARD constituted one of the most important causes of medical morbidity among military recruits in the United States. The

serotypes most commonly associated with respiratory disease were serotypes 4 and 7, followed by 3, 14 and 21. Severe ARD required hospitalizations in 50% of cases at Fort Dix (Top, 1975) and fatal pneumonia with adenovirus type 7 was reported in three previously healthy military trainees (Dudding *et al.*, 1972).

Since the 1980s, the routine use of live oral vaccines to serotypes 4 and 7 among military recruits resulted in a significant decrease in ARD morbidity (Figure 19.3). However, in 1996, vaccine discontinuation resulted in a resurgence of adenovirus-associated respiratory-disease epidemics at military training centres (Kolavic-Gray *et al.*, 2002). Most recruits presented with fever, sore throat and persistent cough. Adenovirus 4 was the most prevalent type recovered, followed by types 3 and 21.

During the pre-vaccine era, recruits used to develop severe signs and symptoms of lower-respiratory-tract infection and pneumonia. During recent respiratory outbreaks (1997, 1998, 2000 and 2001), the hospitalization rates have ranged from 10 to 21%, but these have not been significantly severe (Kolavic-Gray *et al.*, 2002). The low level of pre-existing immunity for adenovirus 4 (12–26%) in young adults may reflect the lack of exposure to this serotype during childhood. Serotype 4 has been uncommonly associated with respiratory disease in adult civilians. The different epidemiology of adenoviruses among civilian and military groups is not completely understood. It may be due to conditions during military training, where individuals from different geographic areas and backgrounds are subjected to crowding and stress. In one study evaluating adenovirus carriage at military entry, no adenoviruses were recovered by culture in throat-swab samples and only one individual was weakly positive by PCR (Echavarría *et al.*, 2003).

Interestingly, adenovirus DNA type 4 was detected by PCR from air filters in sleeping barracks during respiratory outbreaks (Echavarría *et al.*, 2000). Positivity in air filters correlated with the number of hospitalizations due to adenovirus-ARD during the same period. Environmental control of airborne spread of adenoviruses may help

reduce the risk of adenovirus-associated outbreaks during periods of vaccine unavailability.

OCULAR INFECTIONS

Pharyngoconjunctival Fever

PCF is characterized by follicular conjunctivitis and lymphadenopathy, as well as fever, pharyngitis and malaise. Headache, diarrhoea and rash can also be present and 5–10% of patients may have involvement of the cornea. Either one or both eyes may be involved. Infected individuals can shed the virus for about 10 days. Complete recovery without sequelae usually occurs. PCF is seen in children and young adults in discrete outbreaks, but sporadic cases occur at all ages. Community outbreaks of PCF have been associated with inappropriate chlorination systems in swimming pools (Turner *et al.*, 1987). Illness was directly related to hours of exposure to the pool and swallowing pool water. Adenovirus serotypes 3 and 7 have been most associated with PCF. Adenoviruses types 1–7, 11–17, 19 and 21 have also been reported.

Epidemic Keratoconjunctivitis

In contrast to PCF, EKC is highly contagious and serious. EKC can start with conjunctivitis, which may be follicular, followed by oedema of the eyelids, pain, photophobia and lacrimation (Figure 19.5). Superficial erosions of the cornea may occur, followed by deeper sub-epithelial corneal infiltrates with a characteristic round shape. A mild respiratory infection may accompany the symptoms. This clinical entity was identified in 1941, before adenoviruses were initially isolated, in the marine shipyards at Pearl Harbour. ‘Shipyard eye’ was probably transmitted in the medical facilities caring for eye trauma. Adenovirus 8 was the cause of those infections.

The incubation time may be 4–10 days and conjunctivitis may resolve in 2 weeks, although reduced vision, photophobia and foreign-body sensation may persist for

Figure 19.5 Ocular characteristics from a patient in an outbreak of adenovirus keratoconjunctivitis.

months to years. Adenoviruses 8, 19 and 37 are the most prevalent serotypes associated with EKC. In Japan, adenovirus 4 has also been associated with this condition.

EKC outbreaks have been reported in many countries as an important cause of nosocomial morbidity in ophthalmology clinics. Risk factors for EKC were associated with exposure to contact tonometry (Keenlyside *et al.* 1983). Ophthalmic solutions, the hands of medical personnel and towels are also vehicles for the spread. Direct inoculation into the eye appears to be required to cause disease. EKC outbreaks have resulted from eye-fomite-eye inoculation, sharing towels or facecloths, direct contact between children and family members, and even among health-care workers.

GASTROINTESTINAL INFECTIONS

Adenoviruses are the second most common cause of viral gastroenteritis in children less than two years old. The incidence for this disease ranges from 4 to 12% of cases of diarrhoea and it occurs throughout the year. The route of transmission is faeco-oral. During the prodrome, 50% of patients have respiratory symptoms. Diarrhoea is usually watery, nonbloody and with no faecal leucocytes. The mean duration is 10 days. It may be associated with mild fever, vomiting and abdominal pain. Gastroenteritis may also be a sign of systemic infection related to serotypes 3 and 7 that causes respiratory symptoms. Subsequent to gastroenteritis due to adenoviruses, some patients become intolerant to lactose-containing products for up to five to seven months. Other gastrointestinal syndromes associated with adenoviruses have included intussusception, acute mesenteric lymphadenitis and appendicitis. Serotypes 40 and 41, the enteric adenoviruses, are the most prevalent types that cause acute gastroenteritis (van der Avoort *et al.*, 1989). In patients who develop adenovirus enteritis, the enteric strains seem to induce disease that persists longer than that cause by strains other than 40 and 41.

HAEMORRHAGIC CYSTITIS

Adenoviruses can cause acute HC in paediatric populations and in immunocompromised patients. A sudden onset of gross haematuria, dysuria and increased frequency of urination were described. Serotype 11 is the most prevalent type recovered in these patients (Ambinder *et al.*, 1986). Other serotypes, including 34 and 35, have also commonly been recovered from immunocompromised patients. Adenoviruses 11, 34 and 35 can cause persistent infection in the kidney and may be reactivated during

immunosuppression. HC has been highly associated with adenoviruses in bone marrow transplant (BMT) recipients and can represent the first clinical manifestation of a disseminated adenoviral disease (Echavarría *et al.*, 1999). HC has also been described in renal transplant recipients.

ADENOVIRUSES INFECTIONS IN IMMUNOCOMPROMIZED PATIENTS

Adenoviruses are increasingly recognized as viral pathogens that may cause severe disease, including fatal infections, in immunocompromised patients. In recent years, populations of immunocompromised patients have expanded due to advances in transplantation technology and treatment, cancer therapy and the AIDS epidemic. In immunocompromised patients, adenovirus infections tend to be more prolonged and more severe, and may result in fatal outcome. In these patients, infections may occur due to endogenous reactivation or primary infection. Clinical manifestations in immunocompromised patients depend on the underlying disease, affected organ system, patient age and virus serotype (Hierholzer, 1992). Clinical manifestations in these patients include pneumonia, hepatitis, HC, colitis, pancreatitis, meningoencephalitis and disseminated disease (Ambinder *et al.*, 1986; Blanke *et al.*, 1995; Davis *et al.*, 1988; Hierholzer, 1992; Ljungman *et al.*, 1989; Shields *et al.*, 1985). Adenovirus-associated case fatality rates in the immunocompromised have been reported to be as high as 60% for patients with pneumonia, and 50% for those with hepatitis, compared with fatality rates of 15% for pneumonia and 10% for hepatitis in immunocompetent patients (Hierholzer, 1992).

In BMT and haematopoietic stem cell transplantation (HSCT) recipients, adenovirus infections are especially frequent. The incidence of adenovirus infection in these patients has increased in recent years due to a variety of factors, including higher awareness of this pathogen, aggressiveness of conditioning regimens, greater sensitivity of diagnostic methods and systematic screening (Flomenberg *et al.*, 1994). The range for adenovirus infection varies from 5 to 47% depending on the age of patients, conditioning regimens, type of method for diagnosis and clinical sample analysed (Table 19.4). Some of the risk factors are: lower age (paediatric recipients are 2–3.5 times more likely than adults to become infected), allogeneic transplantation, T-cell depletion, unrelated or HLA-mismatched grafts and total body irradiation. The paediatric population may be more vulnerable because they are more likely to experience primary infections. The range for adenovirus disease varies from 10 to 89%, even among adult patients (Table 19.4). Some of the risk factors for adenovirus disease are: the number of sites from

Table 19.4 Prevalence of AdV infection and disease, and serotypes involved in bone marrow and haematopoietic stem cell transplant recipients

Publication (yr)	AdV infection (%)	AdV disease (%)	Species or serotypes
Shields <i>et al.</i> (1985)	5	20	1, 2, 5, 7, 11, 34, 35

Yusuf <i>et al.</i> (2006)	32	75	Nd

which adenoviruses can be detected, immunosuppressive therapy, lymphocytopenia, detection of adenovirus in blood and detection of rising viral load in blood. Severe lymphopenia (<300 cells/mm³) is a risk factor for progression to disseminated disease and is often fatal (Chakrabarti *et al.*, 2002).

Adenovirus infections can be asymptomatic with clinical manifestations. The disease can be localized to a single organ or disseminated. PCR in blood is usually a predictor of disseminated disease (Echavarría *et al.*, 2001a). Therefore, when adenovirus disease is considered, blood specimens should be tested by PCR. Surveillance in blood samples is currently a common practice among HSCT, especially in the child population. The virus can be detected in blood two to three weeks before clinical symptoms develop (Lion *et al.*, 2003). Follow-up and prognosis is better assessed with quantitative PCR methods. Increased viral-load measurements are associated with increased risk of death (Schilham *et al.*, 2002).

Adenovirus in HSCT patients is usually detected within 100 days post-transplant. Clinical manifestations include upper- and lower-respiratory disease such as interstitial pneumonitis, hepatitis, renal disease including HC or nephritis, gastrointestinal disease including haemorrhagic colitis, central nervous system (CNS) disease or disseminated disease (Ambinder *et al.*, 1986; Kampmann *et al.*, 2005; La Rosa *et al.*, 2001; Wasserman *et al.*, 1988; Yolken *et al.*, 1982). HC can be especially severe and may signal the start of dissemination (Echavarría *et al.*, 1999).

Adenovirus mortality varies from 6 to 70% in paediatric and adult transplant patients. A lower mortality rate (2%) was reported when pre-emptive therapy was

instituted (Yusuf *et al.*, 2006). Different adenovirus serotypes have been isolated from these patients, most commonly from species A, B and C (Table 19.4). More than a single serotype can be detected during the course of the infection. In fact, a recent study has shown that 36% of stem cell transplant recipients demonstrated two or more adenovirus strains after transplantation (Kroes *et al.*, 2007).

In the solid organ transplant recipient, the primary site of adenovirus disease is usually related to the transplanted organ. Some of the clinical manifestations described among lung, liver, renal and small bowel transplantations include pneumonia, hepatitis, nephritis, HC, enteritis and disseminated disease. Incidence data for adenovirus disease in solid organ transplant recipients are more limited than for stem cell transplant recipients. Most of the symptomatic and severe infections have been reported in paediatric transplant populations, in liver and in lung allograft recipients, in patients who receive anti-lymphocyte antibodies and in patients with donor-positive/recipient-negative adenovirus status.

In liver transplant recipients, the most frequent clinical manifestation is hepatitis, most commonly associated with adenovirus species C (serotypes 1, 2 and 5). The mortality rate can be as high as 53%.

In renal transplant recipients, the predominant symptom is HC, mostly related to adenovirus species B (serotypes 7, 11, 34 and 35) and a 17% fatality rate. In lung transplant recipients, adenoviruses can cause pneumonia and graft failure that can be fatal (Bridges *et al.*, 1998), and they are more frequent in children than in adults.

Adenovirus infections are frequent in HIV-infected patients and can range from 7 to 29%. The most frequent sites for adenovirus recovery in these patients are the gastrointestinal and urinary tracts. Clinical manifestations include pneumonia, hepatitis, meningoencephalitis, nephritis, gastrointestinal and disseminated disease, which may sometimes be fatal (Khoo *et al.*, 1995; Schnurr *et al.*, 1995). Prolonged adenovirus faecal excretion has been associated with low CD4 counts (Khoo *et al.*, 1995). Some of the fatal cases were caused by serotypes 1, 2 and 3. Co-infection with other micro-organisms including bacteria and fungus is common in these patients; therefore a direct association with adenovirus infection is sometimes difficult to establish. Most adenovirus serotypes infecting the gastrointestinal tract of HIV-infected patients belong to species D, including serotypes 9, 17, 20, 22, 23, 26, 27 and 42–51.

Adenovirus is infrequently found in the urine of immunocompetent patients. In contrast, the frequency of adenovirus detection in the urine of AIDS patients, especially in the pre-HAART (highly active anti-retroviral therapy) era, may achieve 20%, although usually without evidence of bladder inflammation or bleeding (de Jong *et al.*, 1983). This frequency is higher when molecular methods are applied (Echavarría *et al.*, 1998). Serotypes 11, 34, 35 and 42–47 were found in the urine of AIDS patients (Echavarría *et al.*, 2001). Persistence in urine can be as long as 12 months (Horwitz *et al.*, 1984). One study showed that patients with parenteral exposure to HIV were more likely to be adenovirus-positive in urine than those with sexual exposure. In addition, in this study the median time to death was shorter in adenovirus-positive patients than in adenovirus-negative patients (Echavarría *et al.*, 2001b).

Serotypes 43–51 were identified from HIV-infected individuals (de Jong *et al.*, 1999). It has been suggested that the long-term infection seen in AIDS patients and the potential co-infection with more than one serotype may provide the opportunity for mutations within a strain, or for recombination between co-infecting serotypes.

The introduction of HAART has dramatically reduced the incidence and mortality from opportunistic infections in general, including adenoviruses. However, the development of viral resistance and difficulties with compliance with HAART may lead to the re-emergence of adenovirus infections in this population.

OTHER CLINICAL MANIFESTATIONS

Adenovirus have been recovered from cerebrospinal fluid (CSF) and brain tissue from patients with meningoencephalitis. Adenoviruses 3 and 7 were the most prevalent serotypes associated with this syndrome. Severe

encephalitis has also been associated with adenovirus group B. A recent study has shown the presence of species C and F adenovirus in CSF from hospitalized children with CNS infection (Zimmermann *et al.*, 2007). Adenovirus should be included in the differential diagnosis of viral CNS infections.

Adenoviruses can also be the cause of myocarditis. Adenovirus genome has been detected by PCR in myocardial samples from patients with acute myocarditis.

Adenoviruses serotypes 2, 8 and 37 have been isolated in 0.3% of patients with genital lesions attending a sexually-transmitted-disease clinic (Swenson *et al.*, 1995). These findings have suggested that adenoviruses can be sexually transmissible.

Adenovirus 36 can cause obesity in animals. Studies done in rhesus and marmoset monkeys have demonstrated a significant longitudinal association of positive antibody status to adenovirus 36 with weight gain (Dhurandhar *et al.*, 2002). Further studies are needed to determine if such an association exists in humans.

DIAGNOSIS

The syndromes caused by adenoviruses are frequently not clinically distinguishable from other bacterial or viral causes; therefore the laboratory diagnosis of adenovirus infections becomes important. In addition, virus detection and characterization are essential for epidemiological studies and therapy interventions.

Adenoviruses have been isolated in tissue culture from stool, throat swabs, nasopharyngeal (NP) aspirates, conjunctival swabs, urine, cerebrospinal fluid, blood and a variety of biopsy specimens. Sample collection early in the illness is necessary for optimal recovery. Duration of excretion from the onset of symptoms is around one week in respiratory infections, two weeks from eye specimens in those with PCF or KC, and two weeks to twelve months or longer in urine and stool from immunocompromized patients. Adenoviruses are stable and can be transported at room temperature, although prompt shipping to the laboratory is always recommended. Swabs and biopsies should be transported in viral transport media containing serum, albumin or gelatin and antibiotics/antimycotics.

The choice of method for adenovirus diagnosis depends on the type of disease and sample obtained. Adenovirus diagnosis is mostly performed using direct methods. These include virus isolation in cell culture, antigen detection and genome detection with or without amplification, and to a lesser extent particle detection by EM. Indirect diagnosis using serology is limited due to the lack of sensitivity, heterotypic response or antibody production, especially in immunocompromized patients. Serology should therefore be reserved for epidemiologic investigations or

to confirm associations between virus detection and unusual clinical outcomes.

Conventional and molecular methods are used for direct detection of the virus. Some of the limitations of conventional methods are that culture may be prolonged and can be inhibited by neutralizing antibody or other interfering substances, while EM and antigen detection methods may be insensitive. In recent years, the development and application of molecular methods using DNA amplification by PCR has increased sensitivity and rapidity of diagnosis.

Direct Methods

Virus Isolation

Continuous human cell lines of epithelial origin such as A 549, Hep-2, HeLa, human embryonic kidney (HEK) and KB can be used for the recovery of adenoviruses from all clinical specimens (Huang and Turchek, 2000; Landry *et al.*, 1987). Blood rarely yields virus except by PCR, probably due to the presence of neutralizing antibody. All adenovirus serotypes, except the enteric 40 and 41, grow in human epithelial cell lines and produce a cytopathic effect (CPE) characterized by clumping and cell rounding with refractile intranuclear inclusion bodies. The rapidity of CPE depends upon the concentration of infectious particles in the sample, the sensitivity of the cell line and the adenovirus serotype involved. CPE may take from 2 to 28 days to become evident. CPE needs to be confirmed by indirect IF with monoclonal antibodies, by radioimmunoassay or by ELISA. Serotypes 40 and 41 are fastidious and replicate poorly in the previously-mentioned cell lines. They do replicate in Graham-293 adenovirus-5-transformed secondary HEK cell line and in Hep-2 under a special medium.

Cell culture remains the gold standard, although it can be insensitive with some clinical samples (blood), may have fungal or bacterial contamination, and may have inhibitors or be toxic to the host cells.

Histopathology

Histopathologic findings in lung are characterized by diffuse interstitial pneumonitis, necrosis of bronchial epithelial cells, bronchiolitis with mononuclear cell infiltrates and hyaline membrane formation. Infected cells have enlarged nuclei with basophilic inclusions, surrounded by a thin rim of cytoplasm called 'smudge' cells, which are typical of adenovirus infection.

Direct Antigen Detection

Immunofluorescence IF uses monoclonal antibodies, usually directed against the hexon protein. It is especially

useful for respiratory specimens, swabs or biopsies. The advantage of this method is rapidity, as a result can be obtained within two to four hours. However, it lacks sensitivity, depending on sample quality, timing and type of monoclonal antibody used. Sensitivities of 30–60% in comparison to cell culture have been described.

Enzyme Immunoassays EIAs are particularly useful for diagnosing enteric adenoviruses in faecal samples where the antigen is not intracellular. Genus-specific tests and type-specific assays for serotypes 40/41 are commercially available. Most EIAs utilize microtiter plates and adenovirus-specific MAbs as capture and detector reagents. Sensitivity of most enteric adenovirus EIAs compared to 293 cell culture or EM is >90%, but can be lower if variants are circulating. Specificity is usually >97%. Genus-specific assays are sensitive (>95%) when stool specimens are used. Sensitivity is lower (65–75%) with respiratory tract and eye specimens. Urine has the lowest detection rate (August and Warford, 1987; Gleaves *et al.*, 1993). Occasional false-positive reactions occur.

Other antigen-detection tests include immunochromatography (IC), where the specimen migrates laterally along a membrane strip, antigen binds to virus-specific antibodies and a coloured line develops within minutes. The sensitivity of a commercially-available adenovirus IC assay with NP specimens tested at the bedside was 84% compared to culture and PCR, and 95% when the same specimens were retested in the laboratory (Fujimoto *et al.*, 2004). Another antigen detection assay is latex agglutination (LA), which is used primarily for genus-specific detection of adenovirus in stools. LA has similar sensitivity to EIA, although up to 13% of specimens may yield uninterpretable results (Grandien *et al.*, 1987).

Immunohistochemistry This method is used on tissue sections using adenovirus monoclonal antibody directed against the hexon antigen. This method is specific but also lacks sensitivity.

Direct Particle Detection

Electron Microscopy The EM morphology of adenoviruses is unique, allowing rapid identification of the virus (Figure 19.2). EM is mainly used for diagnosis of adenovirus acute gastroenteritis, due to the high number of viral particles excreted (10^6 – 10^8 particles/ml). It requires an electron microscope and highly-trained personnel, and lacks sensitivity. Therefore it is not in current practice in most clinical virology laboratories.

Direct Genome Detection

DNA detection can be performed using molecular methods with or without amplification.

Hybridization Hybridization without amplification has proved to be an appropriate tool for diagnosis in tissue sections in particular, although its lack of sensitivity has been recognized. *In situ* hybridization has been proven to be useful not only for diagnosis but also for studies of pathogenesis.

Polymerase Chain Reaction (PCR) Amplification of the viral genome using methods such as PCR has increased sensitivity and rapidity compared to conventional classical methods. The usefulness and application of this method in the clinical setting has significantly increased in the last few years. It is especially useful when non-infectious virus is present, when viral load is too low to be detected by culture, when interference such as neutralizing antibody may inhibit growth or when results are needed quickly.

Until 1997, few PCR methods for stools and swabs were available for clinical diagnosis (Allard *et al.*, 1990; Morris *et al.*, 1996). Later, different generic and type-specific assays were developed and tested on a range of different clinical samples (Allard *et al.*, 2001; Echavarría *et al.*, 1998; Xu *et al.*, 2000). For clinical diagnosis, generic PCR should be used, and it should be capable of detecting all adenovirus serotypes. PCR primers from the hexon gene or fibre gene, or from the VARNA I and II regions, are usually chosen because they have areas well conserved among serotypes. The hexon gene is located between 0.51 and 0.6 of the genome and has three different segments: a central variable region (nucleotides 403–1356) and two highly-conserved regions flanking it. There are seven hypervariable regions inside the variable region, which differ in sequence and length. Hypervariable region 1 has the highest variability and is related to viral tropism (Crawford-Miksza and Schnurr, 1996).

PCR assays have proven to be highly specific in studying adenovirus in urine, respiratory samples and blood from healthy asymptomatic immunocompetent individuals (Echavarría *et al.*, 1998, 2003; Villamea *et al.*, 2002). Adenovirus DNA has been detected in virtually all clinical samples, so specimen selection depends largely on the associated disease (Table 19.3). In patients with disseminated disease, PCR detected virus in the bloodstream, while other methods could not (Echavarría *et al.*, 1999). The presence of adenoviral DNA in serum was found to be associated with severe or fatal adenovirus infection in BMT recipients (Echavarría *et al.*, 2001a). Since proper management of these patients is dependent on

Figure 19.6 Home-brew PCR for adenovirus. Amplified products are detected in an agarose gel stained with ethidium bromide. M, marker; (+), positive control; (-), negative control. Samples 4, 8, 11, 19, 34 and 35 represent the corresponding adenovirus serotypes. A positive result corresponds to 139 bp product.

early diagnosis and differentiation from other conditions, PCR assays can be valuable as early markers for disease. Most conventional PCR tests are in-house tests where amplified products are detected in stained agarose gels (Figure 19.6) or further developed by southern blot. Some commercially-available PCR assays use ELISA detection (Vabret *et al.*, 2004).

Real-time PCR Real-time PCR assays are more rapid than conventional PCR because amplification and detection of amplified products occur simultaneously. Therefore, results can be obtained within hours, compared to one to two days for conventional methods. In addition, real-time PCR can be used for quantification of the virus. Since higher adenovirus levels in blood have been correlated with a fatal outcome, current studies are using ‘real-time’ amplification methods for the rapid determination and quantification of the virus in different clinical samples (Lankester *et al.*, 2002; Schilham *et al.*, 2002). Several in-house real-time adenovirus PCRs have been developed, initially for BMT or HSCT patients but recently for other patient populations as well (Echavarría *et al.*, 1998; Flomenberg *et al.*, 1997; Hierholzer, 1995; Nagafuji *et al.*, 2004; Sprangers *et al.*, 2003). A recent commercially-available real-time PCR assay performed satisfactorily in detecting all adenovirus serotypes (Figure 19.7). In general, more than one set of primers and several probes are necessary to detect all serotypes when using real-time PCR. All specimen types can be used to obtain a qualitative result by real-time PCR, but blood is frequently submitted to determine viral load in plasma or serum. Nevertheless, currently quantitative real-time adenovirus PCR has some limitations due to the lack of international standard calibrators. Inter-laboratory result variability is expected. Adenovirus DNA can be detected in peripheral cells, whole blood, plasma or serum, giving some different viral-load results. There is no clear cut-off value that predicts disease or outcome. It may

Figure 19.7 Primary curves from a real-time PCR assay with different adenovirus serotypes. The different curves represent the fluorescence level and the corresponding Ct for adenovirus serotypes 7, 18, 19, 31, 35, 40 and 41 with the commercial adenovirus r-gene mix (Argene, Inc). Water was used as a negative control.

therefore be preferable to analyse the viral kinetics for each individual case, considering the adenoviral viral load over time and establishing the relative change rather than the absolute value (Leruez-Ville *et al.*, 2004).

Typing Systems Adenovirus typing is used primarily for epidemiologic investigations, studies of pathogenesis or to reveal the cause of an unusual or especially severe infection. Serologic or molecular typing can be performed. Serologic typing requires an isolate and detects differences in epitopes on the fibre gene and hexon gene. Molecular typing can be performed on isolates and on the original specimen. The two systems differ fundamentally in target, so results do not always concur.

Serologic typing by HA provisionally determines the species of an isolate (Table 19.1); if the isolate is from stool its species is determined by a species F (serotype 40/41) EIA. This is followed by serotyping by haemagglutination inhibition (HAI) or serum neutralization (SN) using serotype-specific antisera. HAI is easier but SN is the definitive test for serotype. There are three major SN assays: a conventional seven-day test in human epithelial cells (or 293 cells for stool isolates); a three-day test in monkey kidney cells, which is the most simple and rapid assay; and a five-day micro-neutralization test using Vero cells (Hierholzer, 1995). Interpretation is not always straightforward, for example HAI and SN fail to agree with intermediate species D variants containing the fibre gene of one serotype and the hexon gene of another. Yet serotyping remains the gold standard against which newer tests are evaluated. Other serologic methods include an immunoperoxidase technique, immune-adherence hemagglutination (HA) and indirect IF with serotype-specific antisera.

Molecular typing is increasingly performed because it is rapid, utilizes molecular equipment and expertise

available now in many laboratories, and does not require expensive and difficult-to-obtain antisera. The restriction enzyme analysis was initially used. It can be applied to purified virus, virus-infected cells or stools from children with diarrhoea (Adrian *et al.*, 1986; Buitenwerf *et al.*, 1985). The starting material is first lysed and then digested with restriction endonucleases (e.g. Sma I), then serotype- and/or genotype-specific band patterns are visualized after agarose gel electrophoresis. Unfortunately, strains that defined the initial restriction enzyme analysis patterns are no longer circulating, so patterns of currently-obtained adenoviruses may be uninterpretable. Co-infections can also cause ambiguous results. restriction enzyme analysis (REA) is still useful for presumptive identification of new serotypes, identification of genotypes (e.g. 7h or 7d2) associated with severe disease, or to confirm results obtained by other means (de Jong *et al.*, 1999; Gray *et al.*, 2005). Other molecular-typing methods include single-stranded conformation polymorphism and heteroduplex mobility (Soares *et al.*, 2004).

Typing by PCR is now preferred by many laboratories. Extracted DNA from an isolate or purified virus is amplified using a generic or multiplex species-specific PCR and hexon-gene or fibre-gene primers (Lu and Erdman, 2006). Serotype is then indicated by measurement of product-length sizes or DNA sequence of fragments generated after cleavage with restriction enzymes, or by DNA sequence. Some schemes detect only limited numbers of serotypes, whereas others are more comprehensive and can demonstrate co-infections (Metzgar *et al.*, 2005; Sarantis *et al.*, 2004). Correlation between hexon-gene-sequence-typing methods and the classic serologic-typing method varies from 71 to 97% (Gray *et al.*, 2007; Kroes *et al.*, 2007). Genotypic analysis may provide an alternative for classical serotyping but some discordance occurs.

Figure 19.8 Clearance of adenoviral hepatitis in a paediatric liver transplant recipient. Histopathology and immunohistochemical stain for adenovirus in liver biopsies before and after ribavirin therapy. Top: before treatment: multiple foci of necrosis with acute inflammation and strong immunohistochemical staining for adenovirus. Bottom: after treatment: only one cell was positive for AdV by immunohistochemistry.

Indirect Methods

Serology

Adenovirus infections can be diagnosed by the presence of specific IgM or IgG seroconversion detected by EIA, IF, haemagglutination inhibition or neutralization. EIA and IF are the methods most frequently used in the diagnostic laboratory. SN assays or haemagglutination-inhibition assays are used for detecting specific antibodies against each adenovirus serotype.

Some of the limitations of serology are: (i) specific IgM is detected in only 20–50% of infections; (ii) false-negative results may occur due to a poor immune

response; (iii) false-positive results may occur due to heterotypic anamnestic responses; (iv) with seroconversion-based tests the diagnosis is retrospective. However, serology is useful and important for epidemiological studies.

TREATMENT

Although no antiviral drug has been formally approved for treatment of adenovirus infection, clinical observation and *in vitro* data have shown that some antivirals may be effective. The strongest antiviral activity was associated

with cidofovir, and a moderate effect was seen with ribavirin and ganciclovir (Arav-Boger *et al.*, 2000; Bordigoni *et al.*, 2001; Hoffman *et al.*, 2001). Clinical studies in immunocompromized patients have used cidofovir or ribavirin, but prospective randomized controlled trials have not been carried out. Ribavirin is a purine nucleoside analogue with *in vitro* activity against RNA and DNA viruses. Different mechanisms have been proposed, including the inhibition of RNA-capping activity, direct inhibition of viral polymerases and increased mutation in newly-synthesized DNA. But it has not been established which is the possible mechanism of action against adenoviruses. The most common adverse effect is reversible mild anaemia. Successful use was described in the treatment of adenovirus HC, pneumonia, enteritis after BMT and hepatitis in a liver transplant recipient (Arav-Boger *et al.*, 2000; Howard *et al.*, 1999) (Figure 19.8). Other authors, however, have described its therapeutic failure (Chakrabarti *et al.*, 1999; Hale *et al.*, 1999). Success seems to be related to early treatment and serotype since only strains from species C (serotypes 1, 2, 5 and 6) are sensitive to ribavirin (Morfin *et al.*, 2005). Therefore, early identification, for example by PCR, followed by typing may permit earlier antiviral treatment.

Cidofovir is an acyclic nucleoside phosphonate analogue used as a broad-spectrum antiviral agent. Incorporation of diphosphate cidofovir results in termination of DNA-chain elongation. All adenovirus serotypes are susceptible *in vitro*. Despite its significant side effects (nephrotoxicity, myelosuppression and uveitis), cidofovir is currently used among BMT recipients and solid organ recipients. Strict monitoring of renal function should be performed in treated patients. Treatment success, defined as disappearance of signs and symptoms and clearance of adenovirus infection, was noted in 20 of 29 (69%) patients in a multicentre study of patients with various clinical manifestations, including gastrointestinal disease, pneumonia, encephalitis and hepatitis (Ljungman *et al.*, 2003). Improvements were noted in 10 of 14 (71%) BMT patients with HC (Nagafuji *et al.*, 2004). Clinical improvement of diarrhoea, cystitis and fever and clearance of the virus was observed in 5 of 7 (71%) children who received cidofovir treatment, despite the persistence of their immunodeficiency measured by CD4 (Legrand *et al.*, 2001). An apparent increased effectiveness in 56 of 57 (98%) was observed when patients were aggressively screened and treated regardless of symptoms or viral load in blood (Yusuf *et al.*, 2006).

A drawback of most of these studies is the lack of data regarding immune recovery after transplantation and its relation to adenovirus infection. A strong association between immune reconstitution (measured by the absolute lymphocyte count and CD4) and development of

adenovirus disease was observed (Chakrabarti *et al.*, 2002).

Antiviral treatment should be considered in patients positive for adenovirus if immunosuppression can not be reduced or if the patient has severe lymphocytopenia (Chakrabarti *et al.*, 2004). Prospective studies on drug efficacy, including active surveillance and evaluation of the immune recovery of the patient, are urgently needed.

Pre-emptive therapy is based on the possibility that adenovirus reactivates initially without clinical symptoms. Early initiation of pre-emptive therapy may be useful in controlling viral replication before the inflammatory response and disease has been triggered. Symptomatic disseminated disease is preceded by a period of asymptomatic viremia. Some investigators have suggested that surveillance of high-risk HSCT recipients and early pre-emptive therapy with cidofovir would be more effective than treatment after symptoms develop. Therefore, the use of pre-emptive therapy with cidofovir is current policy in some hospitals.

Another therapeutic alternative is the use of adenovirus-specific adoptive immunotherapy. Donor lymphocyte infusion has been successfully applied to a few BMT patients with severe adenovirus infection (Chakrabarti *et al.*, 2000; Hromas *et al.*, 1994). *In vitro* production of specific CTL to control adenovirus infections constitutes an active area of research.

The use of intravenous immunoglobulin has been associated with successful recovery, but data is scarce and limited.

PREVENTION

Prevention of adenovirus infections is not yet possible in community or institutional settings, although feasible in hospitals and eye clinics. Adenovirus spread in hospitals can be reduced by isolating infected patients, using good hand-washing practices, cleaning and appropriately disinfecting instruments and equipment (Rutala *et al.*, 2006). Adequate chlorination of swimming pools has also prevented KC epidemics.

Vaccines

To prevent ARD among military recruits, live oral adenovirus type 4 and 7 vaccines were developed in the 1960s. The vaccine serotypes are packaged together in enteric capsules, which bypass the stomach and only replicate once the intestine is reached. These vaccines were licensed in 1980 to US recruits only, who were routinely immunized (Top, 1975). Until recently, these vaccines were highly successful in preventing adenovirus-associated ARD; however, with interruptions of the

vaccine supply due to the manufacturer's decision to terminate production, adenovirus-associated ARD has re-emerged at military basic training facilities (Kolavic-Gray *et al.*, 2002).

The use of adenovirus vaccines has not been extended to young children even though this age group is at particular risk. The lack of attenuation and concern about potential oncogenicity have prevented the use of routine vaccines in civilians.

Adenoviruses as Vectors for Vaccination and Gene Therapy

For gene therapy, several E1-, E3-deleted vectors containing foreign genes have been constructed. The advantages of using adenoviruses as vectors are that they can be produced in large amounts which transduce in both replicating and nonreplicating cells.

Adenovirus vectors for the treatment of genetic diseases carrying the cystic fibrosis transmembrane regulator (CFTR) gene and others with the dystrophin gene have been constructed. Human trials with the CFTR gene have not been particularly promising, due to inefficient gene delivery to target cells and short-lived expression. Since adenoviruses do not integrate into the host chromosome, the expression is usually transient (Russell, 2000).

Other studies for the treatment of cancer used the p53 inserted into adenovirus vectors to restore the anti-oncogenic effect. Although preliminary evidence of efficacy has been reported, definite results are not yet available (Russell, 2000).

A variety of recombinant adenoviruses expressing exogenous genes for vaccination use have been constructed for HIV and rabies. This is an active field of research and significant progress is expected in the future for both gene therapy and recombinant vaccines.

FUTURE PROSPECTS

Given the severity and prevalence of adenovirus diseases among immunocompromized patients, there is a need for effective and nontoxic anti-adenoviruses therapy. Large multicentre prospective controlled clinical trials in different patient populations will be useful to determine the benefits and adverse effects of different antiviral drugs and immunotherapy.

Adenovirus respiratory infections can also be severe and fatal, but still no specific treatment has been proposed for these patients. Some antiviral drugs with *in vitro* activity are used for disseminated disease in immunocompromized patients. Another severe condition occurs in patients who suffered from KC, who were left with sensation of 'foreign body' and vision loss for weeks or

months. The development of topic antiviral drugs for this infection is highly needed.

No adenovirus vaccines are available for civilian populations. The live oral vaccine approved only for US military recruits has been discontinued. Current studies to re-establish production and usage in the military population are under development. New studies are needed in order to develop new and safe vaccines, especially for young children and immunocompromized patients.

Adenovirus vectors show considerable promise for gene therapy and vaccination. Although no significant clinical success has yet been shown with earlier first- and second-generation vectors, third-generation ones are now being studied.

PCR is current practice in most centres for rapid diagnosis and intervention. The quantitation of adenovirus viral load in blood by real-time PCR for treatment and prognosis of disseminated disease is gaining wide acceptance. However, the lack of well-standardized FDA-cleared or -approved assays and the lack of international standards limits the widespread utilization of this test. Determination of the changes in the viral load over time by regular monitoring of the same specimen type in transplant patients may be more useful than determination of the absolute viral load in predicting adenovirus disease.

The presence of more than one adenovirus serotype concomitantly in some patients should be further evaluated as it may provide some insight about adenovirus pathogenesis and host response.

Knowledge of this virus is rapidly expanding. The greater awareness of the pathology, the significant development of diagnostic methods and typing, and the possibility of determining the viral load all help to achieve a better understanding of the pathogenic mechanisms.

²Department of Respiratory Medicine, Imperial College London, London, UK

INTRODUCTION

Rhinoviruses (Figure 20.1) are the major cause of the common cold. Although the majority of infections produce only mild disease, their impact on overall morbidity and their economic cost worldwide is very considerable. More recently, their role in acute exacerbations of asthma and other airway disease has been demonstrated, revealing a more sinister nature than previously thought.

While the recorded history of the common cold is over 2000 years old, already known and commented on by Hippocrates around 400 bc, rhinoviruses were first propagated in 1953 in tissue cultures whose supernatants were able to produce common cold symptoms in volunteers. The first rhinovirus was initially isolated from patients with colds and named in 1957, while three years later cytopathogenic viruses were recovered using human embryo kidney cell cultures (Tyrrell and Parsons, 1960). Other susceptible cell lines were subsequently discovered and used to identify additional serotypes and to study rhinoviral biology and their role in disease. Recently, the genomes of several serotypes have been sequenced and three-dimensional structures have been revealed in atomic resolution. Molecular technologies are rapidly progressing in the development of novel diagnostic tools and, it is hoped, will aid the so far unsuccessful search for an effective treatment.

TAXONOMY

Rhinoviruses are small RNA viruses belonging to the picornavirus (pico = small + RNA) family. The *Picor-*

naviridae also include the enteroviruses, such as polioviruses, coxsackieviruses and echoviruses, the cardioviruses, such as the rodent encephalomyocarditis virus, and the aphthoviruses or foot-and-mouth disease viruses. Rhinoviruses are more closely related to enteroviruses than to the other genera. They are the most numerous of the picornaviruses, with over 100 serotypes identified and numbered by specific antisera in a collaborative programme supported by the World Health Organization (Hamparian *et al.*, 1987). New virus types are constantly emerging by a process of random mutation and immune selection (Lau *et al.*, 2007; Lee *et al.*, 2007b; McErlean *et al.*, 2007; Patterson and Hamparian, 1997; Savolainen *et al.*, 2002). Rhinoviruses are divided into major (90%) and minor (10%) groups, according to their cellular receptor usage (Uncapher *et al.*, 1991). Human rhinovirus 87 (HRV-87) is an exception and does not use either of the above receptors (Vlasak *et al.*, 2003). An alternative categorization, dividing the viruses into groups A and B, based on sensitivity to antiviral compounds and correlating with sequence similarities and pathogenicity has also been proposed (Andries *et al.*, 1990; Lau *et al.*, 2007). Several serotypes are now fully sequenced (Kistler *et al.*, 2007).

Structure

The Capsid

Rhinoviruses are among the simplest infectious agents. Their virion consists of a non-enveloped capsid surrounding a single-stranded positive-sense genomic RNA. In 1985, X-ray crystallography revealed the structure of rhinovirus 14 and poliovirus 1 at atomic resolution

Figure 20.1 Three-dimensional computer-enhanced electron micrography of human rhinovirus 14. (Source: Courtesy of Dr J.Y. Sgro.)

Figure 20.2 Arrangement of the three main structural rhinovirus proteins. The fourth structural protein, VP4, is confined to the interior and hence is not shown.

(Rossmann *et al.*, 1985). These and subsequent studies also using cryoelectron microscopy and more recently hydrogen exchange mass spectrometry (Wang and Smith, 2005) showed considerable structural similarities amongst picornaviruses, such as prominent β -sheets forming a β -barrel, even though the sequence of each virus differs considerably from others in the group. The rhinovirus capsid is composed of 60 identical subunits arranged as 12 pentamers in an icosahedron. Each subunit consists of all four structural proteins of the virus named VP1–VP4, with molecular masses of 32, 29, 26 and 7 kDa respectively. VP1, 2 and 3 are surface proteins interacting with antibody and corresponding to the part of the genome with the highest variability. VP4 is confined to the interior of the capsid and is closely associated with the viral RNA. The arrangement of these structural proteins can be seen in Figure 20.2. Around the fivefold symmetry axis of the capsid there is a 2.5-nm-deep depression shaped by the five VP1 units, forming a ‘canyon’ (Figure 20.1). In most rhinoviruses, VP1 also contains a hydrophobic ‘pocket’

under the canyon, containing an incompletely characterized fatty acid ‘pocket factor’. This pocket is thought to be involved in virus uncoating and is the major target of antiviral compounds (Hadfield *et al.*, 1997). The structural organization of rhinoviruses is independent of serotype (Janner, 2006).

The conformation of the canyon, being physically unreachable by the immunoglobulin Fab, led to the hypothesis that this was the receptor-binding site. Evidence in favour of this hypothesis has been produced (Colonna *et al.*, 1988), demonstrating that the amino acid sequences at the base of the canyon are very well conserved, while the edges of the canyon and the most external portions of the virus capsid are hypervariable and correspond to neutralizing immunogenic sites (Rossmann and Palmenberg, 1988).

Antigenicity

Four such sites, localized in different areas of the capsid of HRV-14, along the edge of the canyon, were characterized by RNA sequencing of mutants that escaped neutralization by specific antisera (Sherry *et al.*, 1986). Nim-1a, Nim-1b on VP1 are positioned above the canyon, while Nim-2 on VP2 and Nim-3 on VP3, are positioned below. HRV-2 has a slightly different pattern, nevertheless, the antigenic sites are still located on the most protrusive regions of the virion. A peptide from VP2 (156–170) of HRV-2, structured like a random coil in solution, was shown to contain enough information to direct the production of neutralizing antibodies against the serotype (Molins *et al.*, 1998). High variability of these regions is implied by the large number of distinguishable serotypes and has been, to a certain extent, molecularly characterized (Horsnell *et al.*, 1995; Kistler *et al.*, 2007).

Expression of foreign peptides such as peptides from respiratory syncytial virus (RSV) or human immunodeficiency virus (HIV) in a rhinovirus vector, has been successful and resulted to an immune response against the specific peptide (Ding *et al.*, 2002; Zhang *et al.*, 1999). Such chimaeric viruses may become potent tools for mucosal immunization.

Receptors

An important function of the viral capsid is to deliver the genomic material intact into a cell following attachment to a cell surface receptor. Initially, it has been shown that almost 90% of rhinoviruses (major group) bind to one receptor on HeLa cells, while the remaining (HRV-1a, -1b, -2, -29, -30, -31, -44, -47, -49, -62) use another (Colonna *et al.*, 1986). The major group receptor was independently identified by three different groups in 1989 (Greve *et al.*, 1989; Staunton *et al.*, 1989; Tomassini *et al.*, 1989) as the intercellular adhesion molecule 1 (ICAM-1). ICAM-1 is a 95-kDa glycoprotein, a member of the immunoglobulin superfamily, physiologically acting as a receptor for the lymphocyte-function associated antigen 1 (LFA-1, CD11a/CD18) and Mac-1, found on leukocytes. It facilitates the interaction of lymphocytes with antigen-presenting cells as well as their migration to inflammatory sites. The binding sites of LFA-1 and major rhinoviruses on the ICAM molecule are distinct but significantly overlapping (Staunton *et al.*, 1990). Furthermore, cryoelectron microscopy proved that the rhinovirus-binding site is positioned in the canyon, verifying the 'canyon hypothesis' (Rossmann, 1994). This hypothesis suggests that one strategy for virus to escape the host immune's surveillance is to protect receptor attachment, as its site in the 'canyon' is largely inaccessible to antigens and resistant to accepting mutations that might inhibit receptor attachment. Recently, the three-dimensional atomic structure of the two N-terminal domains (D1 and D2) of ICAM-1 has been determined. Rhinovirus attachment is confined to the BC, CD, DE and FG loops of the N-terminal immunoglobulin-like domain (D1) at the end distal to the cellular membrane (Bella *et al.*, 1999). Binding of rhinoviruses to ICAM-1 blocks LFA-1/ICAM-1 interaction, possibly downregulating the local immune response and upregulating the viral receptor itself (Papi and Johnston, 1999), while there is evidence that at the same time rhinovirus-ICAM-1 binding induces conformational changes promoting viral uncoating and cell entry (Casasnovas and Springer, 1994). Rhinovirus appears to induce membrane-bound ICAM-1, while decreasing the soluble component, thereby facilitating and promoting cell infectivity (Whiteman *et al.*, 2003).

The minor group viruses bind to members of the low-density lipoprotein receptor (LDLR) family, including the very low-density lipoprotein receptor (VLDL-R) and α_2 -macroglobulin receptor/LDLR-related protein (α_2 MR/LRP) (Hofer *et al.*, 1994). The number of minor group human rhinoviruses has recently been extended to 12, since a recent study has demonstrated that HRV-23 and HRV-25, which were thought to bind to ICAM-1, are neutralized by MBP-V33333, bind LDLR and infect ICAM-1-deficient COS-7 cells (Vlasak *et al.*, 2005). The minor receptor binds to the small star-shaped dome on the icosahedral fivefold axis, in contrast to the major group where the receptor site for ICAM-1 is located at the base of a depression around each fivefold axis (Hewat *et al.*, 2000). Minor group viruses, exemplified by rhinovirus 2, transfer their genomic RNA to the cytoplasm through a pore in the endosomal membrane (Schober *et al.*, 1998). Interestingly, rhinovirus 89, a major group virus, was adapted in culture to replicate in ICAM-1-devoid cells, and LDLR-soluble fragments could not inhibit such replication, suggesting the possibility of additional receptors (Reischl *et al.*, 2001).

Replication

Rhinoviral RNA has a molecular weight of approximately 2 MDa, consisting of some 7200 nucleotides (Duechler *et al.*, 1987). A 5' non-coding region (NCR) of around 620 bases in length and a 3' NCR of 50 bases before a polyadenylated tail are characteristic of all currently sequenced serotypes (Figure 20.3). The long 5' untranslated region is highly conserved and contains several AUG codons upstream of that used to initiate translation. These sequences are within a complex structure, termed the internal ribosome entry site (IRES), which can bind ribosomal subunits directly, without the requirement for a free 5' end or a cap-binding protein (Stoneley *et al.*, 2000). The organization of the genome is shown in Figure 20.3. The structural proteins VP1-4 derive from the P1 region, while P2 and P3 code for the enzymes required for virus replication. The non-structural proteins, seven in total, include two proteases with specific viral cleavage sites (2A, 3C), an RNA-dependent RNA polymerase (3D) (Hung *et al.*, 2002) and a small protein Vpg (3B) which is covalently bound to the 5' end of the RNA and possibly acts as a primer for RNA synthesis (Rowlands, 1995). The remaining non-structural proteins (2B, 2C, 3A) are associated with RNA replication. Interestingly, an internal cis-acting replication element (cre) located within the genome segment encoding the capsid proteins, is required for RNA replication (McKnight, 2003).

The single-stranded, positive-sense RNA can act as messenger RNA and is infectious on its own. As in the other picornaviruses, the genome is translated into a

Figure 20.3 Diagrammatic representation of the rhinovirus genome.

polyprotein from a single, long open reading frame. This polyprotein is processed into the mature proteins by several cleavage steps performed by virus-specific proteases, 2A and 3C. The 2A protease makes the first cleavage between the structural and non-structural proteins, while 3C protease catalyses most of the remaining internal cleavages (Wang, 1999). In recent years, considerable efforts have been made in the development of antiviral compounds targeting 3C due its essential role in viral replication (Wanga and Chen, 2007). With the polymerase, a negative-sense copy of the genome is produced, from which further positive strands are made by viral RNA polymerase and these can act either as messenger RNA, which is subsequently translated, or can be incorporated as genomic RNA in the progeny virus.

Translation requires cellular trans-acting factors that are absent from, or limiting in rabbit reticulocytes, but are more abundant in HeLa cell extracts. At least two such factors have been identified: polypyrimidine tract-binding protein (PTB) and a complex of unr, an RNA-binding protein with five cold-shock domains, and a 38-kDa protein named unrip (unr-interacting protein) (Hunt *et al.*, 1999).

A recent study has reported that translation inhibition in infected cells can be mediated by the cleavage of host proteins, such as the eukaryotic initiation factor 4G (eIF4G) and poly(A)-binding protein (PABP), by viral proteases (Kerekatte *et al.*, 1999).

Rhinoviruses are capable of completing numerous replicative cycles within 6–8 hours with a yield of up to 100 000 viruses per cell (Belsham and Sonenberg, 1996).

PHYSICAL PROPERTIES

Rhinoviruses are small with a diameter of 28–34 nm. Their total molecular weight is approx. 8–8.5 MDa and their buoyant density in caesium chloride is 1.38–1.42 g/ml as fully infectious particles or 1.29 g/ml as empty capsids.

They are resistant to inactivation by organic solvents, including ether and chloroform, due to the absence of lipid envelope around the virion. They are also unaffected

by 70–95% ethanol, 5% phenol and trichlorofluorethane (Macnaughton, 1982). However, weak hypochlorite solution (common bleach) rapidly inactivates infectivity, provided that there is not a high concentration of organic matter present. Rhinoviruses are characteristically labile to extreme pH due to irreversible conformational changes, being inactivated at pH <5 as well as at pH 9–10. Acid sensitivity together with lipid solvent stability tests have been used for the identification of rhinoviruses. In addition, ultraviolet radiation is inactivating for rhinoviruses, while cationic substances such as MgCl₂, are favourable for the replication of most serotypes, appearing to stabilize the virions especially in high temperatures (Blough *et al.*, 1969).

Viability steadily decreases at room temperature, while it remains stable for days at 4 °C, months at –20 °C and indefinitely at –70 °C or lower. Rhinoviruses show considerable variation in their ability to resist heat inactivation at 50–56 °C, with some serotypes completely inactivated at lower temperatures and others quite resistant. Optimal culture temperature ranges from 33 to 35 °C (Killington, Stott and Lee, 1977), but most serotypes are able to productively infect and replicate in HeLa cells at 37 °C (Papadopoulos *et al.*, 1999).

INCUBATION AND TRANSMISSION

Infection with a rhinovirus can be initiated by small doses if the inoculum is delivered effectively to the nasopharynx. In experimental human transmission studies, the frequency of virus shedding after inoculation varied by inoculum size and the titre of the subject's serum-specific anti-serotype antibodies. Subjects with no neutralizing antibody could be infected with an inoculum of less than 10⁴ TCID₅₀ (tissue culture infectious dose₅₀) (Johnston and Tyrrell, 1995). However, susceptible patients, such as those with chronic obstructive pulmonary disease (COPD) may be successfully infected and a cold induced with doses as low as 10 TCID₅₀ (Mallia *et al.*, 2006). The mode of person-to-person transmission has been debated, but it is likely that both direct hand-to-surface-to-hand contact (Gwaltney and Hendley, 1978) and aerosol inhalation (Meschievitz *et al.*, 1984) are involved. A significant

positive relationship between lower levels of outdoor air supply in office buildings and increased frequency of virus detection in air filters has been reported (Myatt *et al.*, 2004). Rhinoviruses are capable of surviving on surfaces for several hours under ambient conditions (Sattar *et al.*, 1993) and transfer of rhinovirus through hand touch can occur in only a few seconds. This means that direct inoculation by rubbing the nares or eyes with infected hands can easily occur. The viral load in oral and pharyngeal secretions is considerably lower than that in nasal mucus. On the other hand there is good experimental evidence (Dick *et al.*, 1987) as well as epidemiologic evidence favouring the predominance of the inhaled route (Johnston *et al.*, 1996).

The incubation period for rhinovirus is one to four days, commonly two to three days. In general, viral shedding peaks two to four days after infection, and lasts for 7–10 days, however, it can persist for as long as three weeks. Viral clearance may be suboptimal in atopic subjects, with around half of them still infected two weeks after an experimental infection (Gern *et al.*, 2000), or more than six weeks after an acute asthma exacerbations (Kling *et al.*, 2005). The possibility of chronic infection has also been demonstrated in lung transplant recipients (Kaiser *et al.*, 2006). Natural transmission increases in relation to high virus titres in nasal secretions, increased symptoms, time spent in contact and social factors such as crowding and hygiene. In families, the interval between initial and secondary infections relates to the quantity and duration of shedding, ranging up to 10 days with an average of three days (Foy *et al.*, 1988). Transmission occurs most frequently from children to adults with a lag of 5–10 days (Contoli *et al.*, 2006).

HOST RANGE

In general, rhinoviruses are extremely host-specific. Human viruses have not been recovered from animals. Under experimental conditions, chimpanzees have been infected, developing a common cold-like disease, as well as gibbons which do not exhibit symptoms. Other primates are less susceptible. Mice develop an immune response to parenterally administered rhinoviruses (Hastings *et al.*, 1991), but intracellular blocks to rhinovirus replication have been described (Yin and Lomax, 1986). Major group rhinoviruses are reported not to bind mouse ICAM-1, thus 10% of the known rhinovirus serotypes use both the human and mouse LDLR to enter cells of either species. Recently, viral replication as well as inflammatory events similar to those seen in humans were observed in a transgenic murine model, in which mouse ICAM-1 extracellular domains 1 and 2 were substituted

with the human domains 1 and 2 (Bartlett *et al.*, 2008). In this model rhinovirus infection induced neutrophilic and lymphocytic airway inflammation and chemokine and pro-inflammatory cytokine production, as in humans. These models are therefore likely to provide a similar boost to research into diseases in which rhinovirus infection is implicated.

PATHOGENESIS

The nose is the main portal for rhinovirus entry, although the eye and oral inhalation may also serve as entry routes. Whether or not an infection can begin in the lower airways is not as yet clearly determined. The nasal epithelium is the primary site of infection. A series of upper airway biopsies suggested that rhinovirus infection may initiate in the nasopharynx, in the area of the adenoid (Winther *et al.*, 1986). A considerable proportion of surgically removed adenoids harbour rhinoviruses (Rihkanen *et al.*, 2004). Rhinovirus replication occurs primarily in the nose, as inferred from comparative titrations of nasal, pharyngeal and oral secretions as well as of droplets from coughs and sneezes. Nevertheless, the fact that rhinovirus replication occurs in the lower airways has been confirmed in several studies (Gern *et al.*, 1997b; Mosser *et al.*, 2002; Papadopoulos and Johnston, 2000) and evidence suggests that this is the norm rather than an exception following infection of the upper airways. Viraemia has not been detected in normal adults, but it may occur during rhinovirus respiratory infections in normal children and is common in the early course of acute asthma exacerbations (Xatzipsalti *et al.*, 2005).

Rhinovirus infection does not produce extensive cytopathology of the nasal mucous membrane; however, the extent correlates with the titre of recoverable virus. *In vitro*, exposure of human primary bronchial epithelial cells to rhinovirus may result in an extensive cytopathic effect (CPE), depending on serotype and culture conditions (Papadopoulos and Johnston, 2000; Schroth *et al.*, 1999). In an already compromised epithelium, such as in the case of asthma, rhinovirus may induce considerable epithelial cytotoxicity (Bossios *et al.*, 2005). Mucosal oedema with sparse infiltration of inflammatory cells, mainly neutrophils, are the predominant histologic changes. Nasal mucociliary clearance is reduced as a result of a reduced ciliary beat frequency and loss of ciliated epithelium (Wilson *et al.*, 1987).

Nasal secretions of infected individuals have increased plasma proteins, such as albumin and immunoglobulin G (IgG), as well as glandular proteins (lactoferrin, lysozyme and secretory IgA, 7F10 immunoreactive mucin) (Igarashi *et al.*, 1993a; Yuta *et al.*, 1998). These

Figure 20.4 Schematic representation of pathogenetic mechanisms of rhinovirus infection. Rhinovirus entry and replication in the nasopharynx induces immune mediators and neurogenic pathways. Viruses are eradicated, but the concurrent vascular leakage and glandular secretion result in the well-known symptoms of the common cold.

findings reflect both increased vascular permeability, usually mediated by vasoactive amines, and glandular secretion commonly induced by cholinergic reflexes and neuropeptides. However, the detailed involvement of any such mediators remains to a great extent speculative (Figure 20.4). Kinins are generated in nasal secretions during natural and experimental colds, while their intranasal instillation causes a sore throat (Naclerio *et al.*, 1988). The list of both pro-inflammatory (interleukin (IL)-1 β , IL-2, IL-4, IL-6, IL-8, IL-11, IL-12, IL-13, IL-16, G-CSF, GM-CSF, TNF- α and interferon gamma (IFN- γ)) and anti-inflammatory (IL-1Ra, IL-10) cytokines induced either *in vitro* or *in vivo* by rhinovirus infections, is long and is growing (Einarsson *et al.*, 1996; Johnston *et al.*, 1998; Papadopoulos *et al.*, 2000; Teran *et al.*, 1997; Zhu *et al.*, 1996, 1999). Several chemokines able to attract neutrophils and eosinophils are also induced after rhinovirus infection of nasal and bronchial epithelium, including RANTES, Gro α , ENA-78, eotaxin and eotaxin-2 (Griego *et al.*, 2000; Papadopoulos *et al.*, 2001). Rhinoviruses are also able to directly activate airway smooth muscle cells *in vitro*, however, it is not clear whether the virus could reach these cells *in vivo* (Grunstein *et al.*, 2001). In a helper T cell type 2 (Th2)-dominant microenvironment, an increased production of eotaxin-1 after infection, by activating intracellular Toll-like receptor 3 (TLR-3) has been observed (Niimi *et al.*, 2007). Oxidative stress and the activation of inflammation-related transcription factors, such as nuclear factor kappa-B (NF- κ B), mediate the elaboration of several rhinovirus-induced cytokines and chemokines (Biagioli *et al.*, 1999; Papi *et al.*, 2002;

Zhu *et al.*, 1997). This is also the case for ICAM-1, which is also significantly upregulated by rhinovirus infection via an NF- κ B-mediated mechanism (Papi and Johnston, 1999). Possible pathways may also be through the stress-activated protein kinase p38 (Griego *et al.*, 2000), Syk (Wang *et al.*, 2006), phosphatidylinositol (PI) 3-kinase, interferon regulatory factor 3 (IRF-3) and activating transcription factor 2 (ATF-2).

The involvement of histamine is uncertain and conflicting results have been obtained from clinical trials of antihistamines. First-generation antihistamines could relieve sneezing and nasal discharge, but these compounds have H₁-blocking, anticholinergic and other central nervous system (CNS) activities, in contrast to second-generation agents, which are less effective in colds. Elevated histamine levels were detected after experimental and wild-type infection in allergic patients but not in normal subjects (Igarashi *et al.*, 1993a). Nevertheless, the second-generation antihistamines loratadine and desloratadine were able to inhibit rhinovirus-induced ICAM-1 upregulation in airway epithelial cells *in vitro* (Papi *et al.*, 2001). In mast cells and basophils, rhinovirus has been shown to increase histamine production *in vitro* (Hosoda *et al.*, 2002).

The arachidonic acid pathways are also involved, suggested by induction of 5-lipoxygenase- and cyclooxygenase-2-positive cells in bronchial biopsies of experimentally infected volunteers (Seymour *et al.*, 2002), as well as upregulation of leukotriene C₄ during experimental infection (Gentile *et al.*, 2003).

As far as the nervous system is concerned, parasympathetic blockade is able to reduce some symptoms of rhinoviral colds (Jacoby and Fryer, 1999). Double-stranded RNA may cause increased bronchoconstriction via increased release of acetylcholine from the vagus nerves because of loss of the muscarinic receptor 2 function on parasympathetic nerves in the lungs (Bowerfind *et al.*, 2002), although this has not been shown with rhinovirus. Furthermore, unilateral inoculation and infection results in bilateral symptomatology, favouring a neural pathway activation (Winther *et al.*, 1986).

Vascular leakage (Igarashi *et al.*, 1993b) and mucus secretion (He *et al.*, 2004; Inoue *et al.*, 2006) result in nasal blockage and stimulation of the sneeze and cough reflexes, resulting in the well-known common cold symptomatology.

Mucosal oedema resulting from vascular leakage, venous sinusoidal engorgement and mucosal inflammatory cell infiltration is a prominent feature, and may lead to complications such as otitis and sinusitis. Indeed, computed tomography (CT) scans obtained during and after acute rhinoviral infection have clearly demonstrated that paranasal sinus occlusion is a common event in rhinovirus colds (Gwaltney *et al.*, 1994).

The mechanisms of asthma exacerbations induced by viral infections in susceptible individuals are another currently investigated issue in rhinovirus pathophysiology. Rhinovirus infection seems to potentiate allergic responses (Calhoun *et al.*, 1994), however, the precise mechanisms have yet to be determined. Inflammatory mediators such as kinins, and pro-inflammatory cytokines induced by rhinovirus infection (see list above), altered cell-mediated immunity, virus-specific IgE and other mechanisms have been proposed, but the relative importance of each of these currently remains unclear (Papadopoulos and Johnston, 2001a). Fewer studies have examined the epidemiology of virus infection in COPD. Between 33 and 70% of exacerbations are associated with symptoms of the common cold. Persistent infection with viruses such as RSV, rhinovirus and adenovirus has been associated with the progression of COPD (Message and Johnston, 2004). Higher plasma fibrinogen, induced sputum IL-6 levels and increased airway eosinophilia have been found at exacerbation (Wedzicha, 2002).

Finally, it has been demonstrated recently that rhinovirus induces the production of angiogenic and pro-fibrotic mediators, which may contribute to airway remodelling. Infection of primary bronchial epithelial cells increases vascular endothelial growth factor (VEGF) (De Silva *et al.*, 2006; Psarras *et al.*, 2002), fibroblast growth factor 2 (FGF-2) (Volonaki *et al.*, 2006) and transforming growth factor beta (Dosanjh,

2006); production of such growth factors is amplified in an atopic environment (Psarras *et al.*, 2002; Xatzipsalti *et al.*, 2008).

IMMUNITY

Both cellular and humoral immunity are activated in response to rhinovirus infection. Virus-specific IgG and IgA serum antibodies remain low for the first week after inoculation and subsequently begin to increase, to reach their peak approximately a month later. IgG antibodies stay at high levels for at least a year, while IgA declines slowly but remains detectable during the same period. Nasal IgA is also produced, becoming detectable two weeks after inoculation, reaching its peak one week later and slowly declining to its original levels by one year (Barclay *et al.*, 1989). The late rise in antibody titres indicates that humoral immunity is not essential for recovery from viral illness. On the other hand, existing antibodies, especially in high titres, are associated with protection against reinfection with the same serotype and/or lessened signs and symptoms (Alper *et al.*, 1998). Possible mechanisms of antibody-mediated virus inactivation include virus aggregation, activation of the complement cascade, prevention of binding to receptor as well as inhibition of uncoating (Rowlands, 1995).

An important role in virus eradication has been attributed to cellular immunity, but the mechanisms involved are not yet understood in detail. In contrast to the high specificity of humoral immunity, rhinovirus-specific T cells can recognize both serotype-restricted and shared viral epitopes (Gern *et al.*, 1997a). Peripheral blood lymphocyte counts are decreased during infection, followed by recovery or even leukocytosis (Skoner *et al.*, 1993). Increased production of IL-2 and IFN- γ after mitogen stimulation as well as increased natural killer cytotoxicity has been found in peripheral blood mononuclear cells (PBMCs) after experimental rhinovirus infection (Hsia *et al.*, 1990). Lymphocytes can be activated both specifically and nonspecifically through a monocyte-dependent mechanism (Gern *et al.*, 1996b). Rhinoviruses infect human macrophages and can replicate efficiently in THP-1, a monocytic cell line which can be differentiated to a macrophage phenotype by treatment with phorbol myristate acetate (PMA) (Laza-Stanca *et al.*, 2006), indicating a potentially direct effect of these cells in antiviral immunity (Gern *et al.*, 1996a). Monocytes stimulated by rhinovirus were also shown to inhibit the allostimulatory capacity of myeloid dendritic cells (DCs), by producing large amounts of the immunosuppressive IL-10 (Stockl *et al.*, 1999). DCs infected by rhinovirus demonstrate a diminished T-cell stimulatory capacity, inducing a deep

anergic state through B7-H1 and sialoadhesin (Kirchberger *et al.*, 2005). The production of type 1 (IFN- γ , IL-12) as well as type 2 (IL-4 and IL-10) cytokines has been documented, and atopic asthmatic individuals appear to respond with relatively deficient type 1 cytokine production (Papadopoulos *et al.*, 2002a; Parry *et al.*, 2000). In a more complex model, PBMCs were exposed to rhinovirus and the resulting supernatants, containing various factors associated with the immune response to the virus, were used to treat epithelial cells during rhinovirus infection. When such conditioned media from normal or atopic asthmatic individuals were used, it was shown that in an 'atopic environment' epithelial inflammation was reduced, while virus replication and the resulting epithelial cytotoxicity were significantly increased (Xatzipsalti *et al.*, 2008). IFNs are critical regulators of a wide array of innate protective responses. Recently, it has been demonstrated that asthmatic bronchial epithelial cells show an impaired IFN- β and IFN- λ production and impaired virus-induced apoptosis, resulting in increased virus replication (Contoli *et al.*, 2006; Wark *et al.*, 2005). Strong lines of evidence support the role of TLRs in the induction of the IFN response. TLR-3 recognizes double-stranded RNA and has been found to be increased after rhinovirus infection in bronchial epithelial cells (Hewson *et al.*, 2005) and in cultured nasal cells (Lin *et al.*, 2007). Its role in human diseases and specifically in rhinovirus-induced respiratory pathology requires further characterization.

EPIDEMIOLOGY

The common cold is probably the most frequent illness afflicting humans and certainly the most common cause for primary care consultations and absenteeism from work or school. The average number of yearly infections in adults is estimated to be between two and five, while this number increases to around 12 in children. A simple estimation would reveal that a normal individual spends between one and two years of his or her life suffering from colds! At least a quarter of six-month-old infants have antibodies against rhinoviruses, while over 90% have such antibodies at the age of two years (Blomqvist *et al.*, 2002).

Rhinoviruses cause about 35–60% of common colds. Interestingly, in contrast to popular belief, early studies were unable to demonstrate any increase in susceptibility to rhinoviral infections after exposure to cold temperatures (Douglas *et al.*, 1967), although this possibility cannot be rejected (Eccles, 2002). In one report, acute chilling of the feet was suggested to induce onset of common cold symptoms in around 10% of subjects who were chilled

(Johnson and Eccles, 2005). Several other epidemiological factors are also involved. Age is certainly important. Infections increase significantly from the second year of life and throughout school age, decreasing subsequently, probably due to neutralizing antibodies induced by previous exposures (Monto, 1995). Increased morbidity and complications reappear in the elderly (Nicholson *et al.*, 1997). Apart from the age-related susceptibility to the virus, socio-economic factors such as nutrition and population density, but most importantly family structure strongly influence the incidence of rhinovirus infections. An infection is usually introduced by a child to other siblings and parents at home, increasing by this way the incidence of the disease in the members of the family (Oliver *et al.*, 2006). Mothers are more susceptible than fathers, possibly because of increased exposure. Transmission at school and daycare facilities is also very high, due to overcrowding, low immunity and children's unhygienic habits (Goldmann, 1992).

A seasonal pattern has been documented in temperate climates, with two peaks occurring: one in autumn, following the opening of schools, and another one in late spring. School attendance is the major factor in determining seasonal patterns; infections occur throughout the winter months, peaking in the first two to three weeks after children return to school (Johnston *et al.*, 1996). Depending on age, season and population, and on the sensitivity of the polymerase chain reaction (PCR) assay, between 3% and 30% of asymptomatic subjects may be found positive by PCR (Marin *et al.*, 2000; Nokso-Koivisto *et al.*, 2002).

All populations are affected. The prevalent serotypes vary from year to year. It is possible that a small number of serotypes may cause most of the illnesses (Monto *et al.*, 1987). Based on the sequence for the VP1 capsid protein of rhinovirus, 101 members of the rhinovirus genus can be subdivided into two distinct genetic species, rhinovirus-A, rhinovirus-B and a single serotype, HRV-87 (Ledford *et al.*, 2004). More recently, analysis of the 5' NCR sequences showed limited homologies between the different serotypes. Despite the development of new diagnostic assays, the variability and the genotypic diversity of rhinovirus clinical strains makes the specific identification of rhinoviruses that cause disease in humans very difficult (Deffernez *et al.*, 2004).

There is a well-documented epidemiological relationship between various aspects of psychological stress, emotional style (Cohen *et al.*, 2003) and the susceptibility to rhinovirus infection (Cohen *et al.*, 1997; Takkouche *et al.*, 2001), the mechanisms of which are still speculative.

The question of whether atopic individuals are more susceptible to colds, develop more severe colds or clear rhinoviruses less effectively than normal subjects is still

incompletely understood. There is evidence for incomplete virus clearance (Gern *et al.*, 2000; Papadopoulos *et al.*, 2002a) and augmented colds in atopic asthmatic subjects (Bardin *et al.*, 1994; Heymann *et al.*, 2005). A recent, well-designed longitudinal study could not find differences between atopic asthmatic and normal subjects with respect to frequency, duration, or severity of rhinovirus colds in terms of upper respiratory symptoms, though there was significantly increased severity and duration of lower respiratory symptoms and falls in lung function in the asthmatic subjects (Corne *et al.*, 2002). Epidemiological studies have confirmed a synergistic interaction between respiratory virus infections and allergen exposure for risk of asthma exacerbations in adults and children (Custovic *et al.*, 2005; Green *et al.*, 2002). Surprisingly, in one report, experimental allergen challenge was able to protect from subsequent rhinovirus infection, suggesting a more complicated interaction (Avila *et al.*, 2000). Hence, repeated low-dose allergen exposure and rhinovirus infection have been found to induce distinct inflammatory profiles within the airways in patients with asthma. No interaction between these two environmental triggers have been noticed, indicating that preceding allergen exposure is not a major determinant of the severity of rhinovirus-induced asthma exacerbations in patients with mild asthma (Johnston, 2003; de Kluijver *et al.*, 2003). The explanations for these apparently contradictory findings will require further study.

CLINICAL FEATURES

The symptoms of the common cold easiest to describe are the ones which everybody has experienced: rhinorrhoea, sneezing, nasal obstruction, sore throat and cough. General malaise and headache may occur, while fever is less common. Mood and mental functioning are also affected, with reduced alertness and slowed reaction times (Smith *et al.*, 1998). Sleep is also significantly impaired (Drake *et al.*, 2000). The course of the disease correlates with virus titres. Symptoms appear after an incubation period of 24–48 hours, reach their peak two to three days later and last for five to seven days in total, persisting occasionally for as long as two to four weeks. Symptom severity is highly variable; on many occasions the disease may be hardly noticed, while around 20% of non-influenza flu-like (fever $\geq 38^{\circ}\text{C}$ plus one respiratory and one constitutional symptom) illnesses can be attributed to rhinoviruses (Boivin *et al.*, 2002). In patients hospitalized with respiratory problems, rhinovirus-related clinical presentations include bronchiolitis and pneumonia at ages less than five years, asthma exacerbations

in older children and adults and pneumonia, COPD exacerbations and congestive heart failure in older adults (El-Sahly *et al.*, 2000). The presence of rhinovirus either alone or in combination with RSV may be related to a more severe clinical presentation of acute bronchiolitis in infants (Papadopoulos *et al.*, 2002b).

Rhinovirus infections may cause significant morbidity in certain patient groups. Infants with bronchopulmonary dysplasia may develop serious respiratory illness, necessitating intensive care unit admission and occasionally mechanical ventilation (Chidekel *et al.*, 1997). This is also the case for children with primary immunodeficiencies (Crooks *et al.*, 2000; Ison *et al.*, 2003). Myelosuppressed individuals may be associated with more severe pneumonia (Ghosh *et al.*, 1999). Pulmonary function abnormalities, disease progression and secondary bacterial infections can result in children with cystic fibrosis (Collinson *et al.*, 1996). Elderly people, especially residents of nursing homes, are also prone to severe disease that can prove fatal (Wald *et al.*, 1995).

Complications

Acute otitis media (AOM) is the most common complication of a viral upper respiratory infection in children. Negative middle ear pressure develops in the majority of common colds in healthy individuals (Winther *et al.*, 2002). Using PCR, rhinoviruses are detected in the middle ear fluid of 25–40% of episodes of AOM. Rhinoviruses were also present in 20% of middle ear fluids of patients with otitis media with effusion at the time of tympanostomy tube placement (Pitkaranta *et al.*, 1998). Rhinovirus is also the predominant virus recovered by reverse transcriptase polymerase chain reaction (RT-PCR) in the middle ear cavity of children with asymptomatic otitis medium with effusion (OME), especially those with a history of longstanding OME or repeated episodes (Chantzi *et al.*, 2006). As previously mentioned, sinus involvement is detected by CT scan in a high percentage of rhinovirus infections, while there is evidence suggesting a causal role of the virus in as many as 50% of episodes of community-acquired sinusitis (Pitkaranta *et al.*, 1997). Recently, the detection of rhinovirus in turbinate epithelial cells of chronic sinusitis patients has also been confirmed (Jang *et al.*, 2006). In all instances, the viruses may also facilitate or contribute to concurrent bacterial infections.

The role of rhinovirus infection in exacerbations of asthma has been well documented in many studies. Upper respiratory tract infections are associated with around 80% of asthma episodes in schoolchildren, with rhinovirus being the most commonly detected causative agent (Johnston *et al.*, 1995) (Figure 20.5). In adults, detection frequencies are lower, possibly due to diminished

Figure 20.5 Upper and lower airway symptom score charts during rhinovirus infection. The arrow indicates the point at which a nasal wash was obtained and rhinovirus aetiology was confirmed with PCR.

viral shedding, although studies using sensitive molecular methodology indicate an involvement in at least half of asthma exacerbations (Nicholson *et al.*, 1993; Teichtahl *et al.*, 1997) and two recent studies using PCR to detect viruses in sputum samples have detected viruses in over three-quarters of asthma exacerbations in adults (Wark *et al.*, 2005). Time trend analysis confirms that viral infections are indeed important in exacerbations in adults as well as children (Johnston *et al.*, 1996). The mechanisms by which rhinoviruses exacerbate asthma include bronchial epithelium-mediated inflammation, induction of an abnormal immune response, neural mechanisms and more, reviewed elsewhere (Papadopoulos *et al.*, 2004).

Common colds are also associated with exacerbations of COPD. It has been suggested that the majority of exacerbations of COPD are associated with bacterial infections but many exacerbations occur after viral infections. The virus detection rates vary according to the methods of virus detection from 48.4% (Papi *et al.*, 2006) to 58.2% (Seemungal *et al.*, 2001). Respiratory viruses have been detected even when the patients are stable, and this suggests that chronic viral infection may occur as well.

Rhinoviruses are also implicated in acute and chronic bronchitis (Seemungal *et al.*, 2000), bronchiolitis and pneumonia (Papadopoulos and Johnston, 2001b; Papadopoulos *et al.*, 2002b). Clinical studies report that rhinovirus infection is the second most frequent agent associated with community-acquired pneumonia (Tsolia *et al.*, 2004) and bronchiolitis in infants and young children (Hayden, 2004; Papadopoulos *et al.*, 2002b).

DIAGNOSIS

Virus cultures, serological tests and more recently nucleic acid detection have been used in the detection of rhinoviruses for diagnostic and research purposes, although rhinovirus diagnostics are rare in clinical laboratories. Virus culture is cumbersome, time-consuming and insensitive, and its diagnostic value is very limited in a clinical setting. Serology is totally impractical as a result of the large number of serotypes. Nucleic acid techniques, mainly PCR, can potentially overcome these difficulties and become the methods of choice for viral detection; a number of protocols are currently under evaluation.

Virus Isolation

The optimal specimen for virus isolation is a nasal wash or a nasal aspirate. Throat or nasal swabs are used as an alternative in the field, or from children where nasal washings are difficult to obtain. Samples should be transported to the laboratory in virus transport medium as soon as possible and put immediately into culture or stored frozen at -70°C . Rhinoviruses replicate in several human embryonic and monkey tissues. However, they replicate best in human fetal lung fibroblasts (WI38, MRC5) and strains of HeLa cells. Samples are inoculated in cell cultures in tubes and are incubated in a roller drum at 33°C . They are then monitored under low-field magnification daily for the development of a CPE. Rhinoviral CPE is characterized by shrinkage and rounding of cells, cellular destruction and detachment of the cell layer (Figure 20.6).

Figure 20.6 Rhinovirus-infected primary human bronchial epithelial cells developing a characteristic cytopathic effect (right), in comparison to control cells (left).

It can be noticed as early as 24 hours after inoculation, while the majority of positive samples develop CPE within eight days. A second passage after this time is usually performed to identify less potent strains (Johnston and Tyrrell, 1995). Confirmation of rhinoviral identity can be performed by acid stability testing and of individual serotypes by neutralization tests using serotype-specific antisera.

Serology

Serological methods can be used for the detection of antiviral antibodies. Neutralization tests can be done in combination with any culture system and have been the only standardized method for a number of years. They are used for antibody detection and quantification once the serotype is known, as in the case of experimental studies with volunteers inoculated with a known serotype, or with a virus isolated from the same patient. Pre- and post-infection serum titres are compared. Unfortunately, due to the large number of serotypes (>100), these tests are only of limited practical value and are not used in routine clinical diagnosis.

Haemagglutination inhibition tests are possible with a subset of rhinoviruses that agglutinate red blood cells. Their results are comparable to those of the neutralization assays, but they are not widely used as they require large amount of virus and can be applied only to a subset of serotypes.

Enzyme-linked immunosorbent assays (ELISAs) are faster and much easier to perform, offer better sensitivity and can be readily adapted to measure different antibody isotypes both in serum and nasal secretions (Barclay and Al-Nakib, 1987). However, as with the other serological assays ELISA is diagnostically useful only when the rhinovirus serotype is already known, or when ELISA is carried out using a virus isolated from the same patient.

Nucleic Acid Detection

Molecular methods for infectious agent identification are steadily becoming more widely applied in regard to a vast array of microorganisms, including rhinoviruses. Different approaches based on the PCR have been investigated in order to optimize the method for research as well as clinical purposes (Andeweg *et al.*, 1999; Blomqvist *et al.*, 1999; Steininger *et al.*, 2001). Most sets of primers derive from the 5' NCR, which is the most conserved between different serotypes. Sensitivity is markedly improved in comparison to virus culture (Hyypia *et al.*, 1998; Johnston *et al.*, 1993). A problem has arisen from the fact that in several instances these procedures could not distinguish rhinoviruses from the closely related enteroviruses. Several approaches, including nested designs, differential hybridization or restriction fragment length polymorphism (RFLP) analysis have addressed this problem successfully (Mori and Clewley, 1994) (Papadopoulos and Johnston, 1999) (Figure 20.7). Nucleic acid sequence-based amplification (NASBA) (Samuelson *et al.*, 1998) and real time PCR are also in development. Thin-film technology has been used to increase sensitivity and versatility of amplicon detection (Jenison *et al.*, 2001). Finally, multiplex PCR approaches for the simultaneous detection of different respiratory viral pathogens, including rhinoviruses, which would greatly facilitate epidemiological studies as well as clinical diagnosis, are also in development. New tests that can detect different respiratory virus types/subtypes (Mahony *et al.*, 2007) using sensitive microarray system (Quan *et al.*, 2007) or multiplex PCR chemistry coupled with high-throughput microsphere flow cytometry (Lee *et al.*, 2007a) have been developed. A database containing information on virus-specific oligonucleotides and primers is available in the internet (Onodera and Melcher, 2002). Multiplex kits for respiratory virus detection, including rhinoviruses, are also commercially available.

Figure 20.7 Agarose gel electrophoresis of PCR products reveal a band at 190 bp in the case of rhinovirus (lanes 1–7) and a 380 bp band or a double 180–200 bp band in the case of enteroviruses (lanes 9–20), after RFLP digestion of picornavirus PCR amplicons. Lane 8 is a ladder.

PREVENTION AND TREATMENT

Intensive efforts over the last 40–50 years on the development of treatment or prevention strategies against rhinovirus-induced common colds have been so far without encouraging results. Approaches that have been investigated include nonspecific and empirical therapies, antiviral and antimediator drug treatments and vaccines (Table 20.1). Frequently inappropriate remedies are applied, resulting in a very high cost burden (Bertino, 2002).

The major obstacle for vaccine development is the high number of serotypes that do not produce heterotypic humoral immunity. Initial attempts have achieved protection against a specific serotype in volunteers inoculated with inactivated viruses. A decavalent vaccine was also tested in humans, resulting in variable responses to the included serotypes and insufficient heterotypic immunity (Hamory *et al.*, 1975). The protective duration of any responses was also undefined. The design of peptide vaccines, especially against T-cell epitopes which seem to be more conserved, appeared promising but has not been progressed (Francis *et al.*, 1987).

Among the pharmacological antiviral agents, IFN- α was the earliest and most widely investigated. IFN is effective if given intranasally before or shortly after exposure to the virus, both in experimental infections in volunteers and in family outbreaks (Douglas and Betts, 1974). However, its high cost and local bleeding and discharge after long-term prophylactic usage have been the major drawbacks for its clinical use. Following the demonstration of an important role of IFNs β and λ in the epithelial response to rhinovirus, these agents are currently potential antiviral candidates.

A large number of compounds able to inhibit rhinoviral infection by preventing virus uncoating and/or cell entry have been investigated. Unfortunately, to date no effective

drug has emerged from this research due to problems in potency, delivery and toxicity of the compounds and the emergence of resistant viral strains (Arruda and Hayden, 1996).

Since much of the symptomatology of the common cold is produced through inflammatory mediators, drugs antagonizing these mediators have been tested. Little benefit was demonstrated by antihistamine treatment, a bradykinin antagonist showed negative results, while anticholinergic sprays are able to reduce rhinorrhoea and sneezing (Johnston, 1997). Corticosteroids were found to have a marginal effect on symptoms, but a rebound appeared when treatment was stopped; moreover they have been associated with increases in viral titres. Speculation on the potential use of macrolide antibiotics, due to their *in vitro* anti-inflammatory effects (Suzuki *et al.*, 2002), were not confirmed in a clinical trial (Abisheganaden *et al.*, 2000), although more recently telithromycin was shown to be effective against acute asthma exacerbations (Johnston *et al.*, 2006).

The inadequacies of specific therapies, in addition to the frequency of the problem, have supported the emergence of nonspecific treatments, including the use of ascorbic acid, zinc gluconate, echinacea, inhalation of humidified hot air or the traditional Japanese herbal medicine *hochu-ekki-to* (Yamaya *et al.*, 2007). For all these remedies the mechanisms are speculative and the evidence frequently contradictory. Despite several blinded studies and meta-analyses, the usefulness of zinc preparations is, at best, marginal (Turner and Cetnarowski, 2000). However, *in vitro* addition of zinc salts is able to potentiate the anti-rhinoviral activity of IFN- α by 10-fold (Berg *et al.*, 2001). Substances with antioxidant properties are also able to inhibit rhinovirus-induced ICAM-1 upregulation *in vitro* (Papi *et al.*, 2002), suggesting a possible mechanism of action for ascorbic acid. Ascorbic acid in

Table 20.1 Efforts towards an anti-rhinoviral therapy

General	
Ascorbic acid, zinc gluconate, inhalation of hot air, echinacea, non-steroidal anti-inflammatory drugs, <i>hochu-ekki-to</i>	Questionable benefit
Anti-inflammatory	
Corticosteroids (oral or inhaled)	Effective in reducing symptoms only in high doses, for a short period and with a rebound effect
Cromolyns	Reduce symptoms and duration of disease. Unknown mechanisms
Antihistamines	Little benefit. Some improvement in sneezing and rhinorrhoea
Anticholinergic nasal sprays	Reduce sneezing and rhinorrhoea
Macrolides	Reduces <i>in vitro</i> the RV-mediated production of pro-inflammatory mediators. Clinical efficacy questionable
Antiviral	
Interferon- α	Able to prevent symptoms, but expensive and with significant side effects
Combination therapies	Combination of interferon- α , ipratropium and naproxen was effective in one clinical trial
Experimental therapies	
Anti-rhinoviral compounds	Enviroxime, WIN compounds, chalcones, pyridazinamines and other. Prevent viral uncoating. Some are currently under clinical trials
Soluble ICAM-1	Inhibits viral attachment of major type viruses to their receptor. Promising in initial clinical trials
Antisense oligonucleotides, 3C anti-proteinases, DNA vaccines, interferons β and λ	Potential routes of future intervention

relatively high doses seems to have a modest benefit in reducing duration of cold symptoms, but potential prophylactic effects have not been confirmed (Hemilä *et al.*, 2007). Although promising results were obtained with the use of cromolyns, which were able to reduce cold symptoms and shorten the duration of the illness (Aberg *et al.*, 1996), these have not been reconfirmed or further exploited. A recent meta-analysis suggested echinacea extracts may reduce the frequency of common colds in experimental rhinovirus challenge studies (Schoop *et al.*, 2006).

A combination approach was also proposed (Gwaltney, 1992), involving the administration of antiviral (IFN- α), anticholinergic (ipratropium) and anti-inflammatory (naproxen) drugs. Although a significant therapeutic result was achieved, together with a decrease in viral shedding, this approach does not appear to have been followed up with further studies.

Advances in molecular biological techniques have renewed interest in novel therapeutic approaches. New antiviral compounds are synthesized by computer-aided design (Joseph-McCarthy *et al.*, 2001), such as drugs that

can fit in the hydrophobic pocket of VP1, stabilizing the capsid proteins and preventing uncoating, or rhinovirus protease inhibitors (Johnson *et al.*, 2002; Tsang *et al.*, 2001). Another possibility includes the use of antisense oligonucleotides which anneal *in vitro* to viral RNA which is subsequently degraded by RNases (Johnston, 1997). A considerable number of such compounds are currently evaluated *in vitro*, while some such as pleconaril and AG7088 (Witherell, 2000) are undergoing clinical trials. These compounds are reviewed elsewhere (McKinlay, 2001).

A soluble form of the major group rhinovirus receptor ICAM-1 can inhibit viral entry and inactivate the virus in most experimental settings. Although soluble ICAM-1 was able to prevent rhinovirus infection in chimpanzees (Huguenel *et al.*, 1997) and initial human trials gave promising results (Turner *et al.*, 1999), this approach appears to have been abandoned due to the expense and issues with frequency of dosing. Recombinant LDLR fragments are also able to inhibit minor group rhinovirus infection *in vitro* (Marlovits *et al.*, 1998), suggesting that

receptor blockage could be an important anti-rhinovirus strategy if such problems can be overcome.

Coronaviruses and Toroviruses

INTRODUCTION

The first coronavirus to be isolated was infectious bronchitis virus (IBV) from chickens (Beaudette and Hudson, 1937) and coronaviruses were first isolated in humans in the mid 1960s using organ cultures of human embryonic trachea or nasal epithelium and in primary human kidney cell cultures (Tyrrell and Bynoe, 1965). Human coronaviruses were usually thought of in the context of the common cold and indeed, the two human coronaviruses – 229E and OC43 – are responsible for approximately 25% of colds. The global outbreak of severe acute respiratory syndrome (SARS) caused by a novel coronavirus (SARS-CoV) led to a resurgence of interest in coronaviruses and to the discovery of number of other previously unrecognized human and animal coronaviruses. This has resulted in renewed interest in the virology and pathogenesis of these viruses and in efforts to develop vaccines and antivirals against them.

Toroviruses were first isolated from cases of diarrhoea in horses in 1972 (Berne virus, the type strain of *Equine torovirus* (EToV)) and neonatal calves 1982 (Breda virus, type strain of *Bovine torovirus* (BToV)) (Weiss and Horzinek, 1987). Subsequently particles resembling these two viruses were observed by electron microscopy in the stools of children and adults with diarrhoea (*Human torovirus* (HTV)) (Beards *et al.*, 1984). More recent studies have confirmed the presence of HTV, especially associated with gastroenteritis.

THE VIRUSES

Coronavirus and *Torovirus* are the two genera within the family *Coronaviridae*, order *Nidovirales*. Both genera have genomes that are nonsegmented, single-stranded RNA of approximately 30 000 nucleotides and positive polarity (Enjuanes *et al.*, 2000).

Coronaviruses are assigned to one of three groups (Table 21.1) on the basis of group-specific (usually non-structural) proteins, genome organization and RNA sequence identity, supported to some extent by antigenic analyses (Enjuanes *et al.*, 2000; Gonzalez *et al.*, 2003). However, with the discovery of SARS-CoV and a number of novel human and animal coronaviruses, an alternative phylogenetic classification system of coronaviruses perhaps needs to be considered (Figure 21.1). Currently, SARS-CoV is officially classified as a group 2b virus. The finding that many novel group 1 and 2 coronaviruses are endemic in bats has led to the suggestion that bats may be the reservoir from which many other animal group 1 and 2 coronaviruses have arisen (Figure 21.1) (Vijaykrishna *et al.*, 2007).

Electron Microscopic Appearance

Coronaviruses and toroviruses are pleomorphic, ether-labile, enveloped viruses with diameters of approximately 120 nm and a buoyant density in sucrose of 1.15–1.18 g ml⁻¹. While coronaviruses are round in shape, toroviruses have a doughnut shape sometimes seen within the virus particle which led to the use of the root 'toro',

Table 21.1 Representative group 1–3 coronaviruses.

Group 1	Human coronavirus 229E (HCoV-229E)
	Human coronavirus NL63 (HCoV-NL63)
	Canine enteric coronavirus (CCoV)
	Feline coronavirus (FCoV)
	Porcine transmissible gastroenteritis coronavirus (TGEV)
	Porcine epidemic diarrhoea coronavirus (PEDV)
	Bat coronaviruses (BtCoVs)
Group 2	Human coronavirus OC43 (HCoV-OC43)
	Human coronavirus HKU1 (HCoV-HKU1)
	Bovine coronavirus (BCoV)
	Canine respiratory coronavirus (CRCoV)
	Porcine hemagglutinating encephalomyelitis coronavirus (HEV)
	Murine hepatitis coronavirus (MHV)
	Feline infectious peritonitis virus (FIPV)
	SARS coronaviruses (SARS-CoVs)
Bat coronaviruses (BtCoVs)	
Group 3	Infectious bronchitis coronavirus (IBV)
	Turkey coronavirus (TCoV)
	Pheasant coronavirus (PhCoV)

from the Latin *torus*, the lowest convex moulding in the base of a column (Figures 21.2a–c). Particles of both genera have club-shaped surface projections or spikes (S) of up to 20 nm in length. The name coronavirus (Latin *corona*, crown) derives from the large spike-like surface projections found on the surface of these viruses which are reminiscent of a crown (Figures 21.2 and 21.3). Electron microscopy of BTV revealed few of the 20-nm spikes but rather an intact fringe of smaller spikes, some 7–9 nm in length (Cornelissen *et al.*, 1997). Toroviruses isolated from human faeces had an intact fringe of 10-nm spikes (Beards *et al.*, 1984). It is possible that the 10-nm spikes are the haemagglutinin esterase (HE) protein. BTV has an HE protein which forms a fringe of spikes approximately 6 nm in length (Cornelissen *et al.*, 1997).

Coronavirus particles within infected cells have a diameter of approximately 85 nm in thin sections of infected cells and are seen within the Golgi or endoplasmic reticulum. There is usually no budding from the plasma membrane and the virus particles typically found attached to the surface of the cell membrane are probably those disgorged from cytoplasmic vesicles (Figure 21.2d).

Composition of Virions

Coronaviruses contain an envelope spike (S) glycoprotein, a smaller integral membrane glycoprotein (M) largely embedded in the virus envelope, and small amounts of a third membrane-associated non-glycosylated protein (E, envelope), and a nucleocapsid protein (N) that surrounds

the genome (Figure 21.3). Some group 2 coronaviruses have an HE protein (see above). By contrast, toroviruses have three structural proteins – S, M, N (Figure 21.2) – and lack the E protein (Figure 21.4).

The S protein of coronavirus is a type I glycoprotein which forms mono- to trimeric complexes for receptor binding and membrane fusion. The membrane-spanning region is near the C-terminus, the actual C-terminus being within the lumen of the virion. The S protein is highly glycosylated (N-linked glycans) and might be proteolytically processed into S1 (N-terminal) and S2 subunits. The S proteins of group 2a and group 3 coronaviruses, for example, IBV, contain a multiple basic motif and are efficiently cleaved into two subunits, S1 and S2 (S2 being a little longer than S1). Most of the S protein of HCoV-OC43 grown in a human rectal tumour cell line is not cleaved but addition of trypsin cleaves S into S1 and S2. This indicates that the extent to which the S protein of HCoV-OC43 is cleaved in various cell types depends in part on the presence of the relevant protease within cells which cleave adjacent to a basic S1–S2 connecting peptide, a situation which also applies to murine hepatitis coronavirus (MHV). Although the S protein of group 1 and 2b coronaviruses lacks a highly basic sequence such as occurs in IBV at the S1–S2 cleavage site, some of the viruses (e.g. SARS-CoV) in these groups could be cleaved by cellular proteases. Protease cleavage is not absolutely necessary for the replication of all coronavirus.

The M protein, a type III glycoprotein, has a short (20 amino acids or so) glycosylated N-terminus at the

Figure 21.1 Phylogenetic tree of RNA-dependent RNA polymerase encoding nucleotide sequences from representative coronaviruses. The phylogenetic tree was built using the neighbour joining method using Poisson correction. Human coronaviruses are underlined. Refer to Table 21.1 for the abbreviations used. Additionally, abbreviations for bat coronaviruses closely related to SARS-CoV include BtCoV-Rp3: *Rhinolophus pearsoni*, BtCoV-Rm1: *Rhinolophus macrotis* and BtCoV-Rf1: *Rhinolophus ferrumequinum*. Civet SARS-CoV represents virus detected in civet cats (*Paguma larvata*).

surface of the virion, followed by three hydrophobic membrane-spanning regions, an amphipathic region and finally a C-terminal tail in the lumen of the virion. The amphipathic and tail regions may be referred to as the endodomain. Cryoelectron microscope visualization of unstained transmissible gastroenteritis coronavirus (TGEV) has revealed the presence of a core structure. It has been proposed that the TGEV virion comprises (i) a core, made of the nucleocapsid (N protein plus genome) and the

endodomain of M and (ii) the envelope, containing S, E and M.

The E protein is present in only trace amounts in virions. The E is known to be critical for the virion formation of coronaviruses. In addition, the E of SARS-CoV and MHV can induce apoptosis. Recently, the E proteins from some of the coronaviruses have been shown to have ion channel activities.

The N protein is a multipurpose protein that plays a vital role during virion assembly. It binds the viral

Figure 21.2 Negatively stained electron micrographs of (a, b) human enteric torovirus showing torus (arrow), crescent (arrowhead) and rod (double arrowhead), (c) a human enteric coronavirus with spikes which are more prominent and readily discernible than those of the torovirus. The shorter (10 nm) projections on the torovirus particles may be the haemagglutinin esterase protein, Bar = 100 nm, and (d) transmission electron micrograph of FRhK-4 cells infected with SARS-CoV, Bar = 1 μ m.

genomic RNA to form a complex of ribonucleoprotein, which is then packaged into progeny viral particles.

Many group 2a coronaviruses including HCoV-OC43 (but not SARS-CoV which is a group 2b coronavirus) contain an additional HE glycoprotein, which forms a 5-nm layer of surface projections. BoTV has an HE protein which is absent from EToV as this virus has an incomplete HE gene. The BoTV HE protein has approximately 30% amino acid sequence identity with that of coronaviruses and influenza C virus. The HE protein is not essential for virus replication *in vitro*.

Comprehensive reviews of these structural and non-structural viral proteins have been extensively summarized by others (Gorbalenya *et al.*, 2006; Lai and Cavanagh, 1997; Masters, 2006).

Viral Transcription and Replication

Both homologous (with viruses of the same species and other coronaviruses) and less commonly heterologous (with viruses of other genera) genetic recombination is a feature of coronaviruses and toroviruses (Lai and Cavanagh, 1997).

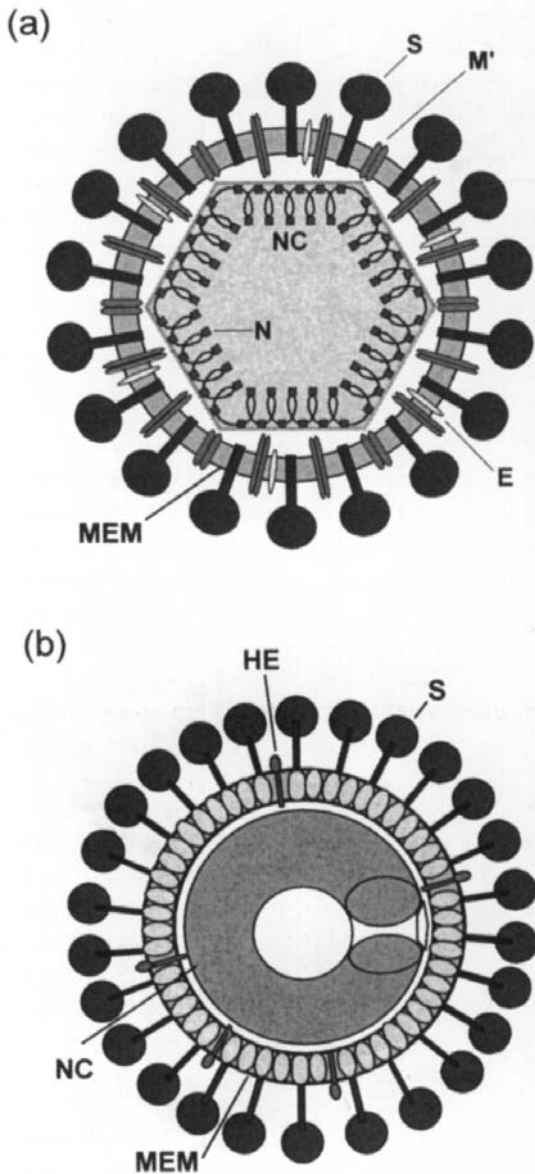

Figure 21.3 Diagrammatic representation of the virions of (a) a coronavirus and (b) a torovirus. Both types of virus have a lipid membrane (MEM), prominent spike proteins (S) and an integral membrane protein (M). HCoV-OC43, but not HCoV-229E, and some toroviruses have a haemagglutinin esterase protein. Coronaviruses, but not toroviruses, contain a small number of molecules of an E protein. (a) Cryoelectron microscopy has indicated the presence of a core structure in coronaviruses, comprising a nucleocapsid (NC: N protein plus genomic RNA) and the endodomain of the M protein. (b) The nucleocapsid of toroviruses has the appearance of a torus.

The transcription and replication of viral RNA is believed to occur on virus-induced double-membrane vesicles in the cytosol of infected cells. The genome organization of EToV and human coronaviruses are shown in Figure 21.4a. They all differ with respect to the number and location of genes that encode proteins believed to be nonstructural that is, not present in virus particles. In HCoV-OC43 all the genes are monocistronic whilst HCoV-229E and SARS-CoV have one and four dicistronic genes respectively.

Members of each coronavirus group tend to have similar nonstructural protein genes located in the same positions of the genome and hence they are referred to as group-specific genes. Their roles are not known. Deletion of one or more of these non-structural genes of group 2 coronaviruses had little effect on virus replication *in vitro*. Consequently they have also been referred to as accessory genes. It is believed, however, that they play a role *in vivo*; deletion of these genes from MHV attenuated the pathogenicity of the virus. Rearrangement of the gene order had little effect on infectivity of MHV (de Haan *et al.*, 2002). Toroviruses do not have any nonstructural protein genes, other than gene 1 (Figure 21.4).

Gene 1 of the coronaviruses (~20 000 nucleotides) and toroviruses encodes proteins required for RNA replication and transcription. In both genera, it comprises two overlapping open reading frames (ORFs), the second one, 1b, being translated by a frameshifting mechanism. These, and the subsequent processing of the gene polyproteins, have been reviewed (Gorbalenya *et al.*, 2006; Masters, 2006).

Transcription in both genera involves the production of a 3' co-terminal nested set of mRNAs (Figure 21.4b). It is generally believed that the transcription involves a template switch (also known as discontinuous RNA synthesis) during the negative-stranded RNA synthesis. The negative copy of the subgenomic (sg) mRNA is then used as the template for sg mRNA production. At the 5' end of each coronavirus gene is a transcription regulatory sequence (TRS) (known as body TRS) while at the 5' terminus of the genome is a leader sequence which also contains a TRS. The sg mRNAs have a copy of the leader sequence fused at the TRS region. The sequence of the TRS varies among the coronaviruses (Thiel *et al.*, 2003). During negative-stranded sg mRNA synthesis, the RNA polymerase is thought to pause after encountering a body TRS. This polymerase may subsequently 'jump' to the leader TRS of the same template to complete the nascent negative-stranded sg mRNA transcription. Thus, this discontinuous RNA transcription would add a common leader sequence to each sg mRNA. The template switching process is determined by the strength of interaction between the nascent negative-stranded

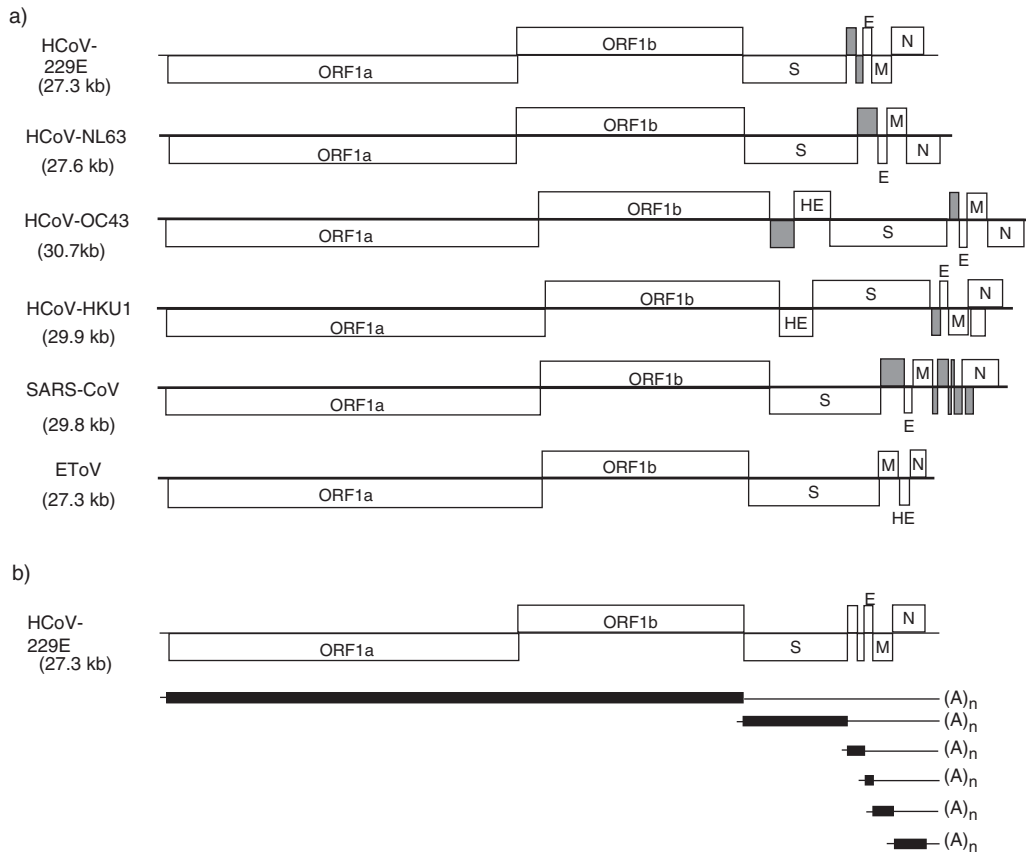

Figure 21.4 (a) Genome organization of the HCoV-229E (group 1), HCoV-NL63 (group 1), HCoV-OC43 (group 2), HCoV-HKU1 (group 2), SARS-CoV (group 2) and equine torovirus. The replicase/polymerase-encoding gene 1, structural protein genes and nonstructural protein genes are shown. Genes for accessory proteins are indicated by grey rectangles. (b) The 3' co-terminal nested set arrangement of coronavirus mRNAs is illustrated for HCoV-229E. The thick black lines indicate the part of each mRNA that is translated.

sg mRNA transcript and the leader TRS (Sola *et al.*, 2005).

Toroviruses have TRS-like sequences at the 5' end of the M, HE and N genes but, unlike coronaviruses, the mRNAs corresponding to these genes do not have a leader sequence fused at their 5' end. However, the S gene, which does not have an obvious TRS sequence, gives an mRNA with a leader sequence, albeit a short one (18 nucleotides) from the 5' end of the genome (van Vliet *et al.*, 2002).

Assembly of Virions

The coronavirus glycoproteins are synthesized at the rough endoplasmic reticulum and are then translocated to the endoplasmic reticulum–Golgi intermediate com-

partment. This is the budding compartment where immature virus particles containing the viral ribonucleoprotein (genome plus nucleocapsid protein) form (Salanueva *et al.*, 1999). The particles progress to the *cis*, medial, *trans*-Golgi compartments and then to the *trans*-Golgi network. Secretory vesicles then transport the virus particles to the cell surface and release them presumably by fusing with the plasma membrane. The coronavirus M protein is not translocated beyond the Golgi compartments, hence this is where virus particles form, not at the plasma membrane. The M protein of toroviruses is also thought to determine the site of virus particle formation. In the case of the coronavirus, E protein is also essential for the formation of virus particles (Raamsman *et al.*, 2000).

Antigenic Structure

Virus-neutralizing and haemagglutination-inhibiting antibodies are induced by both the S and HE proteins of coronaviruses and toroviruses and some antibodies against the coronavirus M protein neutralize virus in the presence of complement.

Epitope mapping of coronaviruses has been done mostly for S protein and has shown that virus-neutralizing epitopes are formed largely by the N-terminal S1 half of the protein, which has much greater amino acid sequence variation (Siddell, 1995). Removal of glycans from the S protein of IBV greatly diminished the binding of virus-neutralizing monoclonal antibodies.

The S protein has been shown to be a major inducer of protective immunity (Buchholz *et al.*, 2004) although the other structural proteins, particularly the nucleocapsid protein, contribute to cell-mediated protection. In the case of feline infectious peritonitis virus (FIPV), the immune response to S protein is believed to exacerbate the disease. FIPV attached to anti-S antibody remains infectious and is more readily taken up by macrophages (antibody-dependent enhancement), within which FIPV replicates (de Groot and Horzinek, 1995). Similar antibody-dependent enhancement has not been reported for human coronaviruses, although there is a report that SARS-CoV spike-bearing viral pseudotypes can enter human B cell lines that lack the virus receptor angiotensin-converting enzyme 2 (ACE2) via FcγRII in the presence of antibody (Kam *et al.*, 2007) and one needs to be alert to this possibility.

Immune electron microscopy has revealed relationships between the toroviruses of humans, equines and bovines. Much remains to be done to establish the extent of variation among human toroviruses.

INITIATION OF INFECTION AND PATHOGENESIS

Cell Attachment Proteins

The S protein serves to attach the virus to cells. The extent to which the HE protein, when present, is also responsible for cell attachment is not clear. The HE proteins, in contrast to the S proteins, of both coronaviruses and toroviruses are not required for replication *in vitro* (Popova and Zhang, 2002). Amino acids 417–547 of the HCoV-229E S protein were required for binding to its cell receptor and the receptor-binding motif of SARS-CoV's S protein has been mapped to the amino acid residues 424–494 (Li *et al.*, 2005b; Wentworth and Holmes, 2007). The role of S protein as a determinant of host cell range has been demonstrated using recombinant coronaviruses

expressing heterologous S proteins. For example, MHV expressing the feline coronavirus (FCoV) S protein was able to successfully infect and replicate in feline cells previously refractory to MHV infection. It is the S1 part of S protein that determines receptor specificity. Experiments with recombinant MHVs showed that the extent of replication of the virus, and the degree of hepatitis in the liver, was determined largely by the S protein. Gallagher and Buchmeier (2001) have reviewed virus entry and pathogenesis for MHV.

Cell Receptors for Coronaviruses

The specificity of virus attachment to host cells can be a major factor in determining host range, tissue tropism and hence pathogenesis. Three cellular proteins – aminopeptidase N (APN), carcinoembryonic antigen cell adhesion molecule 1 (CEACAM-1) and ACE2 – have been identified as the principal receptors for binding group 1 and 2 coronaviruses. The transfer of coronavirus receptors from susceptible cells to other cells can render the latter susceptible to infection (Wentworth and Holmes, 2007).

Human APN has been identified as the receptor for HCoV-229E. This protein is a metalloprotease located on the surface of epithelial cells, including those of the intestine, lung and kidney. Human cells that were not susceptible to canine coronavirus (CCoV) or FCoV became susceptible when transfected with a human/canine chimera of APN. The critical, C-terminal domain was formed by amino acids 643–841 of the canine APN. When amino acids 255–348 of porcine APN were replaced by amino acids 260–353 of human APN, the resulting chimeric protein was able to function as a receptor for HCoV-229E. Thus different parts of APN molecules may function as receptors for most group 1 coronaviruses. Expression of feline APN in rodent cells rendered the cells susceptible not only to FCoV but also to HCoV-229E, CCoV and TGEV. Previous work had shown, however, that human APN would bind HCoV-229E but not TGEV, while porcine APN would bind TGEV but not human coronavirus (HCoV). Surprisingly, HCoV-NL63, also a human group 1 coronavirus, uses ACE2 for receptor binding (Hofmann *et al.*, 2005).

Much less work has been done on receptors for group 2a human coronaviruses. The cellular receptor for MHV (a group 2a coronavirus, like HCoV-OC43), is a member of the CEA family of glycoproteins in the immunoglobulin superfamily (Lai and Cavanagh, 1997). CEACAM-1, is a 424-amino-acid glycoprotein with four immunoglobulin-like domains. A soluble form of this protein has been crystallized and its atomic structure has been deduced (Tan *et al.*, 2002).

The immunoglobulin-loop of human CEACAM-1 confers virus-binding specificity. Different isoforms of

murine CEACAM-1 protein exist. These have extensive differences in the N-terminal immunoglobulin-like domain to which MHV binds and so bind MHV to different extents. Amino acids 38–43 were key elements for binding MHV and for virus-induced membrane fusion (Rao *et al.*, 1997). When a persistent infection of MHV was established in murine 17 Cl 1 cells, which express very low levels of the CEACAM-1 receptor, there was selection of mutant MHVs that were better able to use other molecules as receptors (Schickli *et al.*, 1997).

Human ACE2, an 805-amino-acid glycoprotein, is the primary receptor for SARS-CoV and HCoV-NL63. It is a carboxypeptidase which cleaves angiotensin II to angiotensin-(1-7). In addition to playing a role in regulating the blood pressure and cardiovascular and renal function, the renin–angiotensin system is believed to modulate acute lung injury. The crystal structure of the protein complex comprising the human ACE2 and SARS-CoV receptor-binding domain has been elucidated. The adaptation of the SARS-CoV-like civet virus to humans was associated with key changes in the spike protein which enhance binding to the ACE2 receptor. In comparison to the human SARS-CoV, the civet SARS-CoV-like virus spike has two amino acid substitutions in the spike (N479K; T487S) that adversely affect its interaction with human ACE2 (Li *et al.*, 2005b). Similarly, the civet-like virus that re-emerged to infect humans in late 2003 also had the T487S amino acid substitution and an additional change at L472P compared with human SARS-CoV and this probably contributed to its poor pathogenicity and transmissibility in humans. Thus a small number of spike mutations may be critical for facilitating efficient interspecies transmission. The spike of the SARS-like coronavirus found in bats is markedly different in this region and will not bind human ACE2.

Apart from ACE2, other cellular proteins such as DC-SIGN, L-SIGN and L-SECtin are also able to facilitate virus binding of some coronaviruses (Wentworth and Holmes, 2007). The expression of L-SIGN in cells lacking ACE2 expression allows SARS-CoV binding but not virus replication. It is thus a binding receptor rather than a functional receptor for SARS-CoV.

Involvement of Glycans on Receptors

The S protein of some coronaviruses and the HE protein of group 2a coronaviruses bind to sialoglycoconjugates on cell surfaces and these interactions may also be relevant for virus entry and tissue tropism. Attachment of coronaviruses might be a two-step process. Primary attachment might be mediated by a first receptor, for example, *N*-acetyl-9-*O*-acetylneuraminic acid (Neu5,9Ac₂) for some coronaviruses, a second receptor for example, APN or CEACAM-1 proteins, bringing the virus

and cell membranes closer together for subsequent membrane fusion. Some receptors might fulfil both functions for some coronaviruses.

Both the S and HE proteins of bovine coronavirus (BCoV) bind to cell surface components, an important one being the glycan component Neu5,9Ac₂. This residue acts as a receptor not only on erythrocytes but also on susceptible cell cultures (Schultze and Herrler, 1992). The S protein binds more efficiently than HE to Neu5,9Ac₂ and it has been proposed that the BCoV S protein is responsible for the primary attachment to cells.

HE proteins from different group 2a coronaviruses have different specificities to bind or cleave sialoglycoconjugates. For instance, the HE protein of HCoV-OC43 prefers to bind to Neu5,9Ac₂ and it is also a sialate-4-*O*-acetylsterase. Thus by contributing to both binding and removal of the virus from the cell surface, the HE protein may help virus release as well as virus entry.

Host Range of Coronaviruses

Interspecies transmission of coronaviruses is well recognized in animals. The closely related group 1 coronaviruses, porcine transmissible gastroenteritis virus, canine and FCoV can infect pigs with some disease expression. BCoV can naturally infect dogs and humans and even cause disease in avian hosts. The HCoV-OC43 has >99% amino acid identity in its S and HE proteins with the corresponding proteins of BCoV. A recently discovered respiratory CCoV is a group 2 coronavirus, the S protein of which had 96 and 95% amino acid identity with that of BCoV and HCoV-OC43, respectively. Cross-infection by these viruses has not been studied but a broad host range for them is a possibility (Saif, 2006).

Coronaviruses can undergo dramatic changes in virulence and tissue tropism. Porcine enteric transmissible gastroenteritis virus caused a highly virulent disease in pigs. A spontaneously occurring spike gene deletion mutation led to the emergence of a virus (porcine respiratory coronavirus) with a tropism for the respiratory tract and reduced virulence in pigs. These changes in the spike were responsible for the altered tissue tropism (Ballesteros *et al.*, 1997). Interestingly these deletion mutants arose independently in Europe and North America as these viruses have differences in the size of the spike deletion.

Thus it is no surprise that a civet SARS-like virus was able to establish itself and to transmit and cause disease in humans. In addition to the changes in the civet virus spike that led to a dramatic change, the binding affinity for the human ACE2 receptor also altered. Another striking difference observed in human SARS-CoV is a 29-nucleotide deletion which interrupts the ORF8ab of the civet virus

(Guan *et al.*, 2003). The biological significance of this deletion is still unclear.

Fusion Processes

The S protein of coronavirus is a class 1 fusion protein. The fusion processes for coronavirus viral entry is not completely understood. During the fusion, the S protein undergoes a series of conformational changes. The binding of S to the receptor could induce the separation of S1 from S2, and alter the conformation of S1, generating alternative disulfide linkages within S1. The fusion peptide in the S2 region is then exposed to host cell membrane. This is followed by a series of conformational changes of the S2 protein and the hydrophobic heptad repeat regions (i.e. HR1 and HR2) in the S2 domains of the trimeric complex to form a six-helical bundle at the final stages of fusion. It is believed that a small region rich in tyrosine and tryptophan residues before the transmembrane domain of S2 may help to destabilize lipid bilayers, thereby leading to pore formation and membrane fusion (Wentworth and Holmes, 2007).

EPIDEMIOLOGY

Seroepidemiology indicates that antibodies to 229E and OC43 appear early in life and are ubiquitous by adulthood (McIntosh *et al.*, 1970). Limited data based on enzyme-linked immunosorbent assay (ELISA)-based assays using portions of the recombinant nucleocapsid and pseudotyped virus expressing the NL63 spike protein suggest that the same is true of NL63 (Hofmann *et al.*, 2005; Shao *et al.*, 2007). There is limited seroepidemiology data on HKU1 as this virus still cannot be cultivated efficiently. Preliminary ELISA assays using recombinant HKU1 nucleocapsid protein showed evidence of seroconversion in patients with HKU1 disease but a low (2%) seroprevalence in the community (Woo *et al.*, 2005a).

Community studies have shown that the incidence of, for example, coronavirus 229E infections may vary from year to year from as low as 1% to as high as 34% (Hamre and Beem, 1972). Coronaviruses appear to have a winter–spring seasonality in temperate regions. In subtropical Hong Kong, the seasonality appears to be similar except that NL63 may be found in early summer and autumn (Chiu *et al.*, 2005; Lau *et al.*, 2006). Unlike many other respiratory viral infections, all age groups appear to be uniformly infected with HCoV. Reinfection of individuals with the same HCoV serotype often occurs within months of the first infection, suggesting that even homologous protection is short-lived. Available data suggest that antibodies to one HCoV group may not be protective against infection with viruses from the other HCoV group.

Severe Acute Respiratory Syndrome

SARS emerged as a pneumonic respiratory disease in Guangdong Province, China in November 2002 and within weeks had spread to affect about 8000 patients in 29 countries across five continents, associated with an overall fatality rate of 9.6% (Peiris *et al.*, 2007). A novel coronavirus, SARS-CoV was identified as the aetiological agent (Drosten *et al.*, 2003; Ksiazek *et al.*, 2003; Peiris *et al.*, 2003b). The lack of antibody to SARS-CoV in asymptomatic healthy people in the community suggested that it was a disease that emerged from an animal reservoir (Ksiazek *et al.*, 2003; Peiris *et al.*, 2003b). The earliest human cases of SARS in late 2002 had epidemiological links with live animal markets (Xu *et al.*, 2004). A virus closely related (99.8% nucleotide identity) to SARS-CoV was detected in palm civets (*Paguma larvata*) and other small mammal markets in southern China where live game animals are sold as exotic foods for human consumption (Guan *et al.*, 2003). Humans working in these markets had high prevalence of antibody to SARS-CoV although they had no history of a SARS-like disease, suggesting that they had been infected with the less pathogenic precursor SARS-CoV-like virus. Furthermore, when SARS re-emerged to infect humans in Guangdong in late 2003 and early 2004, the virus was more closely related to the civet-like virus rather than to the human adapted virus that spread worldwide in mid 2003. It was of low pathogenicity and failed to transmit from human to human (Liang *et al.*, 2004), probably as a consequence of the poor affinity of the virus–receptor interaction (see above). Thus it is likely that these animal markets were the interface which allowed the precursor virus to adapt and amplify in animals such as civets and infect humans. However, civets were not the natural reservoir. A SARS-like coronavirus has been found in wild caught bats (*Rhinolophus* spp.) and these appear to be the natural reservoir from which SARS-CoV emerged (Lau *et al.*, 2005; Li *et al.*, 2005a). The nucleotide identity between the bat precursor virus and human SARS-CoV is only around 90% and this precursor virus had to undergo significant adaptation before becoming efficiently transmissible in humans. As bats, civets and a range of other animal species are sold for human consumption within the markets of Guangdong, this provided the ideal milieu for such adaptation to occur (Peiris *et al.*, 2007).

While many SARS patients did not transmit infection at all, a few patients accounted for a disproportionately large number of secondary cases, the so-called ‘super-spreading incidents’. Although host factors may have played a role in these super-spreading events, in many instances it was a combination of host factors and environmental circumstances that facilitated transmission. Overall, the basic reproduction number of SARS was estimated to

be approximately 2–4 (Lipsitch *et al.*, 2003; Riley *et al.*, 2003).

Respiratory droplets were believed to be the major vehicle of transmission and the use of effective droplet precautions did protect healthcare workers (Seto *et al.*, 2003). However, true air-borne transmission probably did occur in some instances through the use of aerosol-generating procedures such as intubation, suction, high-flow oxygen therapy and the use of nebulizers. Infectious virus was also present in faeces (Peiris *et al.*, 2003b) and the largest super-spreading incident at Amoy Gardens in Hong Kong which led to over 300 cases is believed to have occurred through aerosolization of infected faeces in the sewage system in a high-rise apartment (Yu *et al.*, 2004). SARS-CoV retains viability for much longer periods than 229E, suggesting that fomites may also be an important means of virus transmission (Rabenau *et al.*, 2005).

Unlike many other respiratory viral infections, relatively little SARS transmission occurred early (first five days) in the illness (Lipsitch *et al.*, 2003). This was probably related to the low viral load in the upper respiratory tract (and faeces) early in the illness with a peak of viral load at around day 10 of disease (Peiris *et al.*, 2003a). These disease characteristics probably contributed to the dramatic spread in the hospital setting (by which time patients were highly contagious) and the relatively lower transmission within the family setting. Healthcare workers comprised 21% of all cases (Peiris *et al.*, 2007).

Another unusual feature of SARS was that asymptomatic infections was uncommon (Leung *et al.*, 2004b). The absence of large number of asymptomatic transmitters of the disease and the limited transmission in the first five days of illness were fortuitous features of this disease that allowed its successful containment through the application of public health measures such as case detection and isolation.

It is relevant to consider whether SARS may return. Since the interruption of the major global outbreak in July 2003, there is no evidence of continued circulation of the human-adapted SARS-CoV in humans or animals. However, this virus exists in laboratories and there were three laboratory infections in 2003 and 2004, in one instance, leading to transmission in the community. Fortunately, these outbreaks were successfully contained. The SARS-CoV-like civet virus led to four new cases in December 2003 and January 2004, many of whom had a history of contact with the animal market trade, but these civet SARS-CoV were not well adapted to efficient human transmission (see above). The sale of civets in big animal markets in southern China was subsequently banned. While it is possible that an illegal trade continues, this

will probably not provide the same opportunities for interspecies transmission and sustained circulation of virus as may happen in the large organized animal market setting. The original precursor virus still exists in bats and it is conceivable that it may re-emerge, again re-adapt to human transmission and lead to human outbreaks (Peiris *et al.*, 2007).

CLINICAL FEATURES

Association of human disease with coronavirus 229E and OC43 has been conclusively established by infecting human volunteers with cultured virus and documenting ‘common cold’-like symptoms in association with virus replication in the upper respiratory tract (Bradburne *et al.*, 1967; Hamre and Procknow, 1966) thereby fulfilling Koch’s postulates. These studies also established that the incubation period was around two days with peak symptoms occurring at three to four days. Virus was detectable in the respiratory tract around the time of symptom onset and continued to be detectable for around five days. Coronaviruses (229E and OC43) account for approximately 25% of common colds and are second only to rhinoviruses as the causative agent (Makela *et al.*, 1998). The symptoms are those of a nasal discharge, mild sore throat, sneezing, general malaise, perhaps with headache and lasts for an average of six to seven days. Fever and coughing may be exhibited in 10 and 20% of cases, respectively. No difference is observed between 229E and OC43 strains in the pathology of infection. Generally symptoms are indistinguishable from those of colds caused by rhinoviruses. Subclinical or very mild infections are common. HCoV were found in 10% of children with otitis media with effusion, respiratory syncytial virus being associated with approximately 30% of cases (Pitkaranta *et al.*, 1998).

Ethical considerations have precluded human volunteer studies being done with the more recently discovered coronaviruses NL63 and HKU1 or for SARS-CoV. Thus disease association has been indirect, by detecting the virus in the respiratory tract in association with disease. The aetiological link has been conclusive with SARS where the virus and seroconversion to it was almost exclusively associated with clinical disease and there was minimal asymptomatic infection (see above). Furthermore, the virus was demonstrated at the site of pathology, viz. lung and gastrointestinal tracts (Nicholls *et al.*, 2006; Peiris *et al.*, 2003b). Experimental transmission of the virus to cynomolgous macaques led to SARS-like lung pathology (Fouchier *et al.*, 2003). Taken together, these findings satisfy Koch’s postulates for an association of a pathogen and disease. However, in the case of NL63

and HKU1, the association with human disease depends on the virus being more frequently found in the respiratory tract of patients with disease than in matched controls. While detection of these viruses in association with respiratory disease has been observed in many studies worldwide, fewer studies have compared these data with concurrent age-matched controls. These viruses (and also HCoV-229E or HCoV-OC43) can occasionally be found in 'healthy' controls and furthermore, finding multiple respiratory viruses in patients with disease makes it difficult to establish the contribution of each one to the illness (van der Hoek, 2007). Unlike SARS-CoV, neither of these viruses has relevant animal models that can be used to fulfil Koch's postulates. In studies that have used a control group for comparison, 229E and OC43 were associated with 11% of children with acute respiratory tract disease compared with 0.37% of controls ($P < 0.01$), confirming the data from volunteer studies (van Elden *et al.*, 2004). NL63 and HKU1 were not sought in this study. In patients aged 60 years or older, 229E and OC43 were found in 17% of 107 elderly subjects with acute respiratory disease and only 2% of controls. Rhinovirus was more commonly detected (32% of patients and 2% of controls) while influenza was less common (7% of cases and 0% controls) (Graat *et al.*, 2003). In a study of children and young adults, 229E and OC43 were detected in both patients (3.6% of flu-like illness; 7.7% of other respiratory illness) and in controls (3.9%) and there was no statistically significant association with disease (van Gageldonk-Lafeber *et al.*, 2005).

Coronaviruses have also been associated with exacerbations of wheezing in asthmatic children (McIntosh *et al.*, 1973). Coronavirus was detected in approximately 5% of children (Freymuth *et al.*, 1999) and 22% of adults hospitalized because of asthma (Atmar *et al.*, 1998). Allergic patients with a common cold, associated with a number of viruses, including HCoVs (25%), had prolonged nasal eosinophil influx (van Bentem *et al.*, 2001). Whether that would increase the risk of subsequent allergen-induced hypersensitivity reactions is not known.

An experimental model has been established for viral wheeze, involving volunteers (some atopic, others not) with and without a history of viral wheeze (McKean *et al.*, 2001). Over half developed colds after inoculation with HCoV-229E. The viral wheezers reported more upper respiratory tract symptoms than controls. Over half of the wheezers, but none of the controls, reported lower respiratory tract symptoms (wheeze, chest tightness and shortness of breath).

NL63 has been found significantly more often in patients with croup than in controls (17% vs. 4%) and appeared to be an even more important cause of this disease than parainfluenza virus (van der Hoek *et al.*, 2005).

However, studies of cases and controls for association of NL63 with other features of acute respiratory disease have been inconclusive (Boivin *et al.*, 2005; Dare *et al.*, 2007). An alternative, but less definitive approach of establishing disease associations is to identify patients with the virus of interest without any other relevant respiratory pathogen. NL63 was detected as the sole pathogen in 0.4–9.3% of patients with respiratory infection and HKU1 in between 0.3 and 4.4% of patients (van der Hoek, 2007). The symptoms found in patients with NL63 alone included fever, cough, rhinorrhoea, pharyngitis, croup, bronchiolitis, pneumonia and febrile seizures. Some patients had underlying disease. A association of NL63 with Kawasaki disease has not been confirmed. HKU1 was associated with a similar spectrum of disease as seen with NL63 although it was not associated with croup. Febrile seizures were more common in HKU1 infected patients than those with OC43 (Woo *et al.*, 2005b). Between 50 and 80% of patients had underlying diseases (van der Hoek, 2007).

In hospitalized patients, 229E, OC43, NL63 and HKU1 have all been found in upper as well as lower respiratory tract disease, especially in children (Arden *et al.*, 2005; Boivin *et al.*, 2005; Chiu *et al.*, 2005; Sloots *et al.*, 2006; Woo *et al.*, 2005b). These coronaviruses have also been detected in bronchoalveolar lavages of immunocompromised and noncompromised adults, providing additional evidence of their pathogenic potential in the lower respiratory tract (Garbino *et al.*, 2006). Follow-up bronchoalveolar lavage specimens were available from some patients and these were often negative, indicating that the virus was temporally associated with the clinical symptoms.

HKU1 has also been detected in respiratory specimens from patients with diarrhoeal symptoms and in stool specimens in association with fever, otitis and convulsions (Vabret *et al.*, 2006). Thus, it is possible that, as with SARS, HKU1 may lead to disseminated disease.

Coronaviruses have been associated with nosocomial outbreaks of disease in children in neonatal units and in premature babies (Esper *et al.*, 2005; Sizun *et al.*, 1995). Neonates with coronavirus infections had bradycardia, apnoea, hypoxaemia, fever or abdominal distention. Chest X-ray revealed diffuse infiltrates.

As with influenza and respiratory syncytial virus, coronaviruses are also associated with respiratory illness in the elderly (Falsey *et al.*, 2002; Walsh *et al.*, 1999).

Severe Acute Respiratory Syndrome

The incubation period of SARS is estimated to be 2–14 days. SARS typically presents as fever, myalgia, malaise, chills or rigour and fever of acute onset leading in some patients to a rapidly progressing viral pneumonia. A dry cough is common but rhinorrhoea and sore throat are

less prominent. Watery diarrhoea was reported in a proportion of patients. Radiological abnormalities were seen in >60% of cases at presentation. Typically the chest radiograph showed ground glass opacities, and focal consolidation over the periphery and subpleural regions of the lower zones of the lung. One or both lungs may be involved and the radiological changes may shift location. High-resolution computed tomography (CT) scanning allowed detection of abnormalities in a proportion of patients with initially unremarkable chest radiographs. While approximately one-third of patients improved, with defervescence and resolution of the radiographic changes, others progressed to develop increasing shortness of breath, tachypnoea and oxygen desaturation. Extrapulmonary manifestations included hepatic dysfunction, a marked lymphopenia involving both B and T cells (CD4 and CD8 subsets) and NK cells and less commonly, central nervous system (CNS) manifestations (Cheng *et al.*, 2007; Peiris *et al.*, 2003c, 2007).

About 20–30% of patients required management in intensive care and many of them needed mechanical ventilation. The terminal events were severe respiratory failure associated with acute respiratory distress syndrome and multiple organ failure. The overall case fatality rate was 9.6%.

The clinical features of SARS were not pathognomonic and a contact history and virological evidence of infection were important in establishing the diagnosis. The occurrence of clusters of cases of a rapidly progressing pneumonia in a family or hospital setting was suggestive of the disease.

The severity of illness and increasing case fatality was associated with increasing age and presence of other co-morbidities. A higher viral load in nasopharynx and serum early in the disease was an independent risk factor for mortality (Chu *et al.*, 2004b). Children had a milder disease course (Leung *et al.*, 2004a). The elderly may present atypically without fever or respiratory symptoms and failure to recognize such atypical presentations led to catastrophic nosocomial outbreaks (Chow *et al.*, 2004).

Residual impairment of lung function persists into late convalescence including restrictive lung function abnormalities due to lung fibrosis, impairment in diffusion capacity, muscle weakness, and reduced exercise capacity. Psychological sequelae including depression and post-traumatic stress have been reported in survivors (Cheng *et al.*, 2007).

Coronaviruses and Toroviruses Associated with the Human Enteric Tract

Coronavirus-like (non-SARS) viruses have been isolated from faecal specimens from humans (Duckmanton *et al.*, 1997). Some of these viruses were isolated from infants

with necrotizing enterocolitis, patients with nonbacterial gastroenteritis and from homosexual men with diarrhoea who were symptomatic and seropositive for human immunodeficiency virus. Some isolates were shown to be serologically related to OC43. The discovery that a protein found in enterocytes functions as a receptor for HCoV-229E strengthens the likelihood that coronaviruses might replicate in the human alimentary tract.

Evidence has increased that toroviruses are associated with gastroenteritis in humans. In a case–control study of children, an antigen-capture ELISA revealed torovirus in stools from 27% (9/33) of children with acute diarrhoea, 27% (11/41) with persistent diarrhoea and none in controls (Koopmans *et al.*, 1997). Enteroggregative *Escherichia coli* was commonly found in association with the torovirus. In another childhood study electron microscopy revealed a torovirus incidence of 35% (72/206) and 15% in gastroenteritis cases and controls, respectively (Jamieson *et al.*, 1998). Those infected with torovirus were more frequently immunocompromised (43 vs. 16%) and nosocomially infected (58 vs. 31%); experienced less vomiting (47 vs. 68%); had more bloody diarrhoea (11 vs. 2%).

Coronaviruses in the Central Nervous System

Multiple sclerosis (MS) is a chronic disease of the CNS involving multifocal regions of inflammation and myelin destruction. Coronaviruses are one of the many infectious agents that have been proposed as causes for triggering MS and associated with demyelination in humans and rodents (Stohlman and Hinton, 2001). Coronavirus RNA and evidence of virus replication have been detected in the brains of humans and many human neural cell lines have been shown to support the replication of both OC43 and 229E types of HCoV. Murine hepatitis virus infection in mice and rats has long been a model for coronavirus-induced demyelination, although the exact mechanism(s) by which MHV induces demyelination and the role of the immune system in the pathology is not known. Inflammatory mediators, for example, interleukin 1 β , tumour necrosis factor, IL-6 and an MHV-induced immune response that cross-reacts with myelin proteins, have been proposed as possible mechanisms. Peripheral cross-reactive T-cell clones recognizing both HCoV and a myelin antigen have been detected in MS patients. It has also been hypothesized that HCoV RNA might sometimes lead to a low level of viral protein synthesis that could be involved in the stimulation of immune responses within the CNS, exacerbating the effect of coronaviral infection in MS patients (Arbour *et al.*, 2000). Persistent OPC43 and 229E infections have been established in some human neural cell lines.

Pathology and Pathogenesis

There are limited pathology data from patients infected with the non-SARS human coronaviruses because they have been generally mild and those rare instances of fatal disease have not been investigated at autopsy. There is a report of electron microscopic changes in the nasal mucosa of a child with coronavirus infection. There was minimal cytopathology but evidence of active virus replication with virus particles seen within cytoplasmic vesicles and the Golgi apparatus (Afzelius, 1994).

Severe Acute Respiratory Syndrome

Although the major adverse pathology was on the respiratory tract, SARS was a disseminated infection with virus being isolated from the upper respiratory tract, the lungs, faeces and urine (Chan *et al.*, 2004) and with reverse transcription polymerase chain reaction (RT-PCR) evidence of viral RNA in the plasma and serum (Ng *et al.*, 2003). Viral RNA has also been detected in the lymph nodes, spleen, liver, heart, kidney and skeletal muscle (Farcas *et al.*, 2005). Autopsy findings in the patients who died in the first 10 days of illness revealed diffuse alveolar damage, air-space oedema, desquamation of pneumocytes, inflammatory infiltrate and hyaline membrane formation (Franks *et al.*, 2003; Nicholls *et al.*, 2003). Virus antigen was detectable by immunohistochemistry in alveolar epithelial cells and also in macrophages and bronchial epithelium within the first 10 days of illness but rarely after that (Nicholls *et al.*, 2006). This correlates with *in vitro* studies showing that SARS-CoV replicates in differentiated type 2 alveolar epithelium and in ciliated cells in primary human airway epithelium but not in undifferentiated alveolar epithelial cell lines such as A549 (Mossel *et al.*, 2007; Sims *et al.*, 2005). Intestinal epithelial cells had viral particles demonstrable by electron microscopy with no obvious cytopathology and this is consistent with the watery diarrhoea observed clinically (Leung *et al.*, 2003).

Patients with SARS had high serum levels of a range of pro-inflammatory chemokines (IL-8, CCL2, CXCL10) and cytokines (IL-1, IL-6) (Wong *et al.*, 2004) and these same immune mediators were elicited from virus-infected macrophages *in vitro* (Cheung *et al.*, 2005). It is not clear whether these mediators are a reflection of the severe tissue damage or are contributing to the exacerbation of pathology induced by the virus.

Genetic polymorphisms associated with susceptibility to SARS have been identified. Two independent studies have reported an increased susceptibility to SARS associated with low serum levels of mannose-binding lectin (MBL) and that MBL neutralizes the infectivity

of SARS-CoV *in vitro* (Ip *et al.*, 2005; Zhang *et al.*, 2005). Although other genetic polymorphisms have also been reported to be associated with SARS (HLA-B*4601; HLA-B*0707, ICAM-3, CLEC4M), they have not been independently confirmed.

DIAGNOSIS

Diagnosis of HCoV infections was not routinely done in most diagnostic virus laboratories in the past because these viruses are not readily culturable *in vitro* and well-standardized reagents for immunological detection were not available. Antigen-capture ELISAs have been used to detect HCoV antigens in nasal and throat swabs, and nasopharyngeal aspirates, and to detect HTVs in stools (Koopmans *et al.*, 1997). Furthermore, the human coronaviruses 229E and OC43 were considered nothing more than the cause of the 'common cold'. The discovery of SARS and other novel human coronaviruses, the realization that human coronaviruses can cause clinically significant disease and the more widespread use of PCR or molecular diagnostics in clinical virology laboratories is leading to a reassessment.

The specimens for diagnosis of coronavirus infections are typically respiratory specimens (nasopharyngeal aspirates, nasopharyngeal swabs, throat and nose swabs and, when available, bronchoalveolar lavages) and paired sera for seroconversion when appropriate. In the case of SARS, viral RNA was also detectable in faecal specimens and in serum. HKU1 has also been detected by RT-PCR in faeces.

It is notable that the discovery of a novel coronavirus as the cause of SARS relied heavily on the classical virological techniques of virus isolation and electron microscopy, subsequently followed by molecular diagnostics and genome sequencing (Drosten *et al.*, 2003; Ksiazek *et al.*, 2003; Peiris *et al.*, 2003b). The use of virus detection microarrays also independently identified the cell culture isolate as a coronavirus (Wang *et al.*, 2003). Initial partial sequence information was obtained using random primer-based RT-PCR (Drosten *et al.*, 2003; Peiris *et al.*, 2003b) and by consensus primer RT-PCR methods (Ksiazek *et al.*, 2003). The discovery of the new human coronavirus NL63 was achieved by virus isolation followed by a novel approach VIDISCA (virus discovery based on cDNA-AFLP) to identify the virus isolate by deriving fragments of genetic sequence (van der Hoek *et al.*, 2004). HKU1 and novel bat coronaviruses were discovered using consensus primer RT-PCR methods (Poon *et al.*, 2005a; Woo *et al.*, 2005a). Virus detection microarrays are likely to be a strategy of the future (Kistler *et al.*, 2007).

Virus Isolation

HCoV-OC43 and related strains were considerably more difficult to propagate in cell culture than HCoV-229E-related strains and required the use of organ cultures, hence the letters 'OC'. Now, however, cell lines are available for the propagation of both laboratory-adapted HCoV types, although primary isolation remains difficult. 229E and related strains can be isolated in roller culture monolayers of human embryonic lung fibroblasts such as W138 and MRC5 cells and the human embryonic intestinal fibroblast cell MA177. In virus-positive cultures, a gradual cytopathic effect consisting of small, granular, round cells appears throughout the monolayers, especially around the periphery of the monolayers. However, cell sheets are rarely destroyed completely on initial isolation (Myint, 1995).

Vero E6 cells and fetal rhesus kidney cells have been used for the isolation of SARS-CoV (Drosten *et al.*, 2003; Ksiazek *et al.*, 2003; Peiris *et al.*, 2003b). Passage of SARS-CoV in cells leads to the emergence of amino acid substitutions in the spike and M genes related to adaptation to the host cells (Poon *et al.*, 2005b).

HCoV-NL63 can be cultured in tertiary monkey kidney cells and in LLC-MK2 cells. HCoV-HKU1 is difficult to grow but has been isolated in HuH7 cells (Vabret *et al.*, 2006). Human torovirus has not been grown *in vitro*.

Electron Microscopy

Electron microscopy is not routinely used for diagnosis of HCoV causing respiratory disease although it has been sometimes used to detect HCoVs in epithelial cells shed from the nasopharynx of patients after attempted isolation in cell culture (229E strains, SARS-CoV) and organ culture (OC43 type). Immune electron microscopy has been used with convalescent sera from patients.

Enteric HCoVs and HTVs have also been sought in faeces using electron and immune electron microscopy (Duckmanton *et al.*, 1997). The two types of virus are of similar size. HTVs are pleomorphic, sometimes exhibiting a torus (doughnut) appearance and an irregular rod shape. The spikes of coronaviruses, and possibly of toroviruses, are not always clearly revealed by negative staining. Thus the two viruses can be confused if electron microscopy alone is used; corroborative evidence is required (Cornelissen *et al.*, 1998).

Serology

Complement fixation, enzyme immunoassay, immunofluorescence or neutralization tests have been used for serodiagnosis of coronaviruses (Myint, 1995). Immunofluorescence tests on virus-infected cells fixed

in ice cold acetone or virus neutralization tests were used for detecting seroconversion to SARS-CoV and for seroepidemiological studies. Neutralizing antibodies against SARS-CoV peak at around four months after disease onset and decline gradually thereafter. Around 16% of survivors had undetectable levels of neutralizing antibody three years later (Cao *et al.*, 2007). There may be cross-reactions in other serological tests. For instance, immunofluorescent antibody responses to SARS-CoV appear to be associated with anamnestic responses to other human coronaviruses (OC43, 229E) although the converse was not true, possibly because there was no prior immunological memory to SARS-CoV to give rise to the anamnestic responses (Chan *et al.*, 2005). ELISA assays using recombinant nucleocapsid antigens have been described, but positive results must be confirmed by immunofluorescence or microneutralization tests (Woo *et al.*, 2004).

HTV purified from the stool of a patient was used in a haemagglutination-inhibition assay to detect antibodies to HTV in nosocomial cases of gastroenteritis; acute and convalescent sera were examined, revealing rises in antibody titres (Jamieson *et al.*, 1998). Bovine antisera to BTV cross-reacted with the human toroviruses, showing that BTV antisera could be used for human diagnostic purposes. Human convalescent HTV serum reacted with the HE protein of BTV in western blots.

RT-PCR

RT-PCR assays are increasingly used for the diagnosis of respiratory viruses, including coronaviruses (Vabret *et al.*, 2001). Given the limited sequence data available on 229E and OC43, as well as prototype viruses isolated many years ago, it is possible that the incidence of these viruses is underestimated through primers not detecting variant strains. This situation will improve with the availability of more virus sequence data. The design of consensus primers that potentially detect viruses within the coronavirus genus has been useful in our hands. Modifications based on the primers reported by Ksiazek (Ksiazek *et al.*, 2003; Stephensen *et al.*, 1999) targeted at ORF1b appear to perform well, although they are not as sensitive as virus-specific primers for directly detecting HCoV in clinical specimens (Chiu *et al.*, 2005; Poon *et al.*, 2005a).

The application of PCR technology for the detection of HTVs awaits gene sequence data.

Microarray Analysis

Viral microarrays that detect a wide range of known and unknown viral pathogens are being used to identify

pathogens in clinical specimens. These are providing a better insight into the global viral flora present in health and disease and also leading to the detection of novel pathogens (Kistler *et al.*, 2007; Quan *et al.*, 2007; Wang *et al.*, 2002). However, as with PCR-based methods, it is important to have relevant age-matched controls in these studies to be able to interpret the clinical significance of such findings.

PROPHYLAXIS: ACTIVE AND PASSIVE IMMUNIZATION

Active Immunization

There are no vaccines for the group 1 and 2 HCoV, but following the SARS outbreak in 2003 there has been interest in developing a vaccine for SARS. There have been coronavirus vaccines for veterinary use, but they have had limited success and it is perhaps relevant to learn from the successes and limitation of these veterinary vaccines. They have been developed against three group 1 coronaviruses – TGEV, FCoV and CCoV – and the group 3 coronavirus IBV. With the possible exception of IBV vaccines, the coronavirus vaccines have been only marginally effective in the field (Saif, 2005). Live vaccines have been more effective than killed vaccines for TGEV in pigs and IBV in chickens. Serum neutralizing antibodies generally fail to correlate with protection but immunoglobulin A (IgA) antibody in the colostrum is a better correlate of protection against TGEV. For TGEV and IBV, priming with a live attenuated vaccine and boosting with a killed vaccine led to increased mucosal immunity. Vaccinating cats with FCoV vaccines actually led to enhanced disease with the antibody to the spike leading to immunopathology (Olsen, 1993). Vaccines for IBV in chicken are widely used but antigenic variability of the virus poses a challenge because cross-immunity is generally poor (Cavanagh and Naqi, 2003).

Work towards a vaccine for SARS has been reviewed (Cheng *et al.*, 2007; Gillim-Ross and Subbarao, 2006). Experimental challenge studies in mice immunized with DNA vaccines and the use of adoptive transfer and T-cell deletion established that antibodies rather than T cells are the key effectors of vaccine-mediated immune protection (Subbarao *et al.*, 2004). A range of vaccine strategies including the use of inactivated whole virus vaccines, subunit vaccines (including baculovirus-expressed S1 subdomain, trimeric spike protein expressed in mammalian cells), DNA vaccines expressing the spike, the N, M or E proteins, vectored vaccines based on modified vaccinia Ankara (MVA) virus, vesicular stomatitis virus, parainfluenza type 3 or adenovirus vectors, have been

evaluated. An attenuated parainfluenza virus 3 vector individually expressing SARS-CoV spike, E, M and N proteins showed that only the recombinants expressing spike protein were effective in inducing neutralizing antibodies and protecting hamsters from experimental challenge (Buchholz *et al.*, 2004).

Induction of neutralizing antibody responses and, where relevant, T cell responses, were measured. Some of these experimental vaccines have been evaluated in experimental animal models with challenge using infectious SARS-CoV. Experimental challenge of vaccinated animals did not convincingly reveal evidence of immune-mediated disease enhancement, as has been seen with FCoV. As SARS is no longer circulating in the human population, there has been little incentive to take these experimental vaccines to human clinical trials.

These vaccines have all been prepared using the human SARS-CoV. However, it is likely that a re-emergent SARS will arise from re-adaptation of a precursor virus from the animal reservoir. As none of these bat or civet SARS-like CoVs can be cultured *in vitro*, cross-protection of these vaccines against the wild-type animal precursor viruses has not been tested. However, reverse genetics has allowed the reconstruction of animal (civet-like) SARS-CoV and these viruses are less efficiently neutralized by human convalescent antisera to SARS-CoV (Rockx *et al.*, 2007). This possibly reflects that fact that, while the receptor-binding domain is the major SARS-CoV neutralization determinant (Yi *et al.*, 2005), the SARS-CoV from civets does not efficiently bind the human ACE2 receptor. This raises questions whether a vaccine developed against the human SARS-CoV will be effective in protection against a future re-emergent animal SARS-like CoV. More recently, human monoclonals that neutralize both SARS-CoV as well as GDO3 and civet viruses SZ3 and SZ16 have been reported (Zhu *et al.*, 2007). While this provides evidence of the existence of antibody paratopes that will cross-neutralize both human and closely related animal precursors, this does not imply that many of the vaccine strategies used hitherto will predominantly induce antibody to such conserved protective epitopes.

Passive Immunization

Passive immunization with human monoclonal antibodies to the SARS-CoV spike protein have been successful in protecting mice and ferrets from challenge with SARS-CoV (ter Meulen *et al.*, 2004). While some of these monoclonal antibodies failed to cross-neutralize closely related animal viruses, antibodies that cross-neutralize SARS-CoV and strains of civet origin are now available and protect mice from challenge with reconstructed viruses with spike protein that represents both human and

civet viruses (Rockx *et al.*, 2007, 2008). Pools of such antibodies have promise for passive immunization and also perhaps for immunotherapy of patients with SARS-like disease.

THERAPY

Notwithstanding research in this area, antiviral drugs are not currently in use for control of the 'common cold' or other respiratory manifestations caused by HCoV. SARS was a severe pneumonia caused by what was initially an unknown pathogen and the global spread of the disease was contained in a relatively short period of time. As such, there are no controlled clinical trial data on which to base treatment recommendations. Clinical management of SARS is primarily supportive care. Since SARS has no pathognomonic features and presents as a community-acquired pneumonia, appropriate antimicrobial coverage should be given until the diagnosis of SARS is virologically confirmed, at which point antimicrobials could be stopped unless there is reason to suspect secondary bacterial complications.

Initially, given the lack of knowledge of the causative virus or its antiviral susceptibility, ribavirin was used as a broad-spectrum antiviral therapeutic option for SARS. Subsequently there were contradictory results on the *in vitro* antiviral susceptibility of SARS-CoV to ribavirin (Morgenstern *et al.*, 2005; Tan *et al.*, 2004). The discrepant findings may be related to the cell lines used (Vero, Caco-2, pig kidney cells). Interferon (IFN)- α 1, IFN- α 3, leukocytic iIFN and IFN- β have evidence of antiviral effect *in vitro*. The HIV protease inhibitor nelfinavir and a number of other compounds, including glycyrrhizin, baicalin and chloroquine, ACE2 analogues, antiviral peptides targeting the heptad repeat region 2 of the S2 subunit of the spike protein and small interfering RNA (siRNA) have been shown to have antiviral effects *in vitro* (reviewed in (Cheng *et al.*, 2007; Haagmans and Osterhaus, 2006). Some of these compounds have been tested in experimentally infected animals. Pegylated IFN- α significantly reduced lung virus titres in cynomolgus macaques (Haagmans *et al.*, 2004). Interferon- α BD at higher doses and the IFN inducer Ampligen (poly(I):poly(C)) inhibited virus replication in BALB/c mice but nelfinavir, chloroquine and ribavirin did not (Barnard *et al.*, 2006a, 2006b).

Clinical data have suggested that the use of the recombinant consensus IFN- α preparation alfacon-1 together with corticosteroids (Loutfy *et al.*, 2003) and that the use of the protease inhibitor nelfinavir/lopinavir together with ribavirin (Chu *et al.*, 2004a) appears to improve clinical outcome compared to historical controls. Passive

immunotherapy with convalescent plasma containing high neutralizing antibody titres to SARS-CoV was used in some patients with no adverse effects and perhaps some clinical benefit in comparison to historical controls (Cheng *et al.*, 2005). However, these were not controlled clinical trials and the use of historical controls may be misleading.

Immunomodulators including corticosteroid therapy were used in patients with SARS in view of their previous use in acute respiratory distress syndrome. There is, however, no documented evidence of clinical benefit and they may increase viral load in the plasma (Lee *et al.*, 2004) and increase the risk of adverse effects, including avascular necrosis of bone.

In summary, the IFNs appear to be the only class of antiviral agents that has evidence of *in vitro* activity and efficacy in experimental animal models.

ACKNOWLEDGEMENTS

We acknowledge the contribution of Dr David Cavanagh whose chapter in the previous edition of this book formed the basis of the present revision and update. We acknowledge research funding from the National Institutes of Health (NIAID contract HHSN266200700005C) and through a Special Research Achievement Award from The University of Hong Kong to JSMP.

Measles Virus

Sibylle Schneider-Schaulies and Volker ter Meulen

Department of Virology and Immunobiology, University of Würzburg, Würzburg, Germany

INTRODUCTION

Acute measles is normally a mild disease contracted by children and young adults as a result of infection by the highly contagious measles virus (MV) (ter Meulen and Billeter, 1995). MV is an efficient pathogen, persisting in nature in populations large enough to support it, even though it causes an acute infection in any individual only once in a lifetime. Despite this, the virus is distributed worldwide and is antigenically stable. With the advent of molecular epidemiology, however, the existence of MV genotypes has been confirmed. MV has no animal reservoir, and although monkeys are susceptible to infection, transmission from animals is not an important means of introducing the disease into a human community. MV may persist for years in a single individual, yet these infections are rare and not associated with periodic shedding of infectious virus as seen with herpesviruses. A single attack of measles is sufficient to confer lifelong immunity to clinical disease upon reinfection, even in the absence of re-exposure to the virus. Consequently, in order to remain endemic in a given community, the virus must rely on the infection of the young who are still susceptible. So efficient is the process that the first known report of measles (in Egyptian hieroglyphics) failed to recognize the infectious nature of the illness, and described it as a normal part of child growth and development.

In the pre-vaccine era in developed countries the maximum incidence of measles was seen in children aged five to nine years. Infections and epidemics centred around elementary schools, and younger children acquired measles as secondary cases from their school-age siblings. By the age of 20, approximately 99% of subjects tested had been exposed to MV. With the introduction of the measles vaccine the age incidence and percentage of cases in

different age groups has changed markedly. In countries with an optimal vaccine utilization, measles infection has shifted to the teenage group, whereas in areas with ineffective vaccine programmes children up to four years of age reveal a high primary measles attack rate (Centers for Disease Control and Prevention, 1991, 1996). In contrast, in developing countries measles has its greatest incidence in children under two years of age. Here, case fatality rates range from 1 to 5% and can reach 30% in refugee camps and comparable settings, with malnourishment, crowding and intensity of exposure being major determinants of severity and mortality (Moss, 2007). Although a safe and efficient vaccine has been available for over four decades, measles still is a leading cause of death for young children. The Measles Initiative, a partnership between the World Health Organization (WHO), the United Nations, the US Centers for Disease Control and Prevention (CDC), the American Red Cross and other organizations, was launched in 2001 and has since been developing and implementing comprehensive strategies for sustainable measles mortality reduction. As a result, measles deaths worldwide fell from an estimated 873 000 (1999) to 345 000 in 2005 (Wolfson *et al.*, 2007; www.measlesinitiative.org/index3.asp).

THE VIRUS

Although measles has been known for centuries, it was only with the isolation of the virus by Enders and Peebles in 1954 that experimentation became possible. The development of tissue culture systems, the availability of monoclonal antibodies and molecular biological approaches then permitted insight into viral structure and replication. Functional studies on MV control regions and

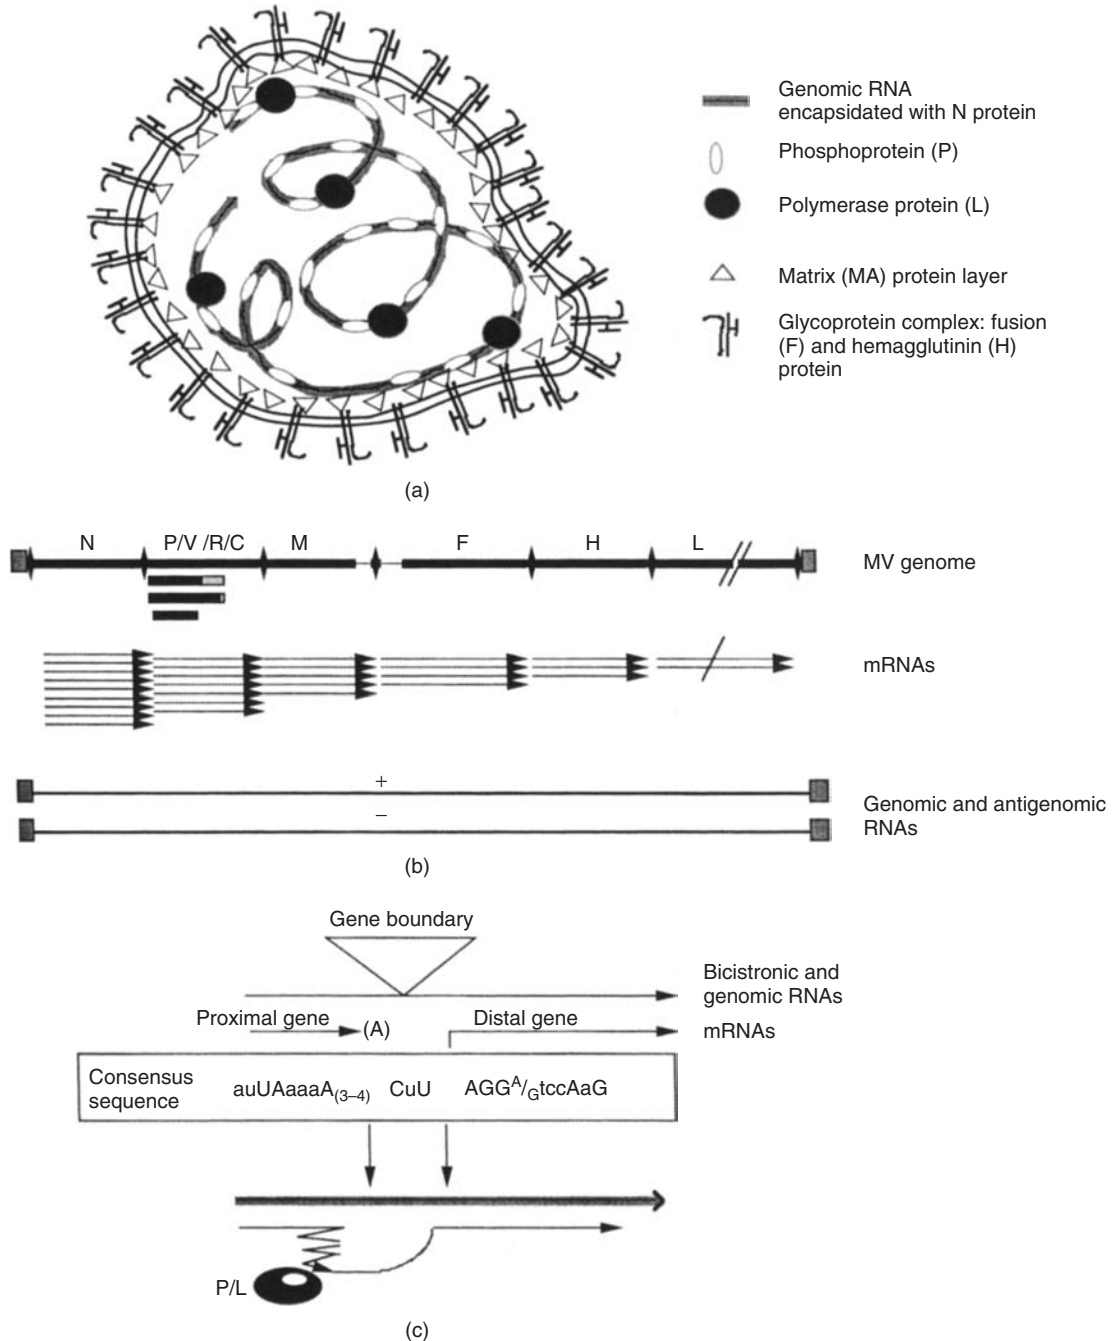

Figure 22.1 (a) Diagrammatic representation of the measles virus particle. (b) MV mRNAs are sequentially transcribed from the genome with decreasing efficiency and encode the structural proteins. In addition, the second gene (the P gene) encodes three nonstructural viral proteins C, R and V. (c) At the gene boundaries, MV genes are separated by conserved intergenic regions where the polymerase complex stutters to polyadenylate the proximal mRNA to subsequently reinitiate transcription of the downstream gene. Alternatively, these signals are neglected by the polymerase when bi- or polycistronic mRNAs are transcribed as well as during genome replication.

proteins extensively benefited from the establishment of a plasmid-driven reverse genetic system which allowed construction and rescue of infectious MVs in tissue culture that carry stable alterations in their genomes (Radecke *et al.*, 1995). Thus, within limitations imposed by the fitness of the mutated recombinant virus, the contribution of single viral gene products within the viral life cycle in tissue culture, but also in experimental infection in animals can be addressed. Meanwhile, a plethora of recombinant MVs have been generated, expressing extra reading frames such as fluorescent or enzymatically active marker genes, which allow tracing of viral replication after experimental infection, and cytokine genes. Moreover, targeted interaction of recombinant MV with its natural or other, desired host cell receptors has been widely studied to gain insight into basic determinants of viral tropism, but also for potential application of systemic, targeted delivery in cytoreductive regimens for malignancies (Iankov *et al.*, 2007). The use of recombinant MV carrying heterologous viral genes (e.g. simian immunodeficiency virus (SIV) or human immunodeficiency virus (HIV) genes) as multivalent vectors for immunization has been explored, although this has been limited to animal studies so far (Tangy and Naim, 2005; Zuniga *et al.*, 2007).

MV is a member of the *Mononegavirales* which comprises the *Rhabdoviridae*, *Filoviridae*, *Henipaviridae*, *Bornaviridae* and *Paramyxoviridae*. As a paramyxovirus, MV has structural and biochemical features associated with this group, but because it lacks a virion-associated neuraminidase activity it is grouped into a separate genus, *Morbillivirus*, of which *Measles virus* is the type species. Other members include: *Peste-des-petits-ruminants virus* (PPRV), which infects sheep and goats, *Rinderpest virus* (RPV), which infects cattle, *Canine distemper virus* (CDV), which infects dogs, *Phocine distemper virus* (PDV), which infects seals and sea-lions, *Dolphin morbillivirus* (DMV) and *Porpoise morbillivirus* (PMV). All these viruses exhibit antigenic similarities, and all produce similar diseases in their host species. Both MV and CDV can persist in the central nervous system (CNS) in their natural hosts and produce chronic neurological diseases.

VIRUS MORPHOLOGY

Measles virus particles consist of a lipid envelope surrounding the viral ribonucleoprotein (RNP) complex, which is composed of genomic RNA associated with proteins (Figure 22.1a). The MV transmembrane fusion (F) and haemagglutinin (H) proteins project from the envelope surface of the particle, extend through the lipid bilayer into the cytosol. It is the N-terminus of the H

protein that protrudes through the cytoplasmic and viral membranes (type II glycoprotein), while the F protein is anchored near the C-terminus (type I glycoprotein). One or both of the cytoplasmic domains are believed to interact physically and functionally with the matrix (M) protein (Tahara *et al.*, 2007), which, in turn, links the envelope to the RNP core structure. The viral genomic RNA is fully condensed with N (nucleocapsid) protein to form the RNase-resistant RNP core structure. *In vitro* experimentation suggests that the virion is able to package more than one genome as long as the 'rule of six' (see below) is maintained (Rager *et al.*, 2002). As the viral genome cannot serve as mRNA, the viral polymerase complex consisting of the P (phospho-) and L (large) proteins is part of the RNP core. Their location within this complex is as yet unknown, as is that of cellular actin, known to be also packaged into the virion structure. The virions are highly pleomorphic, with an average size of 120–250 nm. In an electron micrograph the virion is bounded by a lipid envelope which bears a fringe of spike-like projections (peplomers) 5–8 nm long (Figure 22.2a). The membrane below the spikes is 10–20 nm thick and encloses the helical viral RNP core which has a diameter of 17 nm and a regular pitch of 5 nm. Immediately below the membrane M proteins appear as a shell of electron-dense material.

GENOME STRUCTURE

The viral genome is a nonsegmented RNA molecule of negative polarity that is about 16 kb in length. The genome encodes six structural genes for which the reading frames are arranged linearly and without overlap in the following order: 3' nucleoprotein (N, 60 kDa), phosphoprotein (P, 70 kDa), matrix protein (M, 37 kDa), fusion protein (F, disulfide-linked 41 kDa F₁ and 22 kDa F₂ proteins, cleavage products of a 60 kDa precursor F₀ protein), haemagglutinin protein (H, 80 kDa, existing as disulfide-linked homodimer) and the large protein (L, 220 kDa) encoded on its 5' end (Figure 22.1b) (Rima *et al.*, 1986). The genome is flanked by noncoding 3' leader and 5' trailer sequences that contain specific encapsidation signals and the viral promoters used for viral transcription and/or replication (Parks *et al.*, 2001). The genomic RNA molecule is entirely complexed with N protein with one N molecule covering six nucleotides. This is thought to be the reason why only viral genomes (also including recombinant MVs carrying extra transcription units) whose number of nucleotides is a multimer of six are efficiently replicated by the viral polymerase. Transcription of the viral monocistronic mRNAs is initiated within the 3' leader sequence. The coding regions of the viral genome are separated by

(a)

(b)

Figure 22.2 (a) Electron micrograph of the measles virion (bar = 50 nm). (b) Electron micrograph of purified MV nucleocapsids (bar = 50 nm); both are negatively stained with phosphotungstic acid. (Source: Reproduced with permission from Meadeley, C.R. (1973) *Virus Morphology*, Churchill Livingstone, Edinburgh.)

intergenic regions which consist of a polyadenylation signal at the 3' of each gene, a trinucleotide (CUU, except for CGU at the H/L gene boundary) and a reinitiation signal for the distal gene (Figure 22.1c) (Parks *et al.*, 2001). From the P gene, three nonstructural proteins, C (20 kDa), V (46 kDa) and R (46 kDa) are expressed. Whereas the C protein is encoded within a separate reading frame, V protein is translated from edited P mRNAs where a non-encoded G residue is co-transcriptionally inserted at a particular site by an intrinsic activity of the MV polymerase. It thus shares the N-terminal domain with P protein, yet has a unique cysteine-rich C-terminal domain. About 50% (to yield V protein) of the P mRNAs are edited. At the M-F gene boundary a GC-rich region of about 1 kb in length spans the 3' end of the M gene and the 5' end of the F gene. Several open reading frames have been predicted for this region which could only be accessed by translation from a bicistronic transcript by ribosomal reinitiation. None of the putatively encoded proteins has yet been detected in infected cells.

MV PROTEIN FUNCTIONS

The Viral RNP and Nonstructural Proteins

The fully encapsidated MV genomic RNA serves as a unique target for the viral polymerase to initiate transcription and replication. The N protein, which is phosphorylated at serine and threonine residues, is the most abundant of the MV proteins and acts to condense the viral genomic RNAs into a smaller, more stable and more readily packaged form. This gives the nucleocapsid its helical form and 'herringbone' appearance in the electron micrograph (Figure 22.2b). When expressed in the absence of viral RNA, N proteins self-aggregate into nuclear and cytoplasmic nucleocapsid-like structures. The N-terminal 398 amino acids are important for self-aggregation and RNA interaction, while the C-terminal 125 amino acids protrude from the nucleocapsid. This particular domain reveals an intrinsically disordered structure (Longhi *et al.*, 2003) and interacts with cellular proteins such as Hsp72 and IRF-3. It is by formation of high-affinity protein complexes with the phosphorylated P protein, that self-aggregation and nuclear localization of N proteins are prevented during replication of the viral genome. Similar, interaction with the P protein is essential for folding of the C-terminal domain of the N protein (Johansson *et al.*, 2003). Both the C-terminal and N-terminal domains of P protein are important for N/P complex formation, while another C-terminal motif is essential for oligomerization of the P protein. Phosphorylation on serine residues is crucial for its polymerase cofactor activity in transcription and replication. Stable complexes between P and L are equally

important for these processes. The L protein is a multi-functional RNP-specific RNA polymerase producing mRNAs, replicative intermediates and progeny viral genomic RNAs. Capping, methylation, editing and polyadenylation are thought to be mediated by the polymerase protein in addition to initiating, elongating and terminating ribonucleotide polymerization. Active sites within the protein have not yet been determined, but conserved motifs were identified which suggest a linear arrangement of the functional domains.

Although largely considered as typical cytosolic and nonstructural (such as V protein), C protein was found to shuttle between nucleus and cytoplasm and also to associate with viral particles (Devaux and Cattaneo, 2004; Nishie *et al.*, 2007). Recombinant MVs defective in either V or C protein functions apparently replicated well in tissue culture cells (Radecke and Billeter, 1996; Schneider *et al.*, 1997), yet there is evidence that these proteins regulate the efficiency of MV replication in primary cells or modulate both viral gene expression and induction of or sensitivity to the cellular interferon (IFN) response (Cruz *et al.*, 2006; Escoffier *et al.*, 1999; Nakatsu *et al.*, 2006; Palosaari *et al.*, 2003; Takeuchi *et al.*, 2003). More recently, P protein was found to inhibit IFN signalling as well (Devaux *et al.*, 2007). Not surprisingly, absence of V and C proteins affects MV virulence in animal models (Tober *et al.*, 1998; Valsamakis *et al.*, 1998).

The Envelope Proteins

The RNP core structure is enclosed by a lipid envelope which contains two glycosylated proteins on its external surface, the H and the F protein, which are organized as functional complexes. The H protein mediates binding to cellular receptors, the F protein causes fusion of viral and cell membrane at neutral pH. Both H and F protein are protease-sensitive and can be isolated by gentle detergent lysis of virions, although F protein tends to remain strongly associated with cellular actin. The tendency of spikes to aggregate most likely resides in the hydrophobic tail of each molecule, which normally serves as anchor in the lipid bilayer.

The H protein can be isolated as a tetrameric complex from the cell membrane and efficiently agglutinates red blood cells from sheep and monkeys, but not humans. Glycosylation occurs within a region of 70 amino acids, and is essential for haemadsorption, probably by stabilizing the highly complex tertiary structure of the protein. Analogous to that of its Newcastle disease virus (NDV) orthologue, the ectodomain of the MV H protein is thought to be organized into a membrane proximal stalk and a membrane distal globular head region composed of a six-wing propeller (Crennell *et al.*, 2000). Seven residues located within the globular head domain are

essential for oligomerization and folding of the H protein, and a cysteine residue in the stalk regions for formation of disulfide-linked dimers. In addition, amino acids involved in binding of the H protein to the MV receptors were identified. These, located in the ectodomain, include amongst others, residues 451, 481, 546 and 473–477 (Vongpunsawad *et al.*, 2004).

As revealed by transfection experiments, the H protein also exerts a helper function in F-mediated membrane fusion, probably by directing the fusion domain into the optimal distance to the target cell membrane and stabilizing the interaction. Synthesized as a precursor protein (F₀), F protein is cleaved in the Golgi compartment by subtilisin-like proteases to yield two disulfide-linked subunits, F₁ and F₂. Glycosylation of the F₀ precursor is an essential prerequisite for cleavage, and all the potential N-glycosylation sites reside within the F₂ subunit. Mutations of any of these sites affect cell surface transport, proteolytic cleavage, stability and fusogenic activity of the F protein. Indeed, the contribution of the F₂ subunit to MV fusion has been directly documented (Plempner and Compans, 2003). The F₁ subunit reveals an N-terminal stretch of hydrophobic residues (the fusion domain) and two amphipathic α -helical domains, one of which is adjacent to the fusion domain (HRA) and the other (containing a leucin-zipper motif) is next to the N-terminal of the transmembrane region (HRB). The fusogenic domain within the F₁ subunit is masked during intracellular transport by intramolecular folding, and this most likely prevents fusion of internal membranes (Doyle *et al.*, 2006). A central region mediates interaction with the H protein. Homo- and hetero-oligomerization of the glycoproteins occurs in the endoplasmic reticulum and both interaction strength and fusogenicity of the complex are influenced by their cytoplasmic tails, both independent and dependent of their interaction with the M protein (Plempner *et al.*, 2002). The fully processed F_{1/2} protein is incorporated into the cell membrane as an oligomer. In the intact virion the active site of each protein is presumably carried at the tip of the spike and orientated outwards, away from the hydrophobic tail and towards any possible target cell.

The M protein interacts with the viral RNP and with the plasma membrane. When expressed in the absence of other MV proteins, the protein promotes formation of virus-like particles confirming that, in analogy to its functional orthologues, it essentially triggers late steps in the viral life cycle such as assembly site and budding (Pohl *et al.*, 2007). Consequently, recombinant MVs carrying deletions within the M gene bud highly inefficiently. Physical interaction between M and other viral structural proteins has been difficult to demonstrate, however, M protein modulates the fusogenic activity of the F/H complex and interactions with the glycoprotein cytoplasmic

tails allow the M protein to co-segregate to the apical surface in polarized cells. A recombinant MV defective for the expression of the MV glycoproteins (expressing the glycoprotein of vesicular stomatitis virus instead) revealed the requirement of the MV glycoproteins for packaging the M protein into mature budding virions.

THE REPLICATION CYCLE

Measles Virus Receptor Usage and Tropism

One of the most important parameters determining viral tropism is the availability of specific surface receptors on susceptible cells. MV naturally only replicates in primate hosts. *In vivo* it reveals a pronounced tropism for cells of the haematopoietic lineage, but may, however, at later stages, also replicate in a variety of cell types as it does in tissue culture. Thus, the receptor would be expected to be expressed by most human cells both *in vivo* and *in vitro*. This is true for the first MV receptor identified, CD46 (Griffin and Bellini, 1996), which reveals a wide tissue distribution *in vivo*, and, notably, is expressed on monkey but not on human erythrocytes. Several isoforms of CD46 (due to alternative splicing of a precursor mRNA)

are expressed in a tissue-specific manner and all of them support MV uptake. CD46 contains four repetitive conserved subunits within its ectodomain, with the two most membrane distal being essential for binding of the MV H protein. The molecule's physiological ligand(s), complement components C3b/C4b, bind to membrane-proximal domains (Figure 22.3). As a member of the regulators of complement (RCA) gene family, CD46 is involved in protecting uninfected cells from complement-mediated lysis by recruiting the C3b/C4b components, thereby rendering them accessible to degradation by serum proteases. It is considered of pathogenic importance that CD46 is downregulated from the surface of infected cells or following interaction with MV H protein, as these cells are significantly less protected against complement-mediated lysis *in vitro* (Schneider-Schaulies *et al.*, 1995). The inability of certain MV strains, particularly those isolated and passaged exclusively on lymphocytes, to use CD46 as receptor soon indicated the existence of additional MV receptor(s), and this led to the identification of CD150 (also referred to as signalling lymphocyte activation molecule, SLAM), a CD2-like molecule of the Ig superfamily, as MV receptor (Tatsuo and Yanagi, 2002). CD150 is expressed by activated and memory T and B cells,

Figure 22.3 Schematic representation of CD46 (MCP, membrane cofactor protein) (left), the major protein receptor for attenuated MV strains. MV-binding sites are located within the short consensus repeat (SCR) domains 1 and 2, whereas complement components C3b/C4b bind to SCR 3 and 4, respectively. Proximal to the transmembrane domain, oligosaccharide-rich serine/threonine/proline (STP) domains are located. CD150, a member of the Ig superfamily, (right) is the receptor of all MV strains tested as yet. MV binding occurs at the membrane distal domain (the V domain). Glycosylation sites in the extracellular domains are indicated as are residues in the cytoplasmic domain identified as important for signalling.

and immature thymocytes, but not by freshly isolated monocytes and immature dendritic cells, where expression of this molecule is inducible. For monocytes, this can occur by interaction of the H protein of wild-type MV strains with Toll-like receptor 2 (TLR2), which itself does not serve as an entry receptor (Bieback *et al.*, 2002). As for CD46, the most membrane-distal portion of CD150, the V domain, is important for MV binding, and CD150 is also downregulated in response to infection or H protein interaction. CD150 supports entry of all MV strains known, yet its expression is confined to haematopoietic cells, and thus, alternative MV entry receptors should exist, promoting uptake of wild-type MV into cell types such as endothelial, epithelial (during acute measles) and brain cells (as prerequisite for CNS persistence) (Yanagi *et al.*, 2006).

The contribution of the MV receptors to MV tissue tropism and pathogenicity is not yet understood. Rodents genetically modified to express CD46 or CD150 are not susceptible to MV infection unless the virus is intrathecally applied. Most likely, as yet unknown intracellular factors efficiently restrict MV replication in rodent cells. Infection of brain cells *in vivo*, on the other hand, can occur independently of CD46 expression as documented in mice or rats after intracerebral infection with an attenuated, rodent brain adapted MV strain. In cotton rats which are susceptible to intranasal infection with both attenuated and wild-type MV strains (as revealed by virus isolation from peripheral blood mononuclear cells (PBMCs), development of interstitial pneumonia and immunosuppression) tissue distribution of potential CD150 and CD46 ortho-

logues has not been evaluated due to the lack of appropriate reagents. It has been shown, however, in these animals that infection with the wild-type MV strain or recombinant viruses expressing the wild-type MV H glycoprotein leads to preferential infection of secondary lymphoid tissues and pronounced immunosuppression. These findings lend strong support to the essential role of the interaction of the MV H protein with its receptors in MV pathogenesis *in vivo*.

Intracellular Replication

The time taken for MV replication in a host cell is variable and becomes shorter as the virus adapts to growth *in vitro*. For instance, the Edmonston strain replicates well in Vero cells, an African green monkey kidney cell line, where growth is complete within 6–8 hours and accompanied by effective inhibition of host cell macromolecular synthesis. Other strains, particularly freshly derived isolates, grow more slowly and replication times of 7–15 days are not uncommon. Such viruses often have very little inhibitory effect on the biosynthesis of the host cell. The origin and activation stage of the host cells also influence the efficiency of MV replication as does their ability to produce type I IFN or, in turn, the ability of the virus strain to prevent IFN production and/or signalling.

Following delivery of the viral RNP complex into the cytoplasm, viral transcription is initiated after specific attachment of the polymerase complex to the promoter located within the 3' end of the genome and progresses to the 5' end by transcribing mono- and bicistronic mRNAs (Figure 22.4). At each gene boundary, the polymerase complex resumes transcription of the distal

Figure 22.4 Schematic representation of the events occurring in measles virus replication.

gene or leaves the template. As a consequence, a polar gradient is established for the frequency of viral mRNAs with the N-specific mRNA being the most abundant and the L-specific mRNA the least represented (Figure 22.1b). At the 3' end of each gene, poly(A) tracts are added to the mRNA transcripts, most probably by a polymerase stuttering mechanism at the termination signals (Figure 22.1c). Bi- and polycistronic polyadenylated transcripts spanning two or more adjacent genes are also produced. In the replication mode, the polymerase complex reads through the intergenic boundaries to yield a positive-sense replicative intermediate which is about 100-fold less abundant than that of negative polarity. Transcripts of positive polarity containing the encapsidation signal at their 5' end joined to the N gene sequence are indicative of antigenome replication. Replication of, but not primary transcription from viral genomic RNA is dependent on protein synthesis, and the switch to the replication mode is possibly determined by the accumulation levels of N protein that has to encapsidate the nascent genome and may act as an anti-terminating protein. Not surprisingly, expression and/or function of the L protein are currently targeted by RNA interference approaches or non-nucleoside inhibitors *in vitro* in order to exploit inhibition of the polymerase for therapy (White *et al.*, 2007).

The viral mRNAs direct the synthesis of viral proteins which are translocated and, in case of the glycoproteins, modified through the Golgi apparatus (acquisition of N-linked glycosylation and proteolytic cleavage of the F₀ protein) and finally inserted into the plasma membrane. The F protein associates preferentially with membrane microdomains (also referred to as lipid rafts) and most likely drags the H protein into these structures from where the virus subsequently buds. Nascent RNA genomes condense with N protein to form the nucleocapsid, and P and L proteins bind to these structures in the perinuclear area. Late in infection, nucleocapsids may also enter the cellular nucleus. M protein combines with both cytoplasmic nucleocapsids and plasma membrane resident virus glycoproteins, and possibly interacts with cytoskeletal components during intracellular transport of viral RNPs. Progeny nucleocapsid structures line up beneath these modified areas of the membrane and are pinched off in the budding process. The ability of M protein to aggregate in a crystalline array most likely enables distortion of the membrane into an outward-facing bulge, and ultimately budding of the nucleocapsid inside a small vesicular structure—the new virion (Figure 22.4). During the replication process the large amount of glycoprotein inserted into the cell membrane causes it to develop the capacity to attach to adjacent cells, while the F protein promotes fusion with adjacent cells. Multinucleate

giant cells are thus formed which are pathognomonic for measles infection. Host cells are rapidly killed by fusion, and if this is prevented both survival and virus production are increased.

BIOLOGICAL PROPERTIES OF THE MEASLES VIRUS

Stability

The structure of the virion explains much of the early data concerning the stability and infectivity of the virus, which depends on the integrity of the envelope. Hence the virus is sensitive to any procedure which disrupts this structure, such as detergents or other lipid solvents, including acetone or ether. Particles are acid labile and inactivated below pH 4.5, although they remain infective in the range pH 5–9. The virus is also thermolabile. It may remain infective for two weeks at 4 °C, but it is completely inactivated after 30 min at 56 °C. At 37 °C it has a half-life of 2 hours. Thermolability is probably due to an effect on the internal structure of the particle since haemagglutinin is relatively temperature-resistant. Virus can be stored for prolonged periods at –70 °C and also freeze-dries well. These properties have important consequences for the transport and storage of vaccine.

Haemagglutinin

MV displays haemagglutination activity for erythrocytes from rhesus, patas and African green monkeys and baboons, but not from humans. The H protein mediates attachment to susceptible cells, and consequently, the ability to cross-link erythrocytes which do not support virus replication represents an unnatural process in virus multiplication. Thus the inability to agglutinate erythrocytes from the primary host, which is based on the lack of the major MV receptor component CD46 on these cells, is not surprising. Morbilliviruses have no neuraminidase activity and do not attach to receptors containing sialic acid. Consequently, once attached to a red blood cell, MV does not re-elute rapidly.

H protein inserted into any membranous structure is active in the haemagglutination test. Virus particles separated by isopycnic centrifugation have a buoyant density of 1.23 g cm⁻³ and haemagglutination activity is detected in this area of the gradient. A large amount of haemagglutinating material is also found in the upper regions of the gradient (termed light haemagglutinin) which probably represents H protein inserted into empty membranous fragments of infected cells, or defective virus particles. Haemagglutinating activity in this fraction can exceed

that associated with the intact particles. Notably, MV wild-type strains isolated on B lymphoid cells and not adapted to grow on Vero cells have very low haemagglutination activity. This may be caused by the presence of an additional *N*-linked glycosylation site within their H proteins, but is best explained by their inability to interact with CD46 on monkey erythrocytes. H protein is the major immunogen of the virus, and antibodies directed against this protein have both haemagglutination inhibition (HAI) and virus-neutralizing activities (neutralizing test, NT). However, these antibodies cannot prevent the progressive viral cell-to-cell spread mediated by the F protein. The function of H protein as the major viral attachment protein and downregulation of host cell receptor(s) has already been outlined above. Moreover, receptor ligation by H protein can trigger signalling pathways in host cells, and this may relate to certain aspects of MV-induced immunosuppression (see below).

Haemolysis

The ability to lyse red blood cells once the virus has bound is mediated by the viral F protein. This ability is artificial in the same way that haemagglutination is artificial, since the F protein is not normally called upon to lyse a target cell before productive infection is accomplished. Nevertheless, haemolysis (HL) provides a convenient measure of F protein activity which is more sensitive to pH and temperature than haemagglutination. The optimum temperature for HL is 37°C and optimum pH is 7.4. The ability of paramyxoviruses to fuse at neutral pH accounts for their characteristic cytopathic effect (CPE), the formation of giant cells. Proteolytic activation of the F protein is vital for its activity; although uncleaved molecules can be inserted into mature virus particles, these do not fuse with target cells and are therefore not infectious. Insertion of the N-terminal hydrophobic fusion domain of the F₁ subunit is thought to have a destabilizing effect on the local structure of the target cell and synthetic peptides with similarity to this region but also those corresponding to the heptad repeat regions (which inhibit back-folding of the F₁ subunit into its fusion active conformation after MV receptor interaction) efficiently impair cell fusion. Antibodies directed against the F protein are required for effective containment of virus infection, which can be maintained locally by cell-to-cell fusion. Given the importance of this protein for cell entry, it is not surprising that structurally conserved microdomains within the F protein are exploited as potential target sites for rationally designed antiviral compounds (Plempner *et al.*, 2004, 2005; Sun *et al.*, 2006).

EPIDEMIOLOGY AND RELATEDNESS OF DIFFERENT VIRUS ISOLATES

The efficient spread of the virus is mediated by aerosol droplets and respiratory secretions, which can remain infectious for several hours. The disease incidence in the northern hemisphere tends to rise in winter and spring when lowered relative humidity would favour this form of transmission. In equatorial regions epidemics of measles are less marked but can occur in the hot dry season. Acquisition of the infection is via the upper respiratory tract, the nose and, possibly, the conjunctivae. Virus is also shed in the urine but this is unlikely to be an important means of transmission.

The spread of measles is a convenient example to illustrate the principles of epidemiology; based on calculations, any community of less than 500 000 is unlikely to have a high enough birth rate to supply the number of susceptible children required for the continuous maintenance of the virus in a population. In fact, complete elimination of measles from isolated groups has been documented; these remain free of the disease until MV is reintroduced from outside, and susceptible individuals are once more at risk. Measles often leads to a more serious disease in such communities experiencing the illness for the first time, because all age groups are susceptible to the infection. In general, measles mortality is highest in children under two years of age and in adults. Death from uncomplicated measles is rare in the developed world, yet introduction of the virus to the Fiji Islands in 1875 resulted in an epidemic with a fatality rate of 20–25% and into Greenland in 1951 produced an epidemic which infected 100% of susceptibles and resulted in a death rate of 18 per 1000.

MV isolates have been obtained from many different locations and from patients with different clinical conditions. In serological terms, the virus is monotypic and thus infection by any MV confers immunity to them all. With monoclonal antibodies, antigenic differences between vaccine and wild-type viruses can be observed, though these could not be linked to pathogenicity, replication or transmission. The monotypic nature of MV has masked the existence of a set of genotypes which accumulate mutations continuously. Extensive studies on the molecular epidemiology of MV failed to reveal the existence of MV strains with different pathogenic potential (lymphotropism and neurovirulence, the latter more likely to cause subacute sclerosing panencephalitis (SSPE)) or potential antigenic drift in wild-type MV strains that may impair the protective effect of the current vaccine. They have been highly instrumental in populations where mass vaccination campaigns have been undertaken, because they allow us to define whether any single measles case is due to an imported virus or represents a still inadequate

vaccine coverage or vaccine failure. Thus, in 1995, 60% of the 309 cases of measles reported in the United States were either directly imported or were found to be directly linked to an imported case by routine investigation or molecular epidemiology methods (Rota *et al.*, 1992).

Sequence analysis of vaccine and wild-type MV strains as well as SSPE isolates has allowed classification of these various MVs into lineage groups, referred to as 'clades' (numbered A–H), and within those, different genotypes can be distinguished. Genotyping of a given measles strain is based on the C-terminal 151-amino-acid sequence of the N protein, where up to 10.6% divergence in the amino acid sequence between unrelated strains can occur. For most of the recent isolates, the sequence of the H gene is also available. While some MV clades are more or less extinct (i.e. have not been isolated for at least 15 years), others are still co-circulating (see www.cdc.gov/ncidod/dvrd/revb/measles/index.htm). The activity within a clade is directly mirrored by the heterogeneity of genetically related recent isolates which are drifting on a genetic level. It is indicative of MV re-importation into regions where transmission of indigenous MV is interrupted that MVs of different, genetically unrelated genotypes are isolated during an outbreak. Genetic characterization of MV is a powerful adjunct to the standard epidemiological techniques applied to study measles transmission as it helps to confirm the sources of virus or suggest a source for unknown source cases, or to establish links, or lack thereof, between cases and outbreaks. Molecular surveillance is most beneficial in tracing local genotypic changes over time, and this, analysed in conjunction with standard epidemiological data, has helped to document the interruption of transmission of endemic measles and to measure the effectiveness of measles control programmes. MV vaccine strains (which all fall within clade A) differ widely from wild-type isolates, and SSPE-derived sequences were closely related to those of wild-type viruses. It was even possible to identify wild-type MVs that had circulated in a given population as likely infectious agents found later in SSPE brain material. In the late 1980s and early 1990s, re-importation of wild-type MV of a known genotype into the United States caused about 50 000 cases. In a recent study, seven cases of SSPE were noted which could clearly be assigned to the wild-type MV having caused the acute infection 10 years ago (Bellini *et al.*, 2005). These findings resulted in three important conclusions: first, SSPE develops more frequently than thought (Bellini *et al.*, 2005; Takasu *et al.*, 2003), second, SSPE develops after infection with a wild-type MV and not following vaccination, and third, circulating wild-type viruses and not particular neurotropic strains access the CNS. Thus, the development of complications is not determined by

the virus, but rather by the susceptibility, age and immune status of the host at the time of infection. The biological importance of the fact that all vaccine strains have a genotype substantially different from the currently co-circulating wild-type viruses is unclear. There is, however, no evidence to suggest that the currently used vaccines are not able to control MV infection with viruses of differing genotypes.

CLINICAL MANIFESTATIONS

Acute Measles

Measles was an inevitable disease of childhood prior to the vaccine era, and thus clinical features are well documented. The course of acute measles is illustrated diagrammatically in Figure 22.5. The virus first gains entry into the body through the upper respiratory tract or conjunctiva. Replication is assumed to occur at the site of entry. It is unknown as yet whether epithelial cells in the respiratory epithelium support MV replication, or if the first target cells are professional antigen-presenting cells (APCs) (such as monocytes or tissue-resident macrophages or dendritic cells) which acquire virus by CD150-dependent infection. Whether the interaction with DC-SIGN, a lectin receptor, shown *in vitro* supports entry of MV into dendritic cells (DCs) or internalization *in vivo* is unknown. APCs most likely mediate transport of MV to secondary lymphatics, where MV replicates and causes tissue destruction. The virus then spreads to the rest of the reticuloendothelial system and respiratory tract through the blood (primary viraemia). Giant cells containing inclusion bodies (Warthin–Finkeldy cells) are formed in lymphoid tissues and also on the epithelial surfaces of the trachea and bronchi.

About five days after the initial infection the virus overflows from the compartments in which it has previously been replicating, to infect the skin and viscera, kidney and bladder (secondary viraemia). Giant cells are formed in infected tissues, which are also characterized by lymphoid hyperplasia and inflammatory mononuclear cell infiltrates.

After 10–11 days incubation the patient enters the prodromal phase, which lasts from two to four days. The initial symptoms consist of fever, malaise, sneezing, rhinitis, congestion, conjunctivitis and cough, which increase over the next days and are quite troublesome. A transitory rash of urticarial or macular appearance can sometimes develop within the prodromal phase, but this disappears prior to the onset of the typical exanthem. At this time giant cells are present in the sputum, nasopharyngeal secretions and urinary sediment cells. Virus is present in blood and secretions, and the patient is highly infectious. During this period Koplik's spots, the

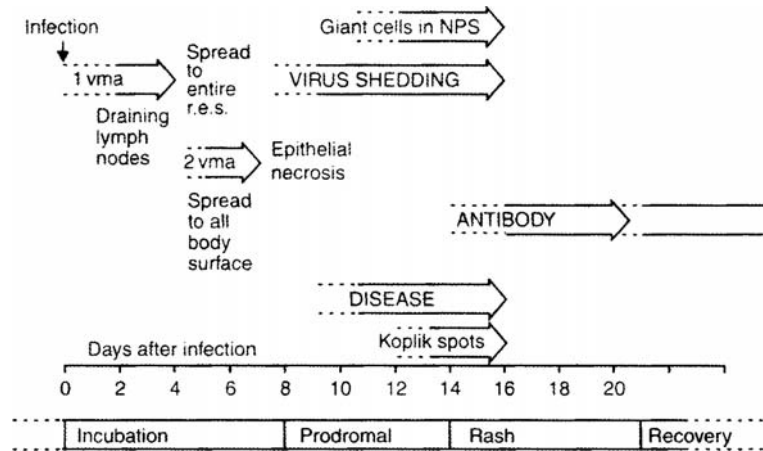

Figure 22.5 The course of clinical measles. The events occurring in the spread of the virus within the body are shown in the lower case lettering. As the virus spreads by primary and secondary viraemia (vma) from the lymph node to the entire reticuloendothelial system (r.e.s.) and finally to all body surfaces, epithelial cell necrosis occurs and disease. The characteristics of the disease are given in upper case lettering.

pathognomonic enanthem of measles, appear on the buccal and lower labial mucosa opposite the lower molars. These raised spots with white centres are characteristic of measles and begin to fade some two to four days after the onset of the prodromal phase as the rash develops. The distinctive rash appears about 14 days after exposure and starts behind the ears and on the forehead. From there the exanthem spreads within three days and involves the face, neck, trunk and upper and lower extremities. Once the entire body is covered, the rash fades on the third or fourth day and a brownish discoloration occurs, sometimes accompanied by a fine desquamation. Histologically, the rash is characterized by vascular congestion, oedema, epithelial necrosis and round cell infiltrates. Once the exanthem has reached its height, fever, conjunctivitis and respiratory symptoms subside. Antibody titres rise and virus shedding decreases from this point, and the patient shows a rapid improvement.

Continuation of clinical symptoms of the respiratory tract or fever suggests complications. In partially immunized children, such as infants with residual maternal antibodies, individuals who have received immune serum globulin or, occasionally, in the course of live vaccine failure, the disease follows a modified course. Then, the illness is generally mild and follows the regular sequence of events seen in acute measles yet with a very reduced symptomatology.

Atypical Measles

This condition is established after incomplete measles vaccination prior to exposure to wild-type MV. The

majority of reported cases received several doses of inactivated vaccine or a combination of inactivated vaccine followed by attenuated live vaccine. Because development of atypical measles was clearly linked to application of the formalin-inactivated vaccine, the latter was abandoned in the late 1960s. Since then, cases of atypical measles have not been reported and thus the disease has disappeared.

Atypical measles presented with sudden high fever, headache, abdominal pain and myalgia, often accompanied by a dry cough and a pleuritic chest. The rash spread, atypically, from the distal, often oedematous extremities, later became purpuric, vesicular or urticarial and involved the palms and soles with a prominent appearance on the wrists and ankles. The majority of cases developed pneumonia with a lobular or segmental appearance accompanied by pleural effusion resulting in respiratory distress with dyspnoea. Recovery from the pulmonary symptomatology was slow, and pulmonary lesions could sometimes be seen by X-ray months after onset of the disease. Marked hepatosplenomegaly, hyperaesthesia, numbness or paraesthesia were occasionally found. The pathogenesis of this disease is still not fully understood. Initially, production of inefficient F protein-specific antibodies unable to block viral spread by cell to cell fusion, possibly because the inactivation procedure changed the immunogenicity of the protein, was considered to be important. This hypothesis was largely dismissed based on findings in monkeys which, upon challenge with wild-type MV, produced F-specific antibodies with all biological properties even though they had been vaccinated with the killed vaccine. These animals developed a strong anamnestic humoral antibody response, although the antibodies were

preferentially of low avidity, complement-fixing and non-protective. Deposition of immune complexes in the lung and a pronounced eosinophilia was also noted (Polack *et al.*, 2003).

Complications of Measles Infection

Complications of acute measles are relatively rare, and result mainly from opportunistic secondary infection of necrotic surfaces such as those in the respiratory tract. Bacteria and other viruses can invade to cause pneumonia or other complications such as otitis media and bronchitis. The most severe complications caused directly by MV are giant cell pneumonia and measles inclusion body encephalitis (MIBE), which occur in the immunocompromised patient, and acute measles encephalitis (AMPE) and SSPE with no precipitating factors known. Other unusual manifestations that may complicate acute measles are myocarditis, pericarditis, hepatitis, appendicitis, mesenteric lymphadenitis and ileocolitis. If measles infection occurs during pregnancy spontaneous abortions, congenital malformations, stillbirth and low birth weight may occur.

Complications in the Immunocompromised

In immunocompromised patients, MV itself may lead directly to a life-threatening pneumonia (giant cell (Hecht) pneumonia) characterized by the formation of giant cells, squamous metaplasia of the bronchiolar epithelia and alveolar lung cell proliferation. Measles infection in such patients is thus a serious threat and is usually severe with a protracted course and frequently fatal. The same applies to MIBE which is, for instance, seen in children with leukaemia undergoing axial radiation therapy. The incubation period ranges from a few weeks to six months, and the patients often present without rash since generation of the latter requires an antiviral immune response. Clinically, the condition resembles and is therefore frequently confused with SSPE and commences with convulsions, mainly myoclonic jerks which are often focal and localized to one site. Other findings include hemiplegia, coma or stupor depending on the localization of the infectious disease process within the CNS. The disease progresses much faster than SSPE and proceeds to death within weeks or a few months. Furthermore, no or only low titres of measles antibodies are detectable in the cerebrospinal fluid (CSF). This kind of infection is probably best regarded as an opportunistic MV infection.

Complications in the Immunocompetent: Acute Measles Post-infectious Encephalitis

Acute encephalitis during measles is a severe complication that occurs at a frequency of about 1 per 1000 of

5000 cases. Although the figures vary among the available reports, fatality can be as high as 15%, and 20–40% of those who recover are left with lasting neurological sequelae. Encephalitis usually develops when exanthem is still present, but it can occasionally also occur during the prodromal stage. The encephalitis is characterized by resurgence of fever, headache, seizures, cerebellar ataxia and coma. In common with post-infectious encephalitis induced by other viruses, demyelination, perivascular cuffing, gliosis and the appearance of fat-laden macrophages near the blood vessel walls can be seen on histology. Petechial haemorrhages may be present and in some cases inclusion bodies have been observed in brain cells. CSF findings in measles encephalitis consist usually of mild pleocytosis and absence of measles antibodies. Long-term sequelae include selective brain damage with retardation, recurrent convulsive seizures, hemi- and paraplegia.

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a rare, fatal, slowly progressing degenerative disease of the brain. It is generally seen in children and young adults and follows measles after an interval of six to eight years, although SSPE cases have also occurred up to 20–30 years after primary infection. Boys are more likely to develop SSPE than girls, and, according to recent reports, the overall incidence is 1 case per 10⁴ cases of acute measles (Bellini *et al.*, 2005; Takasu *et al.*, 2003). No unusual features of the acute disease have ever been demonstrated and other factors are presumed important. Predisposing factors remain unknown, yet immaturity of the immune system upon primary infection may contribute since half of SSPE patients have contracted measles before the age of two years, which is a remarkably high figure considering the proportion of actual measles cases in these young children. Genetic factors may also play a role as indicated by high incidence of SSPE in Papua New Guinea (Takasu *et al.*, 2003) and recent reports on the occurrence of the disease in siblings (Tuxhorn, 2004; Vieker *et al.*, 2003).

The course of SSPE varies considerably, but usually starts with a generalized intellectual deterioration or psychological disturbance which may not be recognized as illness until more definite signs appear. These are neurological or motor dysfunctions and may take the form of dyspraxia, generalized convulsions, aphasia, visual disturbances or mild, repetitive simultaneous myoclonic jerks. In 75% of cases the invasion of the retina by the virus leads to a chorioretinitis, often affecting the macular area followed by blindness. Finally the disease proceeds to progressive cerebral degeneration leading to coma and death. The progression of the disease is variable, remissions are

common and some stages may overlap. The illness inevitably leads to death within one to three years, though this can also occur in a matter of months.

Neuropathological investigations reveal a diffuse encephalitis affecting both the white and grey matter, characterized by perivascular cuffing and diffuse lymphocytic infiltration. Glial cells may proliferate, and fibrous astrocytes, neurons and oligodendroglial cells contain intranuclear inclusion bodies which may occupy the entire nucleus. These, also referred to as Cowdry bodies, contain MV nucleocapsid structures. Giant cell formation or membrane changes consistent with virus maturation have not been observed. The neuropathological lesions lead to characteristic EEG changes consisting of periodic high-amplitude slow wave complexes which are synchronous with myoclonic jerks recurring at 3.5- to 20-second intervals. These periodic complexes (Radermecker) are remarkably stereotyped in that their form remains identical in any given lead. They are bilateral, usually synchronous and symmetrical. Moreover, they usually consist of two or more delta waves and are biphasic or polyphasic in appearance. The pathophysiology of this abnormal EEG pattern is as yet poorly understood, but most investigators regard these complexes in SSPE as characteristic and even pathognomic. It is noteworthy that this EEG pattern is variable within the course of the disease and from one patient to another. Moreover, these typical complexes may disappear as the disease progresses.

Another important and pathognomic finding is the state of hyperimmunity against MV as well as the prominent gammaglobulin increase in CSF. High measles antibody titres except against the M protein are present both in serum and CSF. The isotypes of MV-specific antibodies found in CSF include IgG, IgA and IgD, and in this compartment the immune response is of restricted heterogeneity. Isoelectric focusing experiments have indicated that it is oligoclonally restricted. This is thought to be due to a restricted number of antibody-secreting plasma cells that have migrated into the CNS and synthesize their antibodies there.

Osteitis Deformans and Otosclerosis

Viral-like nuclear and cytoplasmic inclusions that react with antibodies against paramyxoviruses, including MV, have been detected in multinucleated osteoclasts, in osteoblasts, osteocytes, fibroblasts and lymphomonocytes of patients with Paget's disease (Basle *et al.*, 1986). The mechanisms responsible for viral persistence are still unclear, particularly as the disease persists for many years and remains highly localized with new lesions rarely, if ever, developing in previously unaffected bones. One report describes successful amplification of MV N-specific transcripts from mononuclear cells and osteoclast-like

multinucleated cells formed in long-term bone marrow cultures, osteoclast precursors and PBMCs of patients but not of controls (Reddy *et al.*, 1996). Ultrastructural and immunohistochemical studies suggested the presence of MV-like structures and MV antigens and, by reverse transcriptase polymerase chain reaction (RT-PCR), MV N-specific transcripts in bone material from patients with otosclerosis, a disease that shares clinical and histopathological findings with Paget's disease (Arnold *et al.*, 1996). The aetiology of both Paget's disease and otosclerosis is largely unknown, and it is unclear whether detection of MV in bone tissue is of pathogenic significance or just an epiphenomenon.

THE PATHOGENESIS OF MEASLES AND ITS COMPLICATIONS

MV is a lymphotropic virus, and its interaction with the immune system is itself responsible for some of the key features of the disease. A delayed hypersensitivity reaction is implicated in the production of the rash, and could also be involved in the tissue damage observed in AMPE. Furthermore, its interaction with the immune system may be responsible for the modification of the disease process observed in SSPE.

MV pathogenesis is not easily assessed in animal models. As yet, only primates have been found permissive for MV following intranasal infection and develop clinical measles, whereas attempts to induce measles-like disease processes in small animals by this route have largely failed. Cotton rats reveal a certain permissivity to infection by the intranasal route. In addition, CNS infections can be experimentally induced by intracerebral MV infection in mice and rats and these have led to a better understanding of both virological and immunological parameters of MV-induced CNS diseases.

Acute Measles

Characteristic features are a pronounced lymphopenia and a defect in cell-mediated immunity (CMI), as demonstrated in tuberculin-positive individuals who become tuberculin negative. These effects result from virus interactions with cells of the lymphoid system. Following uptake, MV exhibits a pronounced lymphotropism, and replication is detected in the draining lymph nodes rather than at the site of entry. *In vitro*, replication of MV requires mitogen activation of lymphocytes, whereas the ability of monocytes to support productive replication is limited. *In vivo*, the virus remains mainly cell associated and can be isolated from lymphocytes in the early stages of infection, and this is greatly assisted if the cells are

(a)

(b)

(c)

mitogenically stimulated. Only a minor proportion of the patient's PBMCs are infected, and this includes B and T cells and monocytes. Particularly in late stages of the infection, MV is almost exclusively found in monocytes.

Following extensive replication in the lymphoid tissue, virus is spread through a secondary viraemia, and replication continues in the epithelia of the lung and buccal cavity. The epithelia of the respiratory tract and conjunctiva are relatively thin, with about one or two cell layers. These soon begin to break down, and inflammatory reactions lead to the symptoms which mark the onset of the prodromal phase –runny nose, conjunctivitis, malaise and fever. The thicker mucosal surfaces of the buccal cavity are then affected and Koplik's spots appear about 11 days after infection. The appearance of these spots marks the commencement of a delayed-type hypersensitivity reaction (DTH) similar to that which gives rise to the rash. The spots fade some three days after their appearance as the rash itself develops.

Unlike other sites of replication, virus antigen is absent from skin lesions themselves, but rather concentrated near blood vessels and in the endothelial cells of the dermal capillaries. The rash is characterized by vascular congestion, oedema, epithelial necrosis and round cell infiltration, but giant cells are absent. Virus replication does not break through the skin and virus is not shed from this surface. The containment of infection in the skin is thought to be due to the development of cytotoxic T cells which destroy infected tissue and to IFN production which acts to promote cellular resistance to infection. The rash itself results from accumulated damage to the vascular walls caused by this DTH, and is thus mostly not observed in the immunosuppressed. As a typical self-limiting infection, acute measles is controlled and lastly resolved by an efficient cellular immune response. The latter is highlighted by an early activation of a Th1-response which later shifts into a Th2-predominated profile. In addition, the importance of CD8⁺ T cells in controlling the acute infection has been directly demonstrated in experimentally infected rhesus monkeys (Permar *et al.*, 2003a). In support of the importance of T-cell responses in controlling

acute measles, patients with underlying T-cell deficiencies do not develop rash and develop severe complications, while those with agammaglobulinaemia handle measles normally and recover. Antibody titres are usually rising at this stage of the illness, yet are not thought to be the major factor in promoting recovery. MV-infected cells are lysed inefficiently by the classic pathway of the complement activation, although more so by the alternative pathway.

MV-induced Immunosuppression

At the same time as it triggers an efficient virus-specific immune response in the immunocompetent host leading to viral clearance and establishment of a lifelong immunity, measles infection causes a general suppression of responsiveness to other pathogens. This was recognized long before the virus was isolated and almost exclusively accounts for the high morbidity and mortality rates still associated with acute measles. Typically, the patients reveal a marked lymphopenia affecting both B and T cells and are highly susceptible to opportunistic infections. Mechanisms underlying lymphopenia are not entirely clear. Experimental studies suggest that MV may target CD34⁺ stem cells and/or induce thymocyte apoptosis (Manchester *et al.*, 2002), yet when directly analysed in patients, thymic output of lymphocytes was unaffected (Permar *et al.*, 2003b). Possibly, lymphocytes are lost due to viral infection which may initially proceed quite extensively. In addition, it has been proposed that activated T cells expressing high levels of lymphocyte function-associated antigen 1 (LFA-1) are preferentially lost from the peripheral blood due to aberrant homing to tissues. Immunosuppression, however, is still observed up to weeks after the onset of the rash when the lymphocyte counts have returned to normal and MV-infected cells are present with only low frequency or are no longer detectable.

Key features of MV-induced immunosuppression are inhibition of delayed-type hypersensitivity responses and a restricted ability of lymphocytes to proliferate in response to recall antigens, or allogenic and mitogenic stimulation (Figure 22.6a). As only a few infected cells are

Figure 22.6 (a) In the course of and following measles, both delayed-type hypersensitivity reactions (DTH) as measured by tuberculin test and *in vitro* proliferative responses of lymphocytes to mitogen stimulation are suppressed. (Source: Data from Tamashiro *et al.*, 1987 and Hirsch *et al.*, 1984.) (b) Schematic representation of surface receptors on dendritic cells (DCs) interacting with MV. CD46 and CD150 support uptake with subsequent replication of predominantly attenuated (CD46) or all (CD150) MV strains. Uptake can be enhanced by DC-SIGN, a pattern recognition receptor usually endocytosing its ligands. In addition, the ligation of CD46, CD150 and TLR2 can induce or modulate signalling pathways involved in cytokine production. (c) A schematic representation of current models to explain MV-induced immunosuppression at the level of interference of DCs. Inhibitory mechanisms supported by experimentation (such as block of development, maturation and viability as well as functional impairments leading to T-cell loss by apoptosis and/or infection and inhibitory signals provided by surface contact) are shown in standard, those suggested, but not yet proven, in italic letters.

usually detected, several hypotheses have been put forward to explain this finding, and these involve interference of MV with differentiation, function and viability of professional APCs, particularly DCs, which then promote depletion, aberrant differentiation or anergy of contacting T cells (Abt *et al.*, 2006; Schneider-Schaulies and Dittmer, 2006). Though infection of these cells *in vivo* has not yet been verified in humans, MV can interact with DCs *in vitro* independently (via pattern recognition receptors (PRRs) such as TLRs or DC-SIGN) or dependent of infection (because these cells express CD150 and CD46 *in vitro*) (Figure 22.6b). Interaction with PRRs expressed on the surface or internal membranes or in the cytoplasm modulates both the maturation of APCs and their cytokine profile and this is linked to upregulation of major histocompatibility complex (MHC) and costimulatory molecules (Bieback *et al.*, 2002; De Witte *et al.*, 2006), but also promote a release of cytokines which favour differentiation of Th2 cells (Atabani *et al.*, 2001; Fugier-Vivier *et al.*, 1997; Karp *et al.*, 1996). It is currently unclear as to whether interaction with DC-SIGN does affect DC maturation directly or promotes internalization of MV by an endocytic route, however, this molecule clearly enhances MV uptake and thereby subsequent viral replication in these cells (De Witte *et al.*, 2006). *In vitro* infection of DCs has been linked to apoptosis of these and/or depletion of contacting T cells by viral transmission or apoptotic signalling (Servet-Delprat *et al.*, 2003). Independent of T-cell depletion, MV-infected DCs were found to inhibit rather than to promote expansion of co-cultures allogenic T cells, and this has been related to the accumulation of the viral glycoprotein complex on the DC surface membrane (Dubois *et al.*, 2001; Klagge *et al.*, 2000; Schnorr *et al.*, 1997) (Figure 22.6c). *In vitro* and *in vivo* experimentation revealed that signalling by the MV glycoprotein complex interferes with the activation of intracellular signalling cascades in uninfected T cells in a contact-dependent manner (Niewiesk *et al.*, 1997; Schlender *et al.*, 1996; Schneider-Schaulies *et al.*, 2003). As a consequence, these cells arrest in the late G₁ phase of the cell cycle. Thus, MV-infected DCs most likely confer a negative rather than a positive signal to lymphocytes in the T-cell areas of the lymph node and this could play a central role in the induction of a widespread immune suppression. It appears particularly important in this setting that wild-type MV strains and recombinant MVs expressing the wild-type MV H protein reveal a pronounced tropism for secondary lymphatic tissues and a higher immunosuppressive activity (Ohgimoto *et al.*, 2001).

The role of the MV receptors in immunosuppression is not yet understood. The ability of certain MV strains

(either by surface contact of infection) to downregulate CD46 from the cell surface enhances susceptibility to complement-mediated lysis of the affected cells, and this might limit viral spread by cellular depletion. As this property is mainly confined to laboratory-adapted strains, this may represent an attenuation marker rather than contributing to immunosuppression. Consequences of MV-mediated downregulation of CD150 have not been established as yet. This molecule is predominantly expressed on activated lymphocytes, suggesting that these might be efficiently eliminated by MV infection. Both CD46 and CD150 have also signalling properties and thus MV interaction with either of them could probably alter cellular signalling independent of infection. In T cells, however, antibody ligation of either of these molecules was found to provide costimulatory rather than inhibitory signals. It is, however, essentially clear that induction of T-cell unresponsiveness by surface interaction with the MV glycoprotein complex does not require CD46 or CD150.

Acute Measles Post-infectious Encephalitis

It is likely that CNS involvement, even in uncomplicated measles, is common. Transient abnormality of the EEG is detected in about 50% of patients, headache is common and CSF pleocytosis is also observed. The question of whether and how MV targets the CNS in the course of the acute infection is still unknown. It is only exceptionally that MV can be isolated from the brain tissue of AMPE patients, while in the majority of cases MV antigen or RNA are not detectable in the CNS. Therefore, virus-induced autoimmune reaction leading for myelin breakdown is considered as most likely in the pathogenesis of AMPE, and in support of this, myelin basic protein (MBP) as well as T cells expanding in response to this protein *ex vivo* have been found in the CSF of patients. Such MBP-specific lymphoproliferative responses have also been seen for post-infectious encephalomyelitis caused by other viruses such as rubella, varicella or after rabies immunization (Johnson and Griffin, 1986). The latter disorder is probably the human equivalent of experimental allergic encephalitis (EAE) since such patients received rabies vaccine prepared in brain tissue. Since AMPE is characterized by demyelinating lesions in association with blood vessels as in EAE it is not surprising that an MBP-specific lymphoproliferative response is considered to be of pathogenetic importance. How MV leads to a T-cell-mediated autoimmune response is unknown, however, molecular mimicry or a deregulation of autoreactive cells occurring secondary to viral infections may be involved.

Measles Inclusion Body Encephalitis

This condition arises in patients with underlying immunodeficiencies, and is thus very rare and usually not accompanied by intrathecal antibody synthesis. The unprotected cells develop massive unclear and cytoplasmic inclusion bodies consisting of virus nucleocapsids. Infectious virus has not been isolated by conventional methods from brain tissue, suggesting defects in replication. This assumption has been supported by immunohistological and molecular biological studies on brain tissue of a case of MIBE. All viral mRNA species were detectable in brain-derived total RNA samples although the mRNAs for the envelope proteins were highly underrepresented. Both *in vivo* and *in vitro*, viral mRNAs directed synthesis of detectable amounts of N and P protein, yet not of the envelope proteins, indicating these are specifically restricted in MIBE (Baczko *et al.*, 1988). Sequences analyses revealed a high rate of mutations distributed over the entire MV genome, and within M gene, affected the initiation codon which explains why this protein is not expressed in infected MIBE brain tissue (Cattaneo *et al.*, 1987). Defects in MV mRNA transcription and envelope protein synthesis apparently do not largely affect the activity of the RNP complex, which spreads to different areas of the patient's brain. Because production of infectious virus and giant cell formation may never occur, due to the restriction of the envelope proteins, RNP spread is thought to occur by microfusion events.

Subacute Sclerosing Panencephalitis

MV was first implicated in the aetiology of SSPE by immunofluorescence in 1967 and this has since been confirmed by electron microscopy, immunoelectron microscopy (IEM), and finally upon rescue of virus by co-cultivation. Despite this, the manner in which the persistent infection is established in the brain and exactly how this leads to the production of disease are still ill-defined. The virus may enter the CNS during viraemia in acute measles, but once there, replication proceeds slowly and a widespread encephalitis is not established. It is also not known to what extent virus replication *per se* is responsible for the development of lesions, nor what part is played by the immune system.

Virological Aspects

MV replication is usually associated with giant cell formation and release of infectious progeny. In SSPE, free infectious virus has never been isolated either from the brain or from CSF, and histopathological examinations have consistently failed to reveal the morphological changes associated with virus maturation (Schneider-Schaulies and ter

Meulen, 1992). As with MIBE, giant cells and thickening of the plasma membrane indicative of budding sites are absent, indicating aberrant trafficking or absence of viral envelope proteins. Viral nucleocapsids present in the cytoplasm are randomly scattered and show no sign of regular alignment beneath the plasma membrane. Thus, the infection may spread slowly strictly in a cell-associated manner and not involve particle formation. As opposed to the polyclonal response in serum, MV-specific antibodies in the CSF are oligoclonal, suggesting their local production by plasma cells which have invaded this compartment in response to antigens (Dörries *et al.*, 1988). It is only MV-specific antibody titres that are tremendously elevated, while titres against other viruses remain normal. Antibodies specific to all MV proteins are present in serum and CSF, except for M protein which is barely (by serum antibodies) or not recognized (by CSF antibodies).

As pointed out for MIBE, only N and P proteins are consistently detectable in SSPE brain sections by immunohistochemistry, and extensive transcriptional and translational alterations affecting mainly envelope protein-specific genes are observed (ter Meulen and Billeter, 1995; Schneider-Schaulies *et al.*, 2005) which highly impair the synthesis of the corresponding gene products *in vitro* (Figure 22.7). A high rate of mutations all over the MV genome is found, although different genes are affected at different levels. The highest number of alterations accumulate in the M gene, followed by F, H, P and N genes, which are mutated to about the same extent, whereas the L gene is most conserved. Mutations introduced are either point mutations most probably accumulating due to the infidelity of the viral polymerase, or appear as clustered transitions which are thought to result from the activity of a cellular enzyme complex, now referred to as ADAR (adenosine deaminase, RNA-specific). As a result, translation from viral mRNAs is abolished or leads to the synthesis of truncated or unstable MV proteins. These molecular biological data explain the absence of infectious MV particles and the lack of budding and cell fusion processes in SSPE brain tissue. Yet virus has occasionally been rescued from brain tissue obtained post mortem by co-cultivation (Wechsler and Cody Meissner, 1982), and these so-called SSPE isolates can remain cell-associated, spreading through the culture with a gradually enlarging area of CPE or promote particle formation. Sequence analyses revealed that some SSPE isolates are likely contaminations and thereby rather ordinary laboratory MV strains. With the others, it is still unclear whether they represent a small subpopulation of replication/maturation competent viruses or revertants that were selected by isolation and may thus not be representative of the dominant virus population in the infected brain.

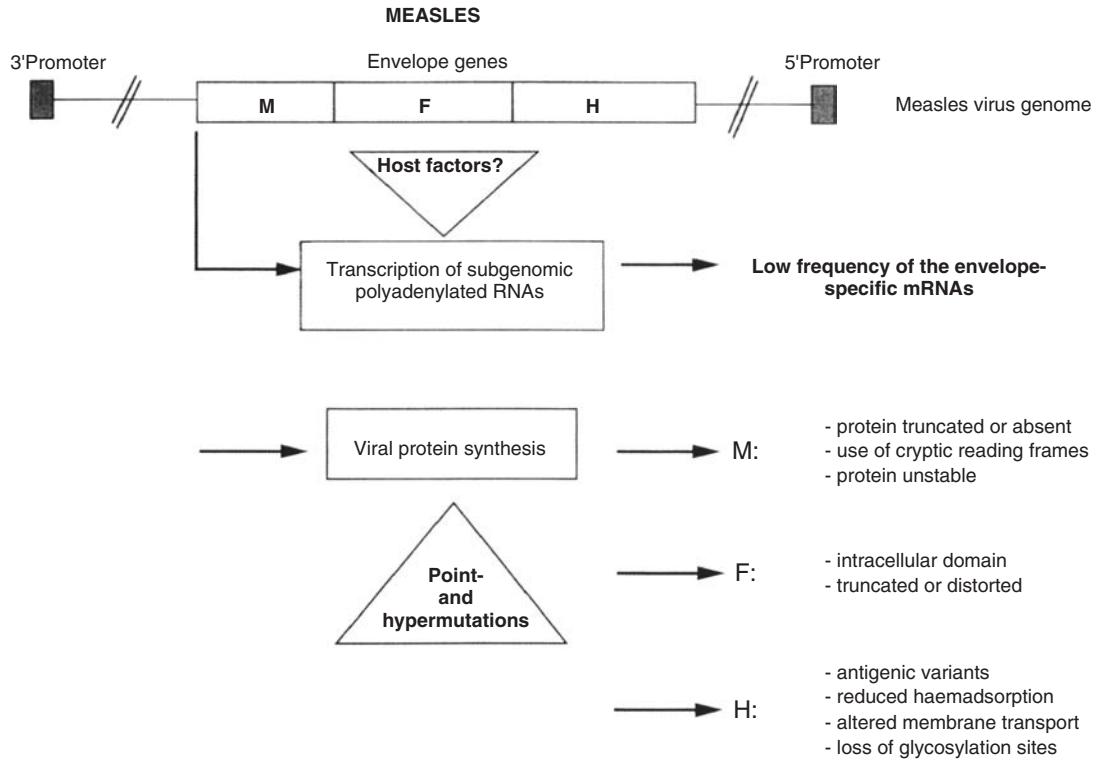

Figure 22.7 Schematic representation of restrictions of MV gene expression found in SSPE brain tissue. MV mRNAs encoding the viral envelope proteins are expressed at low frequency (most probably due to host cell control mechanisms) and, in addition, harbour mutations that prevent the synthesis of functional translation products.

Factors involved in the establishment of persistence by a non-defective MV in brain tissue are ill-defined. In neural tissue culture cells or brain material of experimentally infected animals, intracellular factors can intimately control the efficiency of MV replication and this may be more pronounced with differentiation of the host cells and age of the animals (Schneider-Schaulies *et al.*, 1990). This particularly applied to attenuation of viral transcription and translational control exerted predominantly on MV-specific rather than host cell mRNAs. In addition, ADAR activity actively modifying the primary sequence of viral RNAs has been demonstrated in these cells. Thus, intracellular factors present in brain cells possibly slow down viral replication after primary infection, thereby preventing rapid host cell destruction. Whether these mechanisms efficiently control the maintenance of the persistent infection or other factors, such as mutations within the viral genome, are required has not been resolved.

Immunological Aspects

As for virological factors, immunological features associated with the establishment of SSPE are at best vaguely

understood. Transient immunosuppression and immaturity of the immune system on primary exposure are thought to contribute, yet this has not yet been attributed to specific lymphocyte compartments (Oldstone *et al.*, 2005). In experimentally infected mice, primary MV CNS infection is controlled by CD4, CD8 and B cells in conjunction, rather than by any single subpopulation (Tishon *et al.*, 2006), yet it remains unclear whether defective responses of either of those would favour persistence, as it is unknown if, when and to what extent MV enters the brain during or after acute measles. Nevertheless, given the importance of CMI in the control of MV infection, considerable interest has focused on this response in SSPE patients, which, however, generally revealed a normal immune competence. T cells are present in normal amounts, lymphoproliferation and interleukin synthesis in response to antigenic stimulation are normal and skin grafts are efficiently rejected. The response to MV antigens can be impaired since anamnestic skin tests for these are often negative. Depending on the test system and on the potency and purity of the virus antigens used, a minor inhibition or normal reaction of CMI in comparison to controls can be observed

in SSPE patients. Once the disease becomes clinically visible, the humoral hyperimmune response to MV antigens in serum and CSF is the hallmark of and diagnostic for SSPE. Though this also involves neutralizing antibodies, these are unable to control the infection, and hence, have been proposed to support rather than eliminate persistence. MV-specific antibodies act to cross-link viral proteins on the cell surface which subsequently aggregate to form 'cap structures', also containing M protein, which are internalized from the cell surface. Since the concentration of complement components in the brain is low, complement-mediated lysis there is of low efficiency, and thus, the major effect of antibodies would be to promote clearance of antigen from brain cell surfaces. There is, however, also evidence that the antibody-induced capping process directly regulates viral protein synthesis. Thus, influenza haemagglutinin-specific antibodies can exert an inhibitory effect on the viral polymerase activity. Similar observations were made in cell lines persistently infected with MV or in MV-infected rats where passive transfer of neutralizing H protein-specific monoclonal antibodies prevented acute and promoted the development of a subacute MV encephalitis (Liebert *et al.*, 1990). Thus, the host immune response possibly supports establishment and/or maintenance of SSPE.

DIAGNOSIS

The symptoms of acute measles are so distinctive that a virus laboratory has been rarely called upon for diagnosis. As the vaccination programme takes effect, physicians in areas of high vaccine coverage may, however, become less familiar with the disease. Furthermore, as more patients are placed on immunosuppressive regimens, the need for diagnosis of measles may well increase.

Microscopy

Production of multinucleate giant cells with inclusion bodies is pathognomonic for measles during the prodromal phase. Such cells are detectable in the nasopharyngeal secretions. Clear identification of giant cells and detection of Cowdry inclusion bodies is facilitated if the smear is formalin-fixed prior to haematoxylin and eosin staining. Direct and indirect immunofluorescence have been widely used to stain cells shed in nasal secretions, although it may be necessary to remove antibodies which already coat virus antigens with a low pH buffer. Stained cells include macrophages and ciliated cells as well as giant cells. Urinary sediment cells can be successfully used as well, as immunofluorescence-positive cells are shed in the urine from two days before to up to five days after the appearance of the rash, which makes this specimen superior

to nasopharyngeal secretion in the later stages. Such cells may also be present in the urine 4–16 days after vaccination with the live vaccine. Immunofluorescence is useful for the diagnosis of measles in the pre-eruptive phase or in children vaccinated with killed vaccine, where rash development is atypical. Immunoperoxidase histochemical stains are also used, and the use of monoclonal antibodies has improved sensitivity and reliability of virus detection.

Serological Methods

In common with other infections, diagnosis of measles is made if antibody titres rise by more than four-fold between the acute and the convalescent phases or if measles-specific IgM is found. Traditional tests such as HAI, plaque reduction neutralization (PRN), haemolysin inhibition (HLI), complement fixation (CF) and enzyme-linked immunoassay (EIA) have been extensively used for serological diagnosis of measles. Because sensitive and specific commercial kits are available, EIA has become the most widely used test format. These tests also have the ability to measure measles-specific IgM as well as IgG responses and therefore have particular importance in diagnosis as well as measles control programmes. The recommended laboratory method for the confirmation of clinically diagnosed measles is a serum-based IgM EIA, and several commercially available serum-based capture and indirect IgM EIAs are used worldwide. In the case of SSPE, it is important that CSF is also tested.

Virus Isolation and Detection of Viral RNA

Virus isolation and RT-PCR-based detection of viral RNA are usually limited to specific instances such as suspected infection of the immunosuppressed in the absence of rash, developing pneumonia or unexplained encephalitis. Finally, these techniques can be attempted as a means of retrospective diagnosis.

The lack of sensitive cell lines for efficient growth of MV made cell culture isolation difficult, even when optimal specimens for virus isolation were available. Previous tissue culture cell lines, such as primary monkey kidney cells and Vero cells, were considered as permissive for measles infection. It is now recognized that these cells do not express the appropriate receptor(s) for most wild-type viruses, which explains the low frequency of isolation with these cell types. An Epstein–Barr virus-transformed marmoset B lymphocyte cell line (B95a), a human B lymphoblastoid (BJAB) and, more recently, an umbilical cord cell line proved to be up to 1000 times more sensitive than Vero cells and are currently used for MV isolation (Kobune *et al.*, 1990, 2007). Best success is attained when specimens (usually washing, swabs, Ficoll

gradient purified blood cells stimulated with mitogens or urinary sediments) are collected within five days of rash onset. Samples are mixed with buffered salt solution (pH 7.2) containing antibiotics before application onto tissue culture cells. CPEs develop usually between 48 hours and 15 days, and consist either of a broad syncytium or of a stellate form, both of which can reveal nuclear and cytoplasmic inclusion bodies. If CPE is slow or not clear, MV antigens or RNA can be detected by appropriate methods. RT-PCR analyses using MV N- and/or F-gene specific primers are the most commonly employed in a wide variety of specimens from which RNA is extracted and used as template, including serum, nasopharyngeal aspirates and urine sediment cells. Tissue samples including lung, kidney, skin and brain are also amenable for testing by RT-PCR following appropriate chaotropic salt treatment and nucleic acid extraction.

Diagnosis of SSPE

Formerly, brain biopsy was performed routinely for diagnosis of SSPE and tissue thus obtained was examined for inclusion bodies and virus antigen by immunofluorescence. After recognition of the characteristic intrathecal antibody synthesis, determination of measles antibody titres in the CSF may be sufficient with, if necessary, demonstration of MV-specific heterogeneity by isoelectric focusing in combination with an immunoblot technique (Dörries and ter Meulen, 1984). Virus isolation from SSPE brain tissue is complicated and often fails. As MV replication only occurs within brain cells and viral particles are not released, MV-specific sequences can generally not be amplified by RT-PCR in CSF samples.

MANAGEMENT

As an acute self-limiting disease, measles will run its course in the absence of complications without the need for specific intervention. Treatment is supportive and there are no proven effective antiviral compounds available. Infection of the undernourished, the immunocompromised or children suffering from chronic debilitating diseases is more serious. Such patients, children under one year of age and pregnant women after household contacts can be protected by the administration of human anti-measles gammaglobulin (0.25–0.5 ml kg⁻¹). If given within the first three days after exposure, it is usually effective, yet the effectiveness is partially or completely lost if the globulin is given four to six days, or later, respectively, after exposure.

Ribavirin has been used to treat pneumonitis and SSPE. Respiratory tract infections cause considerable damage

to the ciliated epithelium and this may lead to superimposed bacterial infections. For pneumonia, distinction between primary viral infections and the superimposed bacterial infection can sometimes be difficult, and thus, treatment with antibiotics is required. Treatment of acute post-infectious measles encephalitis (APME) is symptomatic and supportive, and does not differ from that for any other post-infectious encephalitis. Careful attention to fluid and electrolyte balance is essential. Seizure control requires anticonvulsive drugs. Application of steroids did not prove to be beneficial. No specific therapy is known for MIBE. A variety of approaches have been attempted for treatment of SSPE, but as yet there has been no convincing success and almost all cases have proved fatal. The effectiveness of treatment is extremely difficult to evaluate because the course of SSPE is highly variable and spontaneous remissions are common. In addition, being a rare disease, clinical trials are inevitably based on a very small number of patients. Isoprinosine (inosiplex) and IFN (also applied in combination) have been widely used. In the case of isoprinosine, it seems likely that treatment may lengthen survival time if given early in the disease. This effect becomes less pronounced if the drug is administered later.

As mentioned above, RNA interference-based approaches to downregulate synthesis of MV proteins essential for replication (such as the L protein) or development of peptide inhibitors targeting viral entry or, again, polymerase functions, are being exploited *in vitro*, and certainly will be used in suitable animal models once administration and targeting strategies have been established. Whether either of these approaches will make it to clinical application cannot be predicted at present, however, it is likely that application of those will probably be confined to situations which require specific intervention.

PREVENTION

The measles virus has no animal reservoir and is thus an obvious target for a controlled campaign aimed at eradication (Mitchell and Balfour, 1985). In the United States and Canada, where vaccination of all children is required at or before commencing school, startling results have been achieved. Case reports have fallen by over 99% but eradication has not yet been achieved. In other industrialized countries, where vaccination is not mandatory, Germany, Italy and the United Kingdom, distrust of vaccination has led to a lower acceptance rate and consequently, local epidemics continue to occur (e.g. 1000 cases in the Düsseldorf area in Germany in 2006). In developing countries, where the consequences of measles infection are most severe, considerable progress has been

made in controlling acute measles and reducing related mortality by the implementation of mass immunization campaigns.

Any vaccine used must be safe, as measles is not normally a severe illness, and cheap enough for mass administration. Its effectiveness should also be long lasting. Natural immunity is known to last for at least 65 years in the absence of re-exposure to the virus. In 1781 measles disappeared from the Faroe Islands following an epidemic, and was not reintroduced until 1846. Individuals old enough to have experienced the disease 65 years earlier were still protected. The unusual persistence of immunity even in the absence of boosting has suggested that MV may normally persist inside the body, and thus re-stimulates immunity from within.

Inactivated Vaccine

Inactivated vaccine was intended for use in young children less than one year of age, who are most prone to serious complications, to avoid the use of a live vaccine. With the formalin-killed virus preparation, at least three vaccinations were required to elicit a suitable antibody response, which, however, was comparatively low and soon waned. This left vaccinees open to virus attack, and their partial immunity led to serious hypersensitivity reactions to infection and a modified disease course (see section on Atypical measles). Therefore, this vaccine, administered in 1963–1967, was withdrawn from the market soon after notification of the first cases of atypical measles (Clements and Cutts, 1995).

Live Vaccine

The first attenuated vaccine strain was the Edmonston B strain produced by serial passage in human kidney cells, human amnion cells, chick chorioallantoic membrane and, finally, duck embryo cells. When administered intramuscularly or subcutaneously 12–18 months after the disappearance of maternal antibodies, this vaccine achieved seroconversion in 95% of recipients, but side effects of mild measles were common (5–10%). To oppose this, gammaglobulin was administered at doses appropriate to prevent side effects but not to promote vaccine failure. In 1966 a Medical Research Council (MRC) trial conducted in the United Kingdom followed 36 000 children. Measles incidence fell 84% in the first nine months, and decreased by 14% in the next two years. A follow-up study showed that the vaccine remained effective for at least 12 years.

The Edmonston B vaccine was further attenuated and thus rendered less reactogenic by passage in chick embryos at lowered temperature to yield the Schwartz and Moraten (Enders) strains. These indeed lowered the

incidence of post-vaccination febrile convulsions from 7.7 to 1.9 per 1000 recipients, and produced a 95% seroconversion rate, although antibody titres induced by the Schwartz strain declined more rapidly yet also remained at protective levels. Following passage in human diploid cells, a further attenuated strain, the Edmonston Zagreb strain, was obtained which produced higher seroconversion rates than the Schwartz vaccine. Similar observations were made with the AIK-C vaccine, produced in Japan. Titres of protective antibodies were seen to decline in isolated communities but were still detectable 14 years later. Children living in an open environment showed serological evidence of subclinical re-exposure which acted to boost their immunity. The measles vaccine is administered subcutaneously usually between the ages of 9 and 20 months for primary vaccination, either alone or in combination as measles, mumps and rubella (MMR) vaccine. According to recommendation by the American Academy of Pediatrics (AAPs) and the Immunization Practices Advisory Committee (ACIP) of the United States, in industrialized countries the first dose of measles vaccination should be administered at 15 months of age, as delayed primary measles vaccination (at 15 months of age or later) significantly reduces measles risk at later ages. Initial vaccination at 12 months of age is recommended for children living in high-risk areas (areas with a large inner-city urban population where more than five cases among preschool-aged children occurred during each of the last five years or with recent outbreaks among unvaccinated preschool-aged children). Of course, initial vaccination of infants 12–14 months of age is also recommended before travelling to areas in which measles is endemic or epidemic. A second dose is recommended with an interval of at least two months after primary immunization up to four to six years of age by ACIP that is expected to provide protection to most persons who do not respond to their initial vaccination.

Humoral immune responses, as defined by HAI, NT and ELISA, are good and protective as long as the vaccine is given after waning of the maternal antibodies. As with acute measles, the major isotype of MV-specific antibodies is IgG1. Levels of antibodies induced are generally lower than after measles and may decay more rapidly, but are still measurable in most individuals 15 years after immunization in the absence of boosting infections. Activation of CMI is generally thought to be similar to that of acute measles in that both MV-specific CD4 and CD8 T cells are stimulated, although cytotoxic T lymphocyte (CTL) responses after re-stimulation *in vitro* are considerably lower than after natural infection. As in acute measles, administration of live measles vaccine is associated with transient lymphopenia, loss of DTH skin test

responses to recall antigen and decreased *in vitro* proliferative responses to mitogens. Both mild leukopenia and atypical lymphocytosis have also been found after re-vaccination. In general, however, the immunosuppression observed after vaccination is marginal, and is usually not associated with complications. Reports that both measles (contracted early in childhood) and measles or MMR vaccine predispose towards the later development of intestinal bowel diseases –such as Crohn’s disease or ulcerative colitis –or autism have not been substantiated (Afzal *et al.*, 2006; Feeney *et al.*, 1997; Madsen *et al.*, 2002).

In spite of the effectiveness of the vaccine currently in use, which is at least equally effective when administered by aerosol rather than the subcutaneous route (De Swart *et al.*, 2006; Dilray *et al.*, 2007), new candidate measles vaccines are being explored in terms of efficacy (particularly in the presence of maternal antibodies) and other aspects, such as thermostability, standardization, production costs and application mode in animal models. Candidates being evaluated include expression of MV antigens in the context of live viral (like pox and adenovirus) or bacterial (like *Shigella flexneri* and *Salmonella typhimurium*) vectors, subunit or synthetic vaccines (like iscoms, biodegradable particles, lipopeptides) and nucleic acid vaccines (plasmid DNA). In addition, recombinant MV’s various heterologous viral antigens are being tested as vectors for multi-vaccine strategies, yet again so far only in animal studies.

Side Effects of Live Vaccination, Adverse Reactions, Precautions and Contraindications

The measles vaccine has an excellent safety record (National Vaccine Advisory Committee, 1991). While the vast majority of recipients remains asymptomatic, in rare instances a transient rash or low-grade fever, sometimes associated with moderate febrile seizures, is observed after 5–12 days in some vaccinees. Although children with a history of seizures are generally at increased risk for developing idiopathic epilepsy, febrile seizures following vaccinations do not increase the probability of subsequent epilepsy or neurological disorders. Most convulsions following measles vaccination are simple febrile seizures, and they affect children without known risk factors. Nevertheless, parents of children who have a personal or family history of seizures should be advised of the small increased risk of seizures following measles vaccination. CNS conditions such as encephalitis and encephalopathy have been reported with a frequency of less than 1 per million doses administered, an incidence which is lower than that of encephalitis of unknown aetiology. This finding suggests that the reported severe neurologic disorders temporally associated with measles vaccination were not caused by the vaccine.

Live measles vaccine should not be administered to women who are or are considering becoming pregnant within the next three months because of the theoretical risk of fetal infection. The decision to administer or delay vaccination because of a current febrile illness depends on the cause of the illness and the severity of symptoms. Hypersensitivity reactions following administration of live measles vaccine are rare and usually occur at the injection site. People with a history of anaphylactic reactions following egg ingestion should, however, be vaccinated with extreme caution, and individuals who have experienced anaphylactic reactions to neomycin should not be given the vaccine. Unlike with natural measles, exacerbation of tuberculosis has not been observed after measles vaccination.

Vaccination of Immunocompromised and HIV-infected Individuals

Replication of vaccine viruses can be enhanced in immunocompromised recipients, for example with leukaemia, lymphoma, generalized malignancy or therapy with alkylating agents, antimetabolites, radiation or large doses of corticosteroids. Thus, patients with such conditions or therapies (except for HIV infection) should not be given live measles vaccine. Short-term corticosteroid therapy does not contraindicate live measles vaccination. The large number of infants and preschoolers with HIV infection in certain countries has directed special attention to the appropriate immunization of these children. Asymptomatic children in need of measles live vaccination should receive it without prior evaluation of HIV infection state. Moreover, vaccination should be considered for all symptomatic HIV-infected children, including those with acquired immune deficiency syndrome (AIDS), since measles in these children can be severe. Limited data on measles vaccination among both asymptomatic and symptomatic HIV-infected children indicate that the vaccine has not been associated with severe or unusual adverse events (Moss *et al.*, 2002). Exposed symptomatic HIV-infected (as well as other immunocompromised) individuals should receive high doses of measles Ig regardless of their previous vaccination status.

Effectiveness of Vaccination in the Control of Measles

In industrialized countries that have achieved high levels of vaccine coverage, the interval between measles outbreaks increases and sufficiently high levels of vaccination can interrupt endemic transmission. With vaccination, the age distribution of cases is determined by which groups are likely to lack vaccine or measles-induced immunity.

In the pre-vaccine era, an estimated 4–5 million cases occurred annually in the United States and by the age of 15 years 95% of the population had seroconverted. Following the rigorous implementation of the MV vaccination programme, the case reports have fallen dramatically from 500 000 annually to 26 000 in 1978 and 1500 in 1983. From 1984 to 1988 only 3700 cases were registered. As a result of measles vaccination, the mortality and APME have declined and the available experience indicates that this also applies to SSPE. The United States experienced a dramatic increase in acute measles in 1989 and 1990 with 18 193 and 27 786 notified cases, respectively (Atkinson and Orenstein, 1992). The major causes for this resurgence of measles were an unappreciated low vaccine coverage among preschool-aged children, particularly in urban settings, and vaccine failure (waning immunity) in a low percentage of school-aged children who received only a single dose of vaccine. As a result of this measles epidemic and to address the issue of possible waning immunity, the AAP and the ACIP of the United States recommended a change from a one-dose to a two-dose schedule for measles vaccination.

The two-dose schedule is only one strategy used to ensure high vaccine coverage in the quest for measles elimination, particularly in developing countries where malnutrition, crowding and intensity of exposure aggravate measles infection and secondary infections are common and take severe courses in young infants (Aaby, 2007). Therefore, it is especially important to develop and implement vaccine programmes that are effective at conferring protection of the very young and at interrupting transmission to minimize the risk of exposure of the unprotected. As a result of the activity of the Measles Initiative launched in 2001, the incidence of measles-associated fatalities has been reduced by 60% worldwide between 1999 and 2005, and this has even surpassed the targets set by the UN in 2002 to reduce deaths due to measles by half within this period. This has been achieved by implementation of a four-part key strategy involving (i) provision of one dose of measles vaccine to all infants by 12 months of age via routine health services, (ii) a second opportunity for immunization for all children from 9 months to 15 years, generally through mass vaccination campaigns, to cope with primary and secondary vaccine failures, (iii) establishment of effective surveillance and (iv) improvement of clinical management of complicated cases, including vitamin A supplementation, which can effectively reduce measles morbidity. These measures increased vaccine coverage with the first routine dose from 71 to 77% globally between 1999 and 2005, and over 360 million children aged below 15 years received immunization through mass vaccination campaigns. Within this period, reduction of the estimated measles mortality

was most effective in the Western Pacific region (81%), followed by Africa (75%) and the Eastern Mediterranean Region (62%). Overall, more than 7.5 million deaths from measles were efficiently prevented.

Based on these encouraging figures, the Measles Initiative has set new targets to further reduce measles deaths primarily by ensuring that children receive a second dose of the vaccine shortly after the first, which will hopefully effectively meet the goal – elimination from the then 52 member states of the European Region by 2010 – set in 2005 by the WHO Regional Office for the European Region. In other regions, particularly in the 47 ‘priority countries’ that account for approximately 98% of global measles deaths, the four-part strategy will continue to be implemented and there, reduction of measles death by 90% by 2010 at a global level, and of the under-five mortality by two thirds by 2015 is envisaged. It is particularly in the 47 priority countries that national and district immunization plans are lacking, and poor management has led to high dropout rates. In addition, the highly infectious nature of the virus demands that governments build a long-term vision and plan since measles has repeatedly demonstrated its ability to quickly infect areas with low vaccination coverage.

HISTORICAL INTRODUCTION

Rubella was known initially as 'German measles' because it was first described by two German physicians in the mid eighteenth century. It is generally a mild disease and therefore received comparatively little attention until 1941, when its association with congenital defects was recognized by N. McAlister Gregg, an Australian ophthalmologist (Gregg, 1941). Other studies in Australia and elsewhere confirmed these findings and suggested that a very high proportion of mothers who had had rubella during pregnancy delivered infants with congenital malformations (reviewed by Hanshaw *et al.*, 1985). Gregg, in a more extensive survey, reported that 122 of 128 (95%) children whose mothers had had rubella before the 16th week of gestation had congenital defects. However, these early retrospective studies, in which the starting point for investigations was an infant with congenital malformations should be interpreted with caution. Calculation of the true risk of rubella in pregnancy required that rubella in pregnant women should be confirmed serologically; more recent studies involving pregnant women with serologically proven rubella are discussed on pages 566–567.

Early work on the characteristics and transmission of rubella was carried out in human volunteers. Experimental studies using human volunteers showed that the incubation period of rubella ranged from 13 to 20 days and that subclinical infection occurred.

Rubella virus (RV) was not isolated in cell cultures until 1962, when two groups simultaneously published different methods. Parkman *et al.* (1962) inoculated primary

vervet monkey kidney (VMK) cultures with throat washings obtained when rash was present. Although no cytopathic effect (CPE) was observed, when cultures were challenged 7–14 days after inoculation with echovirus 11, the distinct CPE produced by this virus was not observed, suggesting the presence of an interfering agent. The interfering agent was neutralized by rabbit antiserum raised against one of the isolates. This interference assay was used extensively for diagnostic purposes and serological surveys. Weller and Neva (1962) used primary human amnion cultures to isolate the virus from blood and urine taken from typical cases of rubella. After specimens were passed once or twice in these cell cultures, a characteristic CPE with cytoplasmic inclusions was observed. These effects were neutralized by serum obtained from patients convalescent from rubella. The agents isolated in the different cell cultures by these two groups of workers were exchanged and found to be identical.

Studies conducted in different countries showed that the acquisition of rubella antibodies was related to age, social class and geographical location, and that approximately 80% of women of child-bearing age living in urban areas in western countries were immune. A haemagglutination inhibition (HAI) test was not developed until 1967, when it was shown that serum lipoproteins were inhibitors of HAI and must be removed from culture medium and test sera (Stewart *et al.*, 1967).

Clinical and virological investigations carried out during the extensive rubella epidemic in the United States during 1963–1964 led to a greater understanding of the pathogenesis of congenital rubella syndrome

Table 23.1 Key historical events—discovery of rubella and development of rubella control programmes

1881	Rubella accepted as a distinct disease by International Congress of Medicine
1941	Teratogenic effects of rubella first recognized by Gregg in Australia
1962	Rubella virus isolated in cell cultures. Neutralization test developed
1965–1967	Development of attenuated vaccine strains and first vaccine trials
1967	Rubella virus first visualized by electron microscopy
1969	HPV77.DE5 and Cendehill vaccine strains licensed in United States. Vaccination offered to all preschool children
1970	Cendehill vaccine strain licensed in Europe. Vaccination offered to 11- to 14-yr-old schoolgirls
1971–1972	RA27/3 vaccine strain licensed in Europe
1979	RA27/3 replaced other vaccine strains in United States
1986	Rubella genome sequenced
2000	WHO recommends immunization policies for elimination of CRS
2006	123 of 212 (58%) of countries/territories include rubella vaccination in national immunization programmes

(CRS), as well as a further appreciation of its clinical features and sequelae. During this epidemic about 30 000 rubella-damaged babies were delivered (Cooper, 1975). Studies at the time revealed that multisystem involvement was common and the range of abnormalities much wider than previously reported. When maternal rubella occurred in early pregnancy, a generalized infection developed in the fetus, which persisted during the remainder of gestation and into infancy, despite the presence of rubella antibodies. Many infected infants excreted virus and transmitted virus to susceptible contacts. The main historical events associated with rubella are summarized in Table 23.1 and reviewed by Best *et al.* (2005) and Banatvala and Peckham (2007).

THE VIRUS

Classification

Rubella virus is classified as a togavirus and is the only member of the genus *Rubivirus*. The genome structure and replication strategy of RV is similar to viruses of the *Alphavirus* genus of the *Togaviridae*, such as Semliki Forest and Sindbis (Frey, 1994). No antigenic relationship has been shown between RV and any alphavirus or flavivirus.

Structure of the Virus

Electron micrographs show that the RV virion is pleomorphic. The virus particle is about 70 nm in diameter, with a nucleocapsid containing the genomic RNA and a lipid envelope. The virion has two membrane-bound envelope glycoproteins and a nonglycosylated nucleocapsid protein: E1 (58 kDa), E2 (42–47 kDa) and C (32 kDa), respectively. The structure of the RV particle has not been determined, but the structures of alphaviruses, whose

envelope and nucleocapsid proteins are probably similarly organized in the virus particle, have been determined (Mukhopadhyay *et al.*, 2006). The E1 and E2 proteins of these viruses form heterodimers which arrange themselves into trimeric spikes (i.e. three copies each of E1 and E2 in each spike) in the membrane, above the icosahedral nucleocapsid. The main difference between the alphavirus and RV virion components is that the C proteins of RV retain the putative signal peptide of the E2 protein, and are thus bound to the virion membrane by their C-termini.

Genome Structure and Function

The RV genome comprises a positive-sense single-stranded RNA, which is capped at the 5' end and polyadenylated at the 3' end (Frey, 1994). The cap serves as a ribosome recognition site and is required for efficient translation. The RNA is infectious when extracted under appropriate conditions. The base composition of the genome is G 30.8, C 38.7, A 14.9 and U 15.4%. The G+C content of the RNA is very high, which makes some work difficult (e.g. reverse transcription polymerase chain reaction (RT-PCR)). There are some small variations between genomes of various RVs, but most are 9762 nucleotides (nt) in length, with a 40-nt 5' untranslated region, a 5' proximal 6351-nt open reading frame (ORF) coding for the nonstructural proteins (NSPs), including an RNA-dependent RNA polymerase, a 120-nt junction region, a 3' proximal 3192-nt ORF coding for the structural proteins and a 59-nt 3' untranslated region (Zhou *et al.*, 2007). The gene order is 5'-p150-p90-C-E2-E1-3' (Figure 23.1).

Genetic Variation

The level of diversity among RVs is low when compared to some other RNA viruses, such as human immunodeficiency virus (HIV) and poliovirus, and there is no

Figure 23.1 Schematic representation of the transcription and translation of rubella virus structural and non-structural proteins. (Source: Reproduced from Best, Cooray & Banatvala (2005) by permission of Edward Arnold (Publishers) Ltd.) The RV genome consists of two long non-overlapping open reading frames (ORFs), the 5' ORF encodes the nonstructural proteins and the 3' ORF encodes the structural proteins. A p200 polyprotein precursor is translated from the 5' ORF of the genomic RNA. This is subsequently cleaved by a virus-encoded protease to produce the nonstructural proteins p150 and p90. The p200 protein is the principal replication protein for negative-strand RNA synthesis. The negative strand acts as a template for the transcription of the positive-strand 40S genomic and 24S subgenomic RNAs. Synthesis of positive-strand RNAs is dependent on cleavage of p200. The 24S subgenomic RNA is translated into a p110 polyprotein precursor which is proteolytically cleaved by a host-encoded protease and post-translationally modified to produce the structural proteins C, E2 and E1. Within the 5' nonstructural ORF are a number of amino acid sequence motifs of functional significance: methyltransferase (M), papain-like cysteine protease (P) and the macro, Appr-1"-pase-like family (which is conserved among alphaviruses) (X) domains within p150; and helicase (H) and replicase (R) domains within p90.

evidence of more than one serotype even in highly vaccinated populations (Frey *et al.*, 1998). Nevertheless, there is sufficient variability in currently circulating RVs to allow them to be divided into two clades and 13 genotypes (World Health Organization, 2006, 2007) (Figure 23.2). Genetic analysis of RVs has been used to support rubella control and elimination activities (Icenogle *et al.*, 2006). The most commonly used vaccine strain of RV, RA27/3, differs from the most closely related RVs by coding and noncoding nucleotide changes. Thus, the RA27/3 virus can be identified in clinical specimens (Pugachev *et al.*, 1997). There is no evidence that reinfection is due to an antigenic variant, but two viruses isolated from joints exhibit changes in antigenic epitopes in E1 (Bosma *et al.*, 1996; Frey *et al.*, 1998). A comparison of NSP-coding sequences shows that the 1970–2360 nt region of p150 is highly variable.

Replication

Rubella virus probably enters the cell by receptor-mediated endocytosis, but the cellular receptor for the virus has not been identified. The reproductive cycle takes place in the cytoplasm and probably resembles that of the alphaviruses. In alphaviruses, the virion is transported to the endosomal compartment, where the low pH brings about the uncoating of the viral genome and fusion of the E1 and E2 glycoproteins with the endosomal membranes, allowing the viral genome to be released into the cytoplasm. However, the disassembly process may well be different for RV, since the capsid protein is membrane associated. In vertebrate cell cultures the replication of RV is slow and less efficient than that of the alphaviruses. In Vero cells virus

production reaches a peak at 48 hours after infection at high multiplicities of infection (Hemphill *et al.*, 1988). No effect on total cell RNA or protein synthesis has been noted within 72 hours after infection.

The single-stranded genomic RNA and the subgenomic RNA, which codes for the structural proteins, are found in RV-infected cells. The 40S genomic RNA is translated to produce the 2116-amino-acid polyprotein (p200) encoded by the 5' proximal ORF. This polyprotein is cleaved by a viral protease to give two products of 150 and 90 kDa. The p150 contains the proposed methyltransferase and protease motifs, while the p90 contains amino acid motifs indicative of RNA-dependent RNA polymerase and helicase activity (Figure 23.1). An X motif of unknown function is also present, which is a short region of homology between RV and the alphavirus NSP3. p200 is required for synthesis of the negative-sense genome. This is used as a template for the production of both full-length 40S progeny genomes and 24S subgenomic RNA, for which cleavage of p200 is required. The 24S subgenomic RNA, which is capped, methylated and polyadenylated, is translated to produce a 110-kDa polyprotein, which is cleaved by a host cell signal peptidase to produce the three structural proteins C, E2 and E1 (Figure 23.1). All three structural proteins are transported to the Golgi complex. E1 and E2 form heterodimeric complexes, while the C protein forms dimers, which are stabilized by disulfide bond formation shortly before virus release. Glycosylation, transport and assembly of RV proteins all occur in the Golgi and the C protein is known to influence RNA replication. Thus, it is difficult to sort out the precise steps in RV RNA replication and assembly of virions (Chen and Icenogle, 2007). In cell cultures RV is released by budding from intracellular membranes (e.g. Golgi, endoplasmic

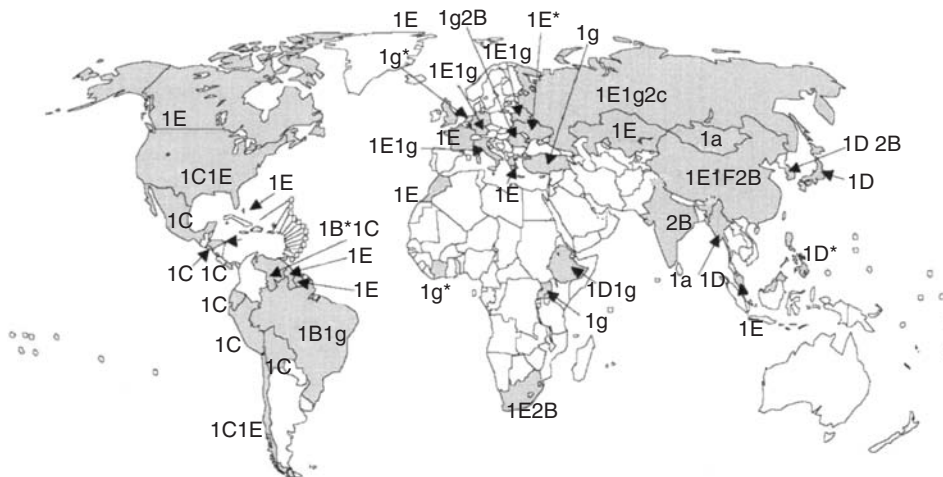

Figure 23.2 Global distribution of indigenous rubella viruses, 1995–2006. (World Health Organization, 2006).

reticulum) and from the plasma membrane. The ability to bud from intracellular vacuoles may enable RV to establish persistent infections (Chantler *et al.*, 2001).

The structure and replication of RV have been reviewed in detail by Chantler *et al.* (2001) and Chen and Icenogle (2007).

Physical and Chemical Properties of the Virus

Physical properties of RV have been reviewed in detail by Horzinek (1981) and Best *et al.* (2005). The virus is stable at 4 °C for over seven days, but is inactivated at 0.1–0.4 log₁₀ TCID₅₀/0.1 ml h⁻¹ at 37 °C and at 1.5–3.5 log₁₀ TCID₅₀/0.1 ml h⁻¹ at 56 °C. It is stable at –70 °C and when stored freeze dried at 4 °C. Stability is enhanced by the addition of proteins to the suspending medium. RV is inactivated by detergents and organic solvents, since the viral envelope contains lipid. The effects of these and other chemicals have been extensively reviewed elsewhere (Frey, 1994; Herrmann, 1979).

Antigenic Characteristics

Only one serotype of RV has been identified, although an antigenic site in the E2 protein recognized by a monoclonal antibody is not conserved among some circulating RVs (Zheng *et al.*, 2003). Vaccination with the RA27/3 vaccine affords protection against all circulating RVs. Although the E1 and E2 proteins are glycosylated, no evidence that glycosylation plays a role in the antigenicity of the virion has been reported.

Humoral and cell-mediated responses are produced against all three structural proteins, although E1 appears to immunodominant (Chaye *et al.*, 1992; Cusi *et al.*, 1989). Information on immunoreactive regions within the structural proteins has been obtained using monoclonal antibodies to map epitopes and by measuring antibody reactivity and T-cell proliferative responses to synthetic peptides and recombinant proteins. E1 has been shown to have at least six independent linear epitopes including two or three neutralizing epitopes within the amino acid region 214–285. The E2 glycoprotein in the mature virion appears to be relatively inaccessible to the immune response, but a number of B-cell epitopes have been identified (Mitchell *et al.*, 1993; Wolinsky *et al.*, 1991). Human sera react with synthetic peptides comprising residues 214–285 of the E1 protein and a recombinant protein containing these epitopes was recognized by most rubella antibody positive sera (Cordoba *et al.*, 2000; Starkey *et al.*, 1995). At least 17 T-cell epitopes have been described on the structural proteins. Conformation-dependant epitopes, which are likely play an important role in the induction of immune responses, have not been identified. Antigenic characteristics of RV have been reviewed in more detail by Chantler *et al.* (2001).

Growth in Cell Cultures

Although humans are the only natural host, RV grows in a wide range of primary and continuous cell cultures (Herrmann, 1979). Wild-type RVs often produce CPE in such continuous cell cultures as RK13 (rabbit kidney) and SIRC (rabbit cornea), but do not produce a reproducible CPE in Vero cells when first isolated. Although a characteristic CPE is usually produced in RK13 cells, the virus may be identified more reliably in both these and Vero cell cultures by immunofluorescence (IF), immunocolorimetric assays or polymerase chain reaction (PCR) (Chen *et al.*, 2007; Zhu *et al.*, 2007). The CPE has been shown to be due to rubella-induced caspase-dependent apoptosis in a number of continuous cell lines (Duncan *et al.*, 2000; Hofmann *et al.*, 1999). The exact mechanism of apoptosis has not been elucidated, but it is dependent on virus replication and is initiated within 12 hours of infection (Cooray *et al.*, 2003). Domegan and Atkins (2002) suggest that the p53 pathway is not involved. Gene expression using gene chip analysis has been compared in a primary cell line of fetal fibroblasts and a cell line of adult lung fibroblasts following infection with RV (Adamo *et al.*, 2008). Gene regulation favoured apoptosis in adult fibroblasts, but not in fetal fibroblasts, in which it appeared that gene expression was antagonistic to apoptosis.

Pathogenicity for Animals

RV infects rhesus (*Macaca mulatta*), vervet (*Cercopithecus aethiops*) and *Erythrocebus patas* monkeys, marmosets (*Sanguinus* species), chimpanzees, baboons, suckling mice, hamsters, ferrets and rabbits (reviewed by Banatvala and Best, 1990; Herrmann, 1979). Monkeys usually develop a subclinical infection with viraemia, virus excretion and an immune response, similar to that in humans. A viraemia and humoral and cell-mediated immune responses have been detected in six to eight week old BALB/c mice, which remain asymptomatic (Chantler *et al.*, 2001). Persistent infection has been established in suckling mice, adult hamsters, ferrets and rabbits.

Attempts to reproduce the teratogenic effects of RV in an animal model have produced inconsistent results. In such studies insufficient attention was given to the use of adequate controls and such factors as virus passage history, species adaptation, route of inoculation, nutrition and the effects of increased handling of the animals.

POSTNATALLY ACQUIRED INFECTION

Epidemiology in the Pre-vaccine Era

Humans are the only known hosts for RV, which had a worldwide distribution before the introduction of rubella

vaccination programmes. In temperate climates outbreaks usually occurred in the spring and early summer. Infection was uncommon in preschool children, but outbreaks involving school children and young adults living in institutional population groups were common. Women of child-bearing age were often infected as a result of exposure to children within their household or as a result of occupational exposure. Occasionally, extensive worldwide pandemics occurred, for example, in the early 1940s and again between 1963 and 1965, when a high incidence was reported in the United States, the United Kingdom and Australia. More commonly, rubella exhibited an increased incidence every three to four years, although within a particular country outbreaks might be localized.

Seroepidemiological studies have provided assessments of the incidence of rubella in different age groups and different geographical areas. Surveys have produced remarkably consistent results. In general, about 50% of 9- to 11-year-old children and about 80–85% of women of child-bearing age had rubella antibodies. Estimates of the basic reproductive number based on this information are $R_0 = 6.1$ (CR 4.3–9.2) (Kanaan and Farrington, 2005).

Rubella in Developing Countries

In an early World Health Organization study more than 80% of women of child-bearing age in mainland areas had HAI antibodies, although antibody prevalence was much lower in some rural areas and island populations (Dowdle *et al.*, 1970). In a more recent review of studies from 45 countries, Cutts *et al.* (1997) reported that less than 10% of women were susceptible to rubella in 13 countries, 10–26% in 20 countries and >25% in 12 countries, including island populations in the Caribbean, which have since adopted rubella vaccination programmes. There may be considerable variation in susceptibility in different parts of each country. The average age of infection varied from two to eight years of age.

Although CRS is now a rare disease in those developed countries that have adopted comprehensive rubella vaccination programmes, the burden induced by CRS imposes a considerable strain on scarce health and educational resources in many developing countries, which was insufficiently appreciated until recently. Although outbreaks of rubella may not always be recognized in developing countries, or rubella-induced rashes misdiagnosed, the incidence of CRS has recently been reported to have been considerably higher (range 0.6–2.2/1000 live births) than during the early years of the rubella vaccination programme in Britain (0.14/1000 during epidemics; at other times, 0.08/1000). Mathematical modelling estimated that there were approximately 110 000 (range 14 000–308 000) cases of CRS in developing countries during 1996 (Cutts

and Vynnycky, 1999); following epidemics this may show a tenfold increase.

Clinical and Virological Features of Primary Infection

Pathogenesis

Rubella virus is spread mostly by droplet from the upper respiratory tract. High concentrations of virus ($>10^5$ TCID₅₀/0.1 ml) may be excreted, but close and prolonged contact is usually required for virus to be transmitted to susceptible individuals. The epithelium of the buccal mucosa and the lymphoid tissue of the nasopharynx and upper respiratory tract probably represent the site of initial virus replication, following which RV spreads to the lymphatic system and establishes a systemic infection. It is likely that mononuclear cells are involved in dissemination of virus to different parts of the body although extracellular virus may be detected in serum.

Clinical Features

The rubella rash appears after an average incubation period of 14 days with a range of 12–21 days. Lymphadenopathy may appear up to a week before the rash and persist for 10–14 days after the rash has disappeared. Lymphadenopathy may be generalized, but the suboccipital, post-auricular and cervical lymph nodes are affected most frequently. Among children, onset is usually abrupt with the appearance of rash and constitutional symptoms usually mild or absent. The rash is at first discrete, and is in the form of pinpoint macular lesions. It appears first on the face and spreads rapidly to the trunk and then to the limbs. Lesions may coalesce, but the rash seldom lasts for more than three days; in many cases it is fleeting. Adults may experience a prodromal phase with such constitutional features as malaise, low-grade fever, headache, coryza, cough, sore throat, anorexia and mild conjunctivitis lasting for one to five days before rash develops. At this time an erythematous pinpoint enanthem may be visible on the soft palate. Rubella may occasionally present with a more severe fever and constitutional symptoms similar to measles.

Complications

Joint involvement is the most common complication of naturally acquired rubella and rubella vaccination, and usually develops as the rash subsides. Although relatively uncommon among pre-pubertal females and males, it may occur in up to 70% of post-pubertal females. Symptoms may vary in severity from a transient stiffness of the joints to an arthritis with pain, swelling and limitation of movement. This usually persists for three to four days, but occasionally for up to a month. The finger joints,

wrists, knees and ankles are most frequently affected. It has been suggested that rubella or rubella vaccination might be a cause of chronic joint disease, as RV or its antigens have been detected in the synovial fluid or synovium of patients with rheumatoid arthritis and seronegative arthritis (rheumatoid factor negative), but more recent studies have failed to confirm these findings (Bosma *et al.*, 1998; Geier and Geier, 2002). However, RV may persist in the synovium as virus has very occasionally been detected in both the synovial fluid and cells of patients with chronic joint disease (Bosma *et al.*, 1998).

Very rarely rubella is associated with other complications. A post-infectious encephalitis may develop in about 1 in 6000 cases within a week of onset of rash; it may also occur in cases without rash. In contrast to measles, the prognosis is usually good with recovery within 7–30 days and death is rare (Chantler *et al.*, 2001). The cerebrospinal fluid (CSF) usually contains cells, mostly lymphocytes, but CSF protein levels are normal. The encephalitis may be immune mediated, since infectious virus or its nucleic acid has been detected only rarely (Frey, 1997), and is not

associated with demyelination or inflammatory damage which is present in other post-infectious encephalitides.

Thrombocytopenia occurs in about 1 in 3000 rubella cases; a purpuric rash, epistaxis, haematuria, subconjunctival haemorrhage and gastrointestinal bleeding have been reported in such cases. Gullain–Barré syndrome, bone marrow aplasia, haemophagocytic syndrome, autoimmune haemolytic anaemia, optic neuritis, Fuchs heterochromic uveitis and relapsing encephalitis are other rare complications of rubella.

Differential Diagnosis

In 20–50% of cases, rubella infection is subclinical. Conversely, typical rubelliform rashes may result from infection by other viruses (e.g. enteroviruses, measles, human herpes viruses 6 and 7). Infections by such viruses as human parvovirus B19 and some arboviruses (e.g. Dengue, Chikungunya and Ross River viruses) may cause both rubelliform rashes and arthralgia (Table 23.2). Because clinical diagnosis is unreliable, it is essential that laboratory tests are conducted on all women who have been

Table 23.2 Differential diagnosis of postnatal rubella in different geographical regions

Virus infection	Geographical distribution								Key features
	Africa	Asia	Australia	Europe	North America	Central America	South America	Pacific

exposed to, or develop rubella-like illnesses in pregnancy; a past history of rubella without laboratory confirmation of the diagnosis must never be accepted as indicative of previous infection and consequent immunity.

Virological and Immunological Features

The relationship between the clinical and virological features of infection is shown in Figure 23.3. Patients are potentially infectious over a prolonged period; pharyngeal excretion may be present for up to a week before the onset of rash, and for seven to ten days thereafter. Although virus may be recovered from the stools and urine, excretion from these sites is more transient. Such specimens are therefore less suitable for virus isolation and do not play an important role in the transmission of virus. Viraemia is present for about a week before the onset of

rash, but, as rubella antibodies develop, viraemia ceases. IgG antibodies detected by enzyme immunoassay (EIA), and radial haemolysis (RH) usually develop six to seven days after onset of rash, while antibodies detected by HAI and neutralization appear a few days earlier. IgM antibodies detected by EIA develop over the first five days after rash (Helfand *et al.*, 2007). The predominant IgG response is IgG1; IgG3 is also detected, but IgG4 is rare (Thomas and Morgan-Capner, 1988).

Rubella induces a mild, transient immunosuppression, as demonstrated by a fall in total leukocytes, T cells and neutrophils and a depression in lymphocyte responsiveness to mitogens and antigens (e.g. PHA and PPD) and suppression of BCG-induced hypersensitivity. Lymphoproliferative responses develop a few days after onset of rash; a mixed Th1/Th2 response is seen (reviewed by Best and Reef, 2009).

HAI, haemagglutination inhibition; Neut., neutralizing; SRH, single radial haemolysis; EIA, enzyme immunoassay.

Reinfection

Natural infection is usually followed by protection from reinfection. When reinfection does occur, it is usually subclinical and is defined by a significant rise in rubella IgG concentration, and/or detection of specific IgM in a patient with pre-existing antibodies. It is more likely to occur in those with vaccine-induced immunity than in those who have been naturally infected. It may be difficult to distinguish between primary infection and reinfection, particularly if blood was not obtained shortly after contact or if sera taken prior to contact (e.g. for screening purposes) are not available.

Reinfection would provide a hazard to the fetus if associated with viraemia. A few well-documented cases of rubella reinfection have been reported where RV was isolated from the products of conception or from children born with congenital rubella (Best *et al.*, 1989; Bulls *et al.*, 2000; Fogel *et al.*, 1996). Morgan-Capner *et al.* (1991) have calculated that the risk of fetal infection is approximately 8% following asymptomatic reinfection in the first 16 weeks of pregnancy, but fetal malformations are rare. The risk of symptomatic reinfection is probably greater. It is not clear why some individuals are susceptible to reinfection as some cases have occurred in women with antibody concentrations >15 IU ml⁻¹. However, it may be due to a failure to produce epitope-specific antibodies. There is no evidence that reinfection is caused by genotypic variants (Bosma *et al.*, 1996; Frey *et al.*, 1998).

CONGENITALLY ACQUIRED INFECTION

Pathogenesis

If acquired at an early gestational age, rubella is likely to induce a generalized and persistent fetal infection, resulting in multisystem disease. This reflects the inefficiency of the placenta to act as a barrier to infection and the fact that the fetus is unable to mount an immune response to eliminate virus early in gestation. Töndury and Smith (1966) demonstrated that the earliest lesions are found in the placenta, which is almost certainly infected during the maternal viraemic phase. However, since RV is also excreted via the cervix for at least six days after the onset of rash, and since it is possible that virus may multiply elsewhere in the genital tract, placental infection by direct contact from an ascending genital infection cannot be excluded. They suggested that RV enters the fetus via the chorion, since necrotic changes to the epithelial cells as well as in the endothelial lining of the blood vessels were present as early as the tenth day after maternal rash. Damaged endothelial cells may then be desquamated into the lumen

of the vessel and transported into the fetal circulation in the form of virus-infected 'emboli', to infect the various fetal organs. Damage to fetal endothelial cells may be extensive, and is the result of viral replication rather than any immunopathological mechanism, due to the lack of immune response in early gestational age before fetal immune responses have developed. Following rubella in the early gestational period the marked absence of any inflammatory cellular response was characteristic. Anomalies were present in 68% of 57 fetuses when maternal rubella was contracted during the first trimester. Eighty per cent were abnormal when rubella was contracted during the first month of pregnancy, with sporadic foci of cellular damage in the heart, lens, inner ear, teeth and skeletal muscle. Additional damage to such malformed organs as the liver, myocardium and organ of Corti resulted from the damage caused to endothelial cells, which may result in haemorrhages in small blood vessels causing tissue necrosis over a prolonged time.

In addition to virus-induced tissue necrosis, RV induces a retardation in cell division. It has been suggested that this is due to a rubella-specific protein, which reduces the rate of mitosis in infected cells. If this occurs during the critical phase of organogenesis, the organs will contain fewer cells than those of uninfected infants and multiple developmental defects are likely to occur. The exact mechanism of teratogenesis has not been determined. However, the lack of RV-induced apoptosis in fetal cells, and persistent interferon and chemokine responses may enable RV persistence (Adamo *et al.*, 2008). Teratogenesis may be caused by retardation of cell division and the disruption of cell survival and proliferation pathways by the noncytotoxic, persistent RV infection.

Virus Persistence

Following intrauterine infection in the first trimester, RV persists throughout gestation and can be isolated from most organs obtained at autopsy from infants who die in early infancy with severe and generalized infections (Bosma *et al.*, 1995a; Cradock-Watson *et al.*, 1989). In infancy RV may also be recovered from nasopharyngeal secretions (NPSs), urine, stools, CSF and tears. RV can be isolated from NPS of most neonates with severe congenitally acquired disease, but by the age of three months the proportion excreting RV declines to 50–60% and by 9–12 months to about 10% (Best and Enders, 2007; Cooper and Krugman, 1967). During the first few weeks after birth, those with severe disease may excrete high concentrations of virus and readily transmit infection to rubella-susceptible contacts. RV excretion may sometimes continue for 12 months or more and RV may

persist in infants with congenitally acquired disease in some sites for even longer. Thus, RV has been recovered from a cataract removed from a three-year-old child and detected by RT-PCR in lens aspirates from children with CRS up to the age of 12 months (Bosma *et al.*, 1995a). RV has also been detected in the CSF of children with CNS involvement up to the age of 18 months. Rubella antigen was detected by IF in the thyroid from a five-year-old child with Hashimoto's disease, and by co-cultivation techniques RV was recovered from the brain of a child who developed rubella panencephalitis at the age of 12 years. Experimental studies have shown that within the CNS the astrocyte is the main cell type in which virus replicates, high levels of virus being expressed. Intrauterine infection involving these cells may perhaps induce focal areas of necrosis resulting in the pattern of neurological deficit observed in CRS (Chantler *et al.*, 1995).

RV is isolated infrequently from neonates whose mothers acquired rubella after the first trimester, probably because fetal immune mechanisms can then effectively terminate infection. Evidence for fetal infection following post-first trimester rubella, comes from serological evidence of fetal infection obtained in 25–33% of infants whose mothers acquired rubella between weeks 16 and 28 of gestation (Cradock-Watson *et al.*, 1980; Miller *et al.*, 1982).

Cell-mediated Immunity

Postnatally acquired rubella causes a transient reduction in lymphocyte responses to phytohaemagglutinin as well as a decrease in the numbers of T cells. CRS might be expected to cause an even greater reduction in responsiveness. Indeed, significantly diminished lymphoproliferative responses to phytohaemagglutinin and rubella antigen, as well as diminished interferon synthesis have been demonstrated (Buimovici-Klein *et al.*, 1979). Impairment of cell-mediated immunity (CMI) responses was related to the gestational age at which maternal infection occurred, and was greatest in infants whose mothers acquired rubella in the first eight weeks of pregnancy. Hosking *et al.* (1983) suggested that children with nerve deafness due to CRS could be distinguished from those with immunity due to postnatally acquired rubella by their failure to produce lymphoproliferative responses to rubella antigen. O'Shea *et al.* (1992) reported that 10 of 13 (80%) children with CRS under the age of three years failed to mount a lymphoproliferative response. Congenitally infected infants have also been shown to have impaired natural killer cell activity and persistent T-cell abnormalities. It is of interest that the defective CMI responses may persist into the second decade of life.

Risks to the Fetus

Maternal Rubella in the First Trimester

Maternal rubella may result in spontaneous abortion, the delivery of a severely malformed infant, an infant with minimal damage or a healthy infant and occasionally in fetal death. The incidence of defects following maternal infection in the first 10 weeks of gestation is 90%, but the risk declines significantly after 12 weeks gestation (see below). If maternal rubella is acquired during the first eight weeks of pregnancy, spontaneous abortion may occur in up to 20% of cases. The rubella-induced congenital anomalies detected are related to the gestational age at which infection occurred (Figure 23.4). Cardiac and eye defects are likely to result when maternal infection is acquired during the critical phase of organogenesis, in the first eight weeks of pregnancy, whereas retinopathy and hearing defects are more evenly distributed throughout the first 16 weeks of gestation.

Maternal Rubella after the First Trimester

Serological studies confirm that a high proportion of infants are infected following maternal post-first trimester rubella, rubella-specific IgM being detected in 25–33% of infants whose mothers had rubella between 16 and 20 weeks of pregnancy (Cradock-Watson *et al.*, 1980; Miller *et al.*, 1982). However, because organogenesis is complete by 12 weeks and in more mature fetuses immune responses may limit or terminate infection, such infants rarely have severe or multiple anomalies. The results of four studies conducted in different countries are shown in Table 23.3. Most surveys have shown that deafness and retinopathy, which *per se* does not affect vision, are likely to be the only anomalies commonly associated with post-first trimester rubella (reviewed by Best *et al.* 2005). Table 23.3 shows that deafness is usually the sole clinical manifestation of fetal infection occurring between 13 and 16 weeks, and is relatively common, but deafness or any other defect is only rarely encountered after this time. These findings emphasize the importance of conducting careful follow-up studies on infants with serological evidence of intrauterine infection as a result of maternal infection occurring between 13 and 18 weeks, particular importance being directed towards the recognition of hearing defects.

Most studies on the risk of rubella in pregnancy have included women who have had symptomatic rubella. Although it has been suggested that the risk of subclinical rubella is less, this has not been confirmed.

Pre-conceptual Rubella

The definitive study conducted in Germany and Britain showed that pre-conceptual rubella did not result in

transmission of RV to the fetus (Enders *et al.*, 1988). Thus, there was no serological or clinical evidence of intrauterine infection in 38 infants whose mothers' rash appeared before or within 11 days after their last menstrual period (LMP). However, fetal infection occurred when there was an interval of 12 days between LMP and rash and all 10 mothers who developed rash three to six weeks after their LMP transmitted infection to their fetuses.

Clinical Features

The frequency and importance of congenital defects involving the heart, eyes and ears were emphasized in the early retrospective as well as in most prospective studies. However, following the extensive 1963–1964 epidemic in the United States, as well as in subsequent epidemics in other parts of the world, a much broader range of rubella-induced congenital anomalies were observed. This

phenomenon is more likely to be due to more careful and prolonged observation than to any change in the biological behaviour or teratogenic potential of the virus. Thus, careful examination of the case notes of infants with congenitally acquired disease who were born before this outbreak showed that such anomalies as thrombocytopenic purpura and osteitis occurred fairly frequently, even though not recorded in the literature. In addition, careful and prolonged follow-up studies showed that CRS was not a static disease, since some features of intrauterine infection might not be apparent for months or years (e.g. perceptive deafness or insulin-dependent diabetes mellitus (IDDM)).

Clinical features of the CRS have been categorized into those that are transient or permanent, some of which may be delayed to appear months or even years later (Table 23.4). The frequency of defects has been reviewed (Reef *et al.*, 2000). The World Health Organization

classifies suspected cases of congenital rubella according to the criteria shown in Table 23.5. Criteria used in the United States were updated in 2001 (Centers for Disease Control and Prevention, 2001a).

Transient Anomalies

Transient anomalies usually present during the first few weeks of life, do not recur and are not associated with permanent sequelae. Their pathogenesis has not been established, but such features as intrauterine growth retardation (small-for-dates babies), cloudy cornea, thrombocytopenic purpura (Figure 23.5), hepatosplenomegaly and haemolytic anaemia are common. About 60% of infected infants fall below the 10th, and 90% below the 50th growth percentile. The above features, which often result from infection acquired at an early gestational age,

Table 23.5 WHO provisional case definition for congenital rubella syndrome

Suspected CRS case: Any infant less than 1 yr of age in whom a health worker suspects CRS. A health worker should suspect CRS when an infant aged 0–11 mo presents with heart disease and/or suspicion of deafness and/or one or more of the following eye signs: white pupil (cataract), diminished vision, pendular movement of the eyes (nystagmus), squint, smaller eye ball (microphthalmus) or larger eye ball (congenital glaucoma). A health worker should also suspect CRS when an infant's mother has a history of suspected or confirmed rubella during pregnancy, even when the infant shows no signs of CRS

Clinically confirmed CRS case: An infant in whom a qualified physician detects at least two of the complications listed in (a) below or one in (a) and one in (b):

- (a) Cataract(s), congenital glaucoma, congenital heart disease, loss of hearing, pigmentary retinopathy
- (b) Purpura, splenomegaly, microcephaly, mental retardation, meningoencephalitis, radiolucent bone disease, jaundice that begins within 24 hours after birth

Laboratory confirmed CRS case: An infant with clinically confirmed CRS who has a positive blood test for rubella-specific IgM (100% of such infants are positive at the age of 0–5 mo; 60% are positive at 6–11 mo). Where special laboratory resources are available the detection of rubella virus in specimens from the pharynx or urine of an infant with suspected CRS provides laboratory confirmation of CRS (60% of such infants shed rubella virus at the age of 1–4 mo; 30% at 5–8 mo; 10% at 9–11 mo)

Congenital rubella infection (CRI): If a mother has suspected or confirmed rubella in pregnancy her infant should have a rubella-specific IgM blood test. An infant who does not have clinical signs of CRS but who has a positive rubella-specific IgM test is classified as having CRI

seldom occur without such other manifestations of congenital disease such as heart and eye defects, and reflect extensive infection which may result in high perinatal mortality rates. Infants with thrombocytopenic purpura have platelet counts ranging from 3 to $100 \times 10^9/l$ (normal = $310 \pm 68 \times 10^9/l$). This is associated with a decrease in the number of megakaryocytes in the bone marrow, although they are morphologically normal. If severely affected infants survive, their platelet count rises spontaneously during the first few weeks of life; rarely, infants may die from such complications of thrombocytopenia as intracranial haemorrhage.

Bony lesions may be present in about 20% of congenitally infected infants. The metaphyseal portion of the long bones are usually involved and radiologically appear as areas of translucency. These lesions, which result from a disturbance in bone growth rather than an inflammatory response, usually resolve without residual sequelae within the first one to two months of age.

About 25% of infants who present at birth with clinical manifestations of CRS also have CNS involvement, usually meningoencephalitis. At birth, these infants may be either irritable or lethargic with a full fontanelle and CSF changes consistent with a meningoencephalitis. Although about 25% of infants presenting at birth with a severe neonatal encephalitis may, by the age of 18 months, be severely retarded and have communication problems, ataxia or spastic diplegia, some infants progress well neurologically despite poor development during their first few months of life.

'Late Onset Disease' Between the ages of about 3 and 12 months, some congenitally infected infants may develop a chronic rubella-like rash, persistent diarrhoea and pneumonitis, which is referred to as 'late onset disease'. Mortality is high, but some infants improve dramatically if treated with corticosteroids. Circulating immune complexes are probably responsible for inducing this syndrome (reviewed by Hanshaw *et al.*, 1985).

Permanent Defects

The major permanent defects which may be present at birth are cardiac and ocular defects and damage to the organ of Corti. These and other defects are listed in Table 23.4. Cardiovascular and ocular anomalies provide the greatest problems.

Cardiac Defects Cardiac defects are responsible for much of the high perinatal mortality associated with CRS, the commonest lesions being the persistence of patent ductus arteriosus, proximal (valvular) or peripheral pulmonary artery stenosis or a ventricular septal defect. In association with such anomalies, a neonatal myocarditis may occasionally occur. RV may also cause proliferation and damage to the intimal lining of the arteries and this may cause obstructive lesions of the pulmonary and renal arteries.

Ocular Defects Most of the classical ocular defects seen in CRS were described by Gregg (1941), who

Figure 23.5 Purpuric rash in newborn infant with congenitally acquired rubella, who was subsequently found to have congenital heart disease and cataract. (Source: Reproduced from Best, Cooray and Banatvala (2005), by permission of Edward Arnold (Publishers) Ltd.)

drew particular attention to the pigmented retinopathy and cataract. Although usually present at birth, cataracts may not be visible until several weeks later. They are unilateral in about 50% of patients, and may be subtotal, consisting of a dense pearly white central opacity (Figure 23.6), or total, with a more uniform density throughout the lens. Microphthalmia may be present in eyes with cataract. Glaucoma occurs much less frequently than cataract, but glaucoma and cataract do not seem to be present in the same eye. Retinopathy is present in about 50% of congenitally infected infants and its presence may provide a useful clinical diagnostic marker. Retinopathy is not the result of an inflammatory response but is due to a defect in pigmentation and usually involves the macular areas. Hyperpigmented and hypopigmented areas give the retina a 'salt and pepper' appearance. Chronic uveitis, choroidal neovascularization, corneal hydrops and keratoconus have also been described. The mechanisms involved may include damage induced by viral persistence causing reduced cell growth rate and life span, virally induced vascular damage or autoimmune phenomena (reviewed by

Figure 23.6 Congenital rubella cataract in a nine-month-old infant. Cataract was also present in the left eye but was removed surgically. (Source: Reproduced from Best, Cooray and Banatvala (2005), by permission of Edward Arnold (Publishers) Ltd.)

Arnold *et al.*, 1994). A recent case series from India has suggested that cataracts are the only clinical eye finding that is useful for screening (Vijayalakshmi *et al.*, 2007).

Hearing Defects Rubella-induced deafness may be unilateral with no characteristic audiometric pattern. Prior to the introduction of vaccination programmes CRS probably represented the commonest cause of congenital deafness in most developed countries, its impact being insufficiently appreciated since there may have been no history of maternal rubella. Deafness may be the only anomaly present, particularly if maternal infection occurred after the first trimester. Thus, in a study on a large number of children aged six months to four years who attended the Nuffield Hearing and Speech Centre in London, it was estimated that about 15% of all cases of sensorineural deafness were the result of CRS.

Delayed Manifestations

Congenital rubella is a progressive disease due to persistent virus infection. Some defects may take months or years before becoming apparent, but persist indefinitely (Cooper and Alford, 2006). Failure to recognize them may not merely be the result of difficulty in their detection, for there is evidence to show that such defects as perceptible deafness, some CNS anomalies and some ocular defects may actually develop later or become progressively more severe.

Hearing Defects On audiological examination, some infants, although they have apparently normal hearing at 9–12 months of age, are found to have severe sensorineural deafness months or even years later. Improvements in technology, such as otoacoustic emissions and auditory

brainstem responses, may be of value in assessing hearing defects in early infancy (van Straaten *et al.*, 1996).

Ocular Defects Glaucoma may develop between 3 and 22 years of age. Other late-onset eye defects are keratic precipitates, keratocornus, corneal hydrops and spontaneous lens absorption. Visual difficulties may develop due to subretinal neovascularization.

Insulin-Dependent Diabetes Mellitus IDDM (juvenile-onset; type 1) is the most frequent endocrine disorder among patients with congenital rubella. It was thought originally to be a rare complication of congenital rubella, but it is now recognized that clinical manifestations may be delayed until adolescence or adult life. A follow-up study of patients in New South Wales who were born with CRS in the 1940s showed that 20% eventually developed IDDM. Follow-up studies in New York on children, most of whom were infected *in utero* during the 1963–1964 epidemic, have shown that 30 of 242 (12.4%) had developed IDDM, although a higher proportion (20%) had pancreatic islet cell antibodies, suggesting that more of these patients were likely to develop IDDM (reviewed in Burke *et al.*, 1985). The mean age of children developing IDDM in this US study was nine years, while all of the Australian patients were in their twenties. Lymphocytic infiltration of the pancreas of an infant with CRS but without IDDM may suggest that RV can initiate a train of events that subsequently results in IDDM in later life. RV has been shown to induce a depression of immunoreactive secreted insulin in human fetal islet cells without being cytolytic (Numazaki *et al.*, 1990). Several experimental studies support the role for autoimmune mechanisms. Thus, Karounos *et al.* (1993) showed that immunoreactive epitopes in the RV capsid shared antigenicity (molecular mimicry) with islet β -cell protein. Ou *et al.* (1999), using clones of T cells from patients with CRS, have described human leukocyte antigen (HLA)-restricted cytotoxic responses to a β -cell autoantigen, GAD65. The HLA types in patients with IDDM are typical of those with autoimmune disease, there being a significant increase in prevalence of HLA-DR3 (reviewed in Burke *et al.*, 1985). Islet cell antibodies have been detected in 20% of these patients; these antibodies have a cytotoxic effect on cultured islet cells and predict the diabetic state. The mechanism by which RV may trigger autoimmune responses remains to be established, since studies on pathogenesis are limited by the lack of a suitable animal model.

Other Endocrine Disorders Thyroid autoantibodies have been detected in 20–40% cases of CRS, about 5% of cases have thyroid dysfunction, including hypothyroidism, hyperthyroidism and thyroiditis. Growth hormone deficiency has also been reported in CRS, suggesting pituitary

dysfunction. Poor growth and early cessation of growth have been reported.

Central Nervous System Disorders Mental retardation, autism and behavioural problems may develop and be progressive. Occasionally children with previously clinically stable congenitally acquired disease may develop a widespread subacute panencephalitis, which is invariably fatal (Chantler *et al.*, 2001; Frey, 1997). About 50 cases have been described in association with CRS and very rare cases following postnatally acquired rubella. Clinical and laboratory features are analogous to measles-induced subacute sclerosing panencephalitis, since, in addition to intellectual deterioration, spasticity and ataxia occur. Histological studies revealed a panencephalitis with a perivascular inflammatory response as well as a vasculitis. RV has been isolated from the brains of such patients, and has also been recovered from their lymphocytes. Rubella antigens have not been detected by IF in sections of brain. High levels of rubella-specific IgG and, occasionally, IgM may be present in the serum, while in the CSF there are elevated levels of protein and immunoglobulin, and oligoclonal bands are found. There is also a high CSF:serum rubella antibody titre ratio. It has been postulated that post-rubella panencephalitis may be a disease mediated by immune complexes or by RV-mediated autoreactivity to brain antigens.

Outlook for Children with Congenital Rubella

As a result of the extent and severity of rubella-induced congenital malformations, any surviving children require continuous and specialized medical care, rehabilitation and education. However, assessment of 25-year-old patients whose mothers acquired rubella during the extensive epidemic in Australia in the early 1940s showed that many had developed far better than had been anticipated in early childhood, despite the presence of hearing and eye defects. Most were of average intelligence, employed, and some had married and had normal children (Menser *et al.*, 1967). In contrast, studies on children with CRS resulting from the 1963–1964 US epidemic showed that they had fared less favourably (Cooper, 1975). This difference is probably due to the survival of children with some of the more severe manifestations of congenital infection, which reflects more modern, vigorous and sophisticated methods of treatment that were not available previously. More recent studies have reported a prevalence of diabetes, thyroid disorders, early menopause and osteoporosis, which is higher than the general population (Forrest *et al.*, 2002; Munroe, 1999). Precocious puberty has also been observed.

Management of Infants and Children with CRS

Clinical Management These children require care by a multidisciplinary team, as many lesions are not apparent at birth and long-term follow-up is required. There are few reports of attempted treatment of CRS; available chemotherapeutic agents have not affected the clinical course of disease (reviewed by Cooper and Alford, 2006).

Isolation Precautions These should be initiated as soon as a congenital infection is suspected. Infants with CRS excrete large amounts of RV initially and may remain infectious for 12 months or more. RV may be readily transmitted to rubella-susceptible individuals. Women of child-bearing age, some of whom may be in early stages of pregnancy, should be dissuaded from visiting such infants unless serological tests confirm that they are immune. It is important that midwives and nursing staff who may have to care for such infants are also shown to be immune to rubella; especially those midwives and nurses who originate from countries without rubella vaccination programmes.

LABORATORY TECHNIQUES AND DIAGNOSIS

Serological Techniques Used for Rubella Antibody Screening

Specific antibodies are associated with protection from rubella (Best and Reef, 2009). A minimum immune titre of 15 IU ml⁻¹ was adopted in the United Kingdom in 1978 in order to avoid the false-positive results obtained in some HAI tests (PHLS Working Party on the Laboratory Diagnosis of Rubella, 1988). More recently, this has been reduced to 10 IU ml⁻¹ for EIA and latex agglutination (LA) assays (Department of Health, 2003; Skendzel, 1996).

Extensive rubella antibody screening of adult women is carried out in order to identify susceptibles who require vaccination. In some countries all antenatal women are tested and those shown to be susceptible are offered a rubella-containing vaccine post partum or post pregnancy. It is particularly important that immigrant women and women planning *in vitro* fertilization are tested. Blood should be obtained from pregnant women for rubella antibody screening when they first book at antenatal clinics. It is advisable to store these specimens for at least a year, so that this pre-exposure specimen can be tested in parallel with later serum samples should a patient subsequently give a history of exposure to a rubella-like illness. In addition, should an infant be delivered with clinical features compatible with an intrauterine infection,

serum obtained in early pregnancy can be tested in parallel with that obtained after delivery and the infant's cord or neonatal blood (Department of Health, 2003). Tests may be carried out for evidence of congenital infection not only by rubella but also by such organisms as cytomegalovirus, parvovirus B19 and *Toxoplasma gondii*.

EIA is used most frequently for screening purposes, while RH and LA may be used for confirmatory purposes. HAI is not recommended since it is time-consuming, labour-intensive and false-positive results may occur due to failure to remove all serum lipoprotein inhibitors from test sera (PHLS Working Party on the Laboratory Diagnosis of Rubella, 1988). EIAs are widely used because they are sensitive, and can be used in automated antenatal screening. LA has the advantage of providing a result within a few minutes. Negative results should be confirmed using a different assay in order to identify sampling errors and monitor the first assay (Department of Health, 2003). Some women fail to produce antibody levels > 10 IU ml⁻¹ even after several vaccinations. These women may be considered to be immune if they have a well-documented history of more than one vaccination.

Serological Techniques Used for Diagnosis

Detection of Rubella-specific IgM

Serological methods are used for the diagnosis of rubella. A diagnosis is usually made by detection of rubella-specific IgM using a commercial EIA, but in the case of a pregnant woman it is necessary to confirm that diagnosis by demonstrating a rise in specific IgG concentration, by detecting low-avidity IgG or specific IgM in a second serum. Care should be taken to ensure that the rubella IgM test employed has a high level of sensitivity and specificity (Tipples *et al.*, 2004). The performance of commercial assays may differ, but it is possible usually to detect specific IgM antibodies within four days of onset of rash and for 4–12 weeks thereafter.

Detection of a Significant Rise in Antibody Concentrations

A significant rise in antibody titre can be detected by a quantitative EIA, HAI or LA titration. Seroconversion can be detected by RH. Although HAI antibodies may develop one to two days after onset of symptoms, IgG antibodies detected by EIA, LA or RH may be delayed until seven to eight days (Figure 23.3).

Measurement of Rubella IgG Avidity

The avidity, or strength of binding of rubella IgG to antigen, increases with time after primary infection (Thomas

and Morgan-Capner, 1990). Several EIA methods have been developed to measure rubella IgG avidity. The diethylamine (DEA) wash method (Böttiger and Jensen, 1997) has the advantage that it detects low-avidity antibody for longer after primary infection than the urea wash method, and it is easier to perform than the DEA shift value method (reviewed by Best and Enders, 2007). Commercially available tests have been evaluated by Mubareka *et al.* (2007).

Tests for rubella IgG avidity are useful to distinguish primary rubella from reinfection, and to determine whether rubella IgM detected in the absence of rash or rubella contact, is a consequence of primary rubella, non-specific IgM or persistence of IgM antibodies.

Use of Oral Fluid and Dried Blood Spots for Surveillance

Rubella-specific IgG and IgM antibodies may be detected in oral fluid using antibody capture immunoassays and results correlate well with serum antibodies (Ramsay *et al.*, 1998). The optimum time for detecting specific IgM is one to five weeks after onset of illness. Using oral fluid, it has been possible to demonstrate that rubella-like illnesses in children under one year of age are due to other viruses, such as parvovirus B19 (Ramsay *et al.*, 2002). Optimum methods for collection, extraction and preservation of samples have been established (Mortimer and Parry, 1991). A commercially available assay suitable for detecting rubella IgM in serum and oral fluid is now available (Vijaylakshmi *et al.*, 2006).

Oral fluid can also be used for reverse transcription nested PCR (RT-nPCR). RV RNA can be reliably detected in samples collected within seven days of onset of rash (Jin *et al.*, 2002). Such samples may provide RV RNA for molecular epidemiological studies.

Dried blood spots and oral fluid have been used successfully for seroepidemiological studies (Hardelid *et al.*, 2008; Perry *et al.*, 1993), but these samples have not been evaluated for screening or management of individual patients. Dried blood spots are particularly useful if the cold chain is unreliable (Helfand *et al.*, 2007).

Detection of Rubella Virus

Rubella virus may be detected in clinical samples by isolation in cell culture, or by RT-nPCR, but these techniques are only available in specialized laboratories. RT-nPCRs are of value for postnatal and prenatal diagnosis of congenital rubella (see below) and have been described in detail (Bosma *et al.*, 1995a, 1995b; Jin and Thomas, 2007; Revello *et al.*, 1997; Zhu *et al.*, 2007). Real-time PCR has also been developed (Rajasundari *et al.*, 2008).

RV can be identified by CPE in RK13 or certain sublines of Vero cells (reviewed by Best and Enders, 2007; Best and O'Shea, 1995). Since the CPE may be difficult to detect, RT-PCR, RT-nPCR or indirect IF are often used to identify RV after two passages in Vero or RK13 cells.

Serological Assessment of Women Developing or Exposed to Rubella-like Illnesses in Pregnancy

Development of a Rubella-like Illness

Guidelines on the management of women with rash illness in pregnancy have been published in the United Kingdom (Morgan-Capner and Crowcroft, 2002). Access to laboratory tests to confirm or refute a diagnosis of rubella is critical, since a clinical diagnosis is unreliable. Blood collected from pregnant women with features of a rubella-like illness as soon as possible after onset of symptoms should be tested for rubella IgM and IgG. Rubella IgM can usually be detected by three to six days after onset of rash, while IgG antibodies detectable by EIA may not be present until six to seven days after onset of rash (Figure 23.3). A second serum should be taken 5–10 days later to confirm the IgM result and to demonstrate seroconversion or a significant rise in specific IgG concentration in positive cases. A significant rise in IgG antibody titre can often be detected within seven days, although occasionally the response may be delayed, in which case it may be necessary to test additional blood samples. Detection of rubella IgM in a single serum is not sufficient to confirm a diagnosis of rubella in the first 20 weeks of pregnancy. Results should be interpreted with caution, taking into account accurate information on the likelihood, date and duration of exposure, date of onset of illness, including presence and distribution of rash, lymphadenopathy and arthralgia and history of rubella vaccination and results of previous rubella antibody screening tests. It is more difficult to make a diagnosis when the pregnant woman presents more than four weeks after onset of symptoms, unless a earlier serum is available. Tests for rubella IgG avidity and immunoblotting would be helpful (Best and Enders, 2007). In such cases all relevant information is required to interpret results.

Although the presence of rubella-specific IgM used to be considered indicative of a recent primary infection, it is now recognized that if sensitive techniques are employed, low and transient concentrations of rubella-specific IgM may persist for several years and may also be detected in reinfection (Best and Enders, 2007). Such findings, and the occurrence of occasional false-positive rubella IgM results, emphasize the importance of assessing clinical and serological data carefully before making a diagnosis of

primary rubella infection, which may result in termination of a precious pregnancy (Best *et al.*, 2002).

Contact with a Rubella-like Illness

Women who give a history of contact with a rubella-like illness should be investigated unless they have rubella antibodies detected in two previous sera, two documented doses of a rubella-containing vaccine or one dose of vaccine followed by detection of rubella antibodies (Morgan-Capner and Crowcroft, 2002). They are much more likely to acquire infection if exposure is close and prolonged, for example, within their own household. It is important that blood is obtained as soon as possible after contact. If rubella IgG antibodies are detected in serum obtained within the incubation period (i.e. 12–14 days of last exposure) it can be assumed that the antibodies result from infection in the past. Patients who present more than 14 days after exposure should be tested for rubella IgM and IgG. Women who are seronegative should be followed up for one month after date of last contact to ensure that seroconversion has not occurred. Seronegative women may experience considerable anxiety during this time, which may be allayed by testing the index case for rubella IgM in serum or oral fluid to determine whether the infection was rubella. Women who remain seronegative should be offered measles, mumps and rubella (MMR) vaccine in the post-partum period.

Diagnosis of Reinfection

Rubella reinfection may be diagnosed by a significant rise in rubella IgG concentrations, sometimes to very high levels, and/or detection of specific IgM in a patient with pre-existing antibodies. If serum samples obtained before reinfection are not available for re-testing, evidence of pre-existing antibody may be accepted if there are at least two laboratory reports of antibodies $>10 \text{ IU ml}^{-1}$ obtained by a reliable technique (not HAI). A documented history of rubella vaccination followed by at least one test for rubella antibodies $>10 \text{ IU ml}^{-1}$ is also acceptable (Best *et al.*, 1989).

It is often possible to distinguish reinfection from primary infection by examining the avidity of rubella IgG antibodies. Sera taken from cases of recent primary rubella reinfection have low IgG avidity, while sera taken from people with distant infection, including cases of rubella reinfection, have higher avidity (Thomas and Morgan-Capner, 1990). Low-avidity IgG can also be detected in oral fluid. Immunoblotting may also be useful as antibodies to E2 do not appear until about three months after primary infection (Meitsch *et al.*, 1997). Diagnosis of reinfection has been discussed in detail by Best and Enders (2007).

Management of Rubella in Pregnancy

Close collaboration between the laboratory and those caring for pregnant women is essential in order that investigations are carried out as quickly as possible. In all cases involving potential rubella in a pregnant woman, the risk of exposure to wild-type RV infection must be considered (e.g. was there travel to a rubella endemic area?). Laboratory test results must be evaluated considering the predictive values of the tests performed. Once a diagnosis of rubella has been established (see above), it is necessary to discuss the risks of congenital infection with both parents. Information on the gestational age at infection is required in order to assess the risk to the fetus. The pregnant woman may wish to consider a termination of pregnancy if infection has occurred in the first 12 weeks of pregnancy when the risk of defects is very high, but this decision may be different after 12 weeks gestation. Prenatal diagnosis may be of value when maternal infection has occurred at 12–18 weeks gestation, when reinfection has occurred in the first 12 weeks of gestation and when equivocal serological results are obtained in the first trimester. Invasive prenatal diagnosis is not indicated when primary rubella is confirmed before the 12th week of gestation, when long-persisting IgM antibodies are detected, as they are not associated with congenital infection (Best and Enders, 2007), and when a seronegative woman has inadvertently received a rubella-containing vaccine. There are no official guidelines for the use of invasive prenatal diagnosis for the diagnosis of congenital rubella infection.

The use of human immunoglobulin may be considered if a susceptible woman has close contact with confirmed rubella infection and a termination is not acceptable. However, the concentration of rubella antibodies in such preparations may be too low to prevent viraemia and its use may mask clinical symptoms, giving a false sense of security (Cooper and Alford, 2006). Serological follow-up is essential to determine whether infection has occurred (Salisbury *et al.*, 2006).

Virological Diagnosis of Congenitally Acquired Infection

Postnatal Diagnosis

Congenital rubella has become a rare disease in countries with effective vaccination programmes, but it should not be forgotten as immigrants and travellers may still be at risk of acquiring rubella in pregnancy. Neonates born to women who have had rubella at any stage of pregnancy and neonates born with clinical features suggestive of congenital rubella should be tested for evidence of congenital rubella infection. In addition, results of laboratory tests are required for case classification

of congenital rubella (Table 23.5). The most common methods for diagnosing congenital rubella are described below.

Detection of Rubella-specific IgM in Cord Blood or Serum or Oral Fluid Taken in Infancy

Rubella-specific IgM antibodies synthesized by the fetus *in utero* are present at birth. The detection of rubella-specific IgM in cord, neonatal or infant sera by an IgM-capture assay is the method of choice for the diagnosis of CRS. Rubella IgM can also be detected in oral fluid (Eckstein *et al.*, 1996; Rajasundari *et al.*, 2008). Specific IgM can be detected in most cases of CRS during the first three months of life, when sensitive methods are used. In the few studies carried out by reference laboratories, specific IgM has been detected in about 85% of infants tested at three to six months of age, in 30–71% at 6–12 months, 27–75% at 12–18 months and 6–67% at 18–24 months. However, it should be noted that the numbers of older children were small and a very sensitive MACRIA was used in some of these studies (Best and Enders, 2007; Chantler *et al.*, 1982; Thomas *et al.*, 1993). The sensitivity of commercially available EIAs have not usually been established for the diagnosis of congenital rubella. However, the absence of specific IgM by IgM-capture assays in the neonatal period virtually excludes symptomatic congenital rubella. If a low or equivocal result is obtained by any assay, a further specimen of serum should be examined and other techniques employed.

Specific IgM is usually detected in infants with asymptomatic congenital rubella infection up to three months of age, but rarely after that time (G. Enders, personal communication, 2006).

Detection of a Persistent Rubella IgG Response in the Infant

The detection of specific IgG may be of value when tests for specific IgM have not been conducted in early infancy. Maternally derived rubella-specific IgG antibodies as well as the infant's specific IgG will be present at birth. The presence of rubella antibody at a time beyond which maternal antibody would normally have disappeared (approximately six months of age) is suggestive of congenital infection. Since rubella is uncommon under the age of one year, specific IgG detected between 7 and 11 months of age may be suggestive of congenital rubella. However, each case must be assessed individually, taking into account such factors as age, maternal vaccination history, presence of clinical findings suggestive of or compatible with congenital rubella, and rubelliform illnesses since birth.

Detection of Rubella Virus in Samples from Infected Infants

Rubella virus may be detected by isolation in cell culture, or more rapidly by RT-PCR-based methods. NPS, urine, oral fluid, EDTA-blood, CSF, lens aspirates and post-mortem tissues may be tested for RV. Specimens can be sent on dry ice or in formal saline for RT-nPCR in a distant laboratory. This has been used in our laboratory to test lens aspirates and to confirm the diagnosis of congenital rubella in children in India (Bosma *et al.*, 1995a, 1995b). FTA filter paper (Whatman) may also be used to collect fluids for RT-PCR (Chibo *et al.*, 2005).

Cooper and Krugman (1967) isolated RV from NPS from most neonates with severe CRS, but by the age of about three months the proportion excreting virus had declined to 50–60%; and to 3% at 13–20 months of age. More recent results demonstrate that RT-nPCR is more sensitive than virus isolation for this purpose. Under three months of age RV RNA was detected in 16/19 (84%) NPS by RT-nPCR and 7/19 (37%) by virus isolation and in 19/25 (76%) urine samples by RT-nPCR and 9/25 (36%) by virus isolation (Best and Enders, 2007). Virus excretion is infrequent in children under one year of age, but has occasionally been detected up to the age of 27 months (Best and Enders, 2007; L. Grangeot-Keros, personal communication, 2007). Rajasundari *et al.* (2008) showed a good correlation between RT-nPCR and detection of rubella IgM and detected a high copy number of RV in lens samples by real-time PCR. Some countries require the documentation of the absence of infectious virus in a CRS infant to lift isolation requirements. In asymptomatic congenital rubella infection RV RNA was detected less frequently and only up to three months of age (G. Enders, personal communication, 2006).

Other Tests

Low-avidity rubella IgG1, lack of antibodies to the SP15 E1 peptide and the E2 glycoprotein, and poor cell-mediated immune responses have been reported in children with CRS under the age of three years (reviewed by Best and Enders, 2007). Rajasundari *et al.* (2008) reported that 18 of 27 (66.6%) infants aged 0–11 months had low-avidity IgG, but further evaluation of the other techniques is required.

Loss of Rubella Antibodies in Congenital Rubella

Although rubella-specific IgG detected by RH and EIA may persist indefinitely, studies on 223 children with congenital rubella following the 1963–1964 US epidemic showed that the HAI antibodies declined more rapidly among congenitally infected children than among their

mothers; by the age of five, 20% of infants with congenital rubella no longer had HAI antibodies (Cooper *et al.*, 1971). Nevertheless, seronegative children failed to develop an HAI response or excrete virus when challenged with rubella vaccine. More recent studies suggest a decreased production of antibodies to the epitopes on the E1 glycoprotein which induce HAI antibodies in some children with congenital rubella, and Forrest *et al.* (2002) reported that at 60 years of age 41% patients with congenital rubella had no detectable rubella antibodies when tested by EIA. Thus, in order to determine the immune status of such children in later life it may be necessary to test sera by EIA, LA or immunoblotting (Meitsch *et al.*, 1997).

Prenatal Diagnosis

A prenatal diagnosis may be made by detecting rubella RNA by RT-nPCR in amniotic fluid or fetal blood obtained by cordocentesis (Best and Enders, 2007; Macé *et al.*, 2004; Revello *et al.*, 1997). When RT-nPCR is used a result can be available within 48 hours. Rubella-specific IgM may also be detected in fetal blood. It is advisable to use all available assays to exclude a diagnosis of CRS (Best and Enders, 2007). There are few reports on the use of ultrasound to detect congenital rubella abnormalities, but Bailão *et al.*, (2005) have recently shown that key ultrasound findings are micrognathia, microcephaly, dystrophic calcification, cataracts, microphthalmos, hepatosplenomegaly and intrauterine growth restriction.

Amniotic fluid is the preferred sample as it is easier to collect than fetal blood. The detection of rubella RNA in amniotic fluid by RT-nPCR has a sensitivity of 86% and a specificity of 91% (Best and Enders, 2007). Ideally, amniotic fluid should be taken seven to eight weeks after onset of maternal rubella infection and not before 21 weeks of gestation. Samples should be tested in triplicate as levels of RV may be low. Chorionic villus biopsies have been used less frequently and therefore detection of virus in these biopsies should be interpreted with caution, as the detection of RV in the placenta may not always reflect fetal infection (Bosma *et al.*, 1995a).

Fetal blood collected in EDTA (not heparin) may be used for detection of RV by RT-nPCR and detection of specific IgM. It should be collected seven to eight weeks after maternal infection and not before 21 weeks gestation. It is advised to test fetal blood for rubella-specific IgM by more than one assay, as levels of IgM may be low.

It should be remembered that there are few published studies on the use of prenatal diagnosis which have included the outcome of pregnancy. False-positive and false-negative results have occurred in all studies and therefore a negative result on a single sample should be interpreted with caution. Repeat testing and collection of

further samples is often necessary (Tang *et al.*, 2003). As fetal infection is not always associated with congenital defects, it is important that the limitation of prenatal diagnosis and the risks of the sampling techniques are explained to the parents. The technical risk of fetal loss associated with amniocentesis is 0.2–1% and with the collection of fetal blood 0.5–2%. Collection of fetal blood is technically demanding and is only carried out in expert fetal medicine units. Prenatal diagnosis has been discussed in detail by Best and Enders (2007).

PREVENTION—RUBELLA VACCINATION

Development and Use of Attenuated Vaccines

The RA27/3 vaccine strain was originally isolated from the fetal kidney of a rubella-infected conceptus and is now the most widely used vaccine worldwide. In Japan and China locally developed attenuated strains are used. The development and use of rubella vaccines has been reviewed (Best and Reef, 2009). Rubella vaccine is usually administered with measles (MR), measles and mumps, (MMR) or measles, mumps and varicella (MMRV) vaccines. Two doses are required to give satisfactory protection against all diseases.

Immune Responses

About 95% of vaccinees develop an immune response some 20–28 days post vaccination although occasionally it may be delayed for up to two months. Rubella-specific IgG and IgA responses can be detected, while virus-specific IgM is detected in about 70% of vaccinees between three and eight weeks after immunization and may occasionally persist for six months and rarely for up to four years (O'Shea *et al.*, 1985). Rubella-specific 7S IgA responses persist for up to 10–12 years but the oligomeric 10S response is transient. The RA27/3 vaccine induces a secretory IgA response which can be detected in NPS for up to five years post vaccination. Antibodies against E1 and C recombinant proteins can readily be detected after RA27/3 immunization (Nedeljkovic *et al.*, 1999), but antibodies to recombinant E2 are detected in <60% of vaccinees (Best and Enders, 2007).

Serum antibodies are long lasting and it is expected that they will provide life-long protection in most vaccinees. Thus, antibodies detected by HAI and RH have been shown to persist for at least 21 years, although in about 10% of vaccinees they decline to low (<15 mIU ml⁻¹) or even undetectable levels within five years. Up to 23% of young women in the United States and Nova Scotia, where there has been little circulation of rubella, have been shown to lack antibodies to rubella. Nevertheless,

when 19 volunteers with low or undetectable antibody levels were challenged intranasally with high-titre RA27/3, only one was viraemic, this being transient and at a low level (O'Shea *et al.*, 1983). Immune responses including cellular responses after rubella vaccination have been reviewed in more detail by Best and Reef (2009).

Protective Efficacy and Reinfection

During outbreaks, the clinical protection afforded by vaccination has been shown to be 90–100% (reviewed by Best and Reef, 2009). Subclinical reinfection may occur in about 7–10% of vaccinees who have received the RA27/3 rubella vaccine. Although specific antibodies correlate with immunity, to date it has not been possible to identify any type or level of antibody which is invariably associated with protection. An antibody concentration of ≥ 10 IU ml⁻¹ is considered to provide protection to the majority of individuals. People with antibodies < 10 IU ml⁻¹ may respond to infection or vaccination with a secondary immune response due to immunological memory.

Evidence of reinfection is usually obtained serologically by demonstrating a significant rise in antibody titre. Experimental studies suggest that reinfection is more likely to occur in those whose immunity is vaccine-induced rather than naturally acquired (reviewed in Best and Enders, 2007; Best and Reef, 2009). A transient rubella-specific IgM response may be detected if serum is tested by a sensitive technique within four to six weeks of exposure. Viraemia has very occasionally been detected in vaccinees who have been reinfected naturally or experimentally. The risk of such reinfection resulting in fetal damage is small.

Virus Excretion

Provided sensitive assays are used, RV may be detected in the NPS of virtually all vaccinees 6–29 days post vaccination. Vaccine strains may also be detected in the breast milk of lactating women. However, vaccine strains are not easily transmitted. This may reflect the low concentrations of virus excreted, or attenuation may result in alteration of the biological properties of the virus to make it less transmissible.

Vaccine Reactions

Rubella vaccines are generally well-tolerated. Lymphadenopathy, rash and joint symptoms may occur some 10–30 days post vaccination although they are usually much less severe than following naturally acquired infection. Lymphadenopathy is often not noticed by vaccinees and, should rash be present, it is usually faint, macular and evanescent. Joint symptoms are rare in

children of both sexes, but up to 40% of post-pubertal females may develop an arthralgia. The small joints of the hands are most commonly affected but such other joints as the wrists, knees and ankles may also be involved. Some vaccinees may experience a vaccine-induced arthritis with swelling and limitation of joint movement. Symptoms rarely persist for longer than about a week and, although recurrences may occur, this is a rare event.

An association between MMR vaccine and chronic inflammatory bowel disease and autism has been suggested by a group at the Royal Free Hospital. This generated considerable public concern about the safety of MMR and led to a decrease in vaccine uptake. However, it should be emphasized that a range of studies have failed to support the association and a number of expert groups who have examined the evidence did not support it (Institute of Medicine, 2001; Salisbury *et al.*, 2006; World Health Organization, 2003a). There is no justification for using single vaccines rather than MMR.

Vaccine Failures

Rubella is a labile virus and therefore inactivated by exposure to heat and light. Manufacturers recommend that vaccine be stored at 2–8 °C and that after reconstitution it should be kept at that temperature, protected from light and used within one hour. Failure to adhere to these instructions is the most frequent reason for vaccinees failing to seroconvert. Approximately 5% of vaccinees fail to respond for unexplained reasons, but usually respond satisfactorily if revaccinated. A few may fail to do so, or respond poorly, because they have a pre-existing low level of antibody, which is undetectable by some techniques. Seroconversion after vaccination may be assessed at about eight weeks after vaccination if required. Passively acquired antibody, whether from blood transfusion, immunoglobulin or maternally acquired, may interfere with vaccine uptake. Vaccination should be delayed for three months following blood transfusion or administration of immunoglobulin (but see below).

Contraindications

As with other live vaccines, patients who are severely immunocompromised as a result of disease or its treatment (including cytotoxic drugs, corticosteroids or radiotherapy) should not be vaccinated. Contraindications should also be extended to those with thrombocytopenia. Many patients with such minor immunodeficiencies as Di-George syndrome and children with juvenile idiopathic arthritis using methotrexate may receive MMR. Children who have had chemotherapy for cancer may be vaccinated with one vaccine dose six months after cessation of chemotherapy (Patel *et al.*, 2007). HIV-positive patients

may be vaccinated unless they are severely immunocompromised (Centers for Disease Control and Prevention, 2006; Salisbury *et al.*, 2006).

If another live vaccine is to be administered at the same time, both should be given simultaneously but at different sites (except in the case of MMR). Alternatively, both vaccinations should be separated by an interval of at least three weeks. A three-week interval should also be allowed between the administration of rubella and BCG. If the patient is suffering from a febrile illness, it is better to delay rubella vaccination. The manufacturer's leaflet should be studied carefully when patients with known hypersensitivity are to be vaccinated, since rubella vaccines contain traces of antibiotics (neomycin and/or kanamycin or polymyxin). There is increasing evidence that MMR vaccine can be given safely to children with an allergy to egg. Pregnancy should be avoided for one month after administration of rubella-containing vaccines (see below). Although passively acquired antibodies may interfere with antibody responses following rubella vaccination, if anti-D is required, it may be given at the same time, but at different sites and from different syringes. Anti-D does not interfere with vaccine-induced antibody responses (Salisbury *et al.*, 2006).

Vaccination During Pregnancy

If a pregnant woman is inadvertently vaccinated there is no indication for therapeutic abortion or prenatal diagnosis (Centers for Disease Control and Prevention, 2001b;

Salisbury *et al.*, 2006). Examination of the products of conception of rubella-susceptible women inadvertently vaccinated during pregnancy has shown that RV may be recovered from the placenta, kidney and bone marrow for up to 94 days after vaccination, indicating that vaccine virus can cross the placenta and establish persistent fetal infection. Follow-up studies on women who elected to go to term following inadvertent vaccination during pregnancy, or within three months before conception, have shown that none of 833 infants had an abnormality compatible with CRS (Table 23.6). However, a specific-IgM response provided virological evidence of congenital infection in 26 of the 708 (3.7%) babies tested. In the US study 212 of the 324 babies were born to women who had received the RA27/3 vaccine. It should be noted, however, that only 293 of 833 (35.2%) women in the combined series were vaccinated in the high-risk period between two weeks before and six weeks after conception (Table 23.6). If rubella vaccines were to induce congenital defects, it may be necessary for infection to occur during a much shorter period than following naturally acquired infection. Many of the cases included in these follow-up studies were vaccinated within the three months before conception, which is probably of minimal risk. These findings have been confirmed by a more recent prospective controlled study in Canada, where 94 vaccinated women were followed up (Bar-Oz *et al.*, 2004). In Iran, 35 infants were born to susceptible women who were vaccinated in pregnancy, two were rubella IgM-positive at birth, but none

Table 23.6 Risk of rubella vaccination in pregnancy: combined data for risk of CRS in infants born to rubella-susceptible women who received rubella vaccination during pregnancy.

Country	Live births to women receiving rubella immunization			
	Within 3 mo of conception or during pregnancy	In the high-risk ^a period	Evidence of infection ^b	Abnormalities compatible with CRS ^b
United States	324	113	6/222 (2.7%)(1–5.8)	0/324 (0%) (0–1.1)
Germany	280 ^c	155	6/280 (2.1%)(0.8–4.6)	0/280 (0%) (0–1.3)
Sweden	5	NK	0/5 (0%) (0–52.2)	0/5 (0%) (0–52.2)
United Kingdom	75 ^d	25	4 ^e /52 (7.7%) (2.1–18.5)	1 ^f /75 (0%) (0–7.2)

^eThree of the rubella IgM-positive infants were born to mothers who were inadvertently immunized within the six weeks after last menstrual period.

^fOne rubella IgM-positive infant had a heart murmur which had resolved by 2 mo of age.

had CRS abnormalities (Hamkar *et al.*, 2006). Further evidence comes from Costa Rica (Badiilla *et al.*, 2007) and Brazil (Minussi *et al.*, 2008) where 170 and >1000 susceptible pregnant women were vaccinated with MR during mass vaccination campaigns and no congenital abnormalities were detected. The theoretical maximum risk of rubella-induced major malformations among infants delivered of susceptible mothers who were vaccinated in the high-risk period has been calculated to be 1.3% (Centers for Disease Control and Prevention, 2001b). This is less than the risk of major malformation occurring in 'normal' pregnancies (approximately 3%). The lack of teratogenicity may well be due to a lower viral load rather than a difference in teratogenicity of the attenuated viruses. One case of vertical transmission with prolonged virus shedding from the infant has been described, but the infant had no signs of CRS.

Vaccination Programmes

Rubella vaccination programmes have had a major impact in preventing CRS in countries that have implemented them.

Vaccination in the United States

Initially, the United States adopted universal childhood immunization. This programme resulted in more than 99% decrease in the number of cases of rubella reported between 1969 and 1988. However, as a number of rubella outbreaks occurred among adolescents and young adults in the late 1970s, further emphasis was placed on vaccinating susceptibles in these older age groups, which resulted in a further decline in rubella notifications. Since 1978 the decline in the incidence of CRS in the United States paralleled the decline in postnatally acquired rubella. Although there was substantial underreporting of CRS, it was anticipated that CRS was on the verge of elimination in the United States in the 1980s. However, in 1989–1990 there was a resurgence of CRS in southern California and among the Amish population in Pennsylvania. This was the result of missed opportunities for rubella screening or vaccination; many of the cases of maternal rubella could have been prevented if post-partum immunization had been carried out following previous pregnancies. Rubella was declared to have been eliminated in the United States in 2004, although occasional imported cases continue to occur (Centers for Disease Control and Prevention, 2005). The US policy results in a financial saving: cost–benefit analysis shows that the cost of rubella in an unvaccinated population is approximately 11 times more than the cost of the vaccination policy.

Vaccination in the United Kingdom

The United Kingdom and other European countries initially adopted a selective vaccination programme, in order to protect women during their child-bearing years. In the United Kingdom from 1970 to 1988, vaccination was directed towards pre-pubertal schoolgirls, and rubella-susceptible women of child-bearing age. The augmentation of the rubella vaccination programme in 1988, in which MMR vaccine was offered to preschool children of both sexes, resulted in a marked reduction in the incidence of rubella with the lowest ever number of cases reported in 1992 (Figure 23.7) (Miller *et al.*, 1993). A rubella outbreak in 1996 was largely confined to 17- to 24-year-old males who had never been offered rubella vaccine. Fortunately, transmission of rubella to pregnant women was limited since 98–99% were immune, either as a result of naturally acquired infection or vaccination as schoolgirls or post partum (Miller *et al.*, 1997). The incidence of rubella has remained low in the United Kingdom since 1996. Vaccination of susceptible women continues, but vaccination of pre-pubertal schoolgirls has been discontinued.

In order to eliminate rubella, it is necessary to monitor the efficacy of rubella vaccination programmes (Vyse *et al.*, 2002). In the United Kingdom this is done by seroprevalence studies in different age groups, including pregnant women, reporting of congenital rubella cases and terminations due to rubella in pregnancy, and monitoring uptake of MMR in children. In the United Kingdom in 1994–1995 only 2% of nulliparous and 1.2% of parous women were rubella susceptible and this, together with the decline in circulation of rubella among young children has resulted in only occasional terminations due to maternal rubella and cases of CRS (Figure 23.8) (British Paediatric Surveillance Unit, 2007; Miller *et al.*, 1997; Tookey and Peckham 1999). However, women who come to the United Kingdom from countries that do not have effective rubella vaccination programmes are more likely to be susceptible. In North London between 1996 and 1999, it was shown that susceptibility was about 5% in women born outside the United Kingdom, with the highest rates of susceptibility among women from Asia and Africa; 23.3% of Sri Lankan women in their first pregnancy were susceptible to rubella (Tookey *et al.*, 2002). Many of the recent reported cases have acquired rubella abroad. Between 1997 and 2006, 14 congenital rubella births were reported in the United Kingdom and Ireland. Nine of the mothers acquired rubella abroad and most of the cases were not diagnosed during pregnancy (British Paediatric Surveillance Unit, 2007). This emphasizes the importance of questioning women who come from developing countries when pregnant, about any illness experienced in early pregnancy, so that appropriate tests can be carried out (Department of Health, 2003).

Figure 23.7 Laboratory reports of rubella in England and Wales, 1984–2004. (Source: Data kindly provided by Dr E. Miller, Health Protection Agency, UK.)

Although the uptake of MMR among children was 92% in 1995, it dropped to 84% in England and Wales in 2002, due to unnecessary public concern about the safety of MMR. This has resulted in measles outbreaks in 2002–2008 and may put unvaccinated girls at risk of rubella in the future.

Current United Kingdom recommendations can be found in ‘Immunization against infectious disease’ (Salisbury *et al.*, 2006). It is recommended that the first dose of MMR be given at 13 months of age and the second dose at any time from three months after the first dose, but is normally given before school entry. All children should have received two doses of MMR before they leave school. MMR vaccine can be given at any age. It should be offered to rubella-seronegative women of child-bearing age, and on entry into college, university, military service or prison if there is no history of MMR vaccination. It is particularly important that healthcare workers are vaccinated. MMR can be given to those with a history of infection with MMR or if they have previously received single vaccines. If there are concerns about vaccination, specialist advice should be obtained rather than leave the child or woman unvaccinated.

Other European Countries

The WHO European region consists of 52 member states, which are culturally and economically diverse. This region aims to eliminate rubella and to reduce the incidence of CRS to <1 : 100 000 live births by 2010. Initially selective vaccination programmes were adopted in countries in Western Europe. Subsequently MMR has been introduced into childhood vaccination programmes and most countries now offer a second dose. In 2004, 47 (90%) countries used a rubella-containing vaccine. Sweden and Finland have already eliminated rubella by use of two dose MMR vaccination programmes. Countries such as Italy have strengthened their vaccination programmes and surveillance of rubella and CRS. Countries in Eastern Europe have undergone significant economic change, which has had an adverse effect on vaccination programmes. The incidence of rubella remains high in Europe and large rubella outbreaks have occurred recently in Romania and the Russian Federation (World Health Organization, 2005a). Nardone *et al.* (2008) reported that more than 10% of children of 2–14 years of age were susceptible to rubella in four countries, which therefore need to strengthen their vaccination programmes. Outbreaks of rubella and cases of congenital

Figure 23.8 Congenital rubella births and rubella associated terminations of pregnancy (TOPs) in England and Wales, 1971–2000. CRI, congenital rubella infection; CRS, congenital rubella syndrome. (Source: From the UK National Congenital Rubella Surveillance Programme, 2003.)

rubella have also occurred in unvaccinated communities in the Netherlands in 2004–2005.

Developing Countries

Rubella vaccination strategies are unsatisfactory in many developing countries (Robertson *et al.*, 1997, 2003), and there is a considerable burden of CRS in many countries. In 2000 WHO proposed strategies for rubella elimination (World Health Organization, 2000), which are summarized

in Table 23.7. The major thrust of the proposal was to ‘piggy back’ rubella with measles (MR) or measles and mumps (MMR) vaccines. By 2006 rubella vaccination was included in national immunization programmes of 123 (64%) WHO member states, an increase of 58% since 1996 (Figure 23.9), with the most impressive coverage seen in the Pan American Health Organization (PAHO) region. By 2004, 43 of 44 countries in the PAHO region had incorporated MR or MMR into their childhood immunization

Table 23.7 Summary of recommendations from WHO for elimination of rubella and congenital rubella

<p>Countries undertaking measles elimination should take the opportunity to eliminate rubella through the use of measles–rubella or MMR vaccine in their childhood immunization programmes, as well as through campaigns. All countries undertaking rubella elimination should ensure that women of child-bearing age are immune and that routine coverage in children is sustained at 80% or above</p> <p>Countries that currently include rubella in their childhood immunization programmes should ensure that women of child-bearing age are immune and should move towards rubella elimination</p> <p>If a global measles eradication goal is established, rubella should be included</p> <p>Rubella vaccine should be considered as a priority for initiatives to introduce new or underutilized vaccines in developing countries.</p>

programmes. This has been combined with mass immunization of adult women or men and women in some countries, in order to avoid shifting the age of infection to susceptible adults (Badilla *et al.*, 2007; Best *et al.*, 2005; Minussi *et al.*, 2008; World Health Organization, 2003b). WHO have published guidelines for surveillance of rubella and congenital rubella (World Health Organization, 1999) and established a measles and rubella laboratory network to aid this work (World Health Organization, 2005b).

Careful consideration is needed before the introduction of rubella vaccination in countries with relatively low measles uptake rates, for example, parts of Africa with uptake rates of about 60%. Intermediate rubella vaccination rates may increase the average age of infection and consequently lead to more cases in young adults, including pregnant women, which would lead to an increase in the incidence of CRS. It is now recognized that children of both sexes and susceptible adult women should be vaccinated in order to eliminate rubella and avoid an increase in incidence of congenital rubella (Hinman *et al.*, 2002; Robertson *et al.*, 1997). The danger of low rubella or MMR vaccination coverage of children was illustrated by an epidemic of rubella in Greece in 1993, with a resulting incidence of CRS of 24.6/100 000 live births (Panagiotopoulos *et al.*, 1999).

Mumps

Pauli Leinikki

National Public Health Institute, Helsinki, Finland

INTRODUCTION

Mumps is an acute infectious disease of children and young adults caused by a paramyxovirus. The description by Hippocrates in the fifth century BC of an epidemic disease with swelling near the ear and painful enlargement of the testis is usually cited as the first description of mumps. Over the last two centuries the disease has been reported from most countries of the world. Outbreaks in military personnel have received special attention, and mumps has been a considerable health problem for the armed forces until recently. In 1918, during the First World War, the mortality rate among the US and French armies was as high as 75/1000 men, causing as serious a problem as caused by the opposing army. Johnson and Goodpasture (1934) were able to show that the disease could be transmitted to rhesus monkeys by means of a filterable agent. Habel (1945) cultured the virus in chick embryo, and as early as in the mid 1940s both live attenuated and inactivated vaccines were tried in experimental animals and human volunteers (Enders *et al.*, 1946; Henle *et al.*, 1951).

THE VIRUS

Mumps virus is taxonomically located in the family *Paramyxoviridae* where, along with Newcastle disease virus and simian virus 5, it forms a separate genus called *Rubulavirus* (Bellini *et al.*, 1998).

Paramyxovirus virions are enveloped spherical particles with surface spikes projecting from the envelope (Figure 24.1). Inside, there is a large, helically arranged nucleocapsid. The virus is sensitive to lipid solvents and

is labile, 90–99% of infectivity being lost in 2 hours at 48 °C in protein-free medium.

Comprehensive details of the structure of mumps virus have been given by Kelen and McLeod (1977) and Strauss and Strauss (1983). The size of the virion shows considerable variation. Usually the diameter is 150–200 nm but bigger virions are occasionally seen (up to 340 nm). A 220-nm filter, which is commonly used in virological laboratories to remove bacteria from biological fluids, may, in certain conditions, retain a large proportion of viral activity. A few virions contain multiple copies of nucleocapsid.

The negative-stranded RNA is a single molecule with about 16 000 nucleotides with seven open reading frames coding for the nucleocapsid (N), the V protein and, after editing, the matrix (M), phosphoprotein (P), the large (L), the fusion (F), the haemagglutinin-neuraminidase (HN) and the small hydrophobic (SH) proteins. At least four nonstructural proteins, designated C, V, W and I, are encoded by the viral genome (Bellini *et al.*, 1998). The gene order (from the 3' end) is NP–P/V–M–F–SH–HN–L (Elango *et al.*, 1988).

NP plays a central role in the encapsidation, transcription and replication of viral RNA. It is the most abundant protein of the virion and of the infected cells. P proteins serve an important role in RNA synthesis. They are components of viral polymerase complexes and probably bind both to NP and L proteins. The M protein forms the structure which underlies the viral envelope. It is important for the assembly of virions during the replicative cycle. The HN glycoproteins agglutinate red cells of many species. Haemagglutination of avian cells is widely used as a diagnostic method for mumps. A separate part of the molecule carries neuraminidase activity, which mediates the attach-

Figure 24.1 Electron micrograph of disrupted mumps virions, revealing the enveloped structure and unfolded nucleocapsid.

ment of the virion to target cells via receptor molecules of the cell which contain sialic acid. The protein also plays a role in the fusion of plasma membranes and viral envelope working together with the F protein.

F protein is actually made of two subunits, F1 and F2, which are formed as a result of proteolytic cleavage of a larger precursor molecule called F0. The F proteins play an essential role in the fusion of membranes. Antibodies reacting with F proteins inhibit haemolysis caused by mumps virus and neutralize it. The F proteins are probably crucial in determining the spread of the virus in a cell population and also in the body. The proteolytic cleavage of F0 to subunits is a host cell function. Failure of this cleavage due either to host cell malfunction or to change in the amino acid composition of F0 results in the production of non-infectious viruses.

The function of SH protein is still unknown. The SH region of the genome has been used for genetic distinction of mumps virus strains. Geographically restricted lineages have been identified which seem to be stable over time but which do not show similar progressive strain evolution as seen in influenza (Afzal *et al.*, 1997).

Antigenic and Genomic Structure of the Virus

Only a single serotype of mumps virus is known (Hopps and Parkman, 1979). It cross-reacts considerably with other members of the genus *Paramyxovirus*. In serum samples derived from mumps patients, significant rises in antibody titres are often seen against heterologous viruses, most often against parainfluenza type 1. The viral glycoproteins HN and F are responsible for the cross-reactivity, while NP and M proteins elicit a more type-specific

response. Two different antigenic preparations are used in the diagnostic laboratory. Mumps V antigen consists predominantly of HN glycoprotein, while mumps S antigen is largely NP. In mumps infections, antibodies develop first against S antigen and only later against V antigen. By measuring antibodies to the two antigens it is possible to make a specific laboratory diagnosis quite early in the course of infection (Figure 24.2).

Antibodies against HN and F proteins neutralize infectious virus but immunoblot analysis reveals that all components of the virion are immunogenic.

Though mumps virus is antigenically monotypic, genetic variation between strains has been described. In particular, the SH gene seems to contain strain-specific variability that can be used for epidemiological and diagnostic purposes. Molecular characterization can help identify transmission pathways of the virus and distinguish between wild-type and vaccine strains.

Replicative Cycle of Mumps

The virion attaches to its specific cellular receptor followed by fusion of the viral envelope with the plasma membrane. Replication occurs exclusively in the cytoplasm. The genome is arranged in a single linear sequence from where the transcription proceeds, so that the polymerase stops and reinitiates mRNA synthesis at each gene junction. Accumulation of viral proteins leads to a switch from transcription to virion maturation. Regulation of the various steps of transcription is a complex process involving different viral proteins. For viral assembly, complete nucleocapsids must be formed that are engulfed into the viral envelope by a budding process whose details are poorly understood (Bellini *et al.*, 1998).

Several details of the molecular biology of mumps still await experimental confirmation. Understanding these events at a molecular level should help us to understand the mechanisms whereby mumps virus can produce acute or chronic infection and which components are crucial for establishing protective immunity.

Figure 24.2 Structural components of the mumps virion.

PATHOGENESIS

Mumps is transmitted by droplet spread or by direct contact, and the primary site of replication for the virus is the epithelium of the upper respiratory tract or eye (Feldman, 1982). The first infected cells form the primary focus, from which the virus spreads to local lymphoid tissues. Further multiplication within this restricted area results eventually in primary viraemia, during which the virus is seeded to distant sites. The parotid gland is usually involved but so may be the central nervous system (CNS), testis or epididymis, pancreas or ovary. A few days after the onset of clinical parotitis, virus can again be isolated from blood, indicating that virus multiplication in target organs leads to a secondary viraemia (Figure 24.3). As a result, virus may again spread to various target organs. The clinical course of mumps virus infection is quite variable: meningitis may precede parotitis by a week, the disease may manifest with orchitis only, with a combination of pancreatitis and orchitis, and so on. Nevertheless, parotitis is the most frequent presentation, occurring in 95% of those with clinical symptoms.

Virus is excreted in the urine in infectious form starting at any time during the two weeks following the onset of clinical disease. It is not known whether virus actually multiplies in renal tissues or whether the virus is of haematogenous origin, but in most cases slight abnormalities can be detected in renal function, such as microscopic haematuria and proteinuria. Virus is also excreted in breast

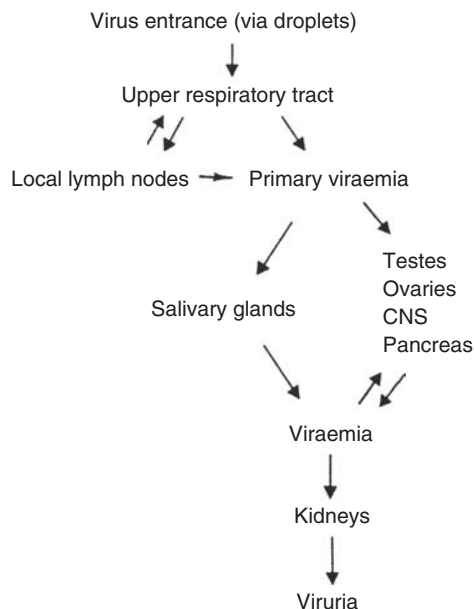

Figure 24.3 Pathogenesis of mumps infection.

milk, and it has been suggested that the virus multiplies in the lactating breast.

Interferon probably plays an important role in the pathogenesis, with the highest concentrations detected within the first few days of illness. Interferon can also be found in saliva and cerebrospinal fluid (CSF). Mumps infection results in a marked increase of specific antibodies of immunoglobulin G (IgG), IgM and IgA classes. It also stimulates a cell-mediated immune reaction which can be demonstrated *in vitro* for a few months after the infection. Which of these responses is most important for protective immunity is not known. Mumps is not a clinical problem in immunocompromised children.

Pathological changes induced by the virus in various organs are nonspecific. In the parotid glands they include serofibrinous exudate and polymorphonuclear cells in the connective tissue and within the ducts. The ductal cells show degeneration. In infected testes the changes may be more pronounced, with marked congestion and punctate haemorrhages. Similar changes have been described in pancreatic tissue.

In meningitis, electroencephalograms usually show little alteration, suggesting the lesions are located predominantly in the meninges. In the rare cases where encephalitis occurs as a complication of mumps, lesions are found in the spinal cord and brain tissue. It seems likely that the lesions are produced from the combined effect of direct viral cytopathic effect and immunopathological destruction of CNS cells. Involvement of the CNS may be associated with symptoms compatible with paralytic disease and deafness but the exact pathogenesis is not known.

On several occasions prolonged involvement of the CNS after clinically manifested mumps meningoencephalitis has been described (Julkunen *et al.*, 1985). Whether this reflects a true replication of virus within the brain tissue over an unusually long period or whether the clinical condition is a result of prolonged immunological damage is not known.

Mumps virus can multiply *in vitro* in human pancreatic islet cells (Parkkonen *et al.*, 1992). The virus can also grow in cell cultures from human joint tissues, causing chronic infection associated with an incomplete replicative cycle (Huppertz and Chantler, 1991).

CLINICAL PICTURE

Classic Parotitis

The incubation period is 16–18 days but may vary from 14 to 25 days. Parotid swelling appears in 95% of those who develop clinical disease (Figure 24.4). The rate of subclinical infections varies somewhat with age but is, on

Figure 24.4 A patient with mumps parotitis.

average, 30%. In a small proportion the symptoms may resemble only mild respiratory tract illness. Patients with classic mumps develop enlargement of one parotid gland which, in 75% of cases, is followed one to five days later by enlargement of the contralateral gland. For one to two days prodromal symptoms may dominate; these include malaise, myalgia, headache and low-grade fever.

Vaccination status of the affected population may influence the clinical presentation of the disease by shifting the prevalent age distribution or affecting the course of the disease by pre-existing immunity. In an outbreak affecting both vaccinated and unvaccinated individuals at all age groups, 57% of the clinically affected people were males and 43% were females, 58% had fever, 57% general malaise, 39% headache, 1% rash. Meningitis was seen in 1%, and orchitis in 7% of the male cases. Complications seem to be less common in vaccinated children (6% vs. 1%; Visser *et al.*, 1998).

The parotid involvement initially causes local tenderness and sometimes earache, and a few days later clinically apparent swelling. This involves the entire gland, including the area in front of the ear lobe. The orifice of the glandular duct becomes red and oedematous, and direct pressure on the glands yields only clear fluid, if anything. Submandibular and sublingual glands are occasionally also involved but practically never without parotid infection.

The parotid swelling starts to subside after four to seven days. Virus shedding into saliva begins a couple of days before clinical parotitis and ends seven to eight days later. Glandular swelling is followed by constitutional

symptoms such as fever, which seldom exceeds 40°C, and pain. These diminish when the swelling has reached its maximum and the general feeling of the patient starts improving.

Recovery is usually rapid. Sometimes presternal oedema and sublingual and laryngeal swelling may alter the classic picture. This is thought to result from lymphatic obstruction in the cervical and mandibular areas. Severe anorexia and photophobia have been described.

Complications

The course of mumps infection may be extremely variable, as described in the section on pathogenesis. Diseases such as orchitis or pancreatitis could therefore be regarded as systemic manifestations of mumps rather than true complications. However, since classic parotitis is so characteristic and clinically dominating, all other clinical features are often regarded as complications. For a further description of the clinical aspects of mumps virus infection see Marcy and Kibrick (1983) and Christie (1974).

Meningitis

Aseptic meningitis is a common complication of mumps patients. As many as 50% may show pleocytosis of the CSF and clinical signs are seen in 1–10%. Mumps meningitis can be associated with parotid swelling but can also occur in its absence, thus causing problems in differential diagnosis. Mumps virus used to be the most common virologically confirmed causative agent of aseptic meningitis before general vaccinations were started. It is two to three times more frequent in male patients than in female and the age distribution is the same as for mumps parotitis.

Symptoms are indistinguishable from other types of aseptic meningitis and they can start from one week before parotid swelling to three weeks after it. Sometimes the clinical picture is more severe, 6–18% of hospitalized patients having symptoms resembling encephalitis (see below).

Laboratory examination of CSF reveals pleocytosis (usually <500 lymphocytes/ml, sometimes up to 1000), normal or slightly decreased sugar. Virus can be isolated from the CSF during the first two to three days after the onset. Later, intrathecal synthesis of mumps antibodies can be demonstrated. Symptoms of meningitis subside 3–10 days after onset, and recovery is complete.

Encephalitis

Clinical features suggesting encephalitis are convulsions, focal neurological signs, movement disorders and changes in sensory perception. Sometimes polio-like paralysis

ensues and even fatalities have been reported. Probably both direct viral invasion and allergic inflammatory reactions lie behind the nervous tissue damage. The incidence of encephalitis is about 1/6000 cases of mumps.

Other Neurological Manifestations

Before vaccination, mumps used to be one of the leading causes of hearing loss in children and young adults. According to a study from military forces in Finland, 4% of mumps cases among military recruits were associated with deafness or significant hearing loss (Vuori *et al.*, 1962). In most cases the condition was transient but permanent dysfunction ensued in a few. Hearing problems did not correlate with meningitis. The incidence of permanent hearing loss has been estimated to be 1/15000 cases of mumps. Sometimes Ménière's disease is a late complication.

Orchitis and Oophoritis

After puberty the incidence of orchitis is 20–30%, and in 20–40% of cases there is bilateral involvement. Symptoms are acute, with pain and tenderness accompanied by fever, nausea and vomiting. The testis may enlarge three- to fourfold within four to five days. There is associated epididymitis in 85% of cases. Late sequelae include atrophy of testicular tissue, which may lead, in cases with bilateral disease, to infertility. Late sequelae of pre-pubertal orchitis are not known.

In females oophoritis is evident in approximately 5% of post-pubertal cases. No correlation with infertility has been recorded. The condition may present with pelvic tenderness and cause problems of differential diagnosis from acute appendicitis.

Pancreatitis

The exact frequency of pancreatitis is difficult to determine, but figures as high as 5% have been proposed. Clinical signs, such as epigastric pain and tenderness accompanied by vomiting, may lead to the diagnosis, which can be confirmed by serum amylase determination. Although the clinical picture may be quite dramatic, the outcome is almost invariably good.

Other Manifestations

Sometimes the lacrimal, thyroid or prostate glands become affected by mumps virus, producing unusual clinical presentations.

Arthralgia or monoarthritis, involving a large joint, are complications of mumps which may develop about two weeks after parotitis. They are most frequent in young male adults.

Myocarditis can usually be found only upon electrocardiographic examination. In 10–15% of all mumps patients typical changes are seen, with no late sequelae.

Transient renal dysfunction is a frequent feature of clinical mumps. In very rare instances severe nephritis and thrombocytopenia may ensue, with a fatal outcome on occasion.

If a pregnant woman contracts mumps she has an increased risk of abortion. This is thought to be due to hormonal imbalance caused by viral infection. No evidence of an increased risk of congenital malformations has been documented in humans, although paramyxoviruses cause CNS abnormalities of the developing fetus in monkeys and mumps virus can cause abnormalities in the developing chick lens.

Endocardial fibroelastosis, a rare condition affecting the inner lining of the heart, is associated with a positive skin test for mumps antigen, but a link between mumps virus and the condition is doubtful.

LABORATORY DIAGNOSIS

Virus Antibody Assays

Different serological tests have been used to demonstrate a rise in the specific antibody titres or the presence of IgM class antibodies. Complement fixation test employing S and V antigens prepared from the virions was earlier frequently used as the most common test. However, due to problems in reagent stability, this technique has been replaced in many laboratories by enzyme immunoassay (EIA) tests. EIA antibody levels correlate with levels of neutralizing antibodies, suggesting that EIA could also reflect the immune status of the individual (Leinikki *et al.*, 1979). However, the extent of cross-reactivity from exposure to closely related paramyxoviruses may cause problems in interpretation of the results in individual cases. The specificity of IgM antibody assays is greatly enhanced by using IgM capture techniques, where IgM class antibodies are separated from other serum constituents in an additional incubation step (Morgan-Capner, 1983).

Haemagglutination inhibition and neutralization antibody assays can be used as supplemental tests for both diagnostic cases and in immunity studies. Other tests, such as haemolysis in gel, can also be applied.

Virus Detection

Mumps virus can be isolated from clinical samples using cell cultures or embryonated eggs. Both saliva and urine can be used as samples for diagnostic or epidemiological investigations. Mumps antigen has also been demonstrated from saliva samples by immunofluorescence

or EIA techniques, allowing easy processing of large numbers of samples. Viral RNA can be detected by polymerase chain reaction (PCR) from oral fluid and used for diagnostic and epidemiological investigations.

EPIDEMIOLOGY AND CONTROL

Mumps is a disease of childhood. In unvaccinated populations the highest incidence is in children between five and nine years of age. The disease is somewhat less contagious than other childhood diseases, such as measles and varicella, and quite a number of children seem to escape the infection before puberty and even beyond. The proportion of seronegatives among medical students was less than 10% in a study of an unvaccinated population. According to a survey in the United States, one-tenth of the population had mumps during each of the first five years of life, 74% had had it by the age of 10 and 95% by 20 years of age (Feldman, 1982).

General vaccinations have changed the epidemiological pattern profoundly. Prior to vaccination, mumps used to be common in most urban areas, while in some less densely populated areas it caused widespread epidemics at two to four year intervals. A few descriptions of outbreaks in isolated areas have been published where the affected population had no pre-existing immunity. As can be expected, age as such did not protect; however, the proportion of subclinical infections increased with age, with the exception of the youngest children (two to three years of age), in whom subclinical infections were also very frequent. Up to 90% of infections at the age of 10–14 years were associated with clinical symptoms, while practically all infections were subclinical beyond 60 years of age. Although the clinical symptoms are usually more severe in adolescents and young adults than in children, the frequency of complications follows closely the frequency of mumps in general. Two well-known exceptions are orchitis and oophoritis, which have a much higher frequency after puberty than before, and meningoencephalitis, which is two to three times more common in males than in females.

In temperate zones of the northern hemisphere a clear-cut seasonal variation is evident. From June to September the number of reported cases is on the average less than one-third of the figures from January to May, according to a survey of 12 years and more than 150 000 cases. The peak months were February and March. No such seasonal variation is reported from tropical countries.

Only one serotype of mumps virus exists and one would expect a life-long immunity after natural infection, yet reinfections have been reported in up to 1–2% of cases. This could indicate that mumps infection is

not able to induce a lifelong protective immunity. Another explanation is that other microbes cause similar clinical pictures: in a recent study of clinically suspected mumps cases in a low prevalence population, a virus other than mumps was the causative agent in about half of the cases. Viruses such as Epstein–Barr virus (EBV), adenovirus, parainfluenza and even enteroviruses were found (Davidkin *et al.*, 2002, personal communication). A third explanation may come from divergent genomic lineages of mumps virus that have been identified by comparing RNA sequences of strains from different outbreaks (Ströhle *et al.*, 1996).

Vaccinations Against Mumps

Control of mumps by immunization can be very successful. In the United States, the number of cases notified to the Centers for Disease Control and Prevention has dropped from over 150 000 annual cases to around 1500 cases in 20 years (Centers for Disease Control and Prevention, 1995). In Finland, with a very high childhood vaccination coverage, the endemic disease has been eradicated (National Public Health Institute, 2001). Large outbreaks of mumps in the neighbouring Russian territories have not led to local outbreaks in Finland in spite of frequent travel across the border.

However, vaccinated populations have also encountered outbreaks of mumps in recent years (Briss *et al.*, 1994; Dias *et al.*, 1996; Visser *et al.*, 1998). These outbreaks have affected mostly young adults in several European countries and the United States. Victims have been unvaccinated or received only one dose of measles, mumps and rubella (MMR) vaccine (Savage *et al.*, 2005). Analysis of the genomic sequence has shown that multiple lineages of virus have co-circulated, suggesting lack of immunity due to either vaccine failures or low vaccination coverage.

A strain called Jeryl Lynn has been used in most vaccinations worldwide since the 1970s. Vaccines containing this strain have proved to be effective in protecting against clinical disease and have even led to eradication in some countries (Peltola *et al.*, 1994). Serious complications are extremely rare: less than one child/million vaccines is affected by aseptic meningitis (Patja *et al.*, 2000).

Another strain called Urabe was introduced as a vaccine in the 1980s. Unfortunately, it proved to be associated with increased frequency of CNS complications and has been withdrawn in most countries. Another vaccine strain, called Leningrad–Zagreb attenuated mumps virus strain, was recently found to be associated with an increase of aseptic meningitis and clinical mumps after mass vaccination campaigns in Brazil (da Cunha *et al.*, 2001). The risk for aseptic meningitis was approximately one case/10 000 doses of vaccine; for mumps it was one case/300 doses.

Table 24.1 Likely problems eliminated by mumps vaccine (Finland 1971 vs. 1997).

	Cases/year 1997	Cases/year 1971 ^a
Number of notified cases	0	22 980
Absent from school or work (person years)	0	650
Meningitis	0	6 400
Encephalitis	0	160
Orchitis	0	1 600
Bilateral	0	500
Male sterility	0	125
Mastitis	0	1 800
Temporary hearing problems	0	920
Permanent hearing problems	0	25
Thyroiditis	0	250
Pancreatitis	0	80
Myocarditis	0	30

^aThe year 1971 was an epidemic year. Finland has a population of about 5 million.

Leningrad strain has also been detected in cases of aseptic meningitis in St Petersburg recently (Davidkin *et al.*, personal communication).

A strain used widely in vaccines, the Rubini strain, has been found to give insufficient protection against wild mumps virus and outbreaks of mumps in previously vaccinated populations have been described (Germann *et al.*, 1996; Tabin *et al.*, 1993).

Even though general vaccination of children against mumps virus has led to significant public health achievements (Table 24.1), mumps remains a challenge to clinical virology. With lowering vaccine coverage among children and variations in the efficacy of the vaccine strains, individual cases and even outbreaks are probable. In particular, individual cases without an obvious epidemiological link may pose significant diagnostic problems and emphasize the importance of virological laboratory diagnosis.

Enteroviruses

Philip D. Minor¹ and Peter Muir²

INTRODUCTION

The enteroviruses belong to a genus of the family *Picornaviridae*. At least 66 enterovirus serotypes have been isolated from humans and around 30 new candidate enterovirus types have been identified in recent years. Their normal site of replication is the intestinal tract, where infection may often be clinically inapparent, or result in a mild, nonspecific illness. However, in a proportion of cases the virus spreads to other organs, causing severe illnesses, the characteristics of which are often typical of individual enterovirus types. Poliomyelitis is one of the most severe diseases caused by an enterovirus, but members of the genus are also implicated in aseptic meningitis, encephalitis, myocarditis, rashes and conjunctivitis. They may cause particularly severe disease in neonates. This chapter describes the virological properties of enteroviruses, and the pathogenesis and clinical aspects of the diseases that they cause. Prevention is, so far, limited to poliomyelitis. Although numerous agents with anti-picornaviral activity have been described, none have thus far become available as chemotherapeutic agents.

THE VIRUSES

Viruses of the *Picornaviridae* show similar morphological, structural and molecular properties and replication strategies. They are currently divided into nine genera by the International Committee for the Taxonomy of Viruses (ICTV): the rhinoviruses, which are one of the causative agents of the common cold (Chapter 20); the enteroviruses, which are closely related to the rhi-

noviruses; the parechoviruses, a recently recognized group which currently consists of four types, two of which were formerly classified as enteroviruses but are now known to be genetically and biologically distinct; the cardiociruses, which cause diseases of mice and other animals; the aphthoviruses, which are causative agents of foot-and-mouth disease of ruminants; the hepatoviruses, a genus encompassing hepatitis A viruses (Chapter 12); the teschoviruses (formerly porcine enteroviruses) and two genera which currently contain a single species representative: the kobuviruses and erboviruses (Minor *et al.*, 1995). The human enteroviruses include the polioviruses (PVs), group A coxsackieviruses (CVA) and group B coxsackieviruses (CVB), enterocytopathic human orphan (echo) viruses (ECVs) and additional numbered enterovirus serotypes, designated EV68–71. These serotypes were originally defined and differentiated on the basis of homologous seroneutralization. Approximately 30 additional enterovirus types have been identified in recent years, defined on the basis of nucleotide sequence similarity rather than serological neutralization. These types have been provisionally designated EV73–101, although they have yet to be formally recognized by the ICTV.

The phylogenetic approach to classification allows the human enteroviruses to be grouped into four major groups or species as described later. Enterovirus types differ in their cultural characteristics, antigenic properties and certain features of their replication cycle, such as the receptor sites by which they gain access to the host cell. In all cases the normal habitat and primary site of replication of the virus is thought to be the intestinal tract.

Physical Characteristics of the Virus Particle

The enterovirus virion is a largely featureless, symmetrical particle, approximately 27 nm in diameter when examined electron microscopically (Figure 25.1a). Non-infectious empty capsids, unlike virions, are penetrated by stain, revealing the virion shell to be approximately 2.5 nm in thickness (Figure 25.1b). The essentially spherical appearance of the particle is consistent with icosahedral symmetry, and this has been broadly confirmed by particle shadowing, which produces pointed and blunt shadows (Figure 25.1c,d). The sedimentation coefficient of the intact virus on centrifugation is 155–160S, while that of the empty capsid is 70–80S. The buoyant density of the virion in caesium chloride gradients is 1.34 g ml^{-1} . A particle with the chemical composition of an enterovirus virion would be expected to have a density of 1.47 g ml^{-1} if freely permeable to caesium ions; the low density of the enteroviruses implies that the virion is essentially impermeable, consistent with the failure of electron microscopic stains to penetrate infectious particles (Figure 25.1a). In the past, the behaviour of the viruses on isopycnic centrifugation has been used as a criterion for differentiating enteroviruses from rhinoviruses and aphthoviruses, both of which have a higher buoyant density in caesium chloride. The enteroviruses are stable to acid pH, also unlike the rhinovirus and aphthoviruses, which are inactivated by brief exposure to pH 2. This property has also been used as a criterion for the identification of a picornavirus as an enterovirus.

Biochemical Structure of the Virus Particle

The infectious particle consists of a capsid made up of 60 copies of each of four viral proteins (VP1–4), arranged with icosahedral symmetry around a single-stranded positive (messenger)-sense RNA genome of approximately 7300 bases. Like many eukaryotic mRNA molecules, the genomic RNA terminates in a sequence of 40–100 adenylic acid residues at the 3' end (the poly(A) tract). At the 5' end, however, it bears a small virally encoded protein (VPg), approximately 22 amino acids long, covalently linked to the RNA by the hydroxyl group of a tyrosine residue. The virion is believed to be entirely devoid of carbohydrate and lacks a lipid membrane, although, as described below, lipid molecules form an integral part of the structure. The particle has a relative molecular mass of 8×10^{-6} , of which the RNA provides 32% and the protein 68% by weight. The four principal structural proteins of the virion are of molecular mass approximately 30 000 (VP1), 27 000 (VP2), 24 000 (VP3) and 7000 (VP4). VP2 and VP4 are formed by the cleavage of a precursor protein, VP0, as the last stage in the maturation of a virus

particle, probably in an autocatalytic process resulting from the encapsidation of the nucleic acid genome.

The absence of a lipid layer has made it possible to obtain crystals suitable for X-ray diffraction studies, and the molecular structures of poliovirus (Hogle *et al.*, 1985) and other picornaviruses have been resolved, such that the interactions involved in maintaining the structural features of the infectious virion are now clear. The three

largest virion proteins, VP1, VP2 and VP3, have a very similar core structure in which the peptide backbone of the protein loops back on itself to form a barrel of eight strands held together by hydrogen bonds (the β -barrel). This core forms a wedge shape, and the amino acid sequences between the sequences forming the β -barrel and the sequences at the N- and C-terminal portions of the protein contain elaborations which include the main antigenic sites involved in the neutralization of viral infectivity.

The proteins are arranged with icosahedral symmetry, with VP1 molecules at the pentameric apices of the icosahedron, orientated such that the pointed end of the wedge-shaped protein points towards the apex. The other two proteins, VP2 and VP3, alternate about the centre of the triangular face of the icosahedron (the threefold axis of symmetry). There are extensive interactions between the three large proteins, and also with the fourth protein, VP4, which is internal. In particular, the N-terminus of VP1 lies under VP3, and the N-terminus of VP3 under VP1. The apical structure formed by VP1 is separated from the plateau formed by VP2 and VP3 by a cleft or canyon; the peak of the VP1 structure is 16.5 nm from the virion centre, while the plateau made up of VP2 and VP3 is approximately 15 nm from the centre. The base of the cleft is of the order of 11 nm from the centre, and it has been postulated that this cleft may contain the regions of the virus to which the cellular receptor attaches. The interactions between the component proteins that form the most stable unit of the structure is a pentamer made up of five copies each of VP1, VP2, VP3 and VP4; it seems likely that this is the basic unit from which the virus is assembled. A diagrammatic representation of the three-dimensional structure of the capsid proteins of poliovirus type 1 is shown in Figure 25.2.

In addition to the protein components of the virus, lipid molecules are also found in the structure. Myristic acid is found covalently attached to the N-terminus of the smallest capsid protein, VP4. The aliphatic chain penetrates the apex of the icosahedron and it is possible that this forms a structural support for the virion. Myristic acid has been found attached to virion proteins in other viruses, including retroviruses and rotaviruses. A second lipid moiety, not yet identified, is present in the structures of PV1 and 3. It has a 16-carbon aliphatic chain which lies in the pocket formed by the β -barrel of VP1. The other end of the molecule has not been observed. Rhinovirus 14 has no such insert, and it is not yet clear how general a feature of enteroviruses this lipid molecule is. However, certain antiviral compounds insert into the corresponding region of rhinovirus 14 and, in so doing, prevent uncoating. It is therefore possible that the lipid plays a part in uncoating or assembly of enteroviruses.

Antigenic Structure of the Virus

The antigenic properties of the enteroviruses provide one of the classical methods of differentiation. In most cases serotype-specific antisera neutralize only virus isolates or strains of the homologous serotype, but this is not always so. For every picornavirus studied in detail, it has been shown that empty capsids prepared under appropriate conditions present major antigenic determinants differently from those of the infectious virus. Moreover, the infectious virus can be readily denatured by relatively mild conditions, such as treatment with ultraviolet light, heating to 56°C for 10 minutes or attachment to a plastic surface in solid-phase enzyme immunoassays (EIAs). The infectious particle is said to express D or N antigenic character, and the empty capsid or denatured virus C or H antigenic character. C antigen is less specific to a particular virus than is D antigen. Thus, there is evidence for cross-reaction of C antigen-specific monoclonal antibodies with PV1, 2 and 3, whereas cross-reaction by neutralizing monoclonal antibodies or those reacting with D antigen is rare. Monoclonal antibodies able to neutralize both PV1 and 2 have been reported (Uhlir *et al.*, 1990) and priming for a secondary response to PV1 or 3 by previous infection with PV2 is documented. Similarly, there is evidence for cross-reaction of ECV 11, 16 and parechovirus 1 with poliovirus with appropriate C-specific antibodies. In addition, some epitopes present on VP1 appear to be conserved among most or all human enteroviruses, and monoclonal antibodies to such epitopes have been used as pan-enterovirus detection reagents (Trabelsi *et al.*, 1995). The difference between particles expressing D and C antigen is due to the conformation of the proteins, rather than to the loss of a protein; cross-reactive epitopes are internalized in the infective virion, but become surface-exposed and thus able to bind antibody following denaturation. Thus, methods based on virus neutralization by antibody are required to determine serotype-specific humoral immunity, while solid-phase EIA or immunoblot methods detect both type-specific and cross-reactive antibody (Muir and Banatvala, 1990).

The antigenic structures involved in the neutralization of picornavirus infectivity have been the subject of much study and have been clarified by the resolution of the molecular structures of PV and rhinovirus and representatives of the other genera outlined above. Neutralizing epitopes have been identified by the isolation of antigenic variants resistant to monoclonal antibodies which are able to neutralize the parental strain, and then characterized by sequencing the genomic RNA. This has revealed four major sites to which neutralizing antibodies bind, formed from a number of exposed surface loops. For PV3 they include: (i) a sequence of VP1 about one-third of the way in from the N-terminus, involving residues 89–100, together

Figure 25.2 Three-dimensional structure of the capsid proteins of poliovirus. The numbers indicate positions of amino acid residues: (a) core structure common to capsid proteins; (b) VP1; (c) VP2; (d) VP3. Reprinted with permission from Hogle *et al.* (1985) The three dimensional structure of poliovirus at 2.9 Å resolution. *Science*, **229**, 1358. American Association for the Advancement of Science.

with sequences from three other loops from VP1, including amino acids 142, 166 and 253; (ii) a complex site involving residues 220–222 of VP1 and 160–170 of VP2 and the C-terminus of VP2; (iii) a complex site involving residues 286–290 of VP1 and 58–60 of VP3 (Minor, 1990). The fourth site involves residues in different pentamers and is therefore only found in the intact virion, while the other sites are also found in some viral subunits. For PV1, the site located at residues 89–100 of VP1 has been implicated in virus neutralization, although to a far lesser extent than for PV3, where the homologous region is the principal target for neutralizing antibodies in sera from immunized animals. The site involving VP3 is the next most common target of antibodies, including

most of the antibodies showing extreme strain specificity for poliovirus, while the site involving VP2 is the least common.

The antigenic structure of PV2 has been less well characterized. The site to which cross-reactive antibodies bind appears to involve sequences around 200–210 of VP3 and 239–245 of VP2, and may be linked to the strain-specific site involving VP1 and VP3 (Uhlig *et al.*, 1990).

Cellular Receptor Sites

Enteroviruses attach to and enter cells by specific cell surface receptors. This was first shown for poliovirus by

the observation that purified genomic RNA was infectious for rabbit cells, whereas the virus itself was not. Competition experiments between different viruses have shown, for example, that all three poliovirus serotypes utilize the same cellular receptor, which is distinct from that for CVB. This phenomenon has been confirmed in a number of cases by the isolation of monoclonal antibodies which specifically block the attachment of certain types of virus by reacting with the host cell rather than with the virus (Minor *et al.*, 1984).

The enteroviruses and picornaviruses in general are responsible for a range of diseases with different target organs. These include the heart (CVB), nerve tissue (PV), liver (hepatitis A virus) and others, as well as the intestinal tract. It is possible that the expression of the receptor sites in specific tissues plays a part in the tropism of the virus, although it is unlikely to be the only factor. This may suggest a novel chemotherapeutic approach for enterovirus infections using synthetic receptor analogues.

The cellular gene encoding the poliovirus receptor has been identified as a previously unknown three-domain protein of the immunoglobulin superfamily termed CD155 (Mendelsohn *et al.*, 1989). The terminal domain is required for activity. Transgenic mice carrying the human *CD155* gene (Koike *et al.*, 1991; Ren *et al.*, 1990) are susceptible to poliovirus infection, with pathology similar to that observed in primates; the animals are not infectable by the oral route. Expression of the receptor occurs in all tissues unless the gene is inserted under the control of a tissue specific promoter, yet replication of the virus is highly restricted. There is evidence that the innate immune response plays a role in the tissue distribution and pathogenesis as when the transgenic mice are crossed onto a strain of mouse lacking an alpha/beta interferon (IFN- α/β), response replication is more general (Ida-Hosonuma *et al.*, 2005).

Mouse cells in culture are not normally susceptible to infection with poliovirus or most other human enteroviruses. When stably transfected with human CD155, however, they are rendered sensitive, and can thus be used to identify poliovirus in the presence of other enteroviruses. This is of value in clinical studies related to the programme to eradicate poliomyelitis, as described later.

Two major CVB receptors have been identified; one is decay-accelerating factor (DAF; CD55), a cell surface protein involved in the complement pathway (Shafren *et al.*, 1995). The second CVB receptor is also used by some adenoviruses and is termed the coxsackie-adenovirus receptor (CAR), a transmembrane cellular adhesion molecule localized to epithelial tight junctions which contains two immunoglobulin-like domains, and is expressed preferentially in brain, heart

and pancreas (Bergelson *et al.*, 1997). Binding of CVB to DAF triggers DAF-mediated cell signalling pathways resulting in actin rearrangements which permit virus movement to tight junctions. Here virus-CAR interaction leads to conformational changes in the viral capsid which precede viral entry and RNA release. Sequential interaction with DAF and CAR thus results in cellular changes even before the virus enters the cell, and ultimately allows CVB to cross the epithelial barrier. (Coyne and Bergelson, 2006).

A number of receptors for other enteroviruses have also been identified. The receptor for ECV1 has been identified as the integrin VLA-2, a known surface molecule (Bergelson *et al.*, 1992). DAF is also a receptor site for many ECVs (Bergelson *et al.*, 1994) and EV70 (Karnauchow *et al.*, 1996). CVA10, 15, 18 and 21 employ ICAM-1, as does the major rhinovirus group. CVB3 also uses nucleolin, and CVA9, $\alpha_v\beta_3$ -integrin.

Strategy of Replication

The genome of the virus is a single positive-strand RNA molecule which acts as a messenger RNA for the synthesis of the viral proteins found in infected cells. The genome can be divided into three regions, a 5' nontranslated region (NTR) of about 750 bases, followed by a large open reading frame encoding a polyprotein which comprises most of the genome, then a second short 3' NTR terminated by a poly(A) tail. The open reading frame can be divided into three regions, P1-P3, which correspond to the primary cleavage products of the polyprotein (see below). The P1 region encodes VP1-4, while the P2 and P3 regions encode nonstructural proteins necessary for virus replication, as detailed below. The genome arrangement is summarized in Figure 25.3. The NTRs are highly conserved, reflecting their importance in virus replication.

The 5' NTR of eukaryotic messenger RNA usually terminates in a methylated guanosine cap, which is important in binding ribosomes and thus translation of the RNA into protein. Thus, most eukaryotic messenger RNA molecules require a free 5' terminus, and initiation of translation internally is not possible. However, it has been shown that the 5' NTRs of poliovirus and other picornaviruses contain an internal ribosomal entry site (IRES), which enables ribosomal binding in the absence of a free 5' capped terminal structure (Pelletier and Sonnenberg, 1988). In fact, poliovirus infection results in the cessation of cap-dependent translation. The mechanism of internal initiation involves binding of cellular proteins, including the eukaryotic translation initiation factors, a pyrimidine tract-binding protein and poly(rC)-binding proteins to the IRES (Hellen *et al.*, 1993). There is evidence that additional cell type-specific proteins also interact with the IRES, and the ability of a given IRES to interact with such

Figure 25.3 Organization of the genome of poliovirus, a typical enterovirus showing the two noncoding regions and the location of the regions coding for the various virus proteins. In the formal nomenclature (Rueckert and Wimmer, 1984), the P1 region encodes the structural capsid proteins, and the P2 and P3 regions encode nonstructural proteins found only in infected cells.

noncanonical translation initiation factors may in part determine the susceptibility of a given cell type to infection with a particular enterovirus (Malnou *et al.*, 2002), since it is known that the availability of cellular receptor proteins is not the sole determinant of tissue tropism.

The viral proteins are translated as a single polyprotein. This precursor protein includes two sequences which act as proteolytic enzymes, and these digest the polyprotein at specific positions during the course of translation. The first (P2A) acts to cleave the structural (P1) from the nonstructural (P2–3) proteins (Figure 25.3), while the second completes all the other processing of the protein, except the final maturational cleavage of VP0 to VP2 and VP4. The nonstructural proteins include proteases (2A, 3C and the intermediate cleavage product 3CD), a polymerase (3D), nucleotide triphosphatase (2C) and the small protein VP_G (3B), which is covalently attached to the 5' terminus of both positive- and negative-sense viral RNA. Proteins 2B and 2BC induce extensive rearrangement of intracellular membranes into vesicles, which are a required component of viral replication complexes. The 2C protein-coding sequence also contains a highly conserved stem-loop RNA structure which is a *cis*-acting replication element (CRE) required for viral RNA synthesis.

In the early stages of the infection process the genome is used predominantly for translation of viral proteins. However as the pool of viral proteins increases, protease 3CD binds to the 5' NTR, repressing translation and favouring RNA synthesis. The positive-sense ge-

nomeric RNA acts as a template for the synthesis of a negative-sense copy. Negative-strand synthesis requires circularization of the genome, in which a ribonucleoprotein complex formed at the 5' NTR interacts with poly(A)-binding protein bound to the 3' poly(A) tail. The viral polymerase (3D) then catalyses the uridylation of the VP_G, using the poly(A) tail of the viral genome as template. The resulting VP_G-poly(U) primes the synthesis of negative-sense RNA. This gives rise to a double-stranded replicative intermediate, which associates with membranous vesicles to form replication complexes. The replicative intermediate acts as a template for further positive-sense strand synthesis. Positive-strand synthesis also requires a uridylated VP_G primer, but in this instance adenosine residues within the loop of the CRE RNA structure serve as the template for uridylation, in a complex between the 5' and 3' NTRs, the CRE and the 3C and 3CD proteins. The resulting uridylated protein (VP_GpUpU(OH)) presumably associates with the 3' terminus of the negative-sense RNA and primes positive-strand synthesis. It is likely that the increasing excess of VP_G-pUpU(OH) over VP_G during the course of infection favours synthesis of the positive over the negative strand. Thus, the different mechanisms involved in uridylation of VP_G and the initiation of transcription for positive- and negative-strand synthesis leads to asymmetrical replication of viral RNA. Positive-sense RNA is the major species made after the early stages of infection and is used both for translation and for packaging into nascent virus.

The assembly of the virus particle involves the synthesis of VP0, VP1 and VP3 as a single unit, which is then assembled into pentamers, followed by the association of 12 pentamers into the virion, a process which involves host factors. The X-ray crystallographic structure of the virus implies that the final maturation cleavage of VP0 to VP2 and VP4 is autocatalytic. Thus, a serine residue is found close to the N-terminus of VP2. A number of serine proteases are known, and it may be concluded that as soon as the proton donor, such as the genomic RNA, is brought into the vicinity of the serine residue the final cleavage will take place. The virus is released from the cell by lysis.

Enterovirus Diversity and Classification

This historical classification of the enteroviruses closely followed the history of enterovirus discovery. Poliovirus was first identified in 1909 by inoculation of monkeys with specimens from cases of paralytic poliomyelitis. In 1948 Dalldorf and Sickles (1948) recovered a new group of agents by inoculation into newborn mice of faecal extracts from two children with paralytic disease. These agents were named coxsackieviruses after the town in

New York State where the isolations were made. CVA and CVB were subsequently differentiated on the basis of their pathology in newborn mice and their capacity to grow in cell cultures, as described below. Following the discovery by Enders *et al.* (1949) that poliovirus could be grown in cell cultures, a third group of enteroviruses, the ECVs, were identified as a cause of human disease. ECVs were nonpathogenic for subhuman primates and newborn mice, but produced cytopathic changes in cell cultures. Within a few years it was found that all three groups of virus were antigenically distinct and consisted of several and, in some cases, numerous serotypes. The virus types comprising each group are summarized in Table 25.1, together with the major diseases with which they are associated and their cultural characteristics.

Since 1970, new enterovirus types have been allocated sequential numbers (68–71) following those allocated to previously identified enteroviruses. Enterovirus types identified more recently using nucleic acid-based methods have also been named provisionally according to this numerical classification, pending ratification by the ICTV.

Complete genomic sequences for representative strains of all human enterovirus types and many other picornaviruses have now been determined. Comparison of such

Table 25.1 Types and characteristics of human enteroviruses

Group	Virus types	Cytopathic effects in cell cultures		Pathology in newborn mice	Major disease associations
		Monkey kidney	Human cell culture		
Poliovirus	3 types (poliovirus 1–3)	+	+	–	Paralytic poliomyelitis; aseptic meningitis; febrile illness
Coxsackie virus group A	23 types (A1–A22, A24)	– or ±	– or ±	+	Aseptic meningitis; herpangina; febrile illness; conjunctivitis (A24); hand, foot and mouth disease
Coxsackie virus group B	6 types (B1–B6)	+	+	+	Aseptic meningitis; severe generalised neonatal disease; myopericarditis; encephalitis; pleurodynia (Bornholm disease); febrile illness
Echovirus	31 types (types 1–9, 11–27, 29–33)	+	±	–	Aseptic meningitis, rash, febrile illness; conjunctivitis; severe generalised neonatal disease
Enteroviruses	4 types (types 68–71)	+	+	–	Polio-like illness (E71); aseptic meningitis (E71); hand, foot and mouth disease (E71); epidemic conjunctivitis (E70)

Table 25.2 Phylogenetic classification of human enteroviruses.

Human enterovirus species	Historical grouping	Types
HEV-A	CVA EV	2, 3, 5, 7, 8, 10, 12, 14, 16 71, 76, 89–91
HEV-B	CVA CVB ECV	9 1–6 1–9, 11–21, 24–27, 29–33
HEV-C	EV CVA	69, 73–75, 77–88, 93, 97, 100, 101 1, 11, 13, 15, 17–22, 24
HEV-D	EV	96
Poliovirus	PV	68, 70, 94 1–3

sequences reveals a surprisingly close relationship between the enteroviruses and rhinoviruses, the genomes of which show a high degree of homology (Stanway, 1990). In contrast, hepatitis A has no significant homology with enteroviruses at the nucleic acid level. Similarly, parechovirus 1 (formerly ECV 22) is also unique in the sequence, showing no homology with other enteroviruses.

The human enteroviruses can be divided into two genetic clusters on the basis of sequence comparisons of the 5' NTR (Hyypä *et al.*, 1997; Pöyry *et al.*, 1996). One includes polioviruses, CVA21 and A24 and EV70, while CVB, ECV, CVA9 CVA16 and EV71 form the second cluster. Similar sequence comparisons of the coding region and 3' NTR reveal four major genetic clusters of the human enteroviruses, and phylogenetic analysis of VP1 sequences now forms the basis of a new classification system in which human enteroviruses are assigned to one of four species (HEV-A to HEV-D; Oberste *et al.*, 1999; Table 25.2). Although the polioviruses fall within the same genetic cluster as HEV-C, they are currently assigned to a distinct species in recognition of their biological uniqueness as agents of poliomyelitis (Minor *et al.*, 1995). Enteroviruses showing >75% nucleotide homology in the VP1-coding region are considered to belong to the same enterovirus type, while those with <70% nucleotide homology are considered distinct types.

Sequenced animal enteroviruses, such as bovine enteroviruses, form groups distinct from the human enteroviruses when either the 5' NTR or the remainder of the genome is considered. Different regions of the genome vary in their homology between enteroviruses and other picornaviruses. Certain sections in the 5' NTR of the genome are near identical in all enteroviruses examined, implying some definite functional constraint; this identity may carry over into the rhinoviruses, but it is possible to identify sequences which are apparently enterovirus-specific. It is further possible to identify regions such as the 3' NTR which are strongly conserved

for a particular species, such as a poliovirus. Finally, certain regions, including those areas encoding the capsid protein VP1, are extremely strain-specific. In principle, as described later, it is possible to exploit these various types of region to devise probes or polymerase chain reaction (PCR) primers that are specific either for enteroviruses in general, for a particular species of enterovirus, for a particular enterovirus (sero)type or even for a particular strain. Such probes are valuable in clinical and epidemiological studies.

Although there is little documented evidence of progressive antigenic variation among enterovirus isolates, antigenically unusual strains can be isolated; for example, PV3 isolated from patients with paralytic poliomyelitis in Finland in 1984 were antigenically clearly distinguishable from classic PV3 strains isolated in the 1950s (Magrath *et al.*, 1986). It may be significant that the cases of poliomyelitis from which the viruses were isolated occurred in people immunized with inactivated vaccine. There is good evidence for recombination between vaccine strains of PV and wild-type PV or other HEV-C viruses. Viruses within a particular human enterovirus species are apparently able to recombine readily. Consequently, the nonstructural protein-coding regions of the genome are not informative beyond the species level. Recombination between enteroviruses may result in strains with biological properties distinct from those of the progenitor strains, and these recombinants be ultimately become established as new enterovirus types.

PATHOBIOLOGICAL AND CLINICAL ASPECTS OF HUMAN ENTEROVIRUSES

Enteroviruses have a worldwide distribution and collectively cause a considerable impact in morbidity and mortality. They exhibit a wide range of biological and pathogenic properties, some of which are characteristic

of specific enterovirus groups or types. The extraordinarily wide range of diseases included in their clinical 'repertoire' contributes to their attraction as subjects for study by the molecular virologist, pathologist, clinician and epidemiologist. An extensive literature of reviews on the clinical, pathological and epidemiological properties of human enteroviruses is available (Pallansch and Roos, 2001; Rotbart, 1995), to which the reader is referred for further detailed information.

The host range of the enteroviruses varies between groups and types. Table 25.1 summarizes the ability of the viruses to replicate and produce cytopathogenic effects in cell cultures of monkey kidney and human origin and their pathogenesis for suckling mice. Poliovirus, unlike other enteroviruses, causes flaccid paralysis in monkeys and chimpanzees when administered into the brain or spinal cord. A feature of coxsackieviruses not shared by other enteroviruses is their pathogenicity for suckling mice. CVA produce widespread myositis in the skeletal muscles of newborn mice, resulting in flaccid paralysis without other obvious lesions. CVB also produce myositis but generally of more focal distribution than that caused by CVA. In addition they cause necrotizing lesions of the brown fat pads (intrascapular cervical and cephalic pads) and, in the case of certain strains, encephalitis with spastic paralysis, pancreatitis, myocarditis, endocarditis and hepatitis in both infant and adult mice. CVA, unlike CVB, replicate poorly if at all in monkey kidney cell cultures. As already mentioned, most ECVs are nonpathogenic in primates and mice.

The common portal of entry for enteroviruses is generally thought to be the alimentary tract via the mouth. Replication of virus in the cells lining the alimentary tract may be preceded by, or accompany, oropharyngeal replication.

A viraemic phase is followed by infection of target organs, for example spinal cord and brain, meninges, myocardium or skin. Incubation periods before onset of disease vary widely from 2 to 30–40 days depending on the clinical manifestation. The pathogenesis of poliomyelitis has been studied extensively (Minor, 1996) but is still not fully understood. According to Bodian, the virus, having entered via the alimentary tract, multiplies locally at the initial sites of virus colonization (tonsils, Peyer's patches) and associated lymph nodes. At this stage virus may be isolated from both throat and faeces. Secondary spread of virus apparently occurs via the blood to other susceptible tissues (e.g. other lymph nodes, brown fat pads and nervous tissue). On the other hand, Sabin held the view that the virus replicates chiefly in the mucosal layers of the intestine or oropharynx, seeding the associated lymphoid tissues, where it does

not necessarily replicate. After a low-level, possibly undetectable viraemia, replication at distant unidentified sites leads to a secondary viraemia, which may result in infection of either the peripheral or central nervous system (CNS) (for further details, see Minor, 1996).

Within the CNS the virus appears to spread along nerve fibres. If local multiplication is extensive, motor neurons are destroyed and paralysis results. The anterior horn cells of the spinal cord are most prominently involved but in severe poliomyelitis the posterior horn and dorsal root ganglia are affected. Shedding of virus occurs from the throat and in faeces and thus transmission of infection occurs independently of invasion of the nervous system.

The pathogenesis of CVB-induced myocarditis is also well studied in murine models, and is discussed below. The major clinical aspects of enterovirus infection are now summarized.

CNS Infections

Paralytic Poliomyelitis

The clinical features and epidemiology of this disease have been reviewed in detail by Minor (1996). Progress towards its eradication is described later.

Poliovirus infection may be asymptomatic or mild and only about 1% of infections result in illness with neurological involvement. Cases of abortive poliomyelitis, often accompanied by fever, malaise, headache, nausea or vomiting, are followed by uneventful recovery. Some patients develop aseptic meningitis with clinical features similar to those caused by other enteroviruses (non-paralytic poliomyelitis). In a small number of cases, paralytic poliomyelitis occurs.

Most cases occur without evidence of an earlier phase of illness. The most predominant sign is acute flaccid paralysis, resulting from lower motor neuron damage. Painful spasms and incoordination of non-paralysed muscles may also occur. Death may be due to respiratory paralysis. In those who survive, some recovery of muscular function is common but may take six months or longer. In epidemics in developed countries in the early 1950s, typically 5% of cases were fatal, 10% showed full recovery with no sequelae, while the remainder showed permanent paralysis to some degree. Isolation of PV from a patient with acute flaccid paralysis confirms the diagnosis of paralytic poliomyelitis in the absence of any other cause. Poliomyelitis, when epidemic, occurs primarily in the summer months in temperate zones. Non-polio enteroviruses, particularly CVA7 and EV71, occasionally cause polio-like illness, and in some regions where wild polioviruses have been eradicated, EV71 is emerging as an important cause of acute flaccid paralysis (Alexander *et al.*, 1994; da Silva *et al.*, 1996).

Many years after maximal recovery from the original attack of poliomyelitis, some patients develop further muscle weakness, the post-poliomyelitis syndrome. There have been suggestions that in some cases this may be due to persistent PV infection of neural cells, based on the detection of intrathecal PV antibody and the presence of PV RNA in cerebrospinal fluid (CSF) (Leparc-Goffart *et al.*, 1996), although there are alternative hypotheses, such as ageing (Munsat, 1991). Persistence of PV or other enterovirus infection of the CNS has also been implicated in the aetiology of motor neuron disease, and the presence of enterovirus RNA in cerebrospinal fluid or neural tissue has been reported in small numbers of patients (Leparc-Goffart *et al.*, 1996; Woodall *et al.*, 1994). However, two other studies found that, while enterovirus RNA can be detected in post-mortem brain and spinal cord tissue of patients with post-poliomyelitis syndrome or motor neuron disease, viral RNA was also detectable in patients with other neurological or non-neurological diseases (Giraud *et al.*, 2001; Muir *et al.*, 1996), and was therefore unlikely to be related to chronic neurological disease.

Aseptic Meningitis

Aseptic meningitis occurs most frequently in young children. Enteroviruses are the commonest cause of aseptic meningitis in countries where mumps has been controlled by vaccination. A febrile illness followed by meningeal signs, with stiffness of the neck or back, and muscle weakness, clinically reminiscent of mild poliomyelitis, may occur (Rotbart, 1995). However, in infections caused by non-polio enteroviruses there is almost always complete recovery from paresis. PV, CVA and CVB (especially types B1–B6, A7 and A9), many ECV (notably types 4, 6, 11, 14, 16, 25, 30 and 31) as well as EV71 have been associated with aseptic meningitis.

Patients with aseptic meningitis have a clear CSF which is usually under normal, or slightly increased, pressure. A pleocytosis, usually of the order of $10\text{--}500\text{mm}^{-3}$, mainly of lymphocytes is often, although not invariably present. During the first day or so after the onset of symptoms, polymorphonuclear leukocytes may predominate. The protein concentration is normal or slightly increased and the CSF glucose concentration is generally within normal limits. Thus, a normal CSF does not exclude enterovirus infection. Enteroviruses can be cultured from CSF, although viral RNA detection by PCR is more sensitive, as described below. In neonates and infants, PCR detection of viral RNA in serum or urine also provides useful evidence of systemic infection.

Enterovirus meningitis is common in neonates, children, and adults under 40 years of age. The frequency of cases in different age groups varies both geographically and temporally, possibly reflecting variations in the

prevalence of enterovirus types, and the prevalence of immunity to the prevailing enterovirus type among different age groups.

Encephalitis

Although herpes simplex virus (HSV) is the most commonly identified pathogen in patients with encephalitis (see Chapter 6), enteroviruses have been associated with encephalitis (Modlin *et al.*, 1991). Enteroviral encephalitis may be associated with aseptic meningitis, or may present with absent or minimal meningeal involvement. Children and young adults are most frequently affected. Although most patients recover uneventfully, a few have neurological sequelae or damage to the hypothalamic–pituitary axis, which causes endocrine disturbance. CSF findings are similar to those occurring in aseptic meningitis. Again, a normal CSF does not exclude enterovirus infection. Viral detection in CSF by PCR is considered proof of aetiology, although the sensitivity of PCR in this setting has not been established. Viral detection at peripheral sites, or viral serology may be required to provide evidence of recent enterovirus infection.

Patients with hypogammaglobulinaemia may develop persistent infections following enterovirus infection, associated with chronic meningeal irritation, encephalitis, insidious intellectual impairment or sometimes a dermatomyositis-like syndrome (Wilfert *et al.*, 1977). Although some patients recover, there is a high mortality rate. Many ECV and CVB have been shown to cause such persistent infections; occasionally, multiple serotypes may be involved. Patients with hypogammaglobulinaemia may also develop paralytic disease following administration of attenuated live polio vaccine. Virus may be recovered from the CSF, sometimes intermittently, although high titres are often present. Treatment with high-titre specific immunoglobulin has not been shown to be particularly effective in eradicating virus from the CNS.

Heart Disease

Myocarditis

A wide range of viruses may cause myocarditis, including ortho- and paramyxoviruses, togaviruses, herpesviruses and adenoviruses. However, CVB are the most commonly identified cause. In addition, current understanding of pathogenesis in viral myocarditis derives mainly from studies of CVB infection, including both clinical studies in humans and experimental studies of CVB3 virus-induced murine myocarditis. Other enteroviruses, including PV, CVA and ECV, may also cause myocarditis, and the relative importance of other non-polio enteroviruses may have been underestimated in recent years because of the wider availability of serological tests for CVB infection.

Acute myocarditis is an inflammatory disease of the heart muscle. Diagnosis therefore requires histological examination of endomyocardial biopsy or autopsy tissue. As this is often not available, it is likely that myocarditis is underdiagnosed. Clinical features are nonspecific and variable.

Neonatal enteroviral myocarditis can be rapidly fatal, and may be confused with congenital heart disease. Other systemic symptoms may be present. The pathological changes vary with the duration of illness. In infants who die early after infection (two to five days), left ventricular dilatation is present. The endocardium and valves are normal, even though the myocardium is pale. Late in infection (9–11 days of illness) the size of the heart is increased, largely due to dilatation of the left, and occasionally the right, ventricle. Microscopically, myofibre necrosis and inflammation are evident. Initially the inflammatory infiltrate is composed of polymorphonuclear leukocytes, but by day 5 or 6 mononuclear inflammatory cells are found.

In contrast to the abrupt, severe and often fatal disease seen in the neonatal period, viral myocarditis in adolescents and adults usually has a delayed onset, often following an upper respiratory (typically influenza-like) or gastrointestinal illness. Acute heart disease may become evident a week to 10 days later and has a presentation that can mimic myocardial infarction, coronary artery occlusion or progressive heart failure. Some patients do not present with heart disease but manifest nonspecific symptoms and signs, such as fever, myalgia and headache; often, cardiac involvement is suspected only because of typical electrocardiogram (ECG) changes. In a proportion the main presenting feature is pericarditis, characterized by acute, often severe, retrosternal chest pain. Other clinical findings include shortness of breath, tachycardia, arrhythmias, murmurs, rubs and cardiomegaly (due to ventricular dilatation or pericardial effusion). Death can supervene due to arrhythmias or congestive heart failure, but this is relatively uncommon. As in the neonatal infection, manifestations of systemic disease in adults may be noted. In CVB infections these may include pleurodynia, meningitis, hepatitis, orchitis, lymphadenopathy and splenomegaly. There may be recrudescences following the acute episode; up to 20% of patients in whom the major presenting feature is pericarditis will experience one or more relapsing episodes in the following months or years (Muir *et al.*, 1989). Acute myocarditis may also lead to chronic myocarditis or dilated cardiomyopathy (DCM), as described below.

Viral infection of the myocardium is believed to be a prerequisite to myocarditis, although antiviral cellular immune responses and autoreactive T cells activated following local tissue damage and release of sequestered

autoantigen are likely to be important effectors of myocardial pathology (Horwitz *et al.*, 2000). At present there is a lack of consensus on the most appropriate treatment for myocarditis. Thus, while steroid therapy has been used, evidence of efficacy is lacking (Mason *et al.*, 1995) and concerns remain that immunosuppressive therapy may result in increased viral replication and persistence (Heim *et al.*, 1994).

Virological investigations including virus isolation, PCR and serological studies, as described later, may assist in establishing a viral aetiology but often give negative or inconclusive findings. Even if cardiac biopsy samples are taken early or the patient dies during the acute phase, it is exceptionally rare to isolate virus or detect virus antigen in heart tissue, although enterovirus RNA may be detected. Because myocarditis may present some time after the initiating viral infection, specific antibody titres may have already peaked. Thus, serological investigation using paired acute and convalescent samples may fail to demonstrate a diagnostic rise in titre. Enterovirus immunoglobulin M (IgM) testing may be used in the absence of suitably paired sera or isolation samples, but IgM seroprevalence in the community can be significant, especially during high-activity seasons, reflecting asymptomatic infection. Thus, a positive result provides only circumstantial evidence of aetiology.

Dilated Cardiomyopathy

Dilated cardiomyopathy is a post-inflammatory disease which is a significant cause of heart failure and sudden cardiac death, and one of the commonest reasons for requiring cardiac transplantation. Enteroviruses are the most commonly identified agents of acute myocarditis, and there is now strong evidence that they also cause persistent infection associated with chronic myocarditis and chronic DCM (reviewed by Muir and Archard, 1994). There is evidence that viral persistence after the initial infection is directly involved in the evolution of DCM (Bowles *et al.*, 1986), although immunopathological mechanisms, including the development of cardiac autoimmunity, may also contribute to chronic disease (Liu and Mason, 2001).

Infectious virus cannot be detected in cardiomyopathic hearts, although a proportion of patients have elevated neutralizing antibody titres (Cambridge *et al.*, 1979) and persistent enterovirus-specific IgM responses (Muir *et al.*, 1989). Viral RNA can be detected in cardiac muscle of a proportion of cases by nucleic acid hybridization (Bowles *et al.*, 1986; Kandolf *et al.*, 1990) or reverse transcriptase-PCR (Archard *et al.*, 1998; Kammerer *et al.*, 1994; Schwaiger *et al.*, 1993). Small numbers of patients with myocarditis or DCM have been treated with IFN- α , either alone or in combination with IFN- β , with evidence of viral clearance and clinical improvement in some.

Murine CVB Disease

Experimentally, CVB replicate and produce inflammatory lesions in the heart, pancreas, liver, spleen and brain in several strains of mice. Studies in weanling and adult animals with CVB have shown that parenteral infection results in viraemia and then replication in target organs. Viraemia is detected within 24 hours and usually persists until day 3. The virus grows in various target organs, with maximum levels achieved by day 3 or 4. After maximum virus growth is established, virus titres decline and are usually undetectable by 7–10 days, presumably due to the induction of neutralizing antibody. Nevertheless, viral RNA may persist in heart and other organs for several weeks or months after clearance of viral infectivity (Reetoo *et al.*, 2000). Murine models may therefore be useful for understanding the molecular basis and pathogenetic consequence of viral persistence following acute myocarditis. The details of viral pathogenesis in murine models vary according to both viral strain and host physiology and immunogenetics. Different host–pathogen combinations are characterized by differences in disease severity, and in susceptibility to persistent infection and chronic disease. The relative contribution of direct virus-mediated pathology, immune-mediated pathology and autoimmunity also varies, as do the cellular and humoral immune effectors. It is likely that this pathogenetic diversity reflects that which occurs in human disease.

Neonatal Infection

CVB and ECV, particularly types 6, 7 and 11, may cause severe and often fatal infection in newborn infants (Abzug *et al.*, 1995; Modlin, 1988). Although there have been occasional reports of intrauterine death resulting from maternal enterovirus infection, there is no confirmed association with congenital abnormalities. Infection may be transmitted transplacentally in late pregnancy, the infant developing heart failure from a severe myocarditis as described above, or meningoencephalitis soon after delivery. More frequently, infection is transmitted perinatally from the mother, or postnatally from other virus-infected infants in nurseries for the newborn or special care baby units. Some infected neonates may be asymptomatic, but others will develop manifestations at three to seven days of age, ranging from a mild febrile illness to fulminating multisystem involvement and death. Myocarditis, pneumonia and meningoencephalitis may be present. A severe hepatitis with jaundice, which results in an increased prothrombin time, and profuse haemorrhage may also occur. These features are indicative of a generalized infection, and neonatal enterovirus infection may be confused with other causes of neonatal sepsis. Enterovirus may be detected in stool, urine, serum, brain, spinal cord and my-

ocardium. It is essential to establish a diagnosis as rapidly as possible in order to guide patient management and institute appropriate infection control measures. In outbreaks of neonatal infection there is some evidence that administration of human convalescent serum containing a high neutralizing antibody titre to the virus serotype identified may be of value in preventing or attenuating infection in susceptible neonates (Abzug *et al.*, 1995; Modlin, 1988).

Bornholm Disease (Epidemic Pleurodynia)

CVB are the commonest cause of this syndrome, but ECV serotypes including 1, 6, 9, 16 and 19, and CVA such as A4, 6, 9 and 10, have also been implicated. Outbreaks involving families are common; more extensive community-wide epidemics have also been reported. The disease usually presents abruptly with fever and chest pain due to involvement of the intercostal muscles, or abdominal pain which results from involvement of the muscles of the upper part of the abdomen. This may be sufficiently severe to mimic an acute surgical condition requiring laparotomy, or myocardial infarction. Some patients have pain localized to the limbs. There is usually muscle tenderness and in some patients swelling may be seen or palpated in affected muscles. Most patients recover within a week, although about 25% of patients may experience relapses, usually within a few days of being symptom-free. Enterovirus isolation from stool and strongly positive virus-specific IgM responses provide evidence of concurrent enterovirus infection.

Enteroviruses have also been implicated in various types of chronic inflammatory myopathies (Bowles *et al.*, 1987), but more recent studies using PCR have failed to demonstrate enterovirus RNA in muscle (Leff *et al.*, 1992).

Herpangina

CVA 1–6, 8, 10 and 22 are associated with herpangina. The illness affects primarily children aged 2–10 years and is characterized by fever, sore throat and pain on swallowing, often associated with vomiting and abdominal symptoms. Small vesicular lesions occur on the fauces, pharynx, palate, uvula and tonsils. Recovery is generally uneventful. Detection of enterovirus in vesicle fluid or other samples may help differentiate this condition from primary HSV infection.

Exanthemata

Hand, Foot and Mouth Disease

An ulcerative exanthem of the buccal mucosa accompanied by mild fever is followed by painful vesicular lesions on the hands or feet. Less commonly, lesions

may be present on the buttocks and genitalia. Family outbreaks are common. This disease has been associated with several enteroviruses, but most commonly with CVA16 and, less frequently, with A4, 5 and 9, and CVB2 and 5. EV71 also causes outbreaks of hand, foot and mouth disease (HFMD). In recent years large epidemics of EV71-associated HFMD have occurred in the Asian and Pacific regions, with complications including aseptic meningitis, acute flaccid paralysis, brainstem encephalitis associated with pulmonary oedema or haemorrhage, myocarditis and herpangina (Chang *et al.*, 1999; Ho *et al.*, 1999). Case fatality rates of up to 0.1% in infants have been reported in these epidemics and significant numbers of survivors have residual neurological sequelae. Enteroviruses can be detected in vesicle fluid or stool, although suckling mouse inoculation or PCR may be required to detect noncultivable CVA.

Rubelliform Rashes

A fine rubella-like maculopapular rash is often a feature of some CVA and ECV infections. Enterovirus infection should thus be considered in the investigation of women exposed to or presenting with rubelliform rash during pregnancy, after exclusion of other causes (see Chapter 23). Most frequently, ECV9 is implicated but often other ECV serotypes and CVA9 may also be involved. Summer outbreaks, most frequently affecting children, are common. Fever, malaise and cervical lymphadenopathy may also occur in patients with rash. Patients generally make an uneventful recovery. Enterovirus detection in stool or throat swab, or the presence of virus-specific IgM, provides evidence of aetiology in the absence of another cause.

Respiratory Infections

Several enteroviruses have been associated with mild illness of the upper respiratory tract, including rhinitis, particularly during the summer and autumn. These include CVA2, 10, 21 (Coe virus), 24 and CVB2 and 5. Coe virus has caused epidemics of pharyngitis in military recruits. Among the ECV which have been isolated from cases of respiratory illness are included types 1, 11, 19 and 20. These viruses most commonly cause outbreaks in young children, in whom pneumonia and bronchiolitis may sometimes occur. Enteroviruses can be detected in nasopharyngeal aspirates, although the interpretation of a positive result must take account of the possibility of a coincidental infection, since enteroviruses can also be detected in respiratory samples from healthy infants.

Conjunctivitis

Several enterovirus serotypes are associated with conjunctivitis. ECV7 and 11 and CVB2 have been isolated from

conjunctiva in sporadic cases. Since the early 1970s, major epidemics of acute haemorrhagic conjunctivitis have been described in Africa, the Americas and the East Asia. Some epidemics are caused by a variant of CVA24 or adenovirus 11, but many are caused by EV70, a virus first identified in 1969.

Unlike most other enterovirus infections, conjunctivitis may result from direct inoculation of virus as a result of hand-to-eye contact, without passage through the intestinal tract. Subconjunctival haemorrhage is more common with EV70 than with CVA24. There is a high attack rate among family members and a short incubation period of one to two days. Recovery is usually complete within one to two weeks and, for CVA24, sequelae are rare. CVA24 and EV70 can be isolated from conjunctival scrapings, and neutralizing antibody tests may be helpful.

Neurological complications may, in a few cases, accompany conjunctivitis due to EV70, and occasionally a polio-like paralytic illness ensues. One in 10 000 patients, mainly adult men, may suffer a residual paralysis. The neurological involvement may develop two or more weeks after the onset of conjunctivitis. The potential for neurovirulence is a worrying feature of EV70 and this calls for vigilance in the investigation of epidemics of conjunctivitis.

Diabetes and Pancreatitis

Type 1 diabetes is an autoimmune disorder in which the insulin-secreting pancreatic islet cells are progressively destroyed. The disease has an extended preclinical incubation period in which islet cell autoantibodies (ICAs) can be detected. Type 1 diabetes occurs more commonly in genetically susceptible individuals, but environmental 'triggers' are also believed to play a role. Although definitive proof is lacking, seroepidemiological evidence, animal model studies and anecdotal case reports all support the hypothesis that enterovirus infections may act as such a trigger. Prospective studies of siblings of cases, who themselves have an increased risk of developing type 1 diabetes, have found that individuals who subsequently develop disease have a higher incidence of enterovirus infections in the pre-diabetic phase than those who remain asymptomatic (Hyöty *et al.*, 1995). These studies also documented a temporal association between ICA seroconversion and preceding enterovirus infection, and enterovirus infections were particularly frequent during the six-month period preceding the first detection of autoantibodies (Hiltunen *et al.*, 1997; Salmiinen *et al.*, 2003). This suggests that enterovirus infection may be involved in the initiation and progression of islet cell damage. Retrospective serological studies of maternal blood samples collected at delivery have reported a higher prevalence of enterovirus-specific IgM in mothers whose

infants subsequently developed type 1 diabetes (Hyöty *et al.*, 1995), suggesting that disease initiation may occur *in utero*. However, enterovirus infection may also precipitate disease onset, as suggested by the presence of enterovirus-specific IgM or enterovirus RNA in serum in a proportion of patients at the time of clinical onset of type 1 diabetes (Banatvala *et al.*, 1985; Clements *et al.*, 1995a; King *et al.*, 1983).

Autoimmunity may arise as a result of molecular mimicry between viral and host antigens, and molecular mimicry between an epitope of the 2C nonstructural enterovirus protein and the islet cell antigen glutamic acid decarboxylase has been demonstrated. However, recent studies in susceptible mouse strains suggest that this may be insufficient in itself to induce type 1 diabetes and that destruction of exocrine pancreas by a pancreatotropic enterovirus infection may release sequestered islet cell antigens, which restimulate autoreactive memory T cells (Horwitz *et al.*, 1998). Thus, successive enterovirus infections may result in frequent restimulation of islet cell-autoreactive T cells, resulting in cumulative loss of islet cells, which eventually culminates in clinical type 1 diabetes.

Although an acute pancreatitis is a predominant feature of CVB infections in mice, there is comparatively little evidence linking this disease with CVB infection in humans. However, the pancreas is often involved in generalized neonatal infection, and CVB4 has occasionally been implicated as a cause of pancreatitis in adults; sub-clinical involvement of the pancreas has been reported in 31 and 23% of CVB5 virus and CVA infections.

Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS) has a number of alternative names: myalgic encephalomyelitis (ME), Royal Free disease, Iceland disease, postviral fatigue syndrome and neuromyasthenia. It occurs as both sporadic and epidemic cases. Although it is a poorly characterized illness, the cardinal feature is excess fatiguability of skeletal muscle, which may be accompanied by muscle pain. Many other symptoms may be present, including headaches, inability to concentrate, paraesthesiae, impairment of short-term memory and poor visual accommodation. Focal neurological signs are rare. Evidence of myopericarditis may be present occasionally.

The clinical spectrum of CFS is broad and diagnosis may be difficult. Physical examination is usually not helpful, although there may be some lymphadenopathy. A history of an initiating nonspecific 'virus' illness may be elicited, and such a corroborated history defines postviral fatigue syndrome. Routine laboratory investigations are usually noncontributory. Some groups, however, have described abnormalities of T cell function and muscle

structure (necrosis and increase in size and number of type II fibres) and function (abnormal jitter potentials and early intracellular acidosis on exercise), although these findings are not consistent. Recovery within a few weeks or months is usual, but in some patients the syndrome persists and may be relapsing.

There is a continuing debate on the aetiologies. Much attention has focused on a viral aetiology, although it is likely that those ascribed to be suffering from the syndrome are a heterogeneous group with organic and functional components contributing in varying degree (Straus, 1996). In Europe, most attention has focused on a possible enteroviral aetiology, while in the United States, various herpesviruses have been implicated. CFS occasionally follows confirmed virus infections, such as varicella zoster, influenza A and infectious mononucleosis, and rarely bacterial and protozoal infections such as *Toxoplasma gondii*, *Leptospira hardjo* and Q fever. Chronic fatigue may also be a prominent feature of chronic hepatitis C, and CFS may be diagnosed if hepatitis C is not suspected. In the majority of cases, however, the initiating viral illness cannot be diagnosed.

Viruses have been implicated not only as a trigger but also as a persistent active infection, although no evidence to support this hypothesis has been forthcoming in recent years. Although some cases may follow infectious mononucleosis, a significant role for chronic Epstein-Barr virus (EBV) infection is no longer considered likely (Straus, 1996). There is some evidence supporting a persistent enterovirus infection. In some studies, but not all, patients with CFS have a higher prevalence of elevated CVB neutralizing antibody titres and specific IgM compared with controls (Behan *et al.*, 1985; Mawle *et al.*, 1995). In one study, approximately 50% of patients had circulating immune complexes containing an enterovirus VP1 antigen detectable with a group-reactive monoclonal antibody. Enteroviruses were isolated only occasionally from faeces by routine methods, but were isolated from approximately 20% of patients when the faeces were acidified to disrupt virus-antibody complexes prior to cell culture (Yousef *et al.*, 1988). However others have been unable to reproduce these findings. Skeletal muscle biopsies from 96 patients have been examined with an enterovirus-specific DNA probe and 20 were positive (Archard *et al.*, 1988), suggesting enterovirus persistence.

Enterovirus RNA has also been detected in serum of patients with CFS (Clements *et al.*, 1995b), and the detection of near-identical viral sequences in sequential samples collected several months apart provides further evidence for persistence (Galbraith *et al.*, 1995). However, others have been unable to detect enterovirus sequences in serum from patients with CFS (Lindh *et al.*, 1996; McArdle *et al.*, 1996).

Thus, there is some evidence that in those cases of CFS with an organic origin enteroviruses may be implicated not only as a trigger but as a persisting infection. Although many treatments have been tried, such as human normal immunoglobulin, plasmapheresis and inosine pranobex, no evidence of efficacy has been presented.

LABORATORY DIAGNOSIS OF ENTEROVIRUS INFECTIONS

Diagnosis of enterovirus infections is useful where exclusion of serious or treatable conditions with overlapping clinical presentation is required. Thus, demonstration of an enteroviral aetiology in patients with meningitis or encephalitis may be helpful in excluding bacterial meningitis or herpes simplex encephalitis, while diagnosis of neonatal enterovirus infection may exclude other causes of sepsis-like illness, such as neonatal herpes simplex or group B streptococcal infection. Diagnosis may also play a role in infection control and epidemiological surveillance. If enterovirus-active antiviral agents become available, viral diagnosis will be necessary to guide appropriate therapy and for assessing therapeutic response. A combination of virus isolation and serological tests has traditionally been used to diagnose enterovirus infections, although molecular diagnosis now provides more rapid and sensitive viral detection in most settings. Timely submission of appropriate isolation samples and paired serum samples maximizes diagnostic yield. In general, demonstration of virus in samples taken from the site of infection provides the most conclusive proof of aetiology. Such samples are not always available, for example, in patients with myocarditis, and in such circumstances demonstration of concurrent viral excretion at peripheral sites, or serological diagnosis, can be used as circumstantial evidence of aetiology. However, it should be remembered that healthy infants and children frequently excrete enteroviruses: indeed, in tropical countries up to 40% of children up to the age of two years may be excreting enteroviruses at any one time. Where live attenuated polio vaccine is still in use, those recently immunized are likely to excrete virus from the upper respiratory tract and faeces for some time. Thus, the possible significance of isolating PV can only be assessed by knowing the vaccine history and clinical features.

Virus Isolation

Enteroviruses can be cultured from solid tissue, blood, CSF, urine, stool and respiratory samples, although the diagnostic significance of enterovirus detection at a normally virologically sterile site is considerably greater than

merely detecting virus in faeces or nasopharyngeal secretions, as discussed above. The most sensitive isolation specimens are faecal samples or rectal swabs. Virus excretion is often intermittent and more than one specimen should be collected, with an interval of 24–48 hours. Faecal excretion of virus commences within a few days of infection and may continue for weeks, especially with PV and Coxsackieviruses, although it rarely exceeds one month with the ECV. Concentrations of virus of $10^5 - 10^6$ tissue culture infectious doses per gramme of faeces are not uncommon.

Isolation from the pharynx is possible during the acute phase of the illness, especially in cases with respiratory symptoms (e.g. ECV9, CVA21 and EV71). The period with the highest rate of isolation is some five days before to five days after the onset of symptoms.

Viral culture of CSF generally gives a low diagnostic yield, and has largely been replaced by PCR testing, as described below, although during certain ECV epidemics up to 80% of CSF specimens have yielded virus.

In fatal cases, autopsy specimens of brain, spinal cord, heart and spleen, or other lymphoid tissue, are useful, especially where there is a recent history of oral polio vaccination, where investigations of the origin of the strain may be required.

PV, CVB, ECV and some CVA (e.g. A9 and A16) are readily isolated in cell cultures prepared from the kidneys of rhesus, cynomolgus or cercopithecus monkeys. Other useful cultures include human embryo kidney and amnion, primary liver carcinoma, rhabdomyosarcoma cells, or strains of diploid cells from human fetal lung. Possibly the most generally useful regimen is the inoculation of cell cultures of primary monkey kidney and human embryo lung fibroblasts. Enteroviruses cannot be readily differentiated by their growth in cell cultures, as all produce a similar cytopathic effect (CPE). Infected cells become rounded, refractile and ultimately shrink before detaching from the cell surface. Once a cytopathic agent has been isolated in cell culture, serological tests or nucleic acid sequencing must be performed to identify the type. Because of the number of potential strains, neutralization tests using individual type-specific sera are not satisfactory, and it is usual to employ either a single-stage procedure using antiserum pools containing selected antisera or a two-step method, first identifying the isolate as belonging to one of four groups, followed by a second test to identify the type. Because of the labour-intensive nature of serotyping procedures, many laboratories now confirm enterovirus isolates by direct immunofluorescence using enterovirus group-reactive monoclonal antibodies (Trabelsi *et al.*, 1995). Further identification is often not performed, but may also be achieved by immunofluorescent staining with serotype-specific monoclonal anti-

bodies. Some enteroviruses, notably most CVA, are not readily detected in cell cultures: if a CVA infection is suspected, specimens can be injected into two or more litters of mice by intracerebral, intraperitoneal and subcutaneous routes. However suckling mouse inoculation is no longer widely available. Neither PV nor ECV can be isolated in mice.

Twelve of the ECV possess the ability to agglutinate human group O erythrocytes. This activity is integral to the viral particle; spontaneous elution may occur at 37°C but this does not destroy the cell receptors, a property which differentiates the ECV from the ortho- and paramyxoviruses. The presence of haemagglutination activity helps reduce the number of possibilities when attempting to identify an enterovirus strain, although this is rarely employed nowadays.

Serological Diagnosis

Neutralization tests have generally been employed for such seroepidemiological purposes as determining the exposure and immunity of a population group to different enteroviruses, including responses to polio vaccination. These tests are labour-intensive and the results are seldom available in less than three to four days. They are no longer widely available, although PV-specific testing may be employed in investigating possible poliomyelitis cases. Antibody titres are compared in paired sera, the first being collected within five days of onset of symptoms, and the second some days later. Significant rises in antibody titre are detected only occasionally and this has led to significance being attached to elevated neutralizing antibody titres. However, elevated titres frequently occur in normal individuals, and so do not confirm recent infection. Significant antibody rises are particularly rare in cardiac disease, probably because cardiac events are a relatively late consequence of enterovirus infection. Serological diagnosis of recent enterovirus infection has also been achieved by detecting virus-specific IgM using M-antibody capture techniques (Bell *et al.*, 1986). IgM responses are frequently directed against group-reactive determinants, thus allowing an assay employing antigens from a limited range of serotypes to be used to detect responses elicited by a wide range of serotypes. The older the patient, the more likely that such heterotypic responses will occur. Enterovirus-specific IgM responses generally last for 8–12 weeks, but in some patients may persist for much longer, occasionally for some years. It has been suggested that such a prolonged response in, for instance, cases of recurrent pericarditis, may indicate persistence of the infecting enterovirus. Approximately 30–40% of patients with myocarditis, 60–70% of patients with aseptic meningitis and 30% of patients with postviral fatigue syndrome give positive results for CVB-specific IgM.

However, approximately 10% of normal adults also give a positive result, presumably reflecting recent asymptomatic infection.

Complement fixation tests and EIAs have also been employed to detect enterovirus-specific IgG, but the high prevalence of antibody in the general population, as measured using these group-reactive tests, and the difficulty in obtaining paired sera to demonstrate rising titres, limits diagnostic utility and these tests are no longer widely available. A rising titre of IgG antibody to PV must be treated with caution, as type 1 or type 3 infections may produce a significant boost to type 2 antibody in individuals previously primed to this type.

Molecular Diagnosis

Complementary DNA probes made by reverse transcription of purified CVB genomic RNA have been used to detect enterovirus RNA in infected cell cultures, infected mice and human tissue biopsies. Although prepared against a single CVB serotype, the probes included RNA sequences which are highly conserved amongst enteroviruses and are thus group-specific. They have been used to detect enterovirus RNA, both in RNA extracts from tissue and by *in situ* hybridization, although infectious virus or viral antigen is rarely detected in these tissues. PCR is technically more straightforward and quicker than nucleic acid hybridization methods, and is therefore more suitable for viral diagnosis. Identification of extremely conserved sequences within the 5' NTR of the enterovirus genome has allowed the design of PCR primers which allow detection of most enteroviruses (Rotbart, 1990) and numerous studies have shown that enterovirus PCR is more sensitive than viral culture for detection of enteroviruses in diverse clinical specimens. In most diagnostic laboratories examination of CSF by enterovirus PCR has replaced virus isolation for diagnosis of enteroviral meningitis, raising the possibility of more rapid diagnosis, which in turn may have greater impact on patient treatment (Schlesinger *et al.*, 1994). Enterovirus PCR is also useful for diagnosis of neonatal infections, where testing of blood, urine, CSF and stool is useful, and enterovirus myocarditis (Martin *et al.*, 1994; Nicholson *et al.*, 1995) if biopsy or autopsy tissue is available.

These enterovirus PCR protocols do not allow serotype or type-specific identification. Although serotypic identification is usually of less clinical urgency, the ability to differentiate polio and non-polio enteroviruses is important for investigation of suspected poliomyelitis cases, for diagnosis of non-polio enterovirus infection in patients recently vaccinated with live polio vaccine, for monitoring wild PV circulation in endemic regions, and for maintaining the polio eradication status of countries and regions which have been declared as polio-free by World

Health Organization (WHO). The ability to differentiate between wild-type and vaccine strains of PV, and between attenuated and neurorevertant vaccine virus is also crucial to the investigation of suspected vaccine-associated paralytic poliomyelitis. A number of PCR methods have been described for group or serotypic identification of PV (Kilpatrick *et al.*, 1996), or intratypic differentiation of wild and vaccine-strain PV (Yang *et al.*, 1991). These assays are available at WHO PV reference laboratories. Similar serotype-specific assays have also been described for other enteroviruses, and these may be of particular use in outbreak investigation once a particular outbreak strain has been identified. More commonly however the 'molecular serotyping' system based on nucleotide sequence analysis and comparison of VP1 sequences already described is used to type enterovirus isolates.

PREVENTION AND TREATMENT OF ENTEROVIRUS INFECTIONS

Vaccination

Experimental immunization with recombinant viruses expressing CVB3 capsid proteins protects mice against CVB3-induced myocarditis. However vaccination against non-polio enteroviruses is not currently available. The multiplicity of antigenic types and the usually mild nature of the diseases make the production of vaccines impractical. The only effective measures for their control are high standards of personal and community hygiene. Quarantine is not effective because of the high frequency of inapparent infections.

The observation that there are only three PV types and the discovery that they will grow in cell cultures of non-nervous tissue from monkeys made possible the development of vaccines against poliomyelitis. Natural infection with PV is by the oral route and results in viral replication in the mucosa of the pharynx and alimentary tract, causing viraemia and stimulating virus-specific IgA and IgG. The route by which the virus gains access to the CNS is not clear; although there is some experimental evidence that it can do so by travelling along autonomic nerve pathways from the site of replication, the greater body of evidence suggests that invasion of the CNS occurs via the bloodstream and may be prevented by circulating antibody. The aim of vaccination is to induce local or systemic immunity to prevent systemic spread and neuroinvasion.

Inactivated Poliovirus Vaccine

The first successful vaccine against poliomyelitis was developed by Salk and took the form of a virus preparation

carefully treated with a low concentration of formalin to inactivate it while retaining its antigenic properties. The very first batches of the vaccine used in the United States contained live virus and caused poliomyelitis in recipients; this was the Cutter incident (Nathanson and Langmuir, 1963) and was attributed to the presence of aggregates of virus which were not penetrated by the formalin. Subsequently better controlled filtration steps were introduced to remove aggregates and the vaccine has a good safety record. The initial vaccine was of relatively low potency because of the difficulty of preparing virus on the required scale, particularly the type 1 component. However the inactivated vaccine for parenteral injection (IPV) was used exclusively in Sweden, Finland, Iceland and the Netherlands and, with acceptance rates of 90% or better, virtually eliminated poliomyelitis. Surveys also show that the circulation of PV in the community was dramatically reduced, despite the fact that the vaccine does not induce detectable levels of secretory IgA and, in theory, would not be expected to prevent alimentary tract infections. In the 1980s supply of vaccine of far higher potency was ensured by the development of large-scale cell culture methods.

Sabin argued that the absence of PV in countries using IPV was due to the use of oral poliovirus vaccine (OPV) in neighbouring countries (Sabin, 1982) but studies in the Netherlands and Sweden have shown that during outbreaks of infection within religious sects refusing vaccination there was little virus circulation in the surrounding community with which they were in contact.

It has been observed that the pattern of virus shedding following virus infection of children previously vaccinated with IPV was related to the antibody titre at the time of infection. The presence of detectable IgG reduced pharyngeal shedding from 75 to 33% of children, but faecal shedding was reduced only when the titre of antibody was high, in excess of 1 : 128. The high standards of hygiene in the Netherlands and Scandinavia, where pharyngeal shedding of PV is probably the major source of infection, may explain the success of IPV in these countries. In 1984 a small outbreak of poliomyelitis with wide circulation of the type 3 strains occurred in Finland, a country which had relied exclusively on the older lower potency IPV but in which poliomyelitis had been unknown for 20 years. The level of type 3 antibody in the community was known to be low and the absence of poliomyelitis was attributed to persisting immunological memory, since revaccination of seronegative individuals induced rapid booster-like responses. The PV strains isolated in the outbreak were antigenically unusual and, in comparison with other PV3 strains, less well neutralized by antisera to reference strains of type 3 virus (Magrath *et al.*, 1986).

Oral Poliovirus Vaccine

The availability in the early 1960s of the live attenuated OPV, which was cheaper to produce and administer, easier to manufacture in quantity and which had some theoretical advantages over inactivated vaccine, led to its rapid adoption worldwide. The vaccine, administered by the oral route, parallels the natural infection and stimulates both local secretory IgA in the pharynx and alimentary tract and circulating IgG. Virus is excreted in the faeces for several weeks and possibly for several days in pharyngeal secretions. During this period the vaccine may spread to close contacts, inducing or boosting immunity in them but also, rarely, causing vaccine-associated paralytic poliomyelitis in recipients or non-immune contacts (see below).

Oral poliovirus vaccine has been used as the main tool of the Global Polio Eradication Initiative of WHO and is still used as part of childhood immunization programmes in many countries, such that individuals receive vaccine as they reach specific ages, typically at two, four and six months. This strategy was extremely effective in reducing the incidence of paralytic poliomyelitis to essentially zero in developed countries, but in other countries it had very little impact.

The Global Eradication Programme

In 1988 the WHO committed itself to the eradication of poliomyelitis by the year 2000. This ambitious goal was stimulated by the success of programmes in South America, where tropical countries had controlled polio by the use of OPV.

The strategy was to use national immunization days (NIDs), in which the aim is to immunize all children under the age of five in a country or region within a short period, usually a few days, and then to repeat the process a few weeks later. This results in a high coverage with fresh vaccine, and the colonization of susceptible individuals with vaccine virus, so breaking transmission. With modern approaches to NIDs two rounds have been enough to control the disease in most countries. The strategy is usually run in parallel with the programme strategy used elsewhere and has resulted in the eradication of poliomyelitis in the Americas, declared free of indigenous PV in 1994, and where the last case due to wild-type PV was seen in 1992, in Peru. The western Pacific region was declared PV-free in 2000 and the European region in 2002 (Centers for Disease Control and Prevention, 2003). At the time of writing, poliomyelitis was endemic in only four countries in the world: India, Pakistan, Afghanistan and Nigeria, although re-importations have been recorded in several other countries. Progress towards eradication of wild-type PV can be followed at the polio eradication website of

WHO: www.polioeradication.org. One index of success in controlling transmission comes from molecular analysis of isolates, which can be classified into different genotypes, which disappear one by one as transmission is broken and they die out. PV2 is completely eliminated first, followed by type 1 and then type 3. In fact the last case of poliomyelitis anywhere in the world attributable to naturally occurring wild-type 2 PV occurred in October 1999; thus complete eradication is theoretically possible.

Difficulties in the Eradication Programme

Most infections with poliovirus are silent, in contrast to smallpox, the only other disease to be eradicated by vaccination. This raises particular problems and makes strategies such as quarantine largely ineffective. Thus if one country in the world continues to support polio circulation, all countries are at risk. This was illustrated by events in Nigeria in 2004. Resistance to vaccination against polio began to develop in response to claims that the vaccine contained steroids which would sterilize recipients, the view that the programme was imposed by Western countries and the fact that the country had other more significant diseases, including malaria, human immunodeficiency virus (HIV) and tuberculosis. As a result the northern provinces ceased vaccination, and within a short period polio had been reintroduced and was circulating in many countries in Central Africa. Moreover the pilgrimage to Mecca resulted in the introduction of polio into Yemen and Indonesia from Nigeria. Resistance to vaccination is thus a major issue.

A second issue arose in northern India, where polio cases were disproportionately found in the Muslim minority population, who for whatever reason were not caught by vaccination activities. The response has included supplementary immunization activities (SIAs) which include house to house vaccine delivery. The scale of the programme is colossal and there continue to be problems in financing it adequately. Delivery of vaccine in areas of conflict, including Pakistan and Afghanistan, is also obviously difficult, and plays a part in the persistence of polio in these two countries.

Polio continues to circulate in northern India and the reasons are not clear. Some children are reported to have received 16 doses of vaccine before the age of five yet have still developed the disease and the usual view is that for unknown reasons oral polio vaccine is less effective in northern India than in any other part of the world.

A recent strategy to attempt to deal with the poor efficacy of OPV in certain areas has been to introduce monovalent polio vaccine. The usual vaccine contains all three serotypes including type 2 but in some areas only one serotype is a problem. Thus the use of all three types may reduce efficacy by competition between the relevant

type and the other two. The use of monovalent type 1 and type 3 vaccines has increased the efficacy of vaccination in certain problem areas. It may be that this could be partly attributed to its being a new strategy, so energizing the vaccine delivery teams, but there is a reasonable scientific explanation for it as well.

The difficulties in finally eradicating the virus from the few remaining countries where it is endemic have led some to call the entire programme into question and doubt its feasibility. On the other hand the success of the programme to date cannot be questioned. Increased usage of IPV has been advocated, and it is clear that the nonreplicating vaccine will play a bigger part in the immediate future as the last pockets are cleared and attention turns to how vaccination against polio could be stopped safely.

The End Game

The success of the eradication programme has focused attention on cases of poliomyelitis caused by the oral vaccine or strains derived from it. For vaccine recipients and their immediate contacts, Nkowane *et al.* (1987) estimated the risk of poliomyelitis in the United States as 1/530 000 primary vaccinees and $1/2 \times 10^6$ overall. Cases associated with the type 1 strain are 10-fold less than with the type 2 and type 3 strains taken together. This incidence should be taken in the context of more than 10 000 cases/year in the United States before the use of vaccines. The rate is the same in India, at the time of writing, to within a factor of 2. Thus there is a low but real incidence of vaccine-associated paralytic poliomyelitis (VAPP), and the virus can clearly spread to others, causing contact cases; this is actually an advantage where wild polio is endemic as it increases effective coverage.

However, a time is rapidly approaching when poliomyelitis will only be caused by the vaccine, raising the question of how vaccination can be safely stopped. Vaccine-associated cases have been a major driver in convincing developed countries to use IPV and the whole of North America and most of the countries of the European Union now use IPV exclusively. The switch has been made easier by the use of combinations including the other childhood vaccines such as diphtheria, tetanus and pertussis, so that one vaccination now immunizes against many diseases.

However there are other reasons for wishing to stop the use of OPV if possible. The ability of the vaccine virus to spread from recipients is an advantage when the virus is endemic as more are vaccinated than the recipient, but becomes a major problem as the wild-type virus is eliminated. In countries where the routine vaccine coverage is poor, immunized and unimmunized children mix freely and transmissible strains can be selected. Outbreaks in

Hispaniola, Egypt, Madagascar and the Philippines and several other countries have been caused by such viruses (Adu *et al.*, 2007; Kew *et al.*, 2005; Shimizu *et al.*, 2004; Vinje *et al.*, 2004). They have included representatives of all serotypes, but most commonly type 1. In most cases the viruses were recombinant strains whose genome included a large sequence unrelated to the vaccine, probably derived from a non-polio enterovirus of group C. At the time of writing there is such an outbreak in Nigeria which is one of the few countries that has not yet eradicated polio. It may be possible to deal with circulating vaccine-derived strains of PV by stopping routine vaccination campaigns of poor coverage with a final NID. This depends on the occurrence of circulating vaccine-derived polioviruses (cVDPV) being relatively rare.

A second vaccine-associated problem is the occurrence of prolonged virus excretion in a proportion of hypogammaglobulinaemic individuals, who may shed virus for several years. Approximately 20 cases of long-term excretion are known at present and the incidence of long-term excretion in patients inadvertently or deliberately given the vaccine is probably of the order of 1% (Halsey *et al.*, 2004). Although most spontaneously cease excreting virus after a period of a few years some continue for very long periods, of which the longest is an individual who has been excreting type 2 PV for over 20 years so far. Such individuals, who are more common and long lived in developed countries, pose a hazard to themselves and to all unimmunized individuals around them. Treatments to stop virus excretion have not been identified (MacLennan and MacLennan 2005; MacLennan *et al.*, 2004).

In view of these considerations, there is a developing interest in replacing OPV with IPV globally, in order to limit excretion of vaccine-strain virus. However it is not known whether IPV can break transmission in tropical settings, and as the vaccine must be given by injection there may also be problems in achieving high coverage.

Containment of Polioviruses After Eradication

When PV as well as poliomyelitis is eradicated there is the possibility that it will re-emerge. Polio has been a laboratory virus for many years and is present in many clinical samples such as faecal specimens taken for reasons not related to polio. Efforts have been made wherever polio has been declared eradicated to identify and contain or destroy such laboratory stocks, and great progress has been made (Dowdle *et al.*, 2006).

However, it will be necessary to manufacture vaccine for some time after eradication, and the most likely kind will be IPV to avoid seeding the world with virus. IPV is prepared from wild-type strains which are grown in very high quantities and there are isolated examples of escape of virus from production facilities in the past. Such

facilities are operated under conditions specified by WHO to ensure that the virus will not escape. It is likely that OPV will be stockpiled as a way of interrupting epidemics should they arise and consideration has been given to the use of the Sabin strains to manufacture IPV. This is in fact extremely difficult from a number of points of view, including the need for clinical trials to demonstrate effectiveness, but it could provide a potential source of OPV should it be needed. Alternative polio strains for production may also be developed (Burns *et al.*, 2006; Macadam *et al.*, 2006)

Re-emergence of Polio After Eradication

Poliovirus could re-emerge after eradication by escape from manufacturing plants, laboratory or other unrecognized reservoirs including long-term excretors of the virus, or by deliberate release by bioterrorists. It is conceivable that a CVA could evolve to fill the vacated niche. It is thus necessary to maintain stocks of polio vaccine to deal with future emergencies. How this is to be done and how the stock is to be used have not been fully worked out as yet.

Antiviral Therapy

It has long been recognized that picornavirus infection in cell culture could be inhibited by agents which bind stably to the virion, preventing cellular attachment, uncoating and intracellular delivery of the viral genome. Although a series of such compounds has been developed, to date only one agent, pleconaril, has sufficiently low toxicity to be a promising therapeutic agent (Romero, 2001). Pleconaril (3-[3,5-dimethyl-4[3-(3-methyl-5-isoxazolyl)propyl]oxy]phenyl]-5-(trifluoro-methyl)-1,2,4-oxadiazole; Picovir) reduces viral replication and morbidity in animal models of enterovirus disease and, in a phase II clinical trial, reduced the duration and severity of picornavirus-related respiratory infections. Pleconaril is also effective in children and adults with enteroviral meningitis, although no benefit was observable in a study of infants under one year with meningitis. Pleconaril was available on a compassionate use basis for life-threatening infections, and reports of such treatments suggested a measure of efficacy in immunocompromised patients with persistent infection, and in neonates with fulminant infection. Although drug-resistant viruses were isolated in cell culture, they appeared to be attenuated with respect to virulence in animal models. However pleconaril has now been withdrawn.

FUTURE PROSPECTS

Poliomyelitis is the most significant disease caused by a human enterovirus, and enormous progress has been

made towards its eradication. It is anticipated that complete eradication of disease caused by the wild-type virus will be achieved in the near future. Other enteroviruses remain and contribute significantly to human disease. New research methods, including the use of genetically cloned and modified viruses and transgenic and genetic knockout animal models, will increase our understanding of viral pathogenesis and may suggest novel therapeutic strategies. The advent of molecular diagnosis will enable the diagnostic laboratory to issue results within a time frame that influences patient management in a way not previously possible using slower methods. The case for developing new vaccines against non-polio enteroviruses continues to be made, particularly where a particular serotype is associated with severe disease or public health risk, although the costs involved are a major obstacle. In the meantime, it is likely that additional antiviral agents will be developed, targeting viral enzymes involved in the replication process as well the structural components of virus particles. Other antiviral strategies under investigation include the use of soluble receptor proteins to block virus uptake, and antisense oligodeoxynucleotides to interfere with viral RNA replication. Here too, though, the costs of development, licensing and marketing may prove a significant barrier to affordable, widely available treatment for enterovirus infections.

Poxviruses

Peter B. Jahrling

National Institute of Allergy and Infectious Diseases Integrated Research Facility, Frederick, Maryland, USA

INTRODUCTION

Viruses classified as members of the *Poxviridae* family include significant human pathogens including variola, the agent of smallpox. During the twentieth century alone, smallpox is estimated to have caused over 500 million human deaths (Tucker, 2001). Yet the disease and the naturally occurring virus itself were eradicated by means of the World Health Organization global eradication campaign (Fenner *et al.*, 1988). This programme of intensively vaccinating all humans in a ring surrounding every suspected case of smallpox was successful in part because variola is a human-only disease; there are no animal reservoirs to reintroduce the virus into the human population. Despite the eradication of naturally occurring smallpox, variola virus remains a concern because of the possibility that clandestine stocks of the virus may be in the hands of bioterrorists (Henderson *et al.*, 1999). The impact of a reintroduction of smallpox virus into the human population now would be even more catastrophic than during the last century; vaccination programmes were abandoned worldwide around 1976, the prevalence of immunosuppressed populations has grown, and mobility, including intercontinental air travel, has accelerated the pace of viral spread worldwide. As an example, monkeypox virus, which persists in endemic foci in West and Central Africa, was recently imported inadvertently into the United States via a shipment of rodents originating in Ghana (Centers for Disease Control and Prevention, 2003a; Charatan, 2003; Reed *et al.*, 2004). More than 50 human infections were documented as a consequence of close contact with infected animals traced back to this shipment. This chapter deals only with the poxviruses that cause human infection.

VIRUS CHARACTERISTICS

Classification

Poxviruses infect most vertebrates and invertebrates, causing a variety of diseases of veterinary and medical importance. The poxvirus family is divided into two main subfamilies, the *Chordopoxvirinae*, members of which infect vertebrates, and the *Entomopoxvirinae*, members of which infect insects. The *Chordopoxvirinae* subfamily is divided into eight genera, one of which is *Orthopoxvirus*, which includes the human pathogens variola, monkeypox virus, and other species which infect humans including cowpox and vaccinia viruses. Members of the poxvirus family are mostly zoonotic pathogens, and, with the exception of the orthopoxviruses, only a minority produce disease in humans (Table 26.1). Poxviruses of domestic animals, such as sheeppox, camelpox and avipox, can cause considerable problems for communities dependent on these animals (Baxby, 1988, 1998).

Morphology

Orthopoxviruses are oval, brick-shaped particles with geometrically corrugated outer surface. The particles sizes range from 220 to 450 nm in length and 140 to 260 nm in width. The outer envelope consists of a lipoprotein layer embedding surface tubules and enclosing a core historically described as bi-concave, due to an electron microscopy fixation artefact. The core contains the viral DNA and core fibrils, and is surrounded by the core envelope and a tightly arranged layer of rod-shaped structures known as the palisade layer. Between the palisade layer and the outer envelope exist two oval masses known as the lateral bodies. (Figure 26.1). Two infectious forms of

Table 26.1 Poxviruses pathogenic for humans

Genus	Virus	Reservoir host	Animal naturally infected	Geographical distribution	Comment
Orthopoxvirus	Smallpox	Humans	—	Formerly worldwide	Last endemic case 1977
	Monkeypox	Squirrels?	Squirrels African rodents Monkeys	West and Central Africa	Eradication confirmed 1979 Rare zoonosis. Overall mortality 10%. Limited case-to-case spread. Recent importation to non-endemic area (USA)
	Cowpox	Rodents	Cats	Europe, western Commonwealth of Independent States	Rare zoonosis. Contact with cattle unusual
	Vaccinia	Buffalo?	Cattle Buffalo	India	Variant of vaccinia. Established in nature
Parapoxvirus	Orf	Sheep	Sheep	Worldwide	Common trivial zoonoses Occupational hazards
	Pseudocowpox	Goats Cattle	Goats Cattle		
Molluscipoxvirus	Molluscum	Humans	—	Worldwide	Trivial infections. Often sexually transmitted
Yattapoxvirus	Tanapox	Monkeys	Monkeys	Kenya, DRC	Rare trivial zoonosis. Obtain travel history

orthopoxviruses (described below) result from the replication cycle.

Phylogenetic Relationships

The evolutionary relationships among the poxviruses have been elucidated by the recent availability of complete DNA sequences for over 30 species. Phylogenetic analysis reveals that variola and camelpox virus are more closely related to each other than any other members of the genus, while vaccinia is most closely related to cowpox virus strain GRI-90 (Gubser and Smith, 2002; Gubser *et al.*, 2004). Interestingly, cowpox virus strain Brighton appears to be less closely related, indicating that there are at least two separate species currently contained under the name cowpox virus. Monkeypox virus does not group closely with any other orthopoxvirus, indicating it diverged from the rest of the members of the genus relatively long ago. Yet vaccination prevents the disease. Concern has been raised that minor modifications to the camelpox virus genome might conceivably result in a virus with the attributes of variola. Virulence or attenuation may hinge on a relatively few number of genetic determinants. For example, variola major (associated with a 30% fatality rate) and variola minor (<1% fatality rate) are >98% identical over the length of the 185 000 kb genome.

As anticipated from the genomic homologies, members of the *Orthopoxvirus* genus are antigenically related. Cross-reacting and species-specific neutralizing antigens have been identified by serum absorption and monoclonal antibody studies (Baxby, 1982). Nine neutralizing epitopes have been identified among the intracellular mature viral (IMV) particles of different species of orthopoxviruses (Czerny *et al.*, 1994), and additional epitopes, believed to be critical in protection against infection *in vivo*, exist on extracellular enveloped viral (EEV) particles (Vanderplasschen *et al.*, 1997; Viner and Isaacs, 2005). Viral antigens contained in the viral envelope are of pre-eminent importance with regard to protective antibody responses: envelope antigens were absent from virion suspensions used for inactivated smallpox vaccines, which proved to be ineffective (Kaplan *et al.*, 1965; Payne, 1980).

Replication

Orthopoxvirus genomes are linear, double-stranded DNA ~200 kb. The genomes encode about 176–266 proteins, including a number of enzymes and factors that are necessary for self-replication and maturation. The central region of the genome contains highly conserved genes that are essential for viral replication, and the

Figure 26.1 (a) Mulberry (M) form of non-enveloped parapox virion; (b) naturally relaxed (extracellular) M form of vaccinia virus and (c) capsule (c) form of vaccinia virus (negative stain; bar = 150 nm).

terminal regions contain less conserved genes that are important for virus–host interactions. The virus contains a number of virus-encoded enzymes, in particular a DNA-dependent RNA polymerase, which transcribes the viral genome (Moss, 2001). Replication takes place in cytoplasmic factories referred to as B-type inclusions, in which virions at various stages of assembly are seen. It is not clear whether or not host cell nuclear factors are involved in viral replication or maturation. Cells infected with some poxviruses (e.g. cowpox, avian poxviruses) also contain electron-dense A-type inclusions, usually containing mature virions; A-type inclusions are easily seen by light microscopy.

Viral replication begins with attachment of viral particles to host cell surface, most likely through cell receptors, and involves expression of early, intermediate and late genes (Moss, 2001). Initial uncoating occurs during entry, followed by synthesis of early mRNAs which are translated to facilitate further uncoating and transcription of intermediate mRNAs. Intermediate mRNAs, in turn, are translated to allow transcription of the late mRNAs. The late mRNAs are translated into structural and enzymatic components of the virions. These components, along with DNA concatemers that are formed during the early phase of replication, are assembled into genomic DNA and packaged into immature virions, which then evolve into brick-shaped infectious IMV particles. IMV particles are infectious only when they are released by cell lysis. They can acquire a second membrane from an early endosomal component to form the intracellular enveloped virion (IEV). IEVs migrate to the cell surface via

microtubules and fuse with the cell membrane to form cell-associated virions (CEV). Finally, CEV induce polymerization of actin to form filaments which effect the direct transfer of CEV to adjacent cells. If CEV become dissociated from the cell membranes they are termed extracellular enveloped virions. While IMV particles are produced in greatest abundance in cell culture, and are the most stable to environmental degradation, CEV and EEV particles are suspected to play a more critical role in cell-to-cell spread in the intact animal (Smith *et al.*, 2002).

Many of the orthopoxvirus gene products interact with and modulate essential functions of the host cells and immune processes (Moss, 2001; Johnston and McFadden, 2003). The limited host range of variola is thought to relate in large part to the unique association of viral gene products with the myriad of host signalling pathways. Therefore, strategies which block such key pathways in the replication and maturation of poxviruses provide potential targets for therapeutic intervention (McFadden, 2005).

CLINICAL ASPECTS OF ORTHOPOXVIRUS INFECTIONS

Smallpox

Variola virus is highly stable and retains its infectivity for long periods outside the host (Huq, 1976). It is infectious by aerosol (Henderson *et al.*, 1999); natural air-borne spread to other than close contacts is unusual, but does

occur (Meiklejohn *et al.*, 1961; Downie *et al.*, 1965). Approximately 30% of susceptible contacts became infected during the era of endemic smallpox (Foege *et al.*, 1975) and the World Health Organization (WHO) eradication campaign was predicated on close person-to-person proximity being required for transmission to occur reliably. Nevertheless, variola virus's potential in low relative humidity for air-borne dissemination was alarming in two hospital outbreaks (Wehrle *et al.*, 1970). Patients with smallpox were infectious from the time of onset of their eruptive exanthem, most commonly from days 3 to 6 after onset of fever. Infectivity was markedly enhanced if the patient manifested a cough. Indirect transmission via contaminated bedding or other fomites was infrequent (Maccallum and McDonald, 1957). Some close contacts harboured virus in their throats without developing disease, and hence might have served as a means of secondary transmission (Sarkar *et al.*, 1973a, 1973b).

After a patient is exposed to aerosolized virus, variola travels from the upper or the lower respiratory tract to regional lymph nodes, where it replicates and gives rise to viraemia, which is followed soon thereafter by a rash (Breman and Henderson, 2002). The incubation period of smallpox averages 12 days (range 9–14 days), and contacts are quarantined for a minimum of 16–17 days following exposure (Breman and Henderson, 2002). Following infection via the respiratory route and replication in local lymph nodes, variola virus disseminates systemically to other lymphoid tissues, spleen, liver, bone marrow and lung. During this asymptomatic, prodromal period, variola virus can be recovered from the blood, but the yield is much lower later in the illness. Clinical manifestations begin acutely with malaise, fever, rigours, vomiting, headache and backache; 15% of patients develop delirium. Approximately 10% of light-skinned patients exhibit an erythematous rash during this phase. Two to three days later an enanthem appears concomitantly with a discrete rash about the face, hands and forearms. Because of the lack of a keratin layer on mucous membranes, lesions there shed infected epithelial cells and give rise to infectious oropharyngeal secretions in the first few days of the eruptive illness, and occasionally 24 hours prior to eruption (Downie *et al.*, 1961). These respiratory secretions are the most important but not the sole means of virus transmission to contacts. Following subsequent eruptions on the lower extremities, the rash spreads centrally during the next week to the trunk. Lesions quickly progress from macules to papules and eventually to pustular vesicles.

Lesions are more abundant on the extremities and face, and this centrifugal distribution is an important diagnostic feature. In distinct contrast to the lesions seen in varicella, smallpox lesions on various segments of the body remain generally synchronous in their stage of development.

From 8 to 14 days after onset, the pustules form scabs, which leave depressed depigmented scars on healing. Although variola titres in the throat, conjunctiva and urine diminish with time (Sarkar *et al.*, 1973a) virus can readily be recovered from scabs throughout convalescence (Mitra *et al.*, 1974) Therefore, patients should be isolated and considered infectious until all scabs separate.

During the last century of smallpox occurrence, two distinct forms of smallpox came to be recognized: variola major and variola minor. The prototypical disease, variola major, was the highly virulent form of historical significance and was still prevalent in Asia and parts of Africa during the twentieth century. Variola minor, first described in Africa by Korte in 1904, was distinguished by its milder systemic toxicity and more diminutive pox lesions (Fenner *et al.*, 1988), although Dixon reported many cases that were indistinguishable from variola major in his extensive comparison of lesion types (Dixon, 1962). A similar mild form, called alastrim, was found by Chapin to have occurred in North America as early as 1896, and subsequently exported to South America, Europe and Australia. Variola minor and alstrim were apparently caused by two distinct viral strains of reduced virulence and both typically caused 1% mortality in unvaccinated patients (Fenner *et al.*, 1988).

According to the Rao classification there were five distinct clinical presentations of variola (Rao, 1972). Three-quarters of cases of variola major fell into the *classic, or ordinary, type*. After the development of prodromal fever and constitutional symptoms, patients developed the typical variola rash, centrifugal in distribution, with synchronous progression from macules to papules, to vesicles to pustules and then scabs. The fatality rate was 3% in vaccinated and 30% in unvaccinated patients. Less frequently other clinical presentations of smallpox occurred, probably as a consequence of difference in host immune response. *Flat-type smallpox*, noted in 2–5% of patients, was characterized by both severe systemic toxicity and the slow evolution of flat, soft, focal skin lesions which did not resemble the classical variola exanthem. This syndrome caused 66% mortality in vaccinated and 95% mortality in unvaccinated patients. *Haemorrhagic-type smallpox*, seen in fewer than 3% of smallpox patients, was heralded by the appearance of extensive petechiae, mucosal haemorrhage and intense toxemia; death usually intervened before the development of typical pox lesions (Downie *et al.*, 1969a). However, on occasion haemorrhagic smallpox also occurred in the classic type later in the disease. Both haemorrhagic and flat-type smallpox may have been heralds of underlying immunodeficiency, and haemorrhagic forms occurred more commonly in pregnant women and very young children (Rao *et al.*, 1963). The fourth presentation was the modified type

which occurred typically but not exclusively in previously vaccinated individuals and was characterized by moderation of constitutional symptoms, typically reduced numbers of lesions and rapid evolutions of lesions with scabs forming by the ninth day of the illness. The *variola sine eruptione* was characterized by occurrence of prodromal fever and constitutional symptoms but these patients, almost all of whom had a history of vaccination, never developed a rash (Rao, 1972). In actuality, the manifestations of variola infection fall along a spectrum, and classification is primarily for the purpose of prognosis.

Bacterial superinfection of pox lesions was relatively common in the days before antibiotics but especially so in tropical environments and in the absence of proper hygiene and medical care (Fenner *et al.*, 1988). Arthritis and osteomyelitis developed late in the course of disease in about 1–2% of patients, more frequently occurred in children, and was often manifested as bilateral joint involvement, particularly of the elbows (Gupta and Srivastava, 1973). Viral inclusion bodies could be demonstrated in the joint effusion and bone marrow of the involved extremity. Cough and bronchitis were occasionally reported as prominent manifestations of smallpox, with attendant implications for spread of contagion; however, pneumonia was unusual (Fenner *et al.*, 1988). Pulmonary oedema occurred frequently in haemorrhagic and flat-type smallpox. Orchitis was noted in approximately 0.1% of patients. Encephalitis developed in 1 in 500 cases of variola major, compared with 1 in 2000 cases of variola minor. Keratitis and corneal ulcers were important complications of smallpox, progressing to blindness in slightly fewer than 1% of cases. Disease during pregnancy precipitated high perinatal mortality, and congenital infection was also recognized.

Partial immunity from vaccination resulted in modified-type smallpox, in which sparse skin lesions evolved variably, often without pustules, and quickly, with crusting occurring as early as the seventh day of illness. Some fully immune individuals would develop fever, sore throat and conjunctivitis (called contact fever) on exposure to smallpox. This lasted several days, but did not give rise to the toxicity or minor skin lesions that signify *variola sine eruptione*.

Individuals who recovered from smallpox possessed long-lasting immunity, although a second attack could occur in 1 in 1000 after an intervening period of 15–20 years (Rao, 1964). Both humoral and cellular responses are important components of recovery from infection. Neutralizing antibodies peak two to three weeks following onset, and last longer than five years (Downie *et al.*, 1969b), and perhaps several decades in some individuals (Viner and Isaacs, 2005).

A recent review of all pathology reports published in English from the last 200 years (Martin, 2002) suggested that in general, otherwise healthy patients who died of smallpox usually succumbed to renal failure, shock secondary to volume depletion and difficulty with oxygenation and ventilation as a result of viral pneumonia and airway compromise, respectively. Degeneration of hepatocytes might have caused a degree of compromise, but liver failure was not usually the proximate cause of death.

Due to the limited tools that were available when smallpox was an endemic disease, much of the pathogenesis remains a mystery. Detailed analysis of the pathophysiology of the disease course using the monkeypox and variola primate models and in comparison with limited clinical and pathology data from human smallpox victims suggest a role for dysregulation of the immune response involving the production of pro-inflammatory cytokines, lymphocyte apoptosis and the development of coagulation abnormalities. In the animal models, high viral burdens were identified in numerous target tissues. It is likely that these viral burdens were associated with organ dysfunction and multisystem failure. Distribution of viral antigens by immunohistochemistry as well as replicating virus by electron microscopy correlated with pathology in the lymphoid tissues, skin, oral mucosa, gastrointestinal tract, reproductive system and liver. Apoptosis was a prominent observation in lymphoid tissues with a striking loss of T cells observed. The cause of this widespread apoptosis remains unknown. However, it is likely that strong production of proinflammatory cytokines at least in part contributes to the upregulation of various proapoptotic genes. The strong upregulation of cytokines may also have contributed to the development of a haemorrhagic diathesis. The detection of D-dimers, as well as other changes in haematological parameters in monkeys that developed classical or haemorrhagic smallpox suggests that activation of the coagulation cascade is a component of both disease syndromes, although in human populations the occurrence of haemorrhagic smallpox was only ~1–3% of the total cases observed.

From these recent studies of variola and monkeypox virus infection in primates, the 'toxaemia' described by clinicians for human smallpox (Fenner *et al.*, 1988) may be fundamentally related to the processes underlying septic shock (Levi *et al.*, 2003). Common denominators include lymphocyte apoptosis, pro-inflammatory cytokines (exuberant production of type I interferons, IL-6, tumour necrosis factor- α , and IFN- γ measurable in plasma); and disseminated intravascular coagulation. Aberrant activation of all of these pathways is a hallmark of pathological activation of the innate immune system and contributes to toxic shock.

To facilitate viral replication, orthopoxviruses generally have the ability to modulate their host's immune response to the pathogen's advantage. Poxviruses encode proteins that target or interrupt the natural inflammatory response, interfere with apoptosis, synthesis of steroids and initiation of the complement system. In general, these proteins block either extracellular immune signals (by mimicking or interfering with cytokine/chemokine proteins and/or receptors); or they work intracellularly by interfering with apoptosis, targeting by the immune system, or intracellular immune cell signalling. A combination of these mechanisms may allow the virus to overcome immunologic surveillance and establish clinical disease in the host (Moss and Shisler, 2001).

Monkeypox

Monkeypox virus was so named because it was first detected in captive Asiatic monkeys; however, the virus has only been found naturally in Africa and evidence points to squirrels (*Funisciurus* spp., *Heliosciurus* spp.) as important reservoir hosts. Recently, a Gambian rat (*Crictomys gambiensis*), rope squirrel (*Funisciurus* spp.) and doormouse (*Graphiurus* spp.) from the African shipment originating in Ghana and implicated in the US monkeypox outbreak were found to be infected with monkeypox by viral isolation and nucleic acid detection (polymerase chain reaction (PCR)) (Centers for Disease Control and Prevention, 2003a; Enserink, 2003). Initial surveys in Zaire (DRC) detected monkeypox-specific antibodies in 85 of 347 (25%) squirrels sampled but from none of 233 terrestrial rodents. Monkeypox-specific antibody has been detected in very few monkeys, which, like humans are probably only occasional hosts (Khodakevich *et al.*, 1988). Subsequent work (Hutin *et al.*, 2001) in the Democratic Republic of Congo (DRC) found evidence of orthopoxvirus seroreactivity in a some terrestrial rodents tested, including Gambian rats (*Crictomys emini*) and elephant shrews (*Petrodromus tetradactylus*).

Historically, as a consequence of smallpox surveillance activities beginning in the 1970s, human cases of monkeypox were recognized for the first time. Alarmingly, monkeypox cases were almost indistinguishable from smallpox. Only occasional human cases were reported from Central Africa following cessation of routine surveillance activities post-smallpox eradication, but there was a resurgence in 1996–1997 which has not yet been fully explained. Increased political unrest leads to population displacement and breakdown of routine control measures, and the levels of vaccine-induced immunity will decline with time. A potentially serious finding that requires clarification is the observation that case-to-case transmission appears to have occurred more frequently during 1996–1997 than earlier (Heymann *et al.*, 1998).

Monkeypox continues to be sporadically reported (Meyer *et al.*, 2002). Comparison of the genomes of smallpox virus and monkeypox virus strains isolated up to 1986 suggested they have evolved separately (Douglass and Dumbell, 1992; Chen *et al.*, 2005) and the results of complete genome analysis (Shchelkunov, 2001) confirms this observation.

Sporadic outbreaks continue to occur and cause concern (Di Giulio and Eckburg, 2004b; Heymann *et al.*, 1998; Rimoin *et al.*, 2007) but most information is available about cases that occurred prior to 1988 (Breman *et al.*, 1980). More recently, monkeypox infection of humans was identified in the United States as a result of exposure to ill prairie dogs, which were probably infected after exposure to infected West African small mammals imported as exotic pets (Charatan, 2003).

The clinical features of human monkeypox are classically described as being similar to those of smallpox (Jezek *et al.*, 1983). Disease begins with a two- to four-day pre-eruptive phase with high fever and prostration. The rash develops and progresses synchronously over two to four weeks, evolving from macules to papules to vesicles and pustules to scabs. Lesions are usually umbilicated, have a centrifugal distribution and involve the palms and soles. Sore throat and frank tonsillitis are frequent during the eruptive phase of human monkeypox (Jezek *et al.*, 1983, 1986). Lymphadenopathy is a common finding that differentiates monkeypox from smallpox (Figure 26.2). Lymphadenopathy has been documented in up to 83% of unvaccinated patients with monkeypox, most frequently arising early in the course of infection, involving the submandibular and cervical nodes with somewhat less frequent involvement of axillary and inguinal nodes.

Clinical manifestations of human monkeypox are probably more diverse and not as stereotypical as those of smallpox. Mild infections were frequent in the first recognized African cases, with 14% of patients having fewer than 25 lesions and no incapacity (Jezek *et al.*, 1983). In a series of 282 patients, the exanthema first appeared somewhere other than the face in 18%, 31% of vaccinated patients had pleomorphic or 'cropping' appearance of rash lesions and 9.4% had what was described as centripetal distribution (Jezek *et al.*, 1987b). All of these features are inconsistent with a mimic of smallpox. Cases from the recent US outbreak tended to be mild with fewer lesions than most African cases. Only 19 of 78 suspected cases in the United States were hospitalized and only two had significant illness requiring some form of medical intervention (Centers for Disease Control and Prevention, 2003b; Sejvar *et al.*, 2004). None of the initial cases was suspected as a smallpox-like disease. A '*sine eruptione*' form of monkeypox has not been described, but the number of serologically diagnosed infections without history

Figure 26.2 Human monkeypox on the eighth day of rash. Note the submaxillary and inguinal lymphadenopathy. (Source: Reproduced from (Fenner *et al.*, 1988) by permission of WHO.)

of consistent rash illness suggest that this is a possibility (Jezek and Fenner, 1988). No haemorrhagic form of human monkeypox has been documented (Di Giulio and Eckburg, 2004a, 2004b).

Complications of monkeypox are more common in unvaccinated people and children (Jezek *et al.*, 1988). During intensive surveillance in the DRC between 1980 and 1986, secondary bacterial superinfection of the skin (19.2% unvaccinated) was the most common complication, followed by pulmonary distress/pneumonia (11.6% unvaccinated), vomiting/diarrhoea/dehydration (6.8% unvaccinated) and keratitis (4.4% unvaccinated). With the exception of keratitis, the incidence of these complications in vaccinated patients was at least threefold less. Alopecia has been noted in a number of cases (Hutin *et al.*, 2001). Encephalitis was detected in at least one case of monkeypox in the DRC and in one of the cases in the US outbreak of 2003 (Jezek *et al.*, 1987b; Sejvar *et al.*, 2004). As in smallpox, permanent pitted scars are often left after the scabs separate.

Severity of disease and death is related to age and vaccination status of patients, with younger unvaccinated children faring worse (Hutin *et al.*, 2001; Jezek *et al.*, 1983, 1987a; Meyer *et al.*, 2002). The case fatality rate in Africa has varied between different outbreaks and periods of increased surveillance. The fatality rate was 17% during 1970–1979, 10% from 1981–1986 and 1.5% from 1996–1997 (Heymann *et al.*, 1998). There were no fatalities among 72 suspected cases in the recent US outbreak (Centers for Disease Control and Prevention, 2003b). The presence of co-morbid illnesses such as measles, malaria or diarrhoeal disease may have a significant impact on mortality in children (Jezek *et al.*, 1988). Cause of death in monkeypox is not universally clear, although 19 of 33 fatalities in one series of patients had pulmonary distress or frank bronchopneumonia, suggesting superimposed bacterial pneumonia.

Other Orthopoxviruses Infecting Humans

Cowpox

Cowpox is a relatively unimportant zoonosis, of interest principally because of recent re-evaluation of its epidemiology. Despite its name, cowpox virus is not enzootic in cattle. The virus is maintained in a variety of European rodents, (Crouch *et al.*, 1995) and the most commonly reported victim is the domestic cat, from which source human infections are acquired (Baxby and Bennett, 1997).

Cowpox is primarily a localized, cutaneous disease (Esposito and Fenner, 2001). Baxby and co-workers reviewed 54 cases of cowpox infection with a detailed discussion of clinical manifestations (Baxby *et al.*, 1994). The disease usually consists single pock-like lesions on the hands or face, although multiple lesions are seen in roughly a quarter of cases. Typical lesions progress from macule to papule to vesicle to pustule to dark eschar, with a haemorrhagic base being common in the late vesicular stage. Progression from macule to eschar is slow, often evolving over two to three weeks. Local oedema, induration and inflammation is common and can be pronounced. Lesions are painful and are accompanied by regional lymphadenopathy. Complete healing and scab separation usually occurs within six to eight weeks of onset, but can take 12 weeks or longer. A majority of patients experience some constitutional symptoms prior to the eschar stage.

The majority of human cowpox infections are self-limited and without complication. Ocular involvement, including the cornea, can occur, but usually resolves without permanent damage. A small number of severe generalized cowpox infections have been reported, including one fatality (Baxby *et al.*, 1994; Pelkonen *et al.*, 2003). Three of these four described cases had a

history of atopic dermatitis, indicating a risk of increased severity of disease analogous to vaccinia.

Epidemiology As indicated above, cowpox is maintained in rodents; in Britain these are bank voles and woodmice (Baxby and Bennett, 1997; Crouch *et al.*, 1995). The domestic cat is the most common source of human infection and this probably explains the occurrence of cases in children; 26% of 54 cases were in children under 12 years. Most feline and human cases occur between July and October, with only occasional cases between January and June. Human cases sometimes occur in which no source is traced, but despite detailed enquiries only three human cases in Britain since 1968 have been traced to a bovine source, and no case of bovine cowpox has been detected since 1976.

Cowpox virus has a wide host range, and an interesting finding has been its occurrence in a variety of captive exotic species in European zoos. Victims have included cheetahs, lions, anteaters, rhinoceros, elephants and okapi, and infection has occasionally been transmitted to animal handlers (Baxby and Bennett, 1997; Pilaski and Roesen-Wolff, 1988).

Buffalopox

Buffalopox infection in humans has not been extensively described. The limited available data suggest that human infection usually occurs in the hands and consists of inflamed and painful pustular lesions progressing through a Jennerian evolution (Baxby and Hill, 1971; Lal and Singh, 1977; Wariyar, 1937). Regional lymphadenopathy and fever can accompany local disease (Wariyar, 1937).

DIAGNOSIS

Clinical Diagnosis

The clinical presentation of smallpox is very similar to that of many other vesicular and pustular rash illnesses, including varicella, herpes simplex, drug reactions and erythema multiforme. While the index of suspicion for an eradicated disease may be low, the failure to recognize a case of smallpox could result in the unwitting exposure of hospital contacts and the seeding of an outbreak. The 'Smallpox: Diagnosis/Evaluation' page (www.bt.cdc.gov/agent/smallpox/diagnosis) is an essential resource to assist the clinician in evaluating a febrile patient presenting with a rash. This site provides an algorithm to quickly determine the likelihood of clinical smallpox, and a standardized worksheet to classify the risk of smallpox using the Centers for Disease Control and Prevention criteria.

Laboratory Diagnosis

Collection of appropriate specimens is paramount for accurate laboratory diagnosis of orthopoxvirus infection. For virologic diagnosis, specimens from skin lesions are most important, because when viraemia does occur in orthopoxvirus infections, it is an early phenomenon (Fenner *et al.*, 1988). Ideally, cutaneous tissue and blood will be sent for diagnostic testing, with other samples being sent at the request of public health officials or experts in the field (Di Giulio and Eckburg, 2004). Detailed instructions for specimen collection can be obtained from the Centers for Disease Control and Prevention (www.cdc.gov/ncidod/monkeypox/diagspecimens.htm). Briefly, vesicles or pustules should be unroofed, with the detached vesicle skin sent placed in a dry tube and the base of the lesion scraped to make a touch-prep on a glass slide. Biopsy specimens should be split (if possible) and sent in formalin and in a dry tube. If scabs are collected, two scabs should be sent in a dry tube. For oropharyngeal swabs, dacron or polyester swabs should be used and transported in dry tubes. Blood should be collected in a marble-topped or yellow-topped serum separator tube (then centrifuged to separate serum) and in a purple-topped anticoagulant tube for whole blood. Clinical specimens potentially containing orthopoxviruses other than variola virus, including monkeypox virus, may be handled in a biosafety level 2 using BSL-3 procedures (Centers for Disease Control and Prevention, 2007).

Many phenotypic and genotypic methods involving virological, immunological and molecular approaches have been used to identify orthopoxviruses.

Phenotypic Diagnosis

In the past, a presumptive diagnosis of orthopoxviruses required a laboratory with capabilities and expertise in viral diagnostics. Microscopists with experience in poxvirus infections can often recognize the characteristic inclusion bodies (Guarnieri bodies, corresponding to B-type poxvirus inclusions in tissue samples under light microscopy. These cytoplasmic inclusions are haematoxylinophilic, stain reddish purple with Giemsa stain, and contain Feulgen-positive material (Kato and Cutting, 1959). Microscopy alone cannot differentiate members of the genus *Orthopoxvirus*; nevertheless, the epidemiological setting can suggest which species is involved. The orthopoxviruses with pathogenicity for humans can (with the exception of molluscum contagiosum) be grown on the chorioallantoic membranes of 12-day-old embryonated chicken eggs, where they form characteristic pocks. These viruses also grow readily in easily obtained cell cultures, including Vero cells, other monkey kidney cell lines, A549 and others. Variola could characteristically be differenti-

ated from other viruses by a strict temperature cut-off at 39°C. Methods for isolation and identification of individual virus species have recently been reviewed (Damon and Esposito, 2002; Meyer *et al.*, 2004). Electron microscopy will reveal the unmistakable brick-like morphology of orthopoxviruses in thin sections of infected materials. Immunogold stains will permit more precise identification to the species level.

Immunodiagnosis

Serologic testing for anti-orthopoxvirus antibodies is an old technique, and various assays were used extensively in the study of smallpox (Fenner *et al.*, 1988). However, significant serologic cross-reactivity exists between all the orthopoxvirus species, therefore, species differentiation is not possible with conventional serologic assays. Techniques developed in the 1980s to detect monkeypox-specific antibodies are complex and are considered unreliable by some experts (Jezek and Fenner, 1988; Karem *et al.*, 2005). Although complement-fixation tests detect antibodies that disappear within 12 months of infection, other traditional techniques such as immunofluorescence assay (IFA), radioimmunoassay, enzyme linked immunosorbant assay (ELISA), haemagglutination inhibition and neutralization assay detect IgG antibodies that are persistent. Thus differentiating antibodies due to acute infection from antibodies due to prior vaccination can be difficult with single specimens.

Recently, IFA and ELISA have been used to detect IgM in acute infection directed against cowpox and monkeypox, respectively (Karem *et al.*, 2005; Pelkonen *et al.*, 2003). Detection of IgM allows for diagnosis of infection after virus detection is impossible because lesions have healed and scabs have separated, but still allows for establishment of recent infection since IgM seems to disappear within six months. In the investigation of the 2003 US monkeypox outbreak, the Centers for Disease Control and Prevention relied on anti-orthopoxvirus IgG and IgM ELISAs for serologic diagnosis (Sejvar *et al.*, 2004). More recently, a combination of T cell measurements and a novel IgG ELISA was employed to enhance epidemiological follow-up studies to this outbreak (Hammarlund *et al.*, 2005; Slifka and Hammarlund, 2006).

Nucleic Acid Diagnosis

The molecular diagnostic approaches, including DNA sequencing, PCR, restriction fragment length polymorphism (RFLP), real-time PCR and microarrays, are more sensitive and specific than the conventional virological and immunological approaches. Of these techniques, sequencing provides the highest level of specificity for species or strain identification, but current sequencing techniques are

not yet practical as rapid diagnostic tools in most laboratories. RFLP analysis (Loparev *et al.*, 2001; Ibrahim and Mellott, 2005) and microarray genotyping (Lapa *et al.*, 2002) also provide high levels of specificity, and when combined with PCR, these approaches can offer high levels of sensitivity as well. Real-time PCR methods provide exquisite levels of sensitivity and specificity (Saijo *et al.*, 2008; Sofi Ibrahim *et al.*, 2003). The basic concept behind real-time PCR is the measurement, by fluorescence detection, of the amount of nucleic acids produced during every cycle of the PCR. Several detection chemistries, for example, intercalating dyes (SYBR Green), hydrolysis probes (5' nuclease or Taqman, minor groove binding proteins), hybridization probes (fluorescence resonance energy transfer (FRET)) and molecular beacons are used. Several instruments for real-time PCR, for example, the ABI 7700, Smart Cycler, LightCycler, RAPID, Opticon, Rotor-Gene and others are commercially available. When combined with portable analytical platforms such as the Smart Cycler or LightCycler, real-time PCR systems can be readily deployed to field sites for rapid testing.

Successful performance of PCR-based diagnostics requires purification of DNA from body fluid and tissue samples, careful design of oligonucleotide primers and probes and optimization of amplification and detection conditions. There are numerous commercial nucleic acid purification methods for a variety of sample types, which involve cell lysis and protein denaturation followed by DNA precipitation or fractionation by reversible binding to an affinity matrix. Selection of appropriate primers, probes and optimization of assay conditions requires knowledge of genome sequences and molecular biology techniques.

One of the basic techniques used in PCR-based diagnostics is gel analysis, where PCR-amplified regions of the genome are separated on agarose gels by electrophoresis, and the amplicon sizes are used to identify the sample. A number of PCR gel analysis assays have been used to identify cowpox, monkeypox, vaccinia or variola viruses from clinical specimens (Dhar *et al.*, 2004; Meyer *et al.*, 2004; Ropp *et al.*, 1995; Schupp *et al.*, 2001).

Long-distance Polymerase Chain Reaction (LPCR)-RFLP analysis requires the amplification of large DNA fragments with high-fidelity DNA polymerase enzymes. The amplified LPCR products are purified on agarose gels and digested with a restriction enzyme. The digested DNA fragments are then electrophoresed on polyacrylamide gels for a constant period of time at constant voltage, stained with ethidium bromide and the restriction pattern is visualized and photographed with a digital camera. The positions for all DNA fragments in each restriction pattern are determined and digitized by appropriate fingerprinting software. From this pattern a similarity coefficient is

calculated for every pair of restriction patterns and used as an index for species differentiation.

Recently developed real-time PCR assays can test clinical specimens for all orthopoxviruses or for specific species such as vaccinia, variola or monkeypox and can be performed in a matter of hours (Egan *et al.*, 2004; Espy *et al.*, 2002; Kulesh *et al.*, 2004; Saijo *et al.*, 2008; Sofi Ibrahim *et al.*, 2003). Real-time PCR was one of the diagnostic techniques used in the investigation of the 2003 US monkeypox outbreak (Sejvar *et al.*, 2004). Because of its sensitivity, rapidity and ease, real-time PCR will likely become the primary method of preliminary diagnosis of orthopoxvirus infection, with isolation and growth in a high-level containment laboratory reserved for confirmation.

MEDICAL MANAGEMENT

Vaccination

During the WHO Global Eradication Programme, most of the human population received vaccinia virus by scarification. While derivation of current vaccinia strains is uncertain, it is not a form of cowpox, and because Jenner lost his original material used for vaccination, the specific source of current vaccinia strains remains unknown (Dixon, 1962). Although there were multiple manufacturers worldwide, and vaccine lots varied with respect to potency and purity, almost all vaccinia administered was derived from one of two lineages, the New York Board of Health and Lister strains (Fenner *et al.*, 1988). Live vaccinia virus suspension is placed as a drop on the skin or drawn up by capillary action between the tines of a bifurcated needle; the nominal dose of live vaccinia was about 10^5 virions. Primary vaccination is usually uneventful; following introduction into the skin, the virus replicates in basal layer keratinocytes, spreading cell-to-cell, and leading to formation of discrete vesicles. Within a week, the vesicle evolves into a pustule surrounded by inflammatory tissue. This lesion scabs over within 10–14 days; eventually, the scab is shed. It was not uncommon for vaccinees to experience tender axillary lymph nodes, fever and malaise for brief periods. Occasionally, however, complications arose with varying degrees of severity. Accidental transfer of vaccinia from the inoculation site was fairly common, but of little consequence unless transferred to the eye. Generalized vaccinia, which involved systemic spread of the virus and eruption of multiple pocks at distant sites, was more serious; in individuals with eczema or atopic dermatitis, however, this could lead to extensive inflammation and secondary bacterial infection. More serious, life-threatening complications arose in vaccines with defects in cell-mediated immunity; the vaccination

site frequently enlarged to form an ulcer, secondary ulcers appeared, and the infection cleared slowly or not at all. The most serious event was post-vaccinal encephalitis. Although rare, this condition was frequently fatal. Historically, death occurred in approximately one in one million primary vaccinations (Fulginiti *et al.*, 2003; Lane and Goldstein, 2003). Concern is that these adverse event might be more frequent and severe if mass immunization were to be resumed in a unselected general population which now includes transplant recipients on immunosuppressive drugs, human immunodeficiency virus (HIV)-infected individuals and geriatric patients.

Protective immunity elicited by live vaccinia is thought to depend on a combination of humoral and cellular immune responses. Using a monkey model where animals are immunized with vaccinia and challenged with monkeypox, Edghill-Smith has shown that vaccinia-specific B cells are critical for protection (Edghill-Smith *et al.*, 2005). Antibody depletion of B cells, but not CD4⁺ or CD8⁺ T cells abrogated vaccinia-induced protection. Edghill-Smith has also shown that simian immunodeficiency virus (SIV)-compromised monkeys could withstand vaccinia if it was preceded by a dose of nonreplicating modified vaccinia ankara (MVA) strain vaccinia, but they were not protected against monkeypox challenge when their CD4⁺ T cell counts were $<300 \text{ mm}^{-3}$.

Adverse events following vaccinia inoculation include generalized vaccinia, eczema vaccinatum, progressive vaccinia and encephalopathy. Generalized vaccinia is characterized by a disseminated maculopapular or vesicular rash, frequently on an erythematous base and typically occurring six to nine days after primary vaccination. Eczema vaccinatum occurs in individuals with a history of atopic dermatitis, regardless of current disease activity, and can be a papular, vesicular or pustular rash. This rash may be generalized or occur as a localized rash with involvement anywhere on the body but has a predilection for areas of previous atopic dermatitis lesions. Mortality ranges from 17 to 30%. Contact precautions should be used to prevent further transmission and nosocomial infection (Cono *et al.*, 2003).

MVA is an alternative vaccine that has promise as a nonreplicating immunogen. It was utilized in Germany in the later stages of global eradication and was shown to be safe and immunogenic, but its protective efficacy has not been established in humans. MVA was generated by more than 500 serial passages in chick embryo fibroblasts, which resulted in multiple deletions and mutations and an inability to replicate efficiently in human and most other mammalian cells (Blanchard *et al.*, 1998). Ultrastructural examination of purified MVA reveals that most of the particles are enveloped; the host restriction occurs at a late

stage of maturation. The presence of enveloped particles is believed to be important in the development of protective immunity. Experimentally, MVA was demonstrated to protect monkeys against a monkeypox virus challenge after one or two doses of MVA or MVA followed by Dryvax (Earl *et al.*, 2004). Surprisingly, a single dose of MVA also protected when challenge followed immunization by as little as 10 days, although protection was not absolute; a modest number of pocks and a low level viraemia occurred in the MVA recipients following challenge. Recently, rhesus monkeys were used in a similar intravenous challenge model to evaluate a DNA vaccine strategy using a combination of four genes (L1R, A27L, A33R and B5R), with promising results (Hooper *et al.*, 2004).

Treatment

Passive Immunization

Vaccinia immune globulin (VIG) is available from the Centers for Disease Control and Prevention as an investigational new drug (IND) in two formulations, intramuscular and intravenous (Hopkins *et al.*, 2004). VIG may be beneficial in treating some of the adverse events associated with vaccination. It has no proven benefit in treatment of smallpox, and its efficacy in treatment of monkeypox infections is unknown. Monoclonal antibodies have been shown to be beneficial in animal models under certain conditions, but this concept has not yet been sufficiently developed for efficacy testing in humans.

Antiviral Drugs

Antiviral drugs would be useful for treatment of orthopoxviral diseases including smallpox, monkeypox and adverse events associated with vaccination. Presently, the only available antiviral drug is cidofovir, which may be offered under emergency use protocols maintained by both the US Department of Health and Human Services and the Department of Defense. Oral formulations of cidofovir analogues with better bioavailability and lower toxicity are currently under development (Raulin, 2005).

The elaborate replication strategy of poxviruses offers a number of potential targets for therapeutic intervention (Harrison *et al.*, 2004), ST-246 (Sbrana *et al.*, 2007) and Gleevec (Reeves *et al.*, 2005) are drugs with potential to effectively treat systemic orthopoxvirus disease. Recently, a severe case of vaccinia vaccinatium occurred in a 28-month-old child who was a household contact of a recent vaccinee. The child was treated with VIG followed by the antiviral drug cidofovir but his condition continued to deteriorate. Finally, ST-246 was administered under an Emergency Use Authorization (EUA), and the child began to recover soon after (Vora *et al.*, 2008).

While inhibition of viral replication may be necessary to halt the pathogenic disease course, it may not be sufficient. It may also be necessary to reverse the effects of the mounting damage that increasingly appears to be the result of a cytokine storm, which accounts for the 'toxicity' of systemic orthopoxvirus infection (Jahrling *et al.*, 2004). In this regard, cytokine antagonists developed to treat bacterial sepsis and other conditions may play a role in the effective management of smallpox- and monkeypox-infected patients.

OTHER POXVIRUSES INFECTING HUMANS

Parapoxvirus

Parapoxvirus infections are widespread in sheep, goats and cattle. Human infections from these sources are a common occupational hazard for those in contact with infected animals.

Parapoxvirus infection in sheep and goats is usually referred to as contagious pustular dermatitis or orf, and the corresponding human infection as orf. Parapoxvirus infection of cattle is usually referred to as paravaccinia, pseudocowpox or ring sores, and the human equivalent as paravaccinia, pseudocowpox or milker's nodes.

Pathogenesis

Infection occurs via cuts and scratches and usually remains localized. Lesions are produced by hypertrophy and proliferation of epidermal cells, often marked, and leukocyte infiltration. Histological examination shows many small multilocular vesicles within the dermis; true macrovesicles rarely occur (Johannesson *et al.*, 1975; Yirrell and Vestey, 1994). Lymphadenopathy, malaise and generalized lesions are relatively uncommon and the immune response is poor (Leavell *et al.*, 1968; Yirrell and Vestey, 1994).

Clinical Features

The progressive stages of human infection have been described in detail (Johannesson *et al.*, 1975; Leavell *et al.*, 1968; Yirrell and Vestey, 1994) and illustrations provided (Diven, 2001). Lesions start as erythematous papules and progress to a 'target' stage. This, seen one to two weeks after infection, has a red centre surrounded by a white halo and an outer inflamed halo. This progresses to a nodular then papillomatous stage, which often has a 'weeping' surface. In some patients this may enlarge and persist for some weeks before resolving, and may cause some concern (see section on Diagnosis below). The lesion resolves via a crusting stage, which may last some weeks. Occasionally very large granulomatous

lesions occur which may need surgical removal (Pether and Guerrier, 1986).

Most patients have only one lesion, but multiple primary lesions may occur. Systemic reaction is relatively uncommon and the lesion is often not particularly painful. Attention has been drawn to erythema multiforme as a common complication of orf, but because most ordinary cases go unreported, the actual incidence of erythema is probably low. The immune response in natural human infection has been investigated (Yirrell and Vestey, 1994). There is a vigorous but short-lived cell-mediated response, and a relatively poor and short-lived humoral response. This is consistent with the occurrence of second attacks in 8–12% of individuals (Robinson and Petersen, 1983; Yirrell and Vestey, 1994).

Diagnosis

Clinical The viruses that cause orf and paravaccinia are closely related (Mercer *et al.*, 1997), and in the UK human cases are reported as ‘orf/paravaccinia’, whatever the animal source (Baxby and Bennett, 1997). Clinical diagnosis of uncomplicated cases in patients with a known animal contact should not cause difficulties. However, most farmworkers and others working with animals recognize the infection and tend not to seek medical attention for routine cases. Consequently a disproportionately large number of reported cases have no known contact with infected animals. Of approximately 500 cases surveyed during 1978–1995, some 45% had no such contact. Clinical diagnosis of such cases, particularly if severe or prolonged, may cause difficulties. In particular, large weeping granulomatous or papillomatous lesions may be misdiagnosed as malignancies, resulting in one case in unnecessary amputation (Johannesson *et al.*, 1975).

Laboratory Virions with the characteristic morphology of parapoxviruses are usually easily seen by electron microscopy in lesion extracts, and this provides a rapid, certain diagnosis. The virus can be grown in cell culture but this is not attempted routinely. Some nucleic acid detection techniques have been published (Torfason and Gunadottir, 2002).

Epidemiology

Human infection is an occupational hazard of farmworkers, abattoir workers, veterinary surgeons and students and others with frequent exposure to sheep, cattle or goats. It is most common in the lambing and calving seasons, and more commonly reported in sheepworkers than catteworkers; this probably reflects differences in animal husbandry. Of 191 cases with a known source surveyed during 1978–1995, 84% had an ovine source and 16%

were from cattle. During the same period 32 cases occurred in abattoir workers (Baxby and Bennett, 1997).

Control

Most workers at risk get infected at some stage and reinfection is not uncommon. The impact of human infection in the farming and meat industries occasionally causes concern, and has led to industrial disputes (Johannesson *et al.*, 1975; Robinson and Petersen, 1983). Individuals should take care not to spread infection by auto-inoculation or to contacts, including animals. The vaccine used to control orf in sheep is fully virulent and has caused human infection.

Molluscum Contagiosum

Although lesions resembling molluscum and containing poxvirions have been detected in, for example, horses, human molluscum contagiosum is regarded as a specifically human infection and there is no evidence of transmission between humans and other animals. Molluscum is a benign skin tumour which occurs worldwide. It has been the subject of a comprehensive recent review (Birthistle and Carrington, 1997).

Pathogenesis

After a variable, sometimes lengthy, incubation period, papules develop, formed by epidermal hypertrophy. This produces a nodule and also extends the dermis downwards, but the basement membrane usually remains intact. Characteristic inclusions (Henderson–Patterson bodies) are formed in the prickle cell layer and gradually enlarge as the cells age and migrate to the surface. These cells are replaced by hyperplasia of the basal cell layer. The inclusion is a well-defined sac packed with virions (Shelly and Burmeister, 1986). The lesion is circumscribed by a connective tissue capsule and the dermis, apart from distortion, remains essentially normal. Occasionally an inflammatory infiltration of the dermis may occur (Brown *et al.*, 1981).

Clinical Features

Infection is via trauma to the skin. The characteristic lesion begins as a small papule and, when mature, is a discrete, waxy, smooth, dome-shaped pearly or flesh-coloured nodule, often umbilicated. There are usually 1–20 lesions but occasionally there may be hundreds. They may become confluent along the line of a scratch and satellite lesions are occasionally seen.

In children, lesions occur mainly on the trunk and proximal extremities. In adults they tend to occur on the trunk, pubic area and thighs, but in all cases infection may be transmitted to other parts by auto-inoculation

(Brown *et al.*, 1981). Individual lesions last for about two months but the disease usually lasts six to nine months (Steffan and Markman, 1989). More severe and prolonged infection tends to occur in individuals with impaired cell-mediated immunity, including HIV infection (Birthingistle and Carrington, 1997).

Diagnosis

The appearance of lesions in normal cases is generally sufficiently characteristic to permit clinical diagnosis. Virions can usually be seen in large numbers if material expressed from the lesion is examined by electron microscopy. The lack of a marked inflammatory response and failure to isolate an agent in cell culture or chorioalantoic membranes (CAM) should eliminate other poxvirus infections.

Epidemiology

Restriction endonuclease analysis of molluscum virus DNA has detected three main subtypes. Their incidence varies from 80 to 90% for MCV-I to about 1% for MCV-III, but all subtypes cause similar lesions and infect the same anatomical sites (Porter *et al.*, 1992; Scholz *et al.*, 1989).

The virus occurs worldwide and tends to be more common in socially deprived areas. Traditional modes of transmission are associated with mild skin trauma such as contact sports and shared towels; however, there is increasing evidence that the disease is sexually transmitted and that genital lesions are more common (Birthingistle and Carrington, 1997).

Control

Infection is benign and recovery usually spontaneous, but treatment may be sought for cosmetic reasons, particularly for facial or multiple lesions. Various treatments have been tried (Birthingistle and Carrington, 1997). Chemical treatments include phenolics, silver nitrate, trichloroacetic and glacial acetic acid. Physical methods include curettage and cryotherapy. Mild trauma may induce a cure, which may be due to release of virus-infected cells accessible to the immune system.

Prevention is based on attention to personal hygiene and, in developing countries, to general improvements in living conditions. Although relatively unimportant *per se*, the possibility that molluscum may act as a marker for more serious conditions has been raised (Oriol, 1987).

Tanapox

Human infection with tanapox virus was first recognized in the Lake Tana area of Kenya in 1957, and particular attention was paid to it during post-eradication smallpox surveillance. An account of 264 laboratory-confirmed

cases from Zaire (DRC), with colour illustrations, is available (Jezek *et al.*, 1985), as is information on the virus itself (Knight *et al.*, 1989). Recent anecdotal reports of human disease outside Africa have been published and illustrate the need to consider poxvirus aetiologies of illness in travellers returning from and emigrants from endemic areas (Croitoru *et al.*, 2002; Stich *et al.*, 2002).

Pathogenesis and Clinical Features

Infection is via the skin. The lesion is characterized by pronounced epidermal hyperplasia with little involvement of the dermis. There is a short prodromal illness with fever and malaise. The lesion starts as a macule and progresses to a raised nodule, which becomes umbilicated. The lesions are relatively large (~10 mm) and usually break down to form ulcers. There is usually erythema and oedema and lymphadenopathy is common. The lesions generally disappear within six weeks. Most (78%) patients have only one lesion, and very few have more than two. They may occur on any exposed area but the head tends to be spared.

Diagnosis

For diagnosis of tanapox the limited geographical distribution should be considered, as well as travel history. The solid nodular/ulcerated lesions are larger and develop more slowly than those of monkeypox, but are smaller and develop more rapidly than those of tropical ulcers.

Virus can be detected by electron microscopy but this would not exclude morphologically similar viruses; nucleic acid tests (Stich *et al.*, 2002) or diagnostic serological tests on lesion extract would do this. Tanapox virus grows in a number of cell lines (e.g. owl monkey kidney, Vero, MRC-5, BSC-1) but not on CAM.

Epidemiology and Control

The virus probably has a simian reservoir and is restricted to Africa, principally Kenya and DRC. Human-to-human transmission does not occur naturally, and it is thought that transmission from monkeys occurs mainly due to overcrowding during flooding, unrest and so on. With the exception of vaccination, measures for the prevention of monkeypox would be applicable to tanapox; however, the mild and sporadic nature of the infection probably means that specific measures are unnecessary.

DIAGNOSIS

When considering a diagnosis of poxvirus infection restricted geographical distributions and potential animal

sources are important features to consider. In many cases the differential diagnosis is between a particular poxvirus infection and other infections, for example, herpes, tropical ulcers, anthrax, bacterial abscess, rather than between two different poxviruses.

Summary of Diagnostic Approaches

Electron microscopy is important in rapid diagnosis and will confirm parapox infection or exclude pox infection altogether if herpes virus is seen. Further information, if required, can be obtained by virus isolation in cell culture and/or CAM, often making use of efficiency of growth at elevated temperatures. Virus-specific antigens may be detected by a variety of techniques, and nucleic acid detection tests for virus-specific gene products by PCR are now widely used (Ibrahim *et al.*, 2003; Meyer *et al.*, 1997; Ropp *et al.*, 1995).

Poxviruses will remain infective at ambient temperatures, particularly if kept dry. If specimens cannot be tested 'on the spot', infectivity is retained during transport by first-class mail without the need for special transport medium. Vesicle fluid should be smeared on a slide and air-dried. On receipt the material can be reconstituted in buffer. Scrapings from molluscrum and parapox lesions can be treated similarly. The infectivity of virus in dried crusts is retained for long periods. Virus may be extracted from such material by freeze-thawing and ultrasonic treatment. However, if the differential diagnosis includes pathogens less resistant than poxviruses, greater care should be taken and appropriate transport media used.

Alphaviruses

Graham Lloyd

Health Protection Agency, Porton Down, Salisbury, UK

INTRODUCTION

One of the original arbovirus definitions was based on biological criteria and described by the World Health Organization (1967) as:

Viruses which are maintained in nature principally, or to an important extent, through biological transmission between susceptible vertebrate hosts by haematophagous arthropods: they multiply and produce viraemia in the vertebrates, multiply in the tissues of arthropods, and are passed on to new vertebrates by the bites of arthropods after a period of extrinsic incubation.

The arboviruses were initially divided into group A (later known as alphaviruses) and group B (later known as flaviviruses), based on the recognition of further antigenically related groups of arboviruses. Advances in our understanding of alphavirus and flavivirus replication and nucleotide sequence data have placed both these groups of viruses as two separate genera in the family *Togaviridae* (Weaver *et al.*, 2005). Currently, 29 known alphaviruses are grouped together into eight complexes (Fauquet *et al.*, 2005). The prototypes of which are western equine encephalitis virus (WEEV), eastern equine encephalitis virus (EEEV), Venezuelan equine encephalitis virus (VEEV), Semliki Forest virus (SFV), Middelburg virus (MIDV), Ndumu virus (NDUV), Trocara virus (TROCV) and salmon pancreas disease virus (SPDV) (Table 27.1). More recently the flaviviruses have been classified as a separate family, the *Flaviviridae*.

Arthropod-borne (arboviruses) are identified as the causative agents for some of the most medically important emerging infectious diseases currently responsible for

significant global health problems (Gubler, 2001). Many of these vector-borne togaviruses are members of the genus *Alphavirus*. Alphaviruses are transmitted to their vertebrate hosts by arthropods (Figure 27.1) and have defined geographic distributions. The eastern equine encephalitis and Venezuelan equine encephalitis lineages are closely related and restricted to the New World, while the Sindbis-like (with the exception of Aura), Semliki Forest (with the exception of Mayaro and Una), Barmah Forest, Middelburg, and Ndumu lineages occur in the Old World. Natural vertebrate hosts include birds and rodents where infection is usually inapparent, but can, under certain circumstances, cause disease and death. When transmission occurs to domestic animals and humans the spectrum of disease varies from a clinically inapparent infection to a severe disease and even death.

THE VIRUS

Morphology

The alphavirus virions are essentially spherical, 60–70 nm in diameter (Figure 27.2) and sensitive to ether and detergent. The virion consists of three components: an outer glycoprotein shell, a lipid bilayer and an RNA-containing core or nucleocapsid (Peters and Dalrymple, 1990). The lipid bilayer is derived from the host cell plasma membrane. The viral-encoded glycoproteins, designated E1 and E2, combine forming glycoprotein spikes that are distributed on the outer surface of the virus and interact with cellular receptors and host-derived antibodies. The glycoproteins are arranged in an icosahedral surface lattice (Harrison, 1986). Complete sequence information available suggests that the viral genomes are 11–12 kb

Table 27.1 Antigenic classification of alphaviruses, global distribution, primary vertebrate hosts, primary and transmission vectors.

Antigenic complex	Virus species	Geographical distribution	Vertebrate host	Primary vector
Barmah Forest	Barmah Forest virus (BFV)	Australia	Birds	<i>Cx. annulirostris</i>
Eastern equine encephalitis	Eastern equine encephalitis virus (EEEV)	North and South America	Birds	Enzootic— <i>Culex</i> spp. Bridge vector— <i>Aedes</i> sp.
	Middelburg virus (MIDV)	South, West and Central America	?	
Ndumu	Ndumu virus (NDUV)	South, West and Central America	?	
Semliki Forest	Semliki Forest virus (SFV)	Africa and Asia	?	<i>Ae. abnormalis</i> and <i>Ae. africanus</i>
	Chikungunya virus (CHIKV)	Africa and Asia	Primates	<i>Ae. africanus</i> and <i>Ae. aegypti</i> <i>Cx. tritaeniorhynchus</i> <i>Ae. aegypti</i>
Western equine encephalitis	Getah virus (GETV)	Asia and Australasia	Mammals	
	Mayaro virus (MAYV)	South America	?	
	Bebaru virus (BEBV)	Asia	&	
	Ross River virus (RRV)	Australia and Oceania	Marsupials	
	Una virus (UNAV)	South America	&	
Venezuelan equine encephalitis	Western equine encephalitis virus (WEEV)	Americas	Birds and mammals	<i>Cx. tarsalis</i>
	Sindbis virus (SINV)	South America	?	<i>Ae. serratus</i>
	Aura virus (AURAV)	North America	Birds	
	Fort Morgan virus (FMV)	Western North America	Birds	<i>Cs. melanura</i>
	Highlands J virus (HJV)	Eastern North America	Birds	
Troara	Whataroa virus (WHAV)	New Zealand	?	
	Venezuelan equine encephalitis virus (VEEV)	The Americas	Mammals	Enzootic cycle— <i>Culex</i> sp. Epizootic cycle— <i>Aedes</i> sp. Epizootic cycle— <i>Aedes</i> sp.
Troara	Trocar virus (TROCV)	Atlantic Ocean and tributaries	Salmon	

in size and encodes four nonstructural proteins (nsP1, nsP2, nsP3, nsP4) at the 5' end and the five structural proteins (proteins C, E3, E2, 6K and E1) at the 3' end. The nonstructural proteins (nsPs) are translated from genomic RNA, and the structural proteins, from subgenomic RNA. Electron cryomicroscopy and image reconstruction of Sindbis virus (SINV), SFV, Ross River virus (RRV) and Aura virus (AURAV) show that the envelope glycoproteins form a $T = 4$ icosahedral lattice (Cheng *et al.*,

1995; Mancini *et al.*, 2000). The capsid proteins form a $T = 4$ icosahedral nucleocapsid arranged in distinct pentameric and hexameric capsomeres on the exterior of the nucleocapsid.

Biochemical and Biophysical Properties

The genome of the alphaviruses consists of a single-stranded (ss) positive-sense RNA, almost 12 000 nucleotides in length, which is capped at the 5' end

Figure 27.1 Schematic transmission and maintenance cycles.

and polyadenylated at the 3' end (Figure 27.3). The naked genome is infectious (Schlesinger and Schlesinger, 2001; Strauss and Strauss, 1994). The sedimentation

Figure 27.2 Electron micrograph of a preparation of Sindbis virus.

coefficient has been reported to be 42–49S. The genome is divided into two regions. The 5' two-thirds of the viral genome codes for the nonstructural proteins and the 3' third encodes the structural proteins (Strauss *et al.*, 1984). Both the structural and nonstructural proteins are translated as polyprotein precursors. The nonstructural polyprotein precursor is cleaved into four nonstructural proteins: nsP1, nsP2, nsP3 and nsP4. These function as the replicase; transcriptase of the virus (Strauss and Strauss, 1986). The structural polyprotein precursor is cleaved to form three major polypeptides. The capsid protein C (30–40 kDa) and the envelope glycoproteins E1 and E2 (45–59 kDa) are found in mature alphavirus particles. In addition, a small glycoprotein termed E3 has been demonstrated in SFV (Garoff *et al.*, 1974). A further small 6K polypeptide is also encoded, but has not been demonstrated in any alphavirus particles.

Replication

Virus attaches to host cell receptors via the E2 glycoprotein spikes on the viral surface. Alphaviruses are able to infect both vertebrate and arthropod hosts and enter the host cell by endocytosis or direct fusion with the plasma membrane. After endocytosis the capsid is thought to be released by low-pH catalysed membrane fusion initiated by the E1 glycoprotein (Wang *et al.*, 1992). Once released, the positive-sense genomic ss RNA is used as the messenger RNA for the translation of the nonstructural proteins (p270 and p230 polyproteins). A virus-encoded transcriptase transcribes the positive-sense RNA into

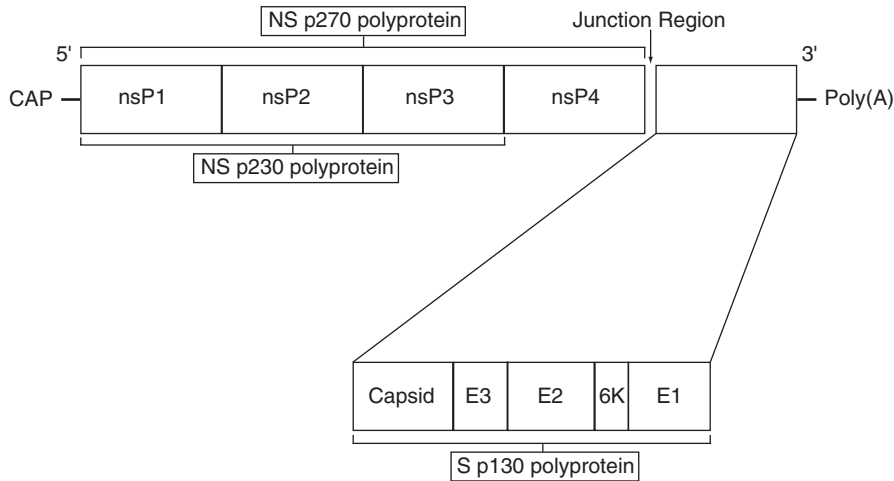

Figure 27.3 Organization of the alphavirus genome. The 5' two-thirds of the viral genome encode the nonstructural proteins, nsP1, nsP2, nsP3 and nsP4. The 3' third encodes the structural proteins. The capsid and envelope glycoprotein (E1 and E2) are located in the lipid bilayer, present in mature alphavirus particles. A third glycoprotein, E3, has been demonstrated in purified SFV. The 6K polyprotein is not known to be a structural protein.

minus-stranded RNA, which then forms a template for the synthesis of the positive-stranded progeny RNA. A subgenomic RNA (26S RNA) containing the last third of the genome is also synthesized. The structural proteins (p130 polyprotein) are translated from the 26S subgenomic protein. The capsid protein is cleaved from the p130 polyprotein; the remainder of the polyprotein moves into the endoplasmic reticulum, the N-terminal section of E3 serving as the signal sequence. Post-translational glycosylation and acylation and further cleavage occurs, yielding four separate proteins (E3, E2, 6K and E1) (Simizu *et al.*, 1984; Weaver *et al.*, 2005). The membrane-embedded proteins move towards the cell surface where virus assembly occurs. The C-terminal region of the E2 interacts with the nucleocapsid and the N-terminal region of the E2 interacts with E1 to form the heterodimer spike structure (Anthony and Brown, 1991; Paredes *et al.*, 1993). Nucleocapsids are assembled in the cytoplasm and maturation occurs by budding through host cell membranes (Garoff *et al.*, 1998).

An important advance in the study of alphaviruses has been the construction of full-length cDNA clones containing the complete viral genome. The production of *in vitro* transcribed RNA can be transfected into cells resulting in the generation of infectious virus. These clones have provided tools to further understand and analyse the factors that influence viral pathogenesis, cell tropism and synthesis and intracellular transport of membrane proteins.

Antigenic and Genotypic Properties

The alphaviruses have a group-reactive nucleoprotein. Complex and type-specific reactivity is determined by the envelope glycoproteins. This antigenic comparison of alphaviruses has been conducted using haemagglutination inhibition (HAI) and complement fixation tests as well as cross-protection tests in mice and neutralization tests in cell culture (Calisher *et al.*, 1980). The E1 glycoprotein of Sindbis contains the antigen responsible for haemagglutination (Chanas *et al.*, 1982). It is assumed that this is also the case for other members of the genus *Alphavirus*. The E2 glycoprotein induces virus-specific neutralizing antibody. On the basis of this, alphaviruses have been divided into six antigenic complexes: WEEV, VEEV, EEEV, SFV, MIDV and NDUV (Peters and Dalrymple, 1990). A further virus Barmah Forest virus (BFV) has been shown to be biochemically typical of the genus, but is not related serologically to members of the six antigenic complexes (Table 27.1). Each complex consists of either a single virus species having no known close relatives, for example EEEV, VEEV, MIDV and NDUV, or several species, subtypes and varieties that are more closely related to each other than the other members of the genus, for example SFV and WEEV. Plaque reduction or kinetic HAI tests can often only distinguish these variants. Kinetic HAI tests have also been used to differentiate between geographical variants of EEEV (Casals, 1964). Studies utilizing monoclonal antibodies have been able to define the alphavirus antigenic cross-reactivity more precisely and map the antigenic determinants.

Table 27.2 Principal alphaviruses of medical importance.

Clinical features	Virus
Fever, rash	Sindbis and Ockelbo
Fever, rash polyarthritis	Ross River and Barmah Forest
Fever, rash, myalgia, arthralgia	Chikungunya, o'nyong-nyong, Mayaro, Sindbis, Ockelbo, Ross River, Barmah Forest and Igo Ora
Fever, encephalitis	Eastern equine encephalitis Western equine encephalitis Venezuelan equine encephalitis Everglades, Semliki Forest

A recent study sequenced one strain of each alphavirus species and this allowed for the classification of alphaviruses into six genotypes (compared with seven antigenic complexes): SINV, NDUV, VEEV, WEEV, BFV and SFV. The authors included EEEV and WEEV in the same genotypic complex; this homology is to be expected as WEEV is thought to be a recombinant virus which derives its nonstructural genes from an EEEV ancestor (Pfeffer *et al.*, 1997).

SPECTRUM OF DISEASES CAUSED BY ALPHAVIRUSES

Alphaviruses cause a wide range of diseases in animals and humans, ranging from a clinically inapparent infection to a severe disease that may result in death. The main target organs are muscle, brain, reticuloendothelial system and the joints. This group of viruses may be clinically divided into those that are associated with fever, rash and polyarthritis found in the Old World or those that cause encephalitis, primarily found in the New World (Table 27.2). MIDV and NDUV are not known to cause disease in humans. Some alphaviruses are also responsible for disease in animals, particularly Equidae.

DIAGNOSIS OF ALPHAVIRUS INFECTIONS

The clinical features in a patient living or having recently travelled to an appropriate geographical region are the essential early components of establishing a differential diagnosis (Table 27.3). However, differentiation from other viral infections may be difficult. For example, it

is sometimes difficult to clinically differentiate infection with RRV from rickettsial, rubella, parvovirus B19 or enterovirus infections. Laboratory confirmation may therefore be required to identify the causative agent.

Laboratory diagnosis of alphavirus infections are determined on the basis of examining acute-phase serum for either immunoglobulin M (IgM) and IgG serological responses, isolation of causative virus or use of molecular techniques to detect evidence of the viral genome. In general, virus isolation is often only successful when acute-phase antibody-negative serum samples are used, particularly when the serum sample is taken in the first 48 hours of illness. Thereafter, the amount of virus in serum reduces rapidly and isolation becomes increasingly difficult. Virus identification is facilitated by the use of murine monoclonal alphavirus-specific antibodies. Virus may be isolated by intracerebral inoculation of suckling mice as well as in a variety of cell culture systems, including monkey kidney (Vero) and mosquito (C6-36) cell lines. Advances in the development of genomic detection methods have improved the early detection of infection. As these are RNA viruses any polymerase chain reaction (PCR)-based assay must first transcribe the RNA into DNA. A reverse transcription polymerase chain reaction (RT-PCR) has been developed for the genus-specific detection of alphaviruses. This utilizes degenerate primers localized within a conserved region of the nonstructural protein (NS1) and has become a routine sensitive and rapid alternative to virus isolation in the diagnosis of an acute infection (Pastorino *et al.*, 2005; Pfeffer *et al.*, 1997; Schuffenecker *et al.*, 2006).

Detection of an appropriate specific antibody response is frequently used to diagnose alphavirus infections. Class-specific IgM assays have been developed to diagnose an acute or recent infection with a particular alphavirus. However, care must be taken in the interpretation of the result, as cross-reactions may occur with other members of the same alphavirus antigenic complex (Table 27.1) (Calisher *et al.*, 1986). A serological diagnosis of a recent alphavirus infection is demonstrated by a rise in specific IgM or IgG antibodies, when acute and convalescent serum samples are tested in parallel. This is usually achieved through using enzyme-linked immunosorbent assay (ELISA), immunofluorescent antibody (IFA) or neutralization tests.

MANAGEMENT AND PREVENTION

Management of alphavirus infections is usually supportive and directed at symptomatic relief, for example the symptomatic relief of joint symptoms with nonsteroidal

Table 27.3 Generalized alphavirus case definition.

Clinical description	An illness with acute onset, with fever $>38^{\circ}\text{C}$, including variations of the following:
	Rash Arthralgia Polyarthritits Myalgia, headache, nausea and vomiting Malaise and weakness Disorientation and drowsiness
Laboratory criteria for diagnosis in one or more areas	Isolation of virus from blood, CSF or synovial joint fluids Positive IgM serology or IgG seroconversion in paired serum Demonstration of virus antigen in autopsy tissue by immunocytochemistry or in serum by ELISA Positive RT-PCR from serum, synovial joint fluid, CSF or autopsy tissue
Case classification	
Suspected	A case that meets the clinical case description
Probable	A case compatible with the clinical description with one of the following: supportive serology (comparable IgG) or positive IgM antibody test in an acute- or convalescent-phase serum
Confirmed	Occurrence at same location and time as other confirmed alphavirus cases A suspected case that is laboratory confirmed, that includes seroconversion and/or virus isolation or PCR positive or epidemiologically linked to a confirmed case or outbreak

anti-inflammatory agents and aspirin. Prevention of alphavirus infections has focused on vector control and the protection of the individual against mosquito bites. A detailed knowledge of the vector and vertebrate host range is therefore essential to allow for a coordinated strategy to prevent and control alphavirus infections. Vaccines are also available against some of the individual alphaviruses infections but not generally available (see below).

ALPHAVIRUSES ASSOCIATED WITH FEVERS AND POLYARTHRTIS

Sindbis Virus

SINV is considered the prototype of the alphaviruses and is the most widely distributed of all known arboviruses. It was originally isolated from *Culex pipiens* and *Culex univittatus* mosquitoes collected in the Egyptian village of Sindbis (Taylor *et al.*, 1955). In Sweden symptomatic disease resulting from infection with a Sindbis-like agent has been termed Ockelbo disease. A Sindbis-related virus has also been described as the cause of Pogosta disease in Finland and as Karelian fever in the Karelian region of the former USSR. Babanki virus is a Sindbis-like agent that occurs in West and Central Africa; the clinical significance of infection with this virus remains to be defined (Peters and Dalrymple, 1990).

Epidemiology and Host Range

SINV occurs in many parts of the world, including Europe, Asia, Africa and Australia. Despite its wide distribution, symptomatic infections in humans have been reported in only a few geographically restricted areas, such as northern Europe and occasionally in South Africa (Malherbe *et al.*, 1963), Australia (Boughton *et al.*, 1984; Doherty *et al.*, 1969) and China (Zhou *et al.*, 1999). Although serological evidence exists that SINV was the causative agent of Pogosta disease it was not till 2002 that the virus was isolated from acutely ill patients (Kurkela *et al.*, 2004). Similar disease is also found in Sweden (Ockelbo disease) and Russia (Karelian fever). The virus is known to infect humans, domestic animals and birds, with birds forming the principal reservoir. Grouse (*Tetraonidae*) and passerines (especially thrushes, *Turdidae*) have been suggested as the amplifying hosts in northern Europe. Humans are not considered to be essential to the survival of the virus in nature. SINV is transmitted among birds by the *Culex* mosquitoes. Infection in birds does not appear to result in disease. Where humans and birds exist in close proximity, for example in the Nile Valley, transmission to humans may occur (Peters and Dalrymple, 1990). Studies from South Africa have shown that the virus is distributed widely throughout the country. Migratory birds may also play a role in distributing SINV over long distances. Supporting evidence is provided by demonstrating that SINV strains obtained

from vast geographic areas of Australia share identical nucleotide sequence profiles (Sammels *et al.*, 1999). Further serological and phylogenetic studies have indicated that South African and northern European SINV strains are closely related, supporting the hypothesis that migratory birds have carried the virus to northern Europe (Buckley *et al.*, 2003; Shirako *et al.*, 1991). Transmission to the avian population and probably to humans occurs annually. Extensive human disease only occurs, however, during years of abundant rainfall and flooding (Jupp *et al.*, 1986; McIntosh *et al.*, 1964). In Europe, disease caused by SINV occurs after excursions into forested areas by, for example, lumberjacks or berry pickers. Here the virus has been isolated from *Culiseta*, *Aedes* and *Culex* mosquitoes.

Clinical Disease

SINV is among the least virulent of the alphaviruses. Serological surveys suggest that infection with SINV is relatively common, but clinically apparent disease is unusual. When symptomatic, the spectrum of disease in humans varies from a mild illness to one consisting of a rash and arthralgia. The illness is usually characterized by a sudden onset of the rash, but occasionally prodromal symptoms may be present. The rash is usually macular or papular but may become vesicular or haemorrhagic. Malaise, fatigue and headache are frequently present (Jupp *et al.*, 1986; Kurkela *et al.*, 2008; McIntosh *et al.*, 1964). The initial joint involvement is usually migratory, followed by a gradual resolution of symptoms.

Ockelbo disease was first described in the central part of Sweden in the 1960s in clusters of patients with fever, arthralgia and a rash (Niklasson and Vene, 1996). Some patients with Ockelbo disease have reported joint symptoms persisting for more than a year and recurrent joint problems were documented in one-third of a group of Swedish patients interviewed two or more years post infection (Niklasson *et al.*, 1988). By contrast, reports from South Africa have emphasized the joint involvement less and have suggested that the involvement is of tendon and periarticular tissue, rather than a true arthritis (McIntosh *et al.*, 1964).

Pogosta disease incidence during 1980–1996 was reported to be the highest in the provinces of North Karelia and Central Finland. In 2002, 600 cases were diagnosed serologically. The highest incidence moved to southern Ostrobothnia. SINV seroprevalence among hospitalized patients in Finland found 19% of the patients were aged < 10 years.

Pathogenesis

It is not clear whether the skin lesions are the result of a direct viral cytopathic effect or are immunopathological.

Evidence to support the former hypothesis comes from Malherbe *et al.* (1963), who demonstrated the isolation of SINV from a vesicle in the absence of a serum viraemia. This was associated with a subsequent rise in specific antibody. Other workers have, however, failed to isolate SINV from skin lesions (McIntosh *et al.*, 1964). The pathogenesis of the joint complications, and whether they are articular or periarticular, is also unclear.

Diagnosis

Isolation of SINV from human sera has been reported as being intermittently successful from the acute phase of the illness, even using sera taken early on in the illness. This is because the viraemia associated with SINV infection is often of low level and transient. In addition, medical attention is frequently sought relatively late in the course of the illness. As mentioned above, SINV has also been isolated from a skin lesion. When inoculated into three- to five-day-old mice, either intracerebrally or intraperitoneally, SINV causes a fatal infection, which is preceded by a short period of paralysis. The virus has also been isolated *in vitro* in fibroblastic cell lines. Antibodies appear 7–10 days after the onset of illness and may be detected by HAI, ELISA and immunofluorescence (Doherty *et al.*, 1969; Espmark and Niklasson, 1984; Kurkela *et al.*, 2008; McIntosh *et al.*, 1964). Although the detection of Sindbis-specific IgM may be of use in diagnosis an acute infection, this class of antibody may remain detectable three to four years after the initial infection. A positive IgM result must therefore be interpreted together with the available clinical information (Lane *et al.*, 2004).

Chikungunya Virus

This virus was first isolated from patients and mosquitoes in the Newala district of Tanzania in 1952–1953 during an epidemic of dengue-like illness (Robinson, 1955; Ross, 1956). The name is derived from a local term for the illness, meaning ‘that which bends up’, referring to the crippling arthralgia and arthritis associated with infection with this virus. Chikungunya virus (CHIKV) is found in the savannahs and forests of tropical Africa as well as in many parts of Asia, including, Cambodia, Vietnam, Burma, Sri Lanka and India (Table 27.4). Between the 1960s and 1990s, the virus was isolated frequently in a number of countries in central and southern Africa including Sudan, Uganda, Democratic Republic of Congo (DRC), the Central African Republic, Malawi, Zimbabwe, Kenya and South Africa. Chikungunya has also been cause of infections in western African countries including Senegal, Benin, Cote d’Ivoire and Nigeria.

In South East Asia, frequent outbreaks of chikungunya were reported from the early 1960s though to

Table 27.4 Origins and geographic distribution of the Semliki Forest virus complex.

Antigenic complex	Species	Origin	Main geographic distribution	Other features
Semliki Forest	Bebaru	Malaysia	Malaysia	Epidemics in East Africa, Indian Ocean Islands and Asia
	Chikungunya	Tanganyika, 1953	Africa, Asia, Philippines and Indian Ocean

	Getah	Malaysia, 1955	Malaysia, Japan, Australia, Cambodia and Philippines	Epidemic in Central African Republic One epizootic in Japan
	Ross River Semliki Forest	Australia, 1959 Africa, 19??	Australasia and South Pacific Africa	
Sagiyama Mayaro Una	Japan, 1956 Trinidad, 1954	Japan and Okinawa Trinidad and South America South America Panama, Surinam, Trinidad and French Guiana		

2003 in India, Pakistan, Malaysia, Indonesia, Cambodia, Vietnam and Thailand (Table 27.4). Numerous large cities in South East Asia including Calcutta and Bangkok have been identified as active sites of transmission and disease. Major disease clusters of chikungunya are increasingly being recorded in areas that have included Senegal 1986 and 1996–1997 (Diallo *et al.*, 1999), Ivory Coast in 1996–1997 (Thonnon *et al.*, 1999), DRC during 1998–2000 (Nur *et al.*, 1999), Indonesia in 2003 (Laras *et al.*, 2005; Porter *et al.*, 2004), Kenya in 2004, Comoros in 2005 (Sergon *et al.*, 2007), the Seychelles, Mauritius, Madagascar and Réunion Island during 2005–2006 and in India 2006–2007 (Ravi, 2006; Saxena *et al.*, 2006). Outbreaks have also occurred continuously with hundreds of thousands of reported cases involving new geographical areas in the Indian Ocean and India.

Associated with the Indian Ocean island outbreaks over 900 imported cases of chikungunya cases have been recorded in Europe, approximately 50 cases in United, mostly amongst returning tourists (Pfeffer, 2006; Warner *et al.*, 2006). In July 2007, the first indigenous transmission of chikungunya in Europe was reported from the rural area in Emilia-Romagna, Italy, where 254 suspected cases were recorded with 74 laboratory confirmed (Rezza *et al.*, 2007). The presumed index case was reported to have returned to the area from Kerala state, India, where an epidemic of the disease was ongoing at the time. By September approximately 300 suspected cases had been identified and the virus had also been isolated from local *Aedes albopictus* found in the local

area, which is widespread in Italy. The emergence of chikungunya in Italy illustrates that this situation could develop in other countries where *Ae. albopictus* is prevalent.

The CHIKV strains from Africa and Asia have been shown to be closely related, using a panel of monoclonal antibodies prepared against strains from Africa and Asia (Blackburn *et al.*, 1995). Sequence analysis of isolates from past outbreaks in Africa, India and South East Asia revealed the existence of geographically clustered lineages of the virus. Powers *et al.* (2000) reported that Asian outbreak strains originated in Africa, but still formed a distinct Asian genotype separate from West African and Central/East African genotypes. More recently the viruses that emerged from the major outbreak originating in the south-west Indian Ocean all align with the Central/East African genotype (Schuffenecker *et al.*, 2006). Gene sequences from recent isolates originating from India also belong to this Central/East African group (Yergolkar *et al.*, 2006).

Epidemiology and Host Range

The epidemiology of CHIKV infections differs in Africa and Asia. In Africa this virus is transmitted in savannahs and forests by *Aedes* mosquitoes, mainly members of the subgenera *Aedimorphus*, *Diceromyia* and *Stegomyia* (Diallo *et al.*, 1999; Jupp and McIntosh, 1990; McIntosh *et al.*, 1977). The most important vertebrates in the cycle of infection are the non-human primates, for example baboons and *Cercopithecus* monkeys. Bush babies and

certain species of bats may also be infected in nature, but their role in viral maintenance is likely to be of secondary importance. Humans may be infected in African villages and rural areas, particularly where *Aedes aegypti* is present in large numbers. In contrast to the situation in Africa, transmission in Asia is primarily from human to human by *Ae. aegypti*. While *Ae. aegypti* was considered as the usual vector, *Ae. albopictus* has been recently involved in the chikungunya outbreak in the Indian Ocean in 2005–2006 (Schuffenecker *et al.*, 2006). This species, native to South East Asia, has succeeded in colonizing both tropical and temperate regions including parts of Europe (Vazeille *et al.*, 2008).

Although the most important vector for CHIKV transmission to humans is the *Aedes* mosquito, transmission has also been described by *Mansonia African*. The active replication of alphaviruses in the mosquito is essential for perpetuation in nature, but the explosive nature of the chikungunya epidemics has led to speculation that mechanical transmission of the virus may also occur from a viraemic host by an uninfected mosquito (Peters and Dalrymple, 1990).

Recent molecular epidemiology studies of CHIKVs isolated from 2005 to 2007 outbreaks has led to the speculation that viral mutations have led to increasing virulence. Genetic studies of CHIKVs suggest three distinct lineages derived from West Africa, Asia and all South/Central/East African genotype which have included strains introduced into Asia.

Clinical Disease

The incubation period varies but is usually 2–4 days with a range of 1–12 days. Chikungunya illness typically begins with an abrupt onset of fever reaching as high as 40°C that may last for 10 days. The fever precedes the rash and joint pains. The most significant manifestation of chikungunya illness is the severe joint pains affecting mainly the small joints of the hands, wrist and feet (Deller and Russell, 1968). This may be associated with an erythematous flush over the face and upper chest in approximately 80% of patients. A maculopapular rash together with a generalized lymphadenopathy appears three to four days later. The arthralgia is most commonly symmetrical and peripheral, being noted in the ankles, toes, fingers, elbow, wrists and knees. Although the arthralgia may resolve within a few weeks, pain, swelling and morning stiffness may continue for months and even years after infection. In rare instances, the rheumatic condition results in joint destruction before resolution after 15 years (Brighton and Simpson, 1984). Petechiae and bleeding from the gums does occur, but there are no significant haemorrhagic manifestations.

During many of the recent outbreaks a number of atypical clinical presentations have been noted. A study from Bangkok concentrating on a paediatric outpatient department showed that the most frequent presenting symptom of CHIKV infection in children was vomiting, which was present in 35% of patients. In addition, 18% had abdominal pain or anorexia. None of the patients in this study were noted to have joint symptoms; arthritis and arthralgia therefore appear to be less prominent features in children. On clinical examination of this paediatric population the most frequent sign was a pharyngitis, which was present in 71% of patients, followed by facial flushing (24% of patients). None of these children had a rash. This study illustrates very clearly that the clinical presentation of chikungunya infections in adults and children differ (Halstead *et al.*, 1969).

In Asia, several virus isolations have been made from severely ill children diagnosed as having haemorrhagic fever, similar to dengue haemorrhagic fever. Haemorrhagic forms of CHIKV infection have been described in India and South East Asia, but these are seldom as severe as dengue haemorrhagic fever. In a hospital-based study in Bangkok about 8% of children with suspected haemorrhagic fever had CHIKV infection (Nimmannitya *et al.*, 1969).

Atypical clinical features have been a particular feature of the 2005–2007 Indian Ocean outbreaks where descriptions of cases have included neurological involvement in adults, fetuses and neonates (Robillard *et al.*, 2006; Schuffenecker *et al.*, 2006). In addition, the first cases of mother-to-child transmission have been reported. It was concluded that mother-to-child CHIKV transmission was frequently a feature in the context of intrapartum maternal viraemia, and often led to severe encephalitic neonatal infection. All infected neonates were found asymptomatic at birth and the median onset of disease was three to seven days. Pain, prostration and fever, together with thrombocytopenia, was observed in all cases studied (Gérardin *et al.*, 2008; Ramful *et al.*, 2007). Finally, a recent study in India has documented a chikungunya case in a 15-year-old female who had developed a sudden unilateral sensorineural hearing loss following an episode of fever, arthralgia and rashes one month earlier (Bhavava *et al.*, 2008)

Pathogenesis

CHIKV may be isolated from the blood early in the course of disease. As the disappearance of the viraemia correlates with the appearance of IgM and IgG antibodies, it would appear that recovery from infection correlates with the development of viral-specific antibody rather than cell-mediated immunity. The haemostatic abnormality

seen in both children and adult patients is possibly the result of an acquired platelet defect as it has been shown that the association of CHIKV with human platelets *in vitro* promotes platelet clumping (Chernesky and Larke, 1977).

Diagnosis

The clinical features described above in a patient who has recently returned from, or is living in, sub-Saharan Africa, Indian Ocean or Asia enables a presumptive clinical diagnosis to be made. In addition, a minority of patients will have a leukopenia with a relative lymphocytosis. In most, however, the white cell count will be normal. The platelet count may be decreased, but this is usually not significant.

CHIKV can be isolated by the intracerebral inoculation of suckling mice or by viral culture in either mosquito or mammalian cell culture systems (Peters and Dalrymple, 1990). Viraemia will be present in most patients during the first 48 hours of disease and may be detected in sera as late as day 4 post onset. Thereafter the amount of virus in serum drops rapidly and recovery becomes increasingly difficult. Early serological techniques found both HAI, IFA and neutralizing antibodies appeared on days 5–7 of the illness. The appearance of these antibodies is associated with a decrease in viraemia (Calisher *et al.*, 1986; Carey *et al.*, 1969; Grivard *et al.*, 2007; Litzba *et al.*, 2008). IgG antibodies rise rapidly and peak in the second week and are detectable by HAI, capture ELISA or IFA methods. Virus-specific IgM antibodies are readily detected by capture ELISA both in patients in the acute phase of illness and those recovering from infection as they persist in excess of six months. However, cross-reaction with other members of the same alphavirus antigenic complex must be considered, so the results obtained must be interpreted with caution (Table 27.2). The use of a specific IgM assay may be especially relevant in an epidemic situation as illustrated during the recent Indian Ocean outbreak. Utilization of a simple indirect ELISA or IFA proves helpful in achieving an acute-phase diagnosis and results showed a strong concordance with early HAI tests (90% agreement) as still used in many parts of the world, although ELISA and IF is able to identify twice as many patients at initial hospital admission (Thein *et al.*, 1992).

The increased use of real-time RT-PCR assays targeting the E1 gene have been developed and proved extremely effective in the early detection of illness both during endemic episodes and as part of the differential diagnosis in returning travellers (Carletti *et al.*, 2007; Edwards *et al.*, 2007; Grivard *et al.*, 2007). The differential diagnosis within the laboratory should include Ross River, dengue, Sindbis and West Nile virus infections.

Vaccine

Currently, no vaccine is available. A formalin-inactivated CHIKV vaccine prepared in monkey kidney tissue culture has been described. Despite being apparently safe and immunogenic, its use has been limited to initial safety studies and laboratory workers (Harrison *et al.*, 1971). More recently a live-attenuated vaccine has been produced and currently undergoing safety and immunogenicity studies.

O’Nyong-nyong Virus

O’nyong-nyong literally means ‘weakening of the joints’. It was first described as an epidemic viral disease in East Africa (Haddow *et al.*, 1960). Antigenically, o’nyong-nyong virus is a subtype of the species chikungunya (Table 27.3).

Epidemiology and Host Range

The initial epidemic began in 1959 in north-western Uganda and spread from there to Kenya, Tanzania, Mozambique, Malawi and Zaire. It involved some 2 million people. Within an infected area spread was rapid, with an extremely high attack rate. In an affected village a high proportion of the population, regardless of age or sex, were incapacitated. This disease was also apparently unknown to the tribes who were affected. The origin of o’nyong-nyong virus is not clear. It might have existed unrecognized prior to the initial epidemic described above, or, conversely, the epidemic may well have resulted from a mutant or recombinant virus. The vectors of this virus are *Anopheles funestus* and *Anopheles gambiae*. It is not known whether a non-human vertebrate host exists. After this initial epidemic very little further information on this virus was obtained until 1978 when it was isolated from *A. funestus* mosquitoes in the Kao Plain in Kenya (Johnson *et al.*, 1981). The re-emergence of epidemic o’nyong-nyong fever in south-western Uganda after an absence of 35 years has recently been described (Rwaguma *et al.*, 1997).

Clinical Disease

The clinical features are similar to those of CHIKV infections, with a sudden onset of a five-day fever often accompanied by a rigour. Characteristic features of the disease include joint pains followed by the development of a rash. Joint pain primarily affects the knees, although ankles, elbows, wrists also can be involved.

The morbilliform macupapular rash erupts on the face extending to the trunk and extremities, four to seven days post onset of infection and is similar to chikungunya. Some fatalities have been described, but morbidity is substantial (Kiwanuka *et al.*, 1999).

Diagnosis

Virus may be isolated in one-day-old mice from serum samples taken during the acute stage of the infection. However, mouse passage or subinoculation into chick fibroblasts may be necessary. The mice demonstrate alopecia and runting. The virus may then be further identified using plaque inhibition, cross-neutralization assays or HAI (Williams and Woodall, 1961). Antibodies to o'nyong-nyong virus may be detected by complement fixation, HAI, ELISA, immunofluorescence and neutralization assays. Interpretation may be difficult due to cross-reaction with CHIKV. In general, however, the antibody titre to the homologous virus will be higher than that to the heterologous virus (Peters and Dalrymple, 1990).

Ross River Virus

RRV is an important arbovirus that is endemic and enzootic in Australia and Papua New Guinea. Also known as epidemic polyarthritis, it is the most common arboviral infection of humans in Australia, being responsible for over an average of 5000 notifications per year (Jacups *et al.*, 2008). In the late 1970s and early 1980s RRV also became endemic in the Pacific Islands (Table 27.4). In Australia approximately 60% of cases arise in tropical and central Queensland (most commonly between January and May). In recent years it has increasingly been identified in travellers returning to Europe and North America (Klupsing *et al.*, 2005).

Epidemiology and Host Range

Until 1979 the distribution of RRV infections was thought to be limited to Australia, Papua New Guinea and the Solomon Islands, all in the western half of the Pacific basin. In Australia both epidemic and sporadic transmission of RRV occurs. Epidemics are characteristically preceded by heavy rainfall or high tides affecting salt marshes, river valleys and irrigated lands in coastal areas. This leads to increase in mosquito numbers (Kelly-Hope *et al.*, 2004) However, other factors, such as temperature, are important—a sudden period of cold can delay the build-up of the vector and so abort an epidemic (Hawkes *et al.*, 1985). The virus was first isolated from *Aedes vigilax*, which is accepted as being the major vector in the coastal regions of Australia. Other mosquito species, including the salt marsh arthropod *Aedes comptorhynchus* found in coastal regions of northern and southern coastal regions and *Culex annulirostris*, which breeds in freshwater habitats, are also considered important vectors (Peters and Dalrymple, 1990). Besides humans, other possible vertebrate hosts include marsupials, domestic animals and rodents (Doherty, 1977).

In 1979 an explosive epidemic of RRV infection occurred in Fiji (Aaskov *et al.*, 1981). The virus spread to American Samoa and then to the Wallis and Futuna Islands and the Cook Islands. The mosquito vector in this region is unknown, although the virus has been isolated from *Aedes polynesiensis*, a mosquito that is found in many parts of the eastern Pacific (Rosen *et al.*, 1981). Evidence suggests that humans are the most important vertebrate host in this region. A study from the Cook Islands showed that the incubation period could be as short as three days and the explosive nature of this epidemic led to speculation that mechanical transmission of RRV may occur. This theory has been supported by laboratory evidence of mechanical transmission of RRV from viraemic donors to uninfected recipient suckling mice. In addition, it has also been suggested that transovarial transmission in mosquitoes is a potential survival mechanism for this virus (Kay, 1982).

The number of annual reported cases of RRV disease has increased during the past decade to between 4 and 6000. However, these figures represent a combination of improved laboratory diagnostic reagents, greater awareness by clinicians, housing developments on salt marshes and migration northwards to warmer climates in retirement (Mackenzie *et al.*, 2001).

Clinical Disease

Infection with RRV does not necessarily result in disease in humans and it has been estimated that 50 subclinical infections occur for each clinically recognized case (Table 27.3). The disease is not fatal. Adults are more likely to be symptomatic than children. The onset of clinical symptoms is characterized by joint pains (epidemic polyarthritis) accompanied by a rash and fever. In a recent postal survey of general practitioners in South Australia the complaint of 'pain in the joints' was the most important symptom for suspecting an infection with RRV, with joint effusion, rash and pyrexia being important signs (Flexman *et al.*, 1998; Stocks *et al.*, 1997). The rash may occur simultaneously with the joint pains or may follow one to two days later. Although the rash is usually macular, maculopapular or papular, vesiculation and petechiae have been described. The rash and joint pains are commonly accompanied by some degree of constitutional upset, including myalgia, headache, anorexia and nausea. The joint involvement is usually asymmetrical and migratory and most often affects the small joints of the hands and feet together with the knees. In addition, there may also be periarticular swelling and a tenosynovitis (Clarke *et al.*, 1973; Hawkes *et al.*, 1985). The arthralgia and arthritis tend to run a relapsing course but with an overall gradual improvement. The symptoms of epidemic polyarthritis may last for 30–40 weeks, with some

patients having symptoms for more than a year. While joint pain, rash and fever are the most common clinical features, glomerulonephritis has also been reported in the acute phase of RRV disease (Fraser *et al.*, 1988). This case report describes a patient presenting with haematuria and proteinuria coincident with an acute RRV infection; the frequency of this complication has yet to be defined.

Pathogenesis

The pathogenesis of disease is not completely understood. While virus has been isolated from the blood, it has not been isolated from either the skin or joints. However, RRV antigen has been detected by immunofluorescence at both of these sites. Histological examination of the skin lesions shows a mononuclear cell infiltration (Fraser *et al.*, 1983). It has also been shown that RRV is capable of infecting human synovial cells (Cunningham and Fraser, 1985). Serum complement is normal and circulating immune complexes do not usually exceed normal levels. It has therefore been suggested that RRV plays a direct role at these sites of inflammation.

Diagnosis

Diagnosis is greatly assisted with knowledge of travel history. A differential diagnosis would also include rubella, other alphavirus-induced arthritis, dengue, rheumatoid arthritis, Lyme disease, parvovirus B19 and other chronic rheumatic diseases (Fraser, 1986).

Isolation of RRV is only successful using acute-phase antibody-negative serum samples. Both mosquitoes and mosquito cell lines have been used. The current method of choice for RRV isolation is the inoculation of the mosquito cell line C6/36. As this virus does not display a cytopathic effect in C6/36 cells, viral antigen is detected using immunofluorescence (Rosen *et al.*, 1981). RRV may also be isolated in Vero (E6) cells. More recently methods have been developed to detect RRV RNA using RT-PCR. This methodology has potential application to virus surveillance programmes in mosquito populations (Sellner *et al.*, 1994).

The most sensitive and established serological assay involves the use of an IgM capture and epitopic blocking enzyme-linked immunosorbent assay (Oliveira *et al.*, 2006). However, there is a complication in that the assay can remain positive for up to two years after the acute infection (Carter *et al.*, 1985). It should be noted that IgM antibody cross-reacts with Mayaro virus (MAYV), CHIKV and SFV occurs with sera from patients with RRV infections (Table 27.4). The presence of RRV-specific IgA or low-avidity IgG can assist the diagnosis of a recent infection (Carter *et al.*, 1987). A more precise diagnosis

can be made using neutralization tests (Kanamitsu *et al.*, 1979).

Vaccine

Preliminary studies into the efficacy of a formaldehyde-inactivated RRV vaccine demonstrated that this candidate vaccine neutralized all strains of RRV tested, but to varying degrees (Aaskov *et al.*, 1997; Kistner *et al.*, 2007). Further studies are awaited with interest as, while RRV does not usually cause a severe disease, it may result in considerable morbidity with an associated loss of productivity.

Barmah Forest Virus

This alphavirus has been recently reported to cause both clinical and subclinical infections in Australia. Clinical disease resulting from BFV infection was first reported in 1986. The first epidemic of human disease occurred in 1992 in the Northern Territory (Mackenzie *et al.*, 1994). To date, Australia is the only country in which this virus has been detected (Hills, 1996).

BFV is the sole member of the seventh alphavirus serocomplex (Table 27.4). The nucleotide sequence of the BFV genome has recently been described and, from amino acid sequence comparisons with sequenced alphaviruses, BFV has been shown to be most closely related to RRV and SFV (Lee *et al.*, 1997). In recent years there has been an apparent increase in incidence of polyarthritis caused by BFV. This prompted a study on the molecular epidemiology of this alphavirus which showed a high degree of sequence homology between BFV isolates with no evidence of geographical or temporal divergence (Poidinger *et al.*, 1997).

Epidemiology and Host Range

BFV is an alphavirus that is enzootic in Australia and has been isolated from the two most common vectors of RRV—*Cx. annulirostris* and *Ae. vigilax*. It has been shown to circulate amongst mosquitoes and terrestrial animals, most noticeably marsupial species. Occupational and recreational exposure to these vectors is therefore an important risk factor for infection with this virus. A higher incidence of antibodies to BFV in RRV antibody-positive blood donors compared with RRV antibody-negative blood donors suggests a common ecology. Further information is required on the duration of viraemia in humans to determine whether other vertebrate hosts are of importance in viral maintenance. Currently, human disease caused by BFV has not been recognized in southern Australia or Tasmania.

Clinical Disease

Human infections have been recognized since 1986 and its incidence has increased through greater clinical awareness and improved laboratory diagnostic methods. Currently, approximately 500 cases are recorded each year (Lindsey *et al.*, 1995). As mentioned above, both clinical and subclinical infections occur. The most common symptoms noted in a study from Queensland were arthritis; arthralgia, myalgia and fever, which were present in approximately 75% of patients (Table 27.3). In addition, half the patients in this study had a rash (Phillips *et al.*, 1990). A more recent study from New South Wales reported lethargy (89%), joint pain (82%) and rash (68%) as the most common symptoms. In the latter study just over half of the patients reported an illness lasting for more than six months. These authors also reported a possible association between the presence of a rash and an improved prognosis (Beard *et al.*, 1997). In general, the symptoms are similar to those associated with RRV infection; laboratory confirmation is therefore necessary to achieve a precise diagnosis. The wider availability of serological testing for BFV infections has also enabled their more unusual features to be described. Recently the first case of glomerulonephritis after BFV infection was diagnosed. The authors suggest that BFV infection should be considered as a possible aetiological agent for glomerulonephritis (Katz *et al.*, 1997).

Diagnosis

Clinical differentiation from RRV infection in patients living in endemic areas is difficult. Laboratory confirmation is therefore necessary for a precise diagnosis to be made. BFV has been isolated from a patient in the mosquito cell line (C6/36). The serological response to infection with this virus in humans remains to be defined precisely. However, in contrast to RRV infections, where the antibody response may be delayed for seven days, past studies demonstrated the presence of both HAI and neutralizing antibody titres in two patients with BFV infection at the onset of symptoms (Phillips *et al.*, 1990). This could either be due to a different serological response to these two viruses or, alternatively, BFV-associated disease may have a less clearly defined onset than that caused by RRV infections.

Igbo Ora Virus

Igbo Ora virus is closely related to both chikungunya and o'nyong-nyong viruses. Human disease associated with infection with this virus is characterized by fever, arthritis and the development of a rash ('the disease that breaks your wings'). The virus was isolated from human

sera from patients in Africa (Nigeria, Central African Republic) in the latter part of the 1960s (Moore *et al.*, 1975) and was responsible for an epidemic that involved four villages in the Ivory Coast in 1984 (Peters and Dalrymple, 1990).

Mayaro Virus

Although infection with MAYV was first recognized in Trinidad in 1954, it was an epidemic in Brazil in 1978 that permitted a detailed evaluation of human infections (LeDuc *et al.*, 1981; Pinheiro *et al.*, 1981; Torres *et al.*, 2004).

Epidemiology and Host Range

MAYV is enzootic in South America, where the suspected vectors are forest-dwelling *Haemagogus* mosquitoes and the vertebrate hosts are marmosets and other non-human primates (Pinheiro and LeDuc, 1998). During the extensive epidemic described by LeDuc *et al.* (1981), 20% of the entire population of approximately 4000 people in the rural village of Belterra in Brazil were infected. The numbers infected were higher among those who lived near a plantation forest. The epidemic began with the onset of the wet season and ended with the onset of the dry season. This correlated with the abundance of the mosquito vector, *Haemagogus janthinomys*. In addition to humans, marmosets and other primates are susceptible to infection (Hoch *et al.*, 1981). It has therefore been suggested that non-human primates play an important role in the maintenance of this virus, as experimental infection of marmosets with MAYV showed that a significant viraemia develops. The role of other vertebrates, for example birds, remains to be defined. Although MAYV is enzootic in several South American countries, the first human cases of Mayaro fever were described in Venezuela by Torres *et al.* (2004). In this recent study the red howler monkey (*Alouatta seniculus*) is the suspected host of MAYV in nature. The associated vectors in this region suggest the involvement of other *Haemagogus* species of that genus, such as *Haemagogus celestae*, *Haemagogus equinus* and *Haemagogus lucifer*.

Clinical Disease

A detailed evaluation of the clinical features of infection with this virus in humans is available from studies done during the 1978 epidemic in Brazil. Mayaro fever is described as a dengue-like, three to five day acute febrile illness accompanied by headache, retro-orbital pain, arthralgia, arthritis, vomiting and maculopapular rash (Pinheiro *et al.*, 1981; Torres *et al.*, 2004). Joint involvement in Mayaro fever may persist for several months

and has been described in some cases as preceding the fever.

Diagnosis

Leukopenia, sometimes accompanied by a modest lymphocytosis, is a frequent finding. A mild thrombocytopenia may also be present. MAYV may be isolated from acute-phase serum samples in an *in vitro* cell culture system using Vero cells. The virus may then be identified using HAI, ELISA or plaque reduction neutralization tests. In addition, MAYV is also pathogenic for infant mice on intracerebral inoculation. In the Belterra epidemic, virus was isolated from the serum in 97% of the patients bled in the first 24 hours after the onset of symptoms. Thereafter viral recovery rates decreased to only 7% on day 4. Serological evidence of a MAYV infection can be achieved by demonstrating a seroconversion using HAI or ELISA in paired serum samples taken from a patient during the acute and convalescent phase of the illness (Pinheiro *et al.*, 1981; Torres *et al.*, 2004). In addition, the use of a MAYV-specific IgM assay has been described as viraemia subsides, which is usually four to five days after the onset of symptoms. Among the case studies of patients identified in Venezuela, IgM antibody was reported to persist for three to six months (Torres *et al.*, 2004). In addition, convalescent sera collected from self-limited febrile disease with polyarthritis similar to that described in patients having MAYV infection showed extremely high IgG antibody levels. This provided further evidence that MAYV was enzootic in the area (Torres *et al.*, 2004). Cross-reactivity of IgM antibody occurs with alphavirus infections by viruses belonging to the same antigenic complex (Table 27.1). However, the ratios of the homologous to heterologous IgM titres are high, allowing a reasonably specific and rapid diagnosis to be made. The IgM assay is therefore a useful diagnostic tool in an epidemic situation (Calisher *et al.*, 1986; Torres *et al.*, 2004).

ALPHAVIRUSES ASSOCIATED WITH ENCEPHALITIS

The alphavirus genus contains four viruses that produce encephalitis in humans: EEEV, WEEV, VEEV and Ev-erglades virus (EVEV). EEEV, WEEV and VEEV were first isolated from the brains of dead horses in the 1930s. The severity of disease associated with infection with this group of viruses differs: EEEV is the most neurovirulent, while infection with VEEV is associated with a febrile illness, with encephalitis occurring infrequently. Focal epidemics of EEEV have periodically occurred in

eastern United States, WEEV is endemic in western United States and Canada and VEEV in Central and South America and occasionally in North America. EVEV is related to EEEV but is restricted to the state of Florida in the United States and only five cases of encephalitis associated with it have been reported, despite a high seroprevalence (27%) in south Florida.

Eastern Equine Encephalomyelitis Virus

Eastern equine encephalomyelitis virus is the most severe of the arboviral encephalitides and an important cause of human disease in the eastern and north central states of the United States and Canada. Its distribution extends through Central America to Trinidad, Brazil, Guyana and as far south as Argentina (Gibbs and Tsai, 1994). This virus is among the most virulent of the alphaviruses. It has been reported that there are two distinct antigenic variants (North American and South American), the former being genetically quite stable (Roehrig *et al.*, 1990). It causes severe disease in humans, certain species of birds such as the pheasant, as well as horses, all of whom have high fatality rates after infection.

Epidemiology and Host Range

The physical, biological and ecological factors associated with epizootic transmission are complex, but the abundance of EEEV circulating in the enzootic cycle and the various characteristics of the epizootic vectors are important determinants of risk. In endemic areas birds are the most important vertebrate host and the natural cycle is between birds and the ornithophilic mosquito, *Culiseta melanura*. Birds vary in their susceptibility, with some, for example the pheasant, developing severe disease, while other avian species suffer no appreciable morbidity or mortality (Peters and Dalrymple, 1990). *Cs. melanura* is thought to be the main endemic vector (Howard and Wallis, 1974). However, because of its ornithophilic nature this mosquito is unlikely to play a major role in the transmission of EEEV to horses or humans. However, the virus escapes from enzootic foci located in swamp areas through bridge vectors such as *Aedes sollicitans* and *Cophilatidia perturbans*, which are thought to be important in the transmission to vertebrates. These species also feed on both mammals and birds and can transmit the virus to humans, horses and other hosts. Both humans and horses are 'dead-end' hosts for EEEV infections; infected birds are therefore necessary for the epidemic spread to these species. In South and Central America the enzootic cycle is maintained in most forests where *Culex (Melanocoon)* spp. are considered the primary vectors (Scott and

Weaver, 1989) Disease in humans often follows an epizootic course in horses. Fewer than five cases of EEEV are reported annually in the United States. Case fatality rates as high as 30% in past epidemics are indicative of the severity of EEEV infection in humans. Even during a major equine epizootic, EEEV-associated disease in humans is rare. In addition to being limited to certain geographical regions, the prevailing climatic conditions, in the form of an unusually hot, wet summer, also play an important role, for this allows for an abundance of the vector *Cs. melanura*. This, together with the presence of a susceptible bird population and an additional vector that can transmit virus from viraemic birds to susceptible horses and humans, are important predisposing factors for the occurrence of human and equine cases. Although the transmission cycles have not been well established, additional reservoirs of infection have been reported in forest-dwelling rodents, bats and marsupials (Ubico and McLean, 1995), reptiles, amphibians (Morris, 1988), white-tailed deer (Schmitt *et al.*, 2007) and African penguins maintained in an aquarium (Tuttle *et al.*, 2005).

Clinical Disease

EEEV infections may produce severe, often fatal encephalitis in humans (Clarke, 1961; Deresiewicz *et al.*, 1997; Farber *et al.*, 1940). The ratio of inapparent to apparent infections is approximately 23 : 1 in adults and 8 : 1 in children under the age of four (Goldfield *et al.*, 1968). The encephalitis associated with EEEV infection tends to be fulminant; a recent study, which reviewed all cases of EEEV infection in the United States between 1988 and 1994, showed a mortality of 36%, with 35% of patients being left moderately or severely disabled. The remaining patients were left mildly disabled, with only one patient recovering fully. The most common clinical features were fever (83%), headache (75%), nausea and vomiting (61%) and malaise and weakness (58%). The incubation period for EEEV is 4–10 days. However, the onset of neurological symptoms was associated with a rapid deterioration of the patient. Eighty-nine per cent (32 of 36 patients) were or became stuporous or comatose, with about one-quarter having seizures. Interestingly, abdominal pain was present in 22% of cases, with two patients presenting with acute abdominal pain in the prodromal period (Deresiewicz *et al.*, 1997). Although it has been suggested that an age of over 40 and a long prodromal course correlates with a good functional recovery (Przelomski *et al.*, 1988), others have found that these parameters do not significantly predict outcome (Deresiewicz *et al.*, 1997). A biphasic course in children is common, beginning with fever, vomiting and headache for one to two days, followed by an apparent recovery,

finally taking the form of a fulminant encephalitis. In children under five years of age who survive the disease, neurological sequelae such as mental retardation, convulsions and paralysis are frequent observations. Deresiewicz and colleagues did, however, demonstrate that high initial cerebrospinal fluid (CSF) white cell counts and the development of severe hyponatraemia were poor prognostic signs, possibly because both could be markers of intense cerebral inflammation (Deresiewicz *et al.*, 1997).

Pathogenesis and Pathology

Post-mortem histopathological studies have demonstrated necrotic foci together with arteriolar and venular inflammation and perivascular cuffing. An inflammatory meningeal infiltrate may be present. Although the distribution of the focal lesions may vary, involvement of the basal ganglia and thalami appears to be prominent (Deresiewicz *et al.*, 1997). Viral particles have been visualized in the oligodendroglial cells by electron microscopy (Bastian *et al.*, 1975). The neurological damage is probably due to a combination of a direct viral cytopathic effect, inflammatory damage and a vasculitis (Peters and Dalrymple, 1990).

Diagnosis

A diagnostic clue may be obtained from the prevailing climatic conditions (a hot wet summer), together with associated illness in the horse and pheasant populations. However, the symptoms are nonspecific and confirmation needs to be obtained serologically or by demonstration of virus in CSF or both. Neuroradiological imaging may be helpful, with focal lesions visible in the basal ganglia, thalami and brainstem (Deresiewicz *et al.*, 1997).

Laboratory diagnosis is based on molecular detection of viral antigen, virus isolation or antibody detection. Samples for isolation can be CSF, blood or central nervous system (CNS) tissue by inoculation into newborn mice or tissue culture using Vero cells or MRC-5 (Sotomayor and Josephson, 1999). As with all alphavirus infections, an acute serum sample should be taken as soon as possible after the onset of illness. EEEV has been isolated from a laboratory worker on the second day of illness (Clarke, 1961). In this case 4 of 25 one-day-old mice died after intracerebral inoculation with a serum sample taken from this patient. Further identification was done serologically. In addition, virus has also been isolated from post-mortem brain tissue taken from a fatal case of EEE. More recently an RT-PCR based assay has been developed to detect EEEV RNA (Voskin *et al.*, 1993).

Serology is an important diagnostic tool. Paired serum samples may be tested in parallel using ELISA (Scott and Weaver, 1989) or plague-reduction neutralization test

(PRNT). A class-specific anti-EEEV IgM antibody in CSF or elevated anti-EEEV IgM antibody detected by IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA) has been described as a rapid and specific diagnostic tool (Centers for Disease Control and Prevention, 2006; Sudhirs *et al.*, 1994). As EEEV is the only species of virus belonging to the eastern equine encephalitis complex (Table 27.1), cross-reaction with heterologous viruses belonging to the same antigenic complex does not pose a diagnostic problem (Calisher *et al.*, 1986).

Prevention and Control

Protection against mosquito bites and control of the vector is important. An effective equine vaccine is licensed in the United States and is recommended for livestock in areas where EEEV transmission is known to occur. Specific control measures to prevent human disease include a formalin-inactivated vaccine derived from a North American strain of EEEV (PE-6) available for horses. No specific antiviral treatment is available and no human EEEV vaccine is currently licensed for human use. The vaccine has been shown not to induce significant levels of neutralization or anti-E2 antibody responses to South American strains of EEEV (Strizki and Repik, 1995). However, as this human disease is rare, even during an equine epizootic, this vaccine is only issued to those individuals engage in an occupation that places them at risk of exposure. Prompt notification of suspected cases of arboviral encephalitis to the local public health authority is also essential. Although vaccination protects equines against disease, it does not reduce the risk of exposure to humans.

Western Equine Encephalitis Virus

The WEEV was first isolated in California in 1930 from the brain of a horse and remains an important cause of encephalomyelitis in horses and humans. The western equine encephalitis complex in the New World contains three additional viruses in addition to WEEV named: Highlands J (HJ), Fort Morgan (FM) and Aura. Only WEEV is recognized as causing human disease (Calisher, 1994). Viruses in the western equine encephalitis complex found in the Old World include Sindbis, Whataroa and Kyzlagach. WEEV causes more human infections than EEEV, but the illness is less severe and mortality seldom exceeds 10%. Its distribution covers the Pacific coast of the United States, but also includes the Great Plains of the United States and Canada and extends into Central America and the northern parts of South America (Chamberlain, 1987; Hardy, 1987; Iverson, 1994; Reeves, 1987). The western equine encephalitis antigenic complex consists of six species (Table 27.5). It has been

suggested that WEEV arose through recombination between a EEEV-like virus and a Sindbis-like virus (Hahn *et al.*, 1988).

Epidemiology and Host Range

The enzootic cycle of WEEV involves passerine birds and culicine mosquitoes. WEEV is transmitted in the western United States by the mosquito *Culex tarsalis*. Birds are the most important vertebrate host. Once infected, the birds develop viraemia with sufficiently high titre to infect the mosquito vectors. Endemic transmission results in a few human cases. In addition, major equine epidemics may result in a significant number of human cases. As with other arboviruses, climatic factors exert a major influence on the epidemiology and distribution of WEEV.

In the eastern United States, WEEV is replaced by Highlands J virus (HJV), whose primary vector is *Cs. melanura*, which is also the primary vector of EEEV. The strictly ornithophilic nature of this vector explains the absence of significant disease outbreaks in the eastern United States. WEEV and HJV are closely related both serologically and at a molecular level.

Clinical Disease

Most WEEV infections of adults are asymptomatic, patients presenting with an incubation period of 5–10 days. In adults there is a sudden onset of fever, headache, nausea, vomiting, anorexia and malaise. In children, fever, headache and malaise occur a few days before the neurological symptoms. Flaccid and spastic paralysis and abnormal reflexes are seen more frequently in children than adults. The estimated case : infection ratio in adults is approximately 1 : 1000. This decreases to approximately 1 : 60 in children and 1 : 1 in babies (Peters and Dalrymple, 1990). Permanent neurological damage is rare in adults but frequent in children who may suffer from mental retardation, spastic paralysis and recurrent convulsions. Drowsiness, headache and mental confusion, sometimes leading to coma, may be seen in adults. *In utero* infection followed by an acute encephalitis has been documented (Shinefield and Townsend, 1953). Recovery from the acute illness may be slow and symptoms such as fatigability, irritability and headache may persist for up to two years (Earnest *et al.*, 1971).

Pathogenesis and Pathology

WEEV is less neurovirulent than EEEV both in humans and horses. Post-mortem examination of the brain of fatal cases shows a perivascular mononuclear and polymorphonuclear infiltrate together with parenchymal necrosis.

Table 27.5 Origins and geographical distribution of the western equine encephalitis virus complex.

Antigenic complex	Species	Origins	Main geographic distribution	Other features
Western equine encephalitis	Aura	Brazil, 1959	North America, Mexico, Guyana, Brazil and Argentina Brazil and Argentina Western United States	Epizootics: North America only
	Fort Morgan	Colorado, 1973		
	Highlands J	Florida, 1964		
Sindbis-like virus	Sindbis	Egypt, 1953	Florida, eastern United States	
	Ockelbo	Sweden, 1982	Africa and Australia	
	Babinki	Cameroon, 1969	Mediterranean and Europe	
	Kyzylagach	Azerbaijan, 1969	Africa	
	Whataroa	New Zealand, 1962	Azerbaijan and China	
			New Zealand	

Diagnosis

During the acute phase of the illness viral isolation may be attempted from blood, throat swabs or a CSF samples using suckling mice, but this is frequently not successful, since by the time it is recognized clinically the viraemic period is over. Virus may usually be isolated from brain biopsy material or post-mortem brain tissue. However, serology, together with the appropriate clinical manifestations in a patient living in or who has recently travelled to an endemic area, forms the most important method of diagnosing of disease associated with infection with WEEV. Classical serological techniques, for example HAI, ELISA, immunofluorescence test and serum neutralization can be used to demonstrate a rise in antibody titre between acute and convalescent serum samples. In addition, the detection of WEEV-specific antigen capture or IgM-capture ELISA can provide a rapid acute-phase diagnosis. However, cross-reaction may occur with other viruses within the complex (Table 27.1). Knowledge of the geographical distribution of the viruses within the complex allows interpretation of a positive IgM result together with the appropriate patient details (Calisher *et al.*, 1986). Antigen detection using nucleic acid sequence-based amplification (NASBA), standard RT-PCR and TaqMan nucleic acid amplification assays with patient serum or CSF is well established (Lambert *et al.*, 2003; Pfeffer *et al.*, 1997).

Prevention and Control

Vector control is an important aspect of the control of all mosquito-borne encephalitides. Outbreaks in humans and horses are associated with unusually high densities of mosquitoes. There is therefore a correlation between *Cx. tarsalis* density and human cases of WEEV infection. Besides vector control, changing behaviour patterns, for example, air-conditioning houses and promoting indoor activities may also protect from vector-borne diseases

and are complementary to mosquito control programmes (Gahlinger *et al.*, 1986). An inactivated vaccine is available to those at risk. An inactivated vaccine is available for horses.

Venezuelan Equine Encephalitis Virus

As the name suggests, VEEV was first isolated in Venezuela in 1938, where it causes important epizootics in horses, but also infects humans. The geographical distribution includes Central and South America. VEEV caused epidemics; epizootics among people and horses in Latin America from the 1920s to the 1970s. It reached the United States in 1971, but no further activity was reported until 1992–1993, when a small outbreak in Venezuela confirmed the re-emergence of VEEV from its enzootic habitat to humans. This was followed by a major outbreak occurring in 1995, involving an estimated 75 000–100 000 people (Rico-Hesse *et al.*, 1995; Weaver *et al.*, 1996). A variant of the virus, known as Everglades virus, is endemic in South-Central Florida and another variant, Mucambo virus, is found in Brazil, Trinidad and Surinam (Table 27.6).

Epidemiology and Host Range

Both epizootic and enzootic strains of VEEV occur. Serotypes IAB and IC are equine virulent, while ID, IE and II, III and IV are equine avirulent (Table 16.6) (Powers *et al.*, 1997; Weaver *et al.*, 1996). The principal vertebrate host for enzootic transmission is the rodent, although birds and other species may play a less important role. Horses may be infected by several subtypes or variants of VEEV (Table 16.1) but they do not play an important role in enzootic transmission which occurs primarily between small mammals and the *Culex* mosquitoes of the subgenus *Melanoconion* (Cupp *et al.*, 1986). In contrast, during equine epizootics horses do play an important role in viral spread. It has been suggested that

Table 27.6 Origins and geographical distribution of the Venezuelan equine encephalitis virus complex.

Antigenic complex	Species	Subtype	Origin	Main geographic distribution
Venezuelan equine encephalitis	I	1 A-B	Trinidad, 1948	
		1C	Venezuela, 1963	Venezuela, Colombia, South and Central America
		1D	Panama, 1961	
		1E	Guatemala, 1968	
		1F	Brazil, 1978	
		II	Everglades	Florida, 1963
	IIIA	Mucambo	Brazil, 1954; French Guinea, 1968	South America and Trinidad
			Colorado, 1974	French Guinea
	IIIB	Tonte		Western North America
		Bijou Bridge		
	IV	Pixuna	Brazil, 1961	South America
V	Cabassou	French Guiana, 1968	French Guiana	
VI	AG80-663	Argentina, 1980	Argentina	

epizootic strains of VEEV are maintained in other mammalian hosts and birds until the conditions are favourable for the development of an equine epizootic. A number of mosquito species have been implicated as likely vectors during epizootics. Human disease usually follows equine disease, but humans are not thought to be important in the maintenance of the epidemic due to low-titre viraemia.

The major outbreaks of Venezuelan equine encephalitis that occurred in Venezuela and Colombia in 1995, involving an estimated 100 000 human cases, were remarkably similar to an outbreak occurring in 1962–1964 (Rico-Hesse *et al.*, 1995; Rivas *et al.*, 1997). Further outbreaks recorded in 1999/2000 and 2003 in Venezuela suggested the persistence of VEEV subtype IC (Navarro *et al.*, 2005). Both outbreaks followed unusually heavy rains which led to an increase in the mosquito vector, and both occurred in the same geographic region. Phylogenetic analysis showed that isolates from the 1995 epidemic of Venezuelan equine encephalitis were closely related to the serotype IC viruses isolated during the 1962–1964 epidemic. As a similar virus was identified in mosquitoes in Venezuela in 1983, the authors raise the possibility of a serotype IC enzootic transmission cycle in northern Venezuela (Weaver *et al.*, 1996).

Epizootic transmission involves horses, mules and donkeys as amplification hosts and the mosquito vectors in the genera *Ochlerotatus*, *Psorophora* and others. Most human cases of Venezuelan equine encephalitis occur during equine epizootics but endemic transmission has been recorded in communities in close proximity to sylvatic enzootic cycles in the absence of equine disease.

Clinical Disease

In horses, enzootic strains of VEEV usually produce a fever and mild leukopenia. In contrast to this, horses infected with epizootic strains exhibit high fevers, severe leukopenia and signs of encephalitis. Only VEEV and EVEV (genetic variant of VEEV in subtype ID) are associated with encephalitis in humans, while the others such as Mucambo cause febrile illness. Natural human epidemics in 1952 and 1995 in Colombia and Venezuela and Panama during 1962–1964, resulted in over 100 000 cases with 500 deaths, demonstrating the highly infectious nature and severity of the disease.

Infection may be subclinical (usually caused by enzootic strains) or result in significant disease caused by epizootic strains of VEEV (Table 27.3). The incubation period lasts for two to five days. Symptoms and signs in patients seeking medical care include fever, chills, severe headache, myalgia, vomiting and diarrhoea. Most patients will have an acute and self-limiting febrile illness; however, convulsions, disorientation and drowsiness may also be present (Weaver *et al.*, 1996). The proportion of cases that develop neurological sequelae appears to vary from outbreak to outbreak. A review of the medical records of patients with convulsions in the 1995 epidemic showed that, although the age varied greatly (from 2 months to 48 years), most were children; however, only approximately 20% of these were under three years of age. Of interest is that about half of these patients had their first seizure between the 5th and 10th day after the onset of their illness and when their temperature had returned to normal (Weaver *et al.*, 1996). A further prospective study which included a total of 13 patients showed that six patients had a severe incapacitating febrile illness lasting three to five

days, two others had a 'flu-like' illness, and the remaining five (38%) were asymptomatic (Martin *et al.*, 1972). The overall mortality is thought to be less than 1%. Fetal loss may occur in pregnant women infected with VEEV.

Transmission can occur by the respiratory route as well as by mosquitoes. Accidental laboratory aerosol infections with epizootic strains of VEEV has been reported to cause a febrile illness with abrupt onset of chills, headache, myalgia, vomiting and pharyngitis two to five days after exposure without evidence of encephalitis (Erenkranz and Ventura, 1974).

Pathogenesis and Pathology

The disease caused by VEEV in humans is relatively mild compared to that caused by either WEEV or EEEV. In horses, as well as other species, there is a clear difference in the pathogenicity of the epizootic and the enzootic strains of VEEV. Epizootic strains are generally more virulent, with infection in horses resulting in viral replication in the lymphoid tissue and bone marrow. This is associated with lymphoid necrosis and a lymphopenia and is accompanied by a high-titre viraemia. Spread to the CNS probably occurs in the bloodstream, resulting in fatal encephalitis in horses, as well as rodents and some primates (Peters and Dalrymple, 1990).

Diagnosis

The diagnosis of VEEV-associated disease should be suspected in patients presenting with a 'flu-like' illness in an appropriate geographical region when there is a concurrent equine epizootic. Material obtained from sick horses confirming an epizootic of VEEV may therefore be an important indicator of human disease. Isolation of virus may be attempted from acute-phase serum and throat swabs as well as from brain tissue obtained from aborted and stillborn fetuses (Weaver *et al.*, 1996). Culture of VEEV has been achieved by inoculation into Vero or mosquito cells or suckling mice (Dietz *et al.*, 1979). Intracerebral inoculation of suckling mice may result in death within 72 hours. Isolates identified in cell culture may be characterized further using VEEV serotype-specific polyclonal sera. Alternatively, detection and genetic characterization may be done using the more recently developed standard RT-PCR, and TaqMan nucleic acid amplification assays with sequencing of the products generated from the E3 and E4 genes (Brightwell *et al.*, 1998; Weaver *et al.*, 1996).

A number of serological assays (IFA, ELISA, HAI) have been described. Acute and convalescent serum samples may be tested in parallel by HAI. This may provide diagnostically useful information. More recently attention has been focused on the use of an IgG ELISA based on

an antigen prepared from the attenuated VEEV vaccine strain of virus. In experimentally infected guinea pigs, VEEV-specific IgG could be detected at 6 days post inoculation, compared with 10 days for HAI antibodies. However RRV-, EEEV- and WEEV-specific IgG exhibit a weak cross-reaction on the IgG ELISA, so results must be interpreted with caution. The appearance of IgG antibodies detectable by ELISA coincides with the development of antibodies detectable by plaque reduction neutralization (PRN) assay. While less sensitive than the IgG ELISA, PRN is more specific and therefore eliminates some of the problems of cross-reaction discussed above. It may therefore be used as a confirmatory test. VEE-specific IgM antibody has been detected as early as four days post inoculation in experimentally infected guinea pigs (at a time at which infectious virus was present in the serum). In summary, suspected cases of VEEV infection may be investigated serologically using a VEEV-specific IgM and IgG ELISA, together with the more specific PRN as a confirmatory test (Coates *et al.*, 1992)

Prevention and Control

Personal protection against mosquito bites together with vector control, as for other alphavirus infections, is important. Control of an equine epizootic by immunizing horses is also important in the prevention of subsequent human disease. Two types of vaccine are currently available for the prevention of Venezuelan equine encephalitis in humans and horses. The first is a live-attenuated vaccine, TC-83, produced by serial passage of wild virus in guinea-pig fetal heart cell culture. While this vaccine has been proven to be efficacious and relatively safe, 25% of individuals immunized develop a clinical illness with a low-grade viraemia. A formalin-inactivated vaccine, C-84, which is derived from the TC-83 strain of virus, has been shown to be safe and provides effective protection in experimental animals injected with virulent VEEV but only limited protection from aerosol challenge.

OTHER ALPHAVIRUSES

Semliki Forest virus

Semliki Forest virus is found in sub-Saharan Africa and has been used as a model virus for research. Although the disease potential for this virus remains to be elucidated, asymptomatic seroconversions have been described. However, the clinical features of infection with SFV have not been well defined. One scientist working with SFV developed an encephalitis and SFV was isolated from both CSF and post-mortem brain tissue (Peters and Dalrymple, 1990). This highlights the necessity for caution

when working with any infectious agents of unknown pathogenic potential. No overt disease was recognized until a large outbreak of a mild febrile illness was reported in Bangui, Central African Republic in 1987. SFV is considered to be maintained in a non-human primate; an *Aedes* mosquito cycle and ticks are also thought to be involved (Pfeffer, 2001).

Getah virus

Getah virus (GETV) was originally isolated from *Culex gelidus* and *Culex tritaeniorhynchus* in Malaysia in 1955. The viruses Sagiyama, Bebaru and RRV are considered to be subtypes of Getah (Kumanomido, 2001; Powers *et al.*, 2001). The virus has been isolated from a wide variety of mosquito species, *Culex* spp. in South East Asia, Japan, the Philippines, China and Australia, and from *Aedes* spp. in Serbia and has the potential to be amplified in domestic pigs (Wen *et al.*, 2007). GETV has been linked to severe encephalitis in horses, producing fever, rash and limb oedema (Fukunaga *et al.*, 2000) Although GETV has not been implicated in human disease, serological studies have demonstrated antibodies to GETV in sera taken from individuals from the Pacific Basin, Japan and China (Johnson and Peters, 1996). Serological cross-reactivity with RRV makes interpretation of serosurvey data difficult.

Una virus

Una virus (UNAV) was first isolated from *Psorophora ferox* mosquitoes originating from the Amazonian region of Brazil in 1959. The virus has also been isolated in Trinidad. Considered to part of the SFV complex of viruses, as yet this virus has not been recognized as causing human disease.

Flaviviruses

Barry D. Schoub¹ and Marietjie Venter²

¹National Institute for Communicable Diseases, Sandringham, Johannesburg, South Africa

²Department Medical Virology, University of Pretoria/Tswane Academic Division, National Health Laboratory Services, Pretoria, South Africa

INTRODUCTION

The *Flaviviridae* are a family of viruses comprising some 94 members and are responsible for a major portion of disease and death in humans and animals. The family is subdivided into three genera: *Flavivirus*, *Pestivirus* and *Hepacivirus*.

Flavivirus

The genus *Flavivirus* consists of 82 confirmed or provisional members. It was formerly termed 'group B arboviruses' and prior to 1984 was placed together with the 'group A arboviruses' within the family *Togaviridae*. However, as knowledge of the flaviviruses increased, it became apparent that their features and properties, for example, their replication strategies, structure and biochemistry, were sufficiently distinctive that they would need to be placed in a separate family, the *Flaviviridae*, with the two additional genera, *Pestivirus* and *Hepacivirus*, being added subsequently. More recently, GB virus C (GBV-C), GB virus B (GBV-B) and GB virus A (GBV-A), which are closely related to hepacivirus, have been tentatively added to the family *Flaviviridae*, although their taxonomic designation remain to be defined.

Most members of the genus *Flavivirus* are arboviruses, which are transmitted between a vertebrate host and an invertebrate (mosquito or tick) host. Replication and amplification of virus occurs in both the vertebrate and invertebrate hosts. With some of the flaviviruses humans may be the major vertebrate host, for example, in the viruses causing dengue and urban yellow fever, and the

virus is maintained by being alternately transmitted from humans to mosquito to humans. In most of the flavivirus infections, the virus is maintained in nature by alternate infection of a variety of mammals or birds, or occasionally other vertebrate hosts, and their respective mosquito or tick vectors. Humans are infected as an accidental event when people intrude into this natural ecosystem. In these situations humans are a 'dead-end' host of no biological significance to the life cycle of the virus. The non-arboviruses that are members of the genus *Flavivirus* may be found in either arthropods or in vertebrates, but not in both, and are of little medical importance.

Whether flaviviruses have a narrow or wide host range, their distribution is dependent on the ecology of their specific vertebrate and invertebrate hosts. Some flaviviruses have very restricted geographic distributions, such as Kyasanur Forest virus, found to date only in Karnataka (previously Mysore) State in India, Omsk haemorrhagic fever virus (OHFV), found in the Omsk district of western Siberia, or Rocio virus in the Santista lowlands and the Ribeira valley of Sao Paulo state in south-east Brazil. By contrast, flaviviruses such as West Nile virus (WNV) are distributed widely through Africa, Asia, large parts of Europe and, more recently, the United States and Canada. Japanese encephalitis virus (JEV) is found in at least 16 countries in a wide belt stretching from eastern to south-eastern to southern Asia, affecting a combined population in excess of two billion. Dengue virus has moved over the past 20 years from South East Asia into the Pacific, the Americas, Africa and Australia, progressively establishing itself in local populations of the widespread human-biting mosquito *Aedes aegypti*.

The clinical manifestations of the majority of flavivirus infections are relatively nonspecific. In endemic areas, the diagnosis of infection is often made on clinical suspicion, especially if the physician is alerted by epidemic activity in the region. Occasionally outbreaks of flavivirus infection may follow climatic events, for example, heavy rains after a period of drought, which result in the formation of numerous stagnant pools, facilitating the breeding of mosquito vectors and also attracting bird life. Outbreaks may follow uncontrolled urbanization and the breakdown of vector control measures, as has occurred in recent yellow fever outbreaks in West Africa. In some situations human cases may follow an extensive zoonosis in the vertebrate host, especially where birds or livestock are involved. Surveillance and epidemiological monitoring, which involve, among other things, the continual and sustained sampling of arthropod vectors and vertebrate hosts for arbovirus activity, is of critical importance in the prevention and management of outbreaks of flavivirus infections. Recently calls have been made for mobile units to be established and sent into the field to conduct clinical diagnosis and therapeutic research, as well as for epidemiological surveillance in endemic areas.

The diagnosis of infection due to flaviviruses becomes particularly difficult in individuals who have travelled from an endemic area and present themselves for medical management many thousands of miles away from their source of infection. In the modern era of jet travel, a history of travel and also a knowledge of the prevalent infections in different parts of the world, are now an important component of infectious diseases medicine. In addition, travellers should be educated to alert their attending physician should they become ill on returning home.

Pestivirus

The second genus in the family *Flaviviridae*, *Pestivirus*, is also referred to as the mucosal disease virus group. The viruses of this genus are the causes of important veterinary diseases worldwide, such as bovine viral diarrhoea, border disease of sheep and hog cholera. They are not known to be spread by arthropod vectors, transmission taking place by direct contact and also via faeces, urine and nasal secretions, as well as vertically. The pestiviruses are not able to infect humans, therefore will not be discussed further.

Hepacivirus

The third and newest genus of the family *Flaviviridae* is *Hepacivirus*. The biochemical and biophysical characteristics of the virus have been determined and have been shown to be characteristic of the family *Flaviviridae*. Hepaciviruses are not arboviruses and are not known to infect

any non-human host in nature. Experimentally, the only animal able to be infected is the chimpanzee. Infection is transmitted by blood transfusion, penetrating injuries with blood-contaminated needles and instruments, sexually, and from mother to child during birth. Since the implementation of widespread screening for hepatitis B virus in blood, hepacivirus has become the major cause of post-transfusion hepatitis. Current screening programmes for hepacivirus have, in turn, reduced significantly the incidence of post-transfusion hepatitis due to this virus.

The most recent member of the family *Flaviviridae* is GBV-C virus. The virus was first detected in 1995 in laboratory tamarins experimentally inoculated with blood from a surgeon with clinical hepatitis. The GBVs, although closely related to hepacivirus, are distinct having only 29% amino acid homology with it. The pathological role, if any, of GBV-C has not yet been established. (GBV-B is a true hepatitis virus of primates, while GBV-A, also an agent of primates, is not known to cause disease.) Hepacivirus and GBVs are dealt with fully in Chapters 12 and 13.

PROPERTIES OF THE VIRUS

The type species of the genus *Flavivirus*, yellow fever virus, has been the most extensively studied member of the family. Recent interest in especially WNV, dengue virus and Japanese encephalitis has increased the knowledge of flavivirus molecular biology substantially.

Morphology and Morphogenesis

The virus particles are spherical, with a diameter of some 40–50 nm. The envelope is tightly applied to a 25–30 nm spherical core and surface peplomers are often visible. Replication of virus takes place in the cytoplasm of the cell in association with the rough and smooth endoplasmic reticulum. Accumulations of viral particles are seen within the lamellae and vesicles and replication is characteristically associated with the proliferation of intracellular membranes.

Biophysical and Biochemical Properties

The S₂₀W of flaviviruses is 70–210, that of pestiviruses is 140 and that of hepacivirus is ≥ 150 . The buoyant density of the flaviviruses in CsCl is 1.22–1.24 g cm⁻³ and 1.15–1.20 g cm⁻³ in sucrose.

The nucleic acid of flaviviruses consists of a single molecule of positive-sense ssRNA of approximately 11 000 nucleotides in length. A single open reading frame (ORF) on the genomic RNA is translated directly into a polyprotein, which is further processed into 10 major

Figure 28.1 Schematic representation of the organization of the flavivirus genome.

proteins—three structural and seven nonstructural proteins. Each of the individual proteins is derived by co- and post-translational cleavage by host cell signalases and the virus-specific proteases encoded by NS2B–NS3. Flanking the ORF, 5' and 3' noncoding regions with conserved secondary structures are found, which may play a role in genome replication and as translation enhancers. In order from the N-terminal, these are the internal RNA-associated C protein and then the two envelope proteins, prM and E, followed by the nonstructural proteins NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5 (Figure 28.1). The lipid bilayer is derived from the host cell membrane. The E and M proteins are inserted into the envelope. The glycoprotein E is rich in mannose and complex glycans. The C protein exists as two forms: a membrane-anchored form (C_{anch}) and the mature virion associated form (C_{vir}) (14–16Da) which remain associated with the membranes of the endoplasmic reticulum and the viral nucleic acid. WNV C proteins have been associated with the induction of apoptosis in infected cells. The prM protein is a glycosylated precursor protein. Co-synthesis of prM and E proteins is essential for correct folding of E suggesting that prM may act as a chaperone and may protect the E protein from degradation during transport to the cell surface in acidic post-Golgi vesicles. Subviral particles are formed when prM and E are expressed together *in vitro*, although their structure differs from the native virus. When virus release from the host cell takes place, prM is cleaved by host cell furin-like proteases, resulting in a smaller nonglycosylated M protein (molecular weight 7–9 kDa) and dimerization of the E protein on the virion surface. The E protein is the most conserved of the flavivirus structural proteins and has an important role in virus attachment and fusion. It is also the major neutralizing antigen. X-ray crystallographic structures of truncated soluble E proteins from tick-borne encephalitis virus (TBEV), dengue 2 and dengue 3 suggests that the E protein exists as a dimer. The individual monomers consist of three distinct structural domains: a central β -barrel (domain I), an elongated dimerization domain (domain II) and an immunoglobulin-like C-terminal domain (domain III). This third domain is the putative

receptor-binding domain for flaviviruses and the target for virus-specific neutralizing antibodies.

The nonstructural proteins play important roles in viral replication and may interact directly with host cell proteins to modulate the immune response to viral infection. The best characterized of the nonstructural proteins are NS1, 3 and 5. NS1 appears to have a role in early replication and signal transduction events. The NS3 protein encodes the viral proteinase that mediates cleavage of the translated polyprotein and is involved in viral RNA replication nucleotide triphosphatase, RNA 5' triphosphatase and helicase activities. The NS5 protein encodes a methyltransferase and a viral RNA-dependent DNA polymerase. The NS2A, NS2NB, NS4A and NS4B proteins are all small hydrophobic proteins with roles in viral replication. In addition they seem to have a function as interferon antagonists, potentially by blocking Stat1 and/or Stat2 phosphorylation (reviewed in Beasley, 2005).

Antigenic and Genetic Properties

The antigenic properties of the genus *Flavivirus* are defined by serological tests, such as the highly cross-reactive pH-dependent haemagglutination inhibition (HAI) test, the less cross-reactive complement fixation (CF) test, and the much more specific neutralization test (NT) or plaque reduction neutralization test (PRNT). Other techniques mainly used for diagnostic serology are IgG and IgM detection by enzyme-linked immunosorbent assay (ELISA) and immunofluorescence assays, for viral RNA detection the polymerase chain reaction (PCR) or related molecular techniques are used. The antigenic features of the virus are characterized by reactivity with antigenic domains and epitopes on the membrane E protein of the virus.

The genus *Flavivirus* is subdivided further into subgroups on the basis of cross-neutralization tests, using a polyclonal hyperimmune mouse ascitic fluid prepared against each member virus. The members of each subgroup give significant cross-neutralization results against each other, whereas the 'unassigned' subgroup contains a miscellany of flaviviruses which will display only limited cross-reactivity with each other or with at least one other virus in any of the established subgroups.

Phylogenetic analysis using partial gene sequences of the NS5 or the envelope gene suggest that the flaviviruses form an extensive series of clades that are defined by their epidemiology and disease associations. These genetic clusters are grouped into mosquito-borne, tick-borne and no-known-vector virus clades, which could be further subdivided into clades defined by their principal vertebrate host. Two distinct epidemiological groups were evident amongst the mosquito-borne flaviviruses, namely (i) the neurotropic viruses, often associated with encephalitic disease in humans or livestock which correlated with the *Culex* mosquito vector and bird reservoirs such as WNV, JEV, Usutu, Murray Valley encephalitis virus (MVEV) and St Louis encephalitis virus (SLEV) and (ii) non-neurotropic viruses, which are associated with haemorrhagic disease in humans, and correlates with the *Aedes* mosquito vector and primate hosts, such as dengue 1–4 and yellow fever. This suggests that the phylogenetic topology may reflect differences in the feeding behaviour and hosts between *Aedes* and *Culex* mosquitoes.

The tick-borne flaviviruses also clustered into two distinct groups. The first group is associated with seabirds while the second, the tick-borne encephalitis complex viruses, is primarily associated with rodents, and includes Kyasanur Forest disease, Langat, Omsk haemorrhagic fever, Powassan and Karshi.

The 'no known vector' flaviviruses form three distinct groups, the first of which are closely associated with bats and genetically closely related to the mosquito-borne viruses (Sepik, Entebbe bat, Sokoluk, Yokose), a second group, also related to bats but genetically more distant to the mosquito-associated viruses (Rio Bravo, Bukalasa Carey Island, Dakar Bat), and a third which includes viruses associated with rodents (Apoi, Cowbone Ridge, Jutiapa, Modoc, Sal Vieja, San Perlita). Geographical clusters are also evident, clustering into Old World or the New World viruses, where mosquito-borne viruses appear to have originated in the Old World (Gaunt *et al.*, 2001).

The antigenic classification of members of the genus *Flavivirus* of medical importance together with their respective vectors, disease manifestations, geographic distribution, vaccine availability and frequency of reported cases, is given in Table 28.1. The flaviviruses that either cause no human disease or have only rarely been reported in association with illness will not be dealt with further here.

YELLOW FEVER

The yellow fever virus is the type species of the genus *Flavivirus* and also the source of its name (Latin: *flavus* = 'yellow'). Yellow fever was one of the classical diseases of antiquity, instilling dread and terror in the

Americas, Europe and Africa from the seventeenth to the twentieth century. It was romanticized in classic works such as Samuel Taylor Coleridge's *Rime of the Ancient Mariner* and Wagner's opera *The Flying Dutchman*. At the turn of the century, the disease almost put paid to the construction of the Panama Canal, and in West Africa yellow fever more than any other disease was responsible for the appellation 'the white man's grave'. As late as 1988, an estimated 44 000 cases with 25 000 deaths were estimated to have occurred in Nigeria in the three years 1986–1988.

History

The disease entity of yellow fever was first described in 1667 in Barbados, and in the following two centuries devastating epidemics raged on the continents of America and Africa and also, to some extent, in Europe. The panic and chaos was matched by the extravagance of the speculations as to the cause. The confusion was further aggravated by the difficulty in distinguishing it from the other tropical plagues of malaria and dengue. In 1848, Nott proposed that yellow fever was transmitted by the bite of a mosquito, a suggestion supported by Beauprethuy in 1854 and Carlos Finlay in 1881. In 1900 the US Army Yellow Fever Commission, under Major Walter Reed, demonstrated in historical experiments on human volunteers that the infection was indeed transmitted by mosquitoes and the following year, Reed demonstrated that yellow fever was due to a filterable agent. Indeed yellow fever was the first human disease shown to be caused by a filterable agent. The discovery of the aetiological agent, however, had to wait a further 26 years when workers of the Rockefeller Foundation's West Africa Yellow Fever Commission demonstrated the transmission of infection from a Ghanaian patient called Asibi to a rhesus monkey, and the subsequent passaging between monkeys. The Asibi strain was later to be the parent strain of the 17D vaccine, developed by Nobel Laureate Max Theiler at the Rockefeller Foundation in New York in 1937.

The 17D vaccine strain was developed by serial passage through mouse embryo culture to chick embryo culture and then through minced chick embryo devoid of nervous tissue. The final vaccine virus, propagated through fertilized chicken eggs, is remarkably attenuated yet immunogenic, and the vaccine has proved to be very safe and effective, probably producing lifelong immunity after a single injection (World Health Organisation 2005a).

Epidemiology

Yellow fever is endemic in the tropics on both sides of the Atlantic. The endemic zone stretches between latitudes 10°N and 40°S in the Americas and 16°N to 10°S in

Table 28.1 Antigenic classification of flaviviruses of medical importance and their clinical and epidemiological features in humans

Subgroup	Virus	Vector	Disease manifestation	Geographic distribution	Vaccine	Frequency of reported cases ^b
Unassigned	Yellow fever	M	Fever, HF, jaundice, etc.	Tropical Africa and South America	Yes	Numerous

^aThese viruses are of very little importance to clinical medicine and will not be discussed further.

^bNumerous, >1000 cases reported, usually many thousands to millions; uncommon, 10–1000 cases reported; rare, <10 cases reported. M, mosquito; T, tick; HF, haemorrhagic fever; TBE, tick-borne encephalitis; CEE, Central European encephalitis; RSSE, Russian spring–summer encephalitis.

Africa, involving 44 countries, 33 in Africa and 11 in South America (Figure 28.2).

In the Americas, effective control of *A. aegypti* has resulted in the virtual disappearance of urban yellow fever from the Western Hemisphere, and the last epidemic of urban yellow fever occurred in Trinidad in 1954. However, jungle fever remains endemic in Bolivia, Brazil, Colombia, Ecuador, Peru, Panama, Venezuela and the Guyanas. The annual incidence by notification is approximately 100 cases, although this is probably a substantially underestimated number. Remarkably, the infection has not extended to the heavy concentrations of *A. aegypti* which have built up in urban centres. Although over 80% of all cases are reported from Africa, the case fatality rate in South America was 47% compared with 11% in Africa in 2004 (World Health Organization, 2005b).

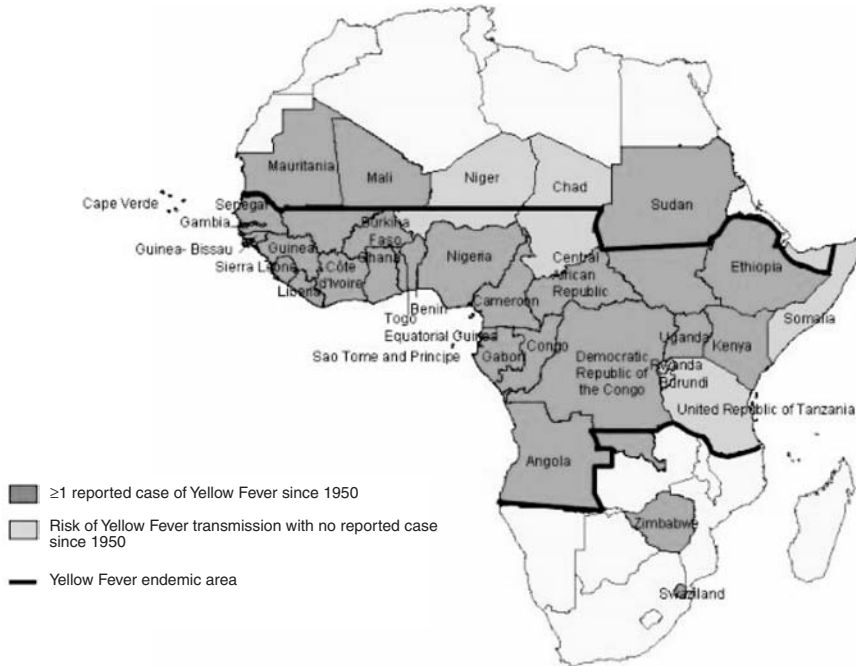

In Africa, recent epidemics of yellow fever have been far more extensive than those in the Americas. The features of jungle yellow fever differ in East and West Africa. In East Africa, endemic yellow fever activity is relatively quiet with few notified cases. However, two vast epidemics took place in 1940 in the Nuba mountains of Sudan, causing 40 000 infections with over 15 000 clinical cases and 1500 deaths. The second epidemic in 1960–1962, the largest epidemic of yellow fever ever recorded, took place in south-western Ethiopia, causing 30 000 deaths in 100 000 clinical cases in a rural population of some 1 million. In contrast to this, in West Africa, frequent outbreaks have occurred, usually on a considerably smaller scale than the two East African epidemics, with the exception of the Nigerian epidemic of 1986–1988, when an estimated 44 000 cases and 25 000 deaths may have occurred (World Health Organization, 1991). Over the last two decades significant epidemics have been reported from several West African countries, both preceding the Nigerian epidemic, in the Ivory Coast (1982) and Burkina Faso (1983), as well as after it, Mali (1987), Angola (1988), Cameroon (1990) and Niger (1990). Yellow fever has expanded into Gabon,

Liberia and Kenya, which reported their first cases since 1950 between 1992 and 1995 (World Health Organization, 2005b).

The transmission cycles of yellow fever and the ecological interrelationships of its vectors and reservoir hosts are complex. Essentially, three cycles of transmission are recognized:

1. The 'enzootic forest cycle' represents the predominant maintenance of infection in its major vertebrate host, the monkey. In South America, *Alouatta*, *Cebus* and *Ateles* monkeys are the major primate reservoir hosts and they are infected by tree hole-breeding *Haemagogus* mosquitoes in the forest canopy. The monkey is, however, only a transient host because of the short-lived viraemia. The major amplification host is the mosquito, which remains infected for life and is also able to pass infection on transovarially. Occasionally a single or a few human cases may occur when people venture into the forests. The cycle in Africa is similar and involves *Cercopithecus* and *Colobus* monkeys, with the *Aedes filfricanus* mosquito as the principal vector.
2. The 'jungle yellow fever cycle' represents the most important epidemiological form of yellow fever with respect to human infection. Epizootic upsurges of yellow fever are frequent, both on the fringes of the rain forests and in the surrounding riverine gallery forests. Human infection occurs when forest mosquitoes invade adjacent plantations, clearings and villages. Once infection has been introduced into the human host, human-to-human transmission sustains the epidemics, resulting in the dramatic outbreaks reported in recent years. In South America, *Haemagogus* mosquitoes and possibly other mosquito species may establish epidemics in humans. In East and Central Africa east of Cameroon, *Aedes simpsoni* will readily bite monkeys and humans. In the East African epidemics in Sudan and Ethiopia, the anthropophilic *A. aegypti* was the most frequently

Yellow Fever epidemiology in Africa at country level, 1950–2004

Yellow Fever epidemiology in America at country level, 1950–2004

responsible mosquito, as well as a number of 'wild' mosquitoes. In West Africa and Central Africa west of Cameroon, *A. simpsoni* does not bite humans and *Aedes fuscifer* is the major vector. In the Nigerian epidemic the major vector was *Aedes africanus*.

3. The 'urban yellow fever cycle' is maintained by *A. aegypti* and was the dominant form of yellow fever before extensive mosquito control eliminated the disease from South American towns. Periodic reinfestations with *A. aegypti* have been observed in many South American countries and have revived fears of a resurgence of urban yellow fever. In West Africa, *A. aegypti*-transmitted yellow fever is still responsible for outbreaks in towns and rural villages.

It is thought that yellow fever emerged in Africa before it was exported to the Americas, most likely through the slave trade. Nucleotide-sequencing analysis of the prM and E proteins identified a total of seven genotypes that have greater than 9% nucleotide variation and 7% amino acid variation. Five of these were identified in Africa, each genotype circulating in different geographic regions. In West Africa, two genotypes were present, West Africa genotype I was found from eastern Ivory Coast and Burkina Faso to Cameroon, as well as Nigeria. The second genotype, West Africa genotype II, was found in western Ivory Coast and Mali to Senegal. Two genotypes were identified in East/Central Africa: the East/Central African genotype which includes strains from the Central African Republic, Central Sudan, Ethiopia and the Democratic Republic of Congo, and the East African genotype, which includes strains from Kenya, southern Sudan, and Uganda. One further genotype was identified based on a single isolate from Angola (Angola genotype). In South America, two genotypes exist. The major genotype, South America genotype I, is found in Brazil, Panama, Columbia, Ecuador, Venezuela and Trinidad, while South American genotype II is mainly found in Peru, and a few isolates from Brazil and Trinidad (reviewed in Barrett and Higgs, 2007).

Clinical Features

The clinical presentation of yellow fever follows the general pattern of arbovirus disease—a short incubation period of three to six days followed by an acute biphasic illness. It is the severity and extent of the second phase of the acute illness which has imparted to this infection its classical notoriety.

The initial phase of illness is characterized by a viraemia that renders the patient infectious to biting mosquitoes and is also responsible for the acute constitutional symptoms. These symptoms last about three days and are generally those of a nonspecific febrile illness: headache, malaise, nausea, lassitude and widespread

muscle pain, especially in the back. The differential diagnosis is wide and includes malaria, other arboviral infections including dengue, typhoid, rickettsial infections, influenza, enterovirus infections and acute human immunodeficiency virus (HIV). With more intensive and careful physical examination of patients, signs and symptoms more suggestive of yellow fever may be revealed, such as flushing of the head and neck, conjunctival injection, strawberry tongue and a relative bradycardia. Probably the majority of clinically manifest yellow fever infections are aborted at this phase of the illness, accounting for the underestimation of the true numbers of cases by up to 500-fold (World Health Organization, 1991).

In cases of severe yellow fever, the early acute illness is followed by a brief period of remission before the onset of the haemorrhagic, hepatic and renal disease. The latter is heralded in by a return of fever, vomiting, abdominal pain, dehydration and prostration. The onset of the haemorrhagic diathesis is usually marked by coffee ground haematemesis, the classic 'black vomit', and bleeding from puncture sites where injections or drip needles have been inserted. This is accompanied by jaundice, albuminuria and oliguria. Deepening jaundice, massive haematemesis or haemoptysis or intra-abdominal bleeding, progressive renal failure, hypotension and shock may occur, followed by stupor, coma and death by the seventh to tenth day. Occasionally the illness may run a rapid fulminant course with death within a few days of onset. Mortality has been estimated to be of the order of 20–50% of cases entering the second phase of illness, although case fatality rates of up to 83% have been reported (World Health Organization, 1990). These figures probably represent a marked overestimate of the fatality rate in the more severe cases which are likely to come to the attention of the health authorities. The differential diagnosis of severe yellow fever is usually that of the causes of viral haemorrhagic fever (HF): Congo–Crimean haemorrhagic fever, Rift Valley fever, meningococcal septicaemia, Marburg and Ebola, generalized herpes simplex, as well as hepatitis B virus infection, leptospirosis and toxic hepatitis. During the severe second phase of illness, virus is usually absent from the blood and antibodies are present, suggesting that autoimmunity may well play a major role in the pathogenesis of severe yellow fever.

Patients who survive generally recover completely, although a chronic phase of illness lasting weeks or sometimes even months may occur in some individuals. This is characterized by prolonged jaundice and disturbances of liver function as well as prolonged renal failure. Occasionally sudden death may occur in the chronic phase as the result of myocardial damage or cardiac arrhythmias.

A number of host factors may affect the clinical expression and severity of yellow fever virus infection.

Age has played a significant role in South American epidemics, the majority of infections occurring in young adults, especially between the ages of 20 and 25. Age distribution has not, however, been a significant characteristic of African epidemics. In some epidemics gender has played a significant role in the distribution of cases, for example, in the 1972–1973 Brazil epidemic there was a marked predominance of males affected—a 9 : 1 ratio, whereas in others there was only a slight male preponderance (e.g. 53% males in the 1986 Nigerian epidemic). More controversial has been the purported association of race and susceptibility to yellow fever, especially in the classical literature, which frequently made reference to the mildness of the disease in the indigenous inhabitants of the African jungle. There is, however, no evidence confirming any difference in susceptibility between races.

There are no known viral factors affecting either transmissibility or virulence. Although genomic heterogeneity has been demonstrated by fingerprinting and sequencing studies and also some antigenic heterogeneity has been observed between isolates, there has been no demonstrable clinical or epidemiological differences between American and African isolates.

Diagnosis

The development of reliable rapid tests for the urgent diagnosis of yellow fever has become a major public health priority in the management of the viral haemorrhagic fevers. The IgM antibody capture ELISA has become the test of choice for rapid serological diagnosis of yellow fever virus infection. Cross-reactions may occur but IgM antibody levels will normally be higher against yellow fever. Immunofluorescence tests using infected cells spotted onto microscope slides and then acetone-fixed can be used for detecting IgG and IgM in patients' sera. In the immunofluorescence test, however, the rheumatoid factor may be a much greater problem than in the IgM antibody capture ELISA, and pre-treatment to remove IgG prior to IgM testing is necessary. The classical techniques, such as HAI, CF and NT tests still have a place in yellow fever surveillance and diagnosis but a fourfold or greater rise in titre would have to be demonstrated before a definitive diagnosis could be made. Specific diagnosis still may be difficult, particularly if the patient has had previous experience of flavivirus infection. In these instances higher titres may appear against heterologous viruses, in keeping with the doctrine of original antigenic sin.

Isolation of virus may be performed in specialized reference laboratories, either by intracerebral or intraperitoneal inoculation of suckling mice or by the intrathoracic inoculation of male *A. aegypti* or *Toxorhynchites* mosquitoes. These techniques are particularly sensitive

and are essential for epidemiological monitoring and research, but unfortunately take up to three weeks to provide an answer. More rapid viral isolation techniques using mosquito cell lines, such as the lines from *Aedes albopictus* (C6–36) and *Aedes pseudoscutellaris* (MOS 61), which are sensitive to infection and, combined with the immunofluorescence test using monoclonal antibodies, may give a diagnosis within three to four days. It is recommended that early antibody is dissociated from viral antigen using dithiothreitol prior to isolation attempts in mosquito cell cultures. An antigen-capture ELISA technique is available which is slightly less sensitive than virus isolation but is able to produce a specific result with the use of monoclonal antibodies in less than 24 hours. A sensitive method for detecting and quantifying viral RNA has been developed using real-time reverse transcription polymerase chain reaction (RT-PCR).

Liver biopsy is contraindicated in acute yellow fever. However, liver tissue from post-mortems may provide useful histopathological information. The classical liver pathology is that of a coagulative mid-zonal necrosis. The inclusion bodies which have been held to be pathognomonic of yellow fever are those in the cytoplasm due to eosinophilic degeneration (Councilman bodies) and intranuclear eosinophilic inclusion bodies (Torres bodies). Many of these features are, however, also found in fatal cases of viral haemorrhagic fever due to other viruses, and the histopathology is now no longer regarded as being diagnostic of yellow fever.

Control

The worldwide control of yellow fever has been achieved by immunization and effective vector control, which have largely eliminated the urban yellow fever cycle due to *A. aegypti*. However, in recent times, poverty, war and competing health priorities have led to a reduction in immunization and surveillance efforts, resulting in a resurgence of disease, especially in the endemic zone of Africa. In addition, reinfestation of towns and villages adjacent to forests with *A. aegypti*, aggravated by the massive uncontrolled urbanization and population migrations to the towns of developing countries, also exacerbated particularly by severe drought, has renewed the spectre of urban yellow fever in Africa.

Prior to 2001 surveillance for yellow fever infection was generally poor. However, since then a network of diagnostic laboratories has been established usually on pre-existing measles networks. A WHO recommended case definition has been drawn up—any clinical presentation of acute onset of fever with jaundice within 14 days of onset of illness.

It is over 50 years since the development of the first yellow fever vaccine by Theiler, and the original method

for the production of chick embryo-passaged 17D vaccine has undergone little modification over the years. The French neurotropic vaccine, developed by passage in mouse brain, is now no longer used because of the prohibitive danger of encephalitic complications. The vaccine is a live attenuated purified product produced by growing vaccine virus in chick embryos and is supplied as a lyophilized preparation, which should be stored frozen or at least kept at temperatures of not more than 5 °C. After reconstitution it should be used immediately and any remnants discarded within an hour. A single dose of 0.5 ml given subcutaneously provides excellent, long-lasting immunity to 99% of vaccinees. Although international health regulations demand booster doses every 10 years, neutralizing antibodies have been shown to persist for over 30 years and immunity is probably life long.

Side effects to immunization occur in less than 5% of recipients and are generally mild, low-grade fever, myalgia and headache. Occasionally, hypersensitivity reactions have been reported, especially in individuals allergic to egg protein. The most serious side reaction, encephalitis, has been reported in 18 cases out of more than 35 million doses of vaccine which have been administered to date. Only two cases have occurred in children over the age of seven months, although the only fatality was in a three-year-old child. Regarding the latter case, it was postulated recently that a change identified in amino acid position 303 of the isolate P-16065 compared with the parent vaccine virus 17D-204 USA may have affected the virulence of the vaccine virus (Jennings *et al.*, 1994).

The contraindications to immunization are those determined by age, pregnancy, history of egg allergy and immunosuppression (Centers for Disease Control and Prevention, 1990). The vaccine should not be given to children under the age of nine months unless travel to an endemic area cannot be avoided but should, at any rate, never be given to infants less than four months of age. The effect of immunization in pregnancy has not been determined; however, being a live attenuated vaccine, it should not routinely be given to pregnant women. However, if travel to an area with ongoing yellow fever cannot be avoided, the danger of infection would far outweigh the theoretical risk to a pregnant mother and her fetus. The vaccine should also be avoided in people with a history of egg allergy or in immunosuppressed individuals, for example, due to HIV infection, malignancy or immunosuppressive treatment. However, as in the case of pregnancy, the relative risks of travel to an endemic area vs. the slight or even theoretical risk of the vaccine would need to be evaluated on an individual basis. Yellow fever vaccine should be administered at least 14 days before departure. Booster doses are required for international travel regulations every 10 years.

Universal immunization of infants with yellow fever vaccine was recommended by WHO and UNICEF in 1988 for the 44 endemic countries in Africa and South America (World Health Organization, 1996a). The vaccine has been incorporated into the routine schedule to be given at nine months of age together with measles vaccine. By the year 2000, however, only 12 African countries had the vaccine in their routine schedule and in these the coverage was disappointingly low, lagging far behind measles. Recognizing the problem of vaccine funding to be a major obstacle, the Global Alliance for Vaccines and Immunization (GAVI) agreed, in 2000, to financially support the provision of vaccine to all eligible countries and brought the total for Africa up to 22 countries. In addition to routine immunization, 'one-off' mass immunization programmes have been carried out in several countries to rapidly reduce susceptibility.

The current worldwide production of yellow fever vaccine is estimated to be of the order of 70 million doses per year. In 2003 the GAVI Board approved the purchase of a stockpile of 6 million doses of vaccine to be used for preventive vaccination campaigns as well as for outbreak response.

Vector control strategies such as aerial spraying, domiciliary spraying and the enforcement of public health regulations to reduce collections of stagnant water and other breeding sites, have had successes in the past in eliminating *A. aegypti* and controlling urban yellow fever. Present-day socio-economic difficulties have, however, hampered recent efforts to again control the reinfestation of villages and towns in Africa. Control of vectors responsible for the jungle yellow fever cycle is impractical.

There still remain many gaps in our knowledge of the epidemiology of the infection and the permanent control of the disease will probably need not only resources to implement what is already known, but also the elucidation of the remaining enigmas regarding the infection.

OTHER MEMBERS OF THE 'UNASSIGNED' SUBGROUP OF FLAVIVIRUSES

Rocio

Rocio virus is an arboviral cause of encephalitis localized to the Ribeira valley and Santista lowlands in the southern coastal region of Sao Paulo state in south-eastern Brazil. The virus was first isolated in 1975 from the brain of a fatal case of encephalitis diagnosed during an unusual epidemic of encephalitis in 1975–1976. No further cases have occurred since 1980, although two children from the Ribeira valley tested positive for IgM antibodies in 1989. A total of 821 cases were diagnosed during 1975–1978, twice as many in males and usually aged 15–30 years.

The virus has been isolated from pools of mosquitoes, such as *Psorophora ferox*, and also from wild birds. The transmission cycle of the virus has not, however, been established. Clinical and epidemiological features of the disease have been reviewed in 821 cases between 1975 and 1978 (Iversson, 1980). The disease commences with nonspecific signs of pyrexia, headache and vomiting. This may then be followed by disturbances of consciousness and signs of encephalitis, including localizing signs. Death may follow a prolonged coma or there may be a sudden fulminant course. Serious neurological sequelae occur in some 20% of clinical cases and the overall case fatality is found to be 10%. The IgM capture ELISA has been used to diagnose Rocio virus infection in children and is preferable to the HAI test for identifying recent infection.

Wesselsbron

Wesselsbron virus was first isolated from a lamb in the village of Wesselsbron in South Africa in 1955. Virus has been isolated from 23 human cases of infection, 11 of them resulting from laboratory infection or infection of laboratory field workers. The vertebrate host is chiefly livestock, especially sheep, and isolations have been made from throughout sub-Saharan Africa, especially South Africa where it is causes a febrile illness in sheep associated with hepatitis, haemorrhage, abortion and mortality in newborn lambs. Isolations have also been made from ostriches. It has also been isolated from pools of wild-caught *Aedes* mosquitoes, such as *Aedes (neo) lineatopennis*. The major vector in sheep is *Aedes caballus-juppi*. Humans are infected by mosquito bite or by direct contact in handling carcasses or tissues of animals that have died of the disease.

Human infection is characterized by a sudden onset of pyrexia, severe headache and retro-orbital pain associated with photophobia and hyperaesthesia of the skin, with an evanescent skin rash frequently present. Muscle and joint pains are also commonly seen. In severe cases signs of encephalitis, such as blurred vision and some mental impairment, may occur. Patients recover after a few days to a week and no permanent sequelae have been reported.

Diagnosis of infection may be achieved by isolation of the virus from blood or serological tests. The HAI test is only useful in individuals with no previous flavivirus infection history, because of the extensive cross-reaction between Wesselsbron and other flaviviruses. The capture IgM assay is the test of choice for diagnosis of recent Wesselsbron infection.

DENGUE

Dengue is, at present, the most important arboviral cause of death and disease in humans (Gubler and Costa-Valez,

1991). The infection has spread widely from South East Asia to the Americas, the Pacific and Africa, now involving several million people annually. In all major tropical areas of the world the incidence of dengue fever (DF) and dengue haemorrhagic fever (DHF)/dengue shock syndrome (DSS) has increased dramatically over the past few years, with an ever-increasing frequency and extent of epidemics and a greater severity of cases. The spectre of the introduction of infection to *A. aegypti* populations in non-endemic countries is of great international concern.

History

Outbreaks of 'break bone fever', in which patients presented with symptoms that included fever, headache severe muscle pain and joint pain, nausea, vomiting and rash, haemorrhagic manifestations and asthenia in convalescence, clinically resembling dengue fever have been recorded since 1779 and 1780 in Java (Indonesia), Cairo and Philadelphia. The name dengue, which means 'affectation' in Spanish, was given following an outbreak of a similar syndrome in Madrid in 1801. Epidemics of dengue-like illnesses occurred at 10- to 30-year intervals throughout tropical and subtropical regions of the world. In 1953, DHF was first recognized in children in Manila, and subsequently detected throughout South East Asia. Although the precise aetiology could not be established and infections such as chikungunya are clinically and epidemiologically very similar, the majority of these epidemics were probably dengue. A dengue pandemic started in South East Asia following the Second World War, spreading to tropical areas across the world including Africa, Oceania and the Americas (Gubler, 2004; Rigau-Perez, 2006). The spread of the disease has been markedly accelerated by the advent of widespread air travel over the last three decades. Dengue fever was generally regarded as a relatively benign illness, affecting predominantly colonial expatriates living in tropical countries and, although responsible for severe and often incapacitating muscle pain, it was seldom lethal. However, the gravity of the dengue pandemic was really confirmed by the recognition in the 1950s of the severe complications of infection, viz. DHF/DSS affecting mainly children in the endemic areas. Epidemics of DHF/DSS ravaged South East Asia and in the following 30 years was responsible for over 700 000 children being hospitalized and over 20 000 fatalities (Halstead, 1984).

In the Western Hemisphere, the first major epidemic of DHF/DSS in Cuba in 1981 was responsible for 24 000 cases of DHF and 10 000 of DSS (sporadic cases of suspected DHF had been reported from Central America since 1968). Only the energetic response of the Cuban health authorities, with intensive education and mass

hospitalization, kept the mortality down to only 158. Following on this epidemic, confirmed or suspected cases of DHF have been reported in the Americas almost every year, with the most severe outbreaks of dengue fever occurring in Peru in 1990, involving over 76 000 cases (Centers for Disease Control and Prevention, 1991a). Dengue returned to Cuba in 1997. Eradication of the vector *A. aegypti* as part of an effort to eradicate urban yellow fever from the American region in the 1950s and 1960s reduced the occurrence of epidemic dengue dramatically in this region, however following the discontinuation of this programme the geographic distribution of this vector is much wider than before it began. By 2003 DHF has been reported from 24 countries of the American region, and DHF is now considered endemic in these countries. At present it is estimated that 2.5 billion people live in high-risk areas, and more than 100 million infections occur per year, including 250 000–500 000 cases of DHF with a average fatality rate of 5% (CDC epidemiological data, www.cdc.gov/ncidod/dvbid/dengue/index.htm). Imported cases of dengue in travellers returning to temperate countries are reported in the United States annually and DHF was reported in two cases in the United Kingdom in 1991 (Jacobs *et al.*, 1991). Blood donations collected during a dengue outbreak in Hong Kong were thought to have resulted in two cases of dengue from infected transfusion blood.

Virus Properties and Host Range

The dengue viruses form a subgroup of the genus *Flavivirus* and although extensive cross-reactivity is seen with serological tests such as HAI which cannot reliably distinguish dengue from many other flaviviruses, NT tests are able to define dengue virus as a distinct antigenic subgroup. There are four serotypes of dengue based on NT tests. However, with all serological tests there is extensive cross-reactivity between the four serotypes, although they are distinguishable with the highly specific PRNT test. Following natural infection, all four genotypes induce specific but not cross-protective long-term immunity. Dengue serotypes 1, 3 and 4 show a closer antigenic and genetic relationship to each other than dengue 2. However, within each of the serotypes, considerable heterogeneity and strain variation is demonstrable by sequence analysis as well as antigen signature analysis using monoclonal antibodies. Severe disease may be caused by all four types. DHF is associated with reinfection with a heterologous secondary dengue virus infection. Dengue viruses exhibit 65–70% sequence homology, but although serotype cross-reactive protective immunity exist early after primary infection, this response wanes after six months and the host becomes susceptible to the remaining three

heterologous serotypes (Green and Rothman, 2006; Halstead, 2003). The only vertebrate hosts of dengue virus in nature are humans and several species of Asian and African sub-human primates. Other vertebrates can be infected experimentally only with difficulty, including baby mice, which usually require several blind passages of patient material to obtain an isolate. The invertebrate hosts of dengue are members of the genus *Aedes*, especially the subgenus *Stegomyia*. The most important mosquito hosts as far as human infection is concerned are *A. aegypti*, *A. albopictus* and *A. polynesiensis*. Other *Aedes* species, including *A. africanus*, *A. leuteocephalus* and the *A. furcifer* group, are involved in the maintenance of the forest cycle of dengue in Africa, whereas in Asia the mosquitoes concerned belong to the *A. niveus* complex.

Epidemiology

Dengue displays many epidemiological similarities to yellow fever and chikungunya viruses and there is considerable overlap in the ecologies of these three virus infections. Essentially there are three transmission cycles of dengue: a forest cycle in primates and involving forest species of *Aedes*; a rural or semi-rural cycle in humans, with the peri-domestic *Aedes* species being the vectors; and an urban cycle in humans involving domesticated *Aedes* species. By far the most important of these three for both endemic and epidemic human dengue is the urban cycle. It is, in fact, doubtful whether the forest cycle plays any significant direct role in human dengue.

The two major mosquito vectors of urban dengue are *A. aegypti* and *A. albopictus*. Although *A. albopictus* is considered more sensitive to oral infection with dengue viruses, *A. aegypti* is a more important vector for human disease and is especially responsible for explosive epidemics. The anthropophilic *A. aegypti* usually preferentially feeds on humans and occasionally also on domestic animals, while the purely domestic *A. albopictus* randomly feeds on humans, domestic animals and feral animals and birds. To establish infection, *A. aegypti* would need to feed on individuals with high levels of viraemia, and this may select for viral strains of higher virulence, which are more likely to produce the severe epidemics associated with *A. aegypti*. In addition, the biting habits of *A. aegypti*, which characteristically takes interrupted blood meals and will thus feed on a number of individuals before becoming engorged, enhances its ability to spread the virus. It is thus not unusual for a single mosquito to spread infection among several individuals at a single feeding. In both mosquitoes, biting activities are maximal soon after daybreak and in late afternoon, and are related to human activities and movements. Outbreaks associated with both vectors are climatically influenced by heavy rainfall and high temperature.

The recent upsurge of dengue in existing endemic zones and the spread to new areas has been attributed to modern phenomena of human and social behaviour. Infestations of *A. aegypti* in tropical towns and villages, which were controlled by extensive spraying and other vector control measures in the 1950s and 1960s, have now re-emerged due to uncontrolled urbanization and the mass migration of rural populations into informal housing settlements and squatter camps on the peripheries of cities and towns. These population movements have been accentuated by famine, poverty and war. Stagnant water pools and lack of reticulated water supplies have provided ample opportunities for mosquito breeding, coupled with the breakdown of vector control in many tropical countries. Overcrowding and grossly inadequate housing, which is so characteristic of the sprawling slums of the tropical world, greatly facilitate the spread of vector-borne diseases and is especially conducive to dengue transmission resulting from the interrupted feeding habits of *A. aegypti*. The spread of infection has also been enhanced by the modern era of jet travel, which facilitates the transportation of infected individuals to non-infected areas, creating the threat of the introduction of infection if infestations of *A. aegypti* are sufficiently high. Modern air travel has also been responsible for increasing the number of imported cases of dengue into countries where physicians are, in the main, ignorant to the infection, resulting in perplexing diagnostic difficulties until a history of travel to endemic zones is elicited.

More recently, the influence of international trade in the spread of dengue has been observed. Motor vehicle tyres and casings from South East Asia containing remnant pools of water where infected *A. albopictus* mosquito larvae have been found, have been shipped to various non-endemic areas of the world, posing a serious threat of introducing both the virus as well as its vector.

An increase in frequency of epidemic dengue/DHF has been observed over the past 30 years as all four serotypes spread throughout the tropical parts of the world. Today the tropical world has become hyperendemic with multiple dengue virus serotypes co-circulating. This may have contributed to the emergence of DHF in the Pacific and the Americas. In Asia major DHF epidemics have been reported in Sri Lanka, India, Pakistan, Taiwan, China and the Maldives islands since the 1980s caused by all four serotypes. Reintroduction of dengue viruses in the early 1970s in the Pacific has resulted in DHF epidemics caused by all four serotypes.

Although surveillance in Africa has been poor, epidemic dengue fever caused by all four serotypes has been reported in mainly West and East Africa. Major epidemics have been reported in the Seychelles (1977), Kenya (1982, dengue 2), Mozambique (1985, dengue 3), Djibouti

(1991–1992, dengue 2), Somalia (1994, dengue 2). Prior to 1980, major dengue epidemics were last reported in South Africa in 1920, in the Durban area and in Senegal. The outbreak in South Africa was probably imported and the virus did not establish in the local mosquito population. An enzootic forest cycle that involves non-human primates and a number of mosquito species has been reported in West Africa involving dengue 2 viruses. DHF has not been reported in Africa and the Middle East although sporadic cases of clinically compatible DHF were reported in Mozambique, Djibouti and Saudi Arabia.

Dengue/DHF has emerged dramatically in the American region. Only dengue 2 was found in 1970 in the Americas although dengue 3 may have been present in areas of Colombia and Puerto Rico. Dengue 1 was introduced in 1977, causing major epidemics over a period of 16 years. This was followed by introduction of dengue 4 and a new strain of dengue 2 from South East Asia in 1981. The latter resulted in the first major DHF epidemic in the Americas in Cuba, spreading rapidly and causing outbreaks of DHF in Venezuela, Colombia, Brazil, French Guiana, Surinam and Puerto Rico. Today DHF is endemic in various countries across the American region. A new strain of dengue 3 also caused a dengue/DHF epidemic in Nicaragua, Panama and Costa Rica. Sequencing data suggest that this strain was imported from Sri Lanka and India and was distinct from strains previously found in the region. (Information from the Centers for Disease Control and Prevention website: www.cdc.gov/ncidod/dvbid/dengue/index.htm; reviewed by Gubler, 2004.)

Clinical Features

The majority of infections with dengue virus, based on the extent of population seropositivity, are asymptomatic. Clinical manifestations of dengue occur in two forms—classical dengue fever and DHF/DSS. Classical dengue fever is an acute disease characterized by a sudden onset of fever, severe headache which is typically frontal in distribution, together with retro-orbital pain, nausea and vomiting. Severe muscle and bone pain and arthralgia are characteristic of dengue and usually more pronounced in the back, which led to it being termed ‘break bone fever’ by Dr Benjamin Rush in 1778. He also aptly described the associated severe depression as ‘break heart fever’. There is frequently a diffuse, discrete maculopapular rash which usually heralds the recovery phase of the illness. In spite of the severity of symptoms, which may be incapacitating, the disease is temporary and full recovery takes place.

The grave complication of DHF/DSS is governed by two factors, prior infection and age. Thus, DHF and DSS occurs in approximately 0.18 and 0.007%, respectively, of cases of primary DF compared with 2.0 and 1.1%,

respectively, of dengue fever due to secondary infection (Halstead, 1981). It is also rare in individuals over the age of 15 years. DHF/DSS resembles yellow fever in its biphasic presentation. The first phase is not unlike uncomplicated dengue fever. This is followed by a brief remission of symptoms, when the fever subsides to normal or close to normal. There is then a sudden deterioration in the patient's condition, marked by profound prostration, hypotension, circulatory collapse and manifestations of bleeding and shock. Bleeding is seen commonly as petechiae in the skin and mucous membranes, especially in the oral cavity, ecchymosis, bleeding at injection and skin puncture sites, gastrointestinal bleeding and haemorrhagic pneumonia.

The cause of the haemorrhagic diathesis in DHF is complex. There is evidence of vascular injury with increased permeability and extravasation of fluid from the vascular into the interstitial fluid compartment, producing hypotension and DSS. Bleeding due to vascular damage is suggested by the presence of petechiae and a positive tourniquet test. In addition there is a marked thrombocytopenia, although it is not yet clear what the relative contributions of impaired platelet formation due to direct suppression of megakaryocyte production in the bone marrow or excess destruction due to endothelial damage. Evidence exists for both. Third, there is haematological evidence of a consumptive coagulopathy with a moderate increase in fibrin degradation products which, however, rarely reaches the stage of disseminated intravascular coagulation.

The definition of DHF is controversial. The WHO criteria for DHF are an acute onset of fever, haemorrhagic manifestations, which include at least a positive tourniquet test, a thrombocytopenia of 100 000 per ml or less and a haemoconcentration with a haematocrit increase of 20% or more. Manifestations of haemorrhagic fever, however, do differ from country to country and amendments to the criteria have been proposed to include, amongst others, references to the age of the patient (≤ 16 years). The severity of DHF/DSS has been graded by the WHO from I to IV (Technical Advisory Committee on DHF for the South East Asian and Western Pacific Regions, 1980):

- Grade I—Fever with nonspecific constitutional symptoms, the only haemorrhagic manifestations being a positive tourniquet test.
- Grade II—As for grade I, but with specific haemorrhagic manifestations.
- Grade III—Signs of circulatory failure or hypotension.
- Grade IV—Profound shock with pulse and blood pressure undetectable

Since the emergence of DHF among the severe dengue syndromes, cases of 'unusual manifestations' with bleak

prognosis have been identified that do not fit into the above grades. These include encephalopathy and less frequently encephalitis, hepatic failure, cardiomyopathy as well as dengue fever with severe haemorrhage, and more recently acute respiratory distress syndrome and acalculous cholecystitis. These cases do not fit into the WHO definition of severe DHF and are not well defined. Their frequency differs between populations and outbreaks (Rigau-Perez, 2006).

Pathogenesis of DHF/DSS

The pathogenesis of DHF/DSS has been studied intensively for a number of decades. Although the pathways to the development of severe dengue have not, as yet, been definitively established, significant advances in the immunopathogenesis has brought us closer to understanding the mechanism behind DHF in recent years. DHF is characterized by a short-lived plasma leakage that is thought to be immune mediated. Heterologous secondary dengue virus infection has been linked in epidemiological investigations to plasma leakage syndrome and bleeding diathesis/DHF. Ninety per cent of DHF cases occur in secondary heterologous dengue virus infection whereas only 10% occur in primary infection most often in infants in the second half of their first year of life. In the latter group maternal transmission of non-neutralizing dengue virus antibodies are thought to be involved in antibody-dependent enhancement in which pre-existing dengue antibodies bind to heterologous dengue virus, thereby enabling enhanced viral entry through monocytes and other FcR-presenting target cells. Dengue virus target cells are mainly cells of the reticuloendothelial system (spleen, liver, bone marrow) and include monocytes, lymphocytes, Kupffer cells as well as alveolar macrophages. Infection of these cells by dengue virus results in the production of immune mediators that will shape the adaptive and cellular immune responses.

Several mechanisms may work together to result in plasma leakage. Complement activation and plasma leakage may be triggered by the circulation of high levels of secreted NS1 in the presence of pre-existing heterologous non-neutralizing anti NS1 antibody. The role of antibody-mediated enhancement is not yet fully understood. It is thought that upon primary infection, antibodies are generated against the cell surface expressed proteins E and NS1. The E protein contains serotype-specific and serotype cross-reactive neutralizing epitopes. The sequence of dengue virus infection plays a role in the beneficiary or disease enhanced effect of cross-reactive memory humeral immune response. For example, serum containing neutralizing cross-reactive antibodies against dengue 3 was beneficial upon secondary infection, but the same did not hold true for secondary infection with dengue 1 or 2. The effect of antibody-dependent enhancement is

believed to be a result of an increase in viral entry that results in an increased viral burden in the host upon heterologous secondary infection. *In vitro* studies have shown that anti-E antibodies enhance infection through FcR2, while anti-prM antibodies were able to enhance infection of both FcR2 and non-FcR2-bearing cells (reviewed in Green and Rothman, 2006).

Recent reports have suggested that low-avidity cross-reactive T cells raised to the first infecting dengue virus serotype predominate during a secondary heterologous infection which may lead to immunopathology by inducing an altered profile of cytokines that could lead to plasma leakage. Evidence suggests that host factors may be a key issue in susceptibility to DHF since only limited numbers of secondary infections result in plasma leakage syndrome. Both protective and pathogenic roles have been assigned to different human leukocyte antigen (HLA) alleles but with disparate results. Protective roles have been assigned to HLA A33 in ethnic Vietnamese and A*0203 in ethnic Thai populations while a pathogenic role has been associated with HLA A24 in Vietnamese and A*0207 in Thai populations. Other genes that have been implicated in protection include the vitamin D cell receptor which may be associated with a stronger T helper cell response, FcγR2A which is associated with reduced opsonization by IgG2, and reduced antibody enhancement, the CD209 promoter, DCSIGN1-336 that through decreased expression reduces the susceptibility of dendritic cells for dengue virus infection. A variant of TNF-308 which is associated with high levels of tumour necrosis factor-α (TNF-α) production has been associated with more severe disease (reviewed in Green and Rothman, 2006).

The alternative hypothesis of Rosen (1986) holds that the severe complications of DHF/DSS are the direct results of properties of the virus, that is, the consequence of infection with unusually virulent strains of dengue circulating in a particular area and giving rise to outbreaks of DHF/DSS. However, strain variations exist within serotypes and no consistent relationship between strain variation and either virulence or heightened infectivity has been reliably demonstrated.

Diagnosis

The clinical diagnosis of dengue, both the uncomplicated dengue fever form and DHF/DSS, is often unreliable. Dengue fever may resemble clinically a variety of acute febrile illnesses, although the severe muscle and bone pain is suggestive of dengue. Similarly, DHF may resemble other causes of haemorrhagic fever, although thrombocytopenia with haemoconcentration and signs of a moderate consumptive coagulopathy is suggestive of dengue.

The most widely used serological test is the HAI test, detecting antibodies as early as four days post onset. A

specific diagnosis of dengue can be made early in primary infections, but cross-reactions with other flaviviruses occur in late primary or secondary infections. The IgM antibody capture ELISA (MAC ELISA) is now used during outbreaks of dengue, and there are rapid assays available for the detection of dengue IgG and IgM, although cross-reaction may occur with the IgG assay. The IgM antibodies may persist for over three months, so the test is also useful for retrospective studies, but this persistence may cause diagnostic problems in areas where dengue is endemic. A combined IgG and IgM assay, detecting high levels of IgG indicating secondary infection, is useful in dengue endemic areas. Immunofluorescence assays have been used successfully to detect dengue IgG and IgM antibodies. The CF test is more specific than the HAI test, but the antibodies detected by this assay appear later and disappear earlier. The NT and PRNT tests are the most specific and sensitive but are difficult to perform and thus tend to be used only for specific purposes.

Virus isolation is difficult and if mice are used, a number of blind passages are usually required. Intracerebral inoculation of adult or larval *Toxorhynchites* spp. is a sensitive and rapid method for the isolation of dengue virus, giving results in two to three days. The use of a rapid centrifugation method may increase sensitivity and reduce time scales. Intrathoracic inoculation of mosquitoes is easier and just as sensitive, but head squashes cannot be made or tested for specific dengue antigen for at least seven days post inoculation. The most commonly used system of virus isolation is the inoculation of mosquito cell lines, viz. *A. albopictus* (C6-36), *A. pseudoscutellaris* (AP-61) and *Toxorhynchites ambionensis* (TRA-248), which are almost as sensitive as mosquito inoculation, which allows specific results to be obtained within two to three days using fluorescent-labelled monoclonal antibodies. A combination of MAC-ELISA and RT-PCR on peripheral blood leukocytes has been shown to give high levels of sensitivity and specificity.

Several RT-PCR assays have been developed for diagnosis, quantification and typing of dengue virus in acute-phase serum and post-mortem tissues (Lanciotti, 2003). These methods are the most sensitive for detection of dengue virus and eliminate problems of cross-reactivity, although the virus nucleic acids can only be detected during the acute phase. Real-time RT-PCR assays that make use of TaqMan probes have also recently been reported for these purposes, which further improves the sensitivity and time to diagnosis and typing (Kong *et al.*, 2006).

Control

There is, at present, no licensed dengue vaccine. Current strategy is to develop a vaccine against all four serotypes.

Several candidate vaccines have been developed, including live attenuated mono- and tetravalent formulations, inactivated whole virus vaccines and recombinant sub-unit vaccines. Although some of these vaccine candidates have reached phase 1 or 2 clinical trials, to date none of them has been licensed for human use mainly because of high reactogenicity. Evaluation of further live attenuated tetravalent vaccine candidates in cynomolgus macaques is ongoing (Edelman *et al.*, 2003; Kitchener *et al.*, 2006; Koraka *et al.*, 2007; Sun *et al.*, 2003).

Because of the lack of availability of a vaccine, control of dengue depends on (i) surveillance to obtain early warning of epidemics or preferably to be able to predict impending epidemics and (ii) effective vector control.

Epidemiological surveillance may be of two types: first, proactive surveillance in interepidemic periods in endemic areas or in countries that are not yet infected but are vulnerable to the introduction of new infections because of high infestations of *A. aegypti*; second, reactive surveillance, where monitoring is instituted once suspected or confirmed cases of dengue have already occurred. This form of surveillance is very insensitive as numerous cases may occur that are not suspected to be dengue before authorities are alerted to the outbreak. In the Comoros Islands, dengue type 1 was diagnosed in 62/116 clinical cases in 1993. However, an investigation to determine the prevalence of dengue infection in over five year-olds, using a dengue IgM assay, estimated that at least 60 000 recent cases had occurred at that time.

A number of instruments of surveillance may be used for proactive monitoring. Disease surveillance requires intensive educational efforts, especially at peripheral primary health care level, to alert health care workers to the possibility of dengue. It is, however, very difficult to sustain interest, especially if no cases materialize. Viral and serological surveillance involves the active recruitment of specimens, for example, as carried out in Puerto Rico, where blood samples are collected by collaborating physicians on a regular basis and sent for analysis. Interest and cooperation is also difficult to sustain. The use of blood samples sent to laboratories for testing for acute febrile illnesses or 'viral syndromes' may be an easier way of recruiting specimens for serological testing. Surveillance may also utilize the routine investigation of all viral haemorrhagic fever cases, which should include tests for dengue. Vector surveillance may be of benefit to demonstrate low infestations (house index of <1%) or to look out for the introduction of exotic mosquito species, for example, *A. albopictus*.

Vector control aims at the elimination of the main mosquito vector, *A. aegypti*. While this is technically feasible, with both adulticide campaigns using ultra-low-volume spraying with malathion and also

larvicide treatment of stagnant water, the costs are high and the effects are temporary. In many tropical countries where *A. aegypti* eradication had been achieved, reinfestations have taken place to levels equalling, or even exceeding, those in pre-control times. However, long-term community-based programmes need to be implemented in endemic countries. In non-endemic countries there should be a vigilant monitoring for the possible importation of dengue, for example, through motor car tyres, or travellers or migrants from endemic areas.

ZIKA

Zika virus is closely related to dengue virus and antigenically cross-reacts with it and may give false-positive diagnostic test results for dengue. 'Zika fever' also resembles dengue fever in its clinical presentation although in a milder form.

The virus was first isolated in the Zika forest of Uganda in 1947. It has been described in West, East and Central Africa and, subsequently, in Malaysia, Indonesia and most recently (2007) in the Yap island of Micronesia. Like dengue, the vector is *Aedes* spp. mosquitoes and its epidemiology follows that of other aedine-borne viral infections.

Clinically zika fever is characterized by a low-grade pyrexia, maculo-papular rash, which is often pruritic, starting on the face and spreading to the trunk and lower extremities. Arthralgia involving mainly the small joints of the hands and feet and occasionally also large joints, is a common feature. Less commonly there may be conjunctivitis with retro-orbital pain, headache, myalgia, ankle oedema, lymphadenopathy and diarrhoea. Symptoms generally last for two to seven days and clear without sequelae. Limited observations of infections in pregnancy have not demonstrated any adverse effects on the infant—making it important to differentiate from rubella which it may resemble clinically.

JAPANESE ENCEPHALITIS

Japanese encephalitis is the major arbovirus cause of encephalitis in the world. First described as a clinical entity in Japan in 1870, the virus was isolated in 1935. It is now thought to be responsible for about 50 000 cases annually, half of whom are left with permanent neurological or psychological handicap, and in a further quarter it is rapidly lethal. Infection has been demonstrated in 16 countries in South East Asia, stretching to India in the west and to southern Russia in the north—a population of over 2 billion people.

Viral Features and Host Range

Japanese encephalitis virus shows some cross-reactivity with SLEV, WNV and MVEV, and together they form the mosquito-borne encephalitis complex. The virus is antigenically relatively homogeneous and recovery from infection results in solid protection. Nucleic acid analysis, however, has revealed some significant heterogeneity. Using PCR sequencing, isolates of JEV could be separated into four distinct genotypic groups, each group found in separate geographic divisions. Antigenically there is cross-protection across all groups and the epidemiological significance remains to be established. In the early part of the year 2000, Japanese encephalitis reappeared in the Australasian region and isolates were identified as genotype I, whereas all previous isolates were genotype II.

The vertebrate hosts of JEV are humans and domestic animals with aquatic birds playing a major amplifying role. The major mosquito vector of the virus is *Culex tritaeniorhynchus*, although a number of other species of the genera *Culex*, *Monsonia*, *Aedes* and *Anopheles* have yielded isolates of JEV.

Epidemiology

Nestling birds, particularly of the heron family, play an important epidemiological role in the dissemination of JEV, with a second cycle involving domestic animals, particularly the pig. In seroprevalence studies, high NT antibodies were found in several other animal species, for example, cattle, horses, dogs, monkeys and bats. As with the wild bird population, the high turnover of the domestic pig population resulting in a continuous supply of susceptible animals is a contributing factor to the pig being a major amplifying host for JEV. The virus rarely causes disease in domestic animals, although fatal encephalitis in horses and abortions in sows have been recorded. Studies on birds have implicated other species, whose main habitat is the rice paddies, as vertebrate hosts of JEV—these water birds include herons and bitterns. In India ardeid birds such as cattle egrets are implicated.

JEV has been isolated from many species of mosquito but the principal vector in many areas is *C. tritaeniorhynchus*. Other mosquitoes, mainly the *Culex* spp., are considered to be important in specific regions, for example, *Culex gelidus* in South East Asia, for the transmission of JEV.

Humans are a 'dead-end' host and play little role in the amplification of the virus. Japanese encephalitis is thus predominantly a rural problem, with disease closely related to rainfall and irrigation.

Sequence analysis of the C/PrM and E genes have identified four virus genotypes while a single strain of JEV isolated in Singapore in 1952 from a patient who

originated in Muar, Malaysia (Muar strain), may represent a fifth genotype. Genotype I consists of isolates from northern Thailand, Cambodia and Korea, genotype II contains isolates from southern Thailand, Malaysia, Indonesia and northern Australia, genotype III includes mainly isolates from temperate regions of Asia, (Japan, China, Taiwan, the Philippines, and the Asian subcontinent, while genotype IV includes isolates from Indonesia. Although genotypes I and III occur in epidemic regions, while II and IV are associated with endemic disease, differences in clinical epidemiology may not be linked to the genotypes as initially postulated. Several strains have been identified that do not fit this paradigm. Examples include Vietnam epidemic disease that occurs in the north and endemic disease that occurs in the south, although genotype III strains have been isolated in both areas, and a genotype I strain that has recently been found in northern Australia. No significant differences were observed in mouse neuro-invasiveness between genotypes. Phylogenetic analysis suggests that genotypes IV and V are the oldest and most divergent from the other genotypes while genotypes I–III evolved more recently. Since all genotypes are present in Indonesia (excluding New Guinea) and Malaysia it is postulated that JEV originated here, from where individual genotypes spread to Australia and New Guinea (genotype I and II); Taiwan and the Philippines (II and III); Thailand, Cambodia and Vietnam (I, II III); Japan, Korea and China (I and III) and India, Sri Lanka, and Nepal (genotype III) (reviewed in Solomon *et al.*, 2003).

Clinical and Pathological Features

Infection with JEV is considerably more widespread than the incidence of encephalitis would indicate. Infection may present nonspecifically as a mild febrile illness or as an aseptic meningitis, or, rarely, as a variety of inflammatory manifestations in the viscera. The typical disease manifestations of acute meningomyeloencephalitis have been widely estimated to occur at between 1/20 (Rodrigues, 1984) to 1/600–800 persons infected (Halstead, 1981).

The major target cells for JEV are the T lymphocyte and the peripheral blood mononuclear cells. In fatal cases of encephalitis, viral antigen is also demonstrable in the neurons. Factors determining the neuro-invasiveness of JEV involve both viral and host factors. Nucleotide sequencing of non-neurovirulent mutants of JEV have demonstrated single base changes in the coding region for E protein (Cecilia and Gould, 1991). Age is an important host factor determining neurovirulence, encephalitis being more common and more severe in the young as well as in elderly individuals. Experimental work in rats has shown a relationship between neurotropism and

neuronal maturity in that the virus selectively infects immature neurons (Ogata *et al.*, 1991). The reason for greater neuro-invasiveness in the elderly is unknown, but is consistent with the features of the related St Louis encephalitis and WNV, which similarly display greater neuro-invasiveness in the elderly.

The typical case of Japanese encephalitis commences after an incubation period of one to two weeks, with fever and headache, followed rapidly by depression of the level of consciousness, progressing from stupor to coma. Localizing cranial nerve and other neurological signs occur in about 30% of cases and in children generalized seizures are common—the frequency of seizures in patients increases with the severity of the encephalitis. A quarter of cases of clinical encephalitis will recover with no permanent sequelae and a quarter will die rapidly. The remaining half will recover with varying degrees of permanent neuropsychiatry sequelae. In addition, especially in children, the virus may persist in lymphocytes and reactivate to give recurrent disease after recovery (Sharma *et al.*, 1991).

Grave prognostic signs include a short prodromal period, deep coma, decerebrate posture, breathing abnormalities and the ability to isolate virus from the cerebrospinal fluid (CSF). Recently a reduction of serum iron levels has been demonstrated in patients due to the sequestering of iron in the spleen, and a direct relationship between low serum iron and prognosis has been shown (Bharadwaj *et al.*, 1991).

The pathology of the brain in fatal cases has revealed micro foci of necrosis scattered throughout the central nervous system, but especially involving the thalamus, the basal ganglia and the deep cerebral nuclei.

Diagnosis

Routine diagnosis is usually carried out by serology using HAI, immunofluorescence, CF or ELISA techniques. Test results should, however, be treated with caution because of extensive cross-reactivity with other flaviviruses and because up to a quarter of patients fail to demonstrate a serological rise in titre due to their late presentation to medical attention. A preferable serological test is the MAC-ELISA on serum or CSF, or a more recently developed particle agglutination assay, which detects JEV-specific IgM. The detection of specific IgM antibodies in CSF is diagnostic of acute Japanese encephalitis.

Virus isolation from blood is rarely successful during the acute illness because the viraemic phase is probably over by the time central nervous system symptoms appear. Virus isolation from the CSF is usually also unsuccessful and, if positive, indicates a poor prognosis, as mentioned above. A variety of isolation techniques are very sensitive

to JEV, including intracerebral inoculation of suckling mice, intrathoracic inoculation of live mosquitoes, the use of common mammalian cell lines such as Vero and LLC-MK2 and mosquito cell lines, especially those of *A. albopictus* and *A. pseudoscutellaris*.

Control

The major component of the control of Japanese encephalitis is widespread immunization of both humans and domestic animals, especially pigs. A number of human vaccines have been developed. A formalin-inactivated lyophilized vaccine of mouse brain origin, derived from the Nakayima-NIH strain of JEV, is prepared by Biken, Japan, and widely used in Japan and Korea and also by travellers to endemic areas. In China, a BHK-prepared inactivated vaccine is used. Both vaccines are highly immunogenic and protection rates of over 90% are achieved. Experimental live attenuated vaccines are being developed and Chinese workers have successfully attenuated the SA14 strain by 100 passages in BHK cell culture (Stephenson, 1988). The live attenuated vaccine (SA14-14-2) is now widely used in China. Recombinant DNA technology also holds promise for the future development of safe, effective Japanese encephalitis vaccines (Konishi *et al.*, 1991). ChimeriVax-JE using YF 17D as a live vector for the envelope genes of SA14-14-2 is in the trial stage. Similarly, a number of veterinary vaccines have been used in pigs and horses. Vaccination thus holds the potential to eliminate Japanese encephalitis. Reports of allergic reactions to the Biken vaccine have resulted in a cautionary warning being issued against routine administration of Japanese encephalitis vaccine to travellers, except to those who are likely to be at high risk in endemic areas, particularly rural areas, for a month or longer during the season of vector activity (Nothdurft *et al.*, 1996).

Because humans are only an incidental host, interruption of transmission of the virus would be independent of the extent of immunity in human populations, and eradication of infection would need to aim for the elimination of virus circulating in the vertebrate reservoir of domestic animals. At present, economic realities preclude anything approaching a sufficiently widespread programme of immunization in domesticated pigs.

Vector control is difficult because of community resistance to mosquito control programmes, which need to include and may significantly tamper with subsistence agriculture of rural populations. Thus, methods which have been attempted include short-term drainage of rice fields and attempts to introduce more drought-resistant rice in order to reduce potential mosquito-breeding sites. Ultra-low-volume insecticide spraying has had limited success, with increasing insecticide resistance, especially

in *C. tritaeniorhynchus*. Measures to prevent biting by mosquitoes, such as the use of insect repellents, mosquito netting, and so on, should be encouraged. Most biting activity is concentrated at nightfall.

ST LOUIS ENCEPHALITIS

St Louis encephalitis virus was isolated in 1933 from human brain following an outbreak of encephalitis in St Louis, Missouri. It was the major cause of epidemic viral encephalitis in the United States before the appearance of WNV in the United States in 1999. Although the distribution of the virus ranges from southern Canada to Argentina and a few sporadic cases have been reported in South and Central America, virtually all cases of human disease have occurred in the United States.

Viral Features and Host Range

Antigenically, SLEV is closely related to the other members of the Japanese encephalitis subgroup of flaviviruses. In addition, cross-immunity to other flaviviruses has also been demonstrated, including dengue virus type 2. Antigenic heterogeneity has been shown with monoclonal antibodies, although there is no evidence that this has any epidemiological implications. Phylogenetic analysis of the E protein suggests that SLEV isolates form a monophyletic group in which isolates are generally clustered according to geographic origin. Only 10% variation exists between the strains from different regions. Isolates from Panama and South America predominantly fall into two large groupings, while isolates from the United States form two other major groups. Several strains from South and Central America were identified that were more closely related to strains isolated in the United States. This suggested that SLEV is predominantly maintained locally although strains are occasionally transported between regions (Kramer and Chandler, 2001).

The major vertebrate hosts of SLEV are birds, especially sparrows (*Passer domesticus*), which act as the main amplifying host (Centers for Disease Control and Prevention, 1991b). In addition, small mammals such as raccoons, opossums and rodents are also infected, as well as a variety of domestic animals. However, other than birds, there is no evidence that animals play any role as maintenance or amplifying hosts.

Invertebrate vectors of SLEV are various species of *Culex* mosquitoes, depending on location. In the rural west it is *Culex tarsalis*, in the northern and southern regions of the central United States it is mainly *Culex pipiens* and *Culex quinquefasciatus*, and in Florida *Culex nigripalpus*.

Epidemiology

In all parts of the United States the transmission cycle of SLEV involves birds and mosquitoes. Humans and probably domestic animals are incidental and dead-end hosts. Epidemiological characteristics, however, differ in the three regions described above. Thus, in the central United States, where *C. pipiens* and *C. quinquefasciatus* are the major vectors, epidemic outbreaks result from the build up of virus in house sparrows and mosquito larvae breeding in discarded containers and open house foundations, characteristic of older housing construction. Regular outbreaks have occurred at approximately 10-year intervals until 1977, followed by irregular, unpredictable outbreaks observed in large urban localities. In the western United States, SLEV occurs as low-grade endemic activity transmitted by *C. tarsalis* and associated with agricultural irrigation, although there are exceptions, such as the large focal outbreak in Los Angeles in 1984, which was probably due to *C. pipiens* acting as an accessory vector.

Clinical Features

The majority (over 90%) of infections with SLEV are asymptomatic. In clinically apparent cases the disease is characterized by an abrupt onset of a febrile illness accompanied by constitutional symptoms of malaise, nausea, vomiting and headache. Occasionally there may be a more slow insidious onset. Central nervous system involvement may be in the form of aseptic meningitis or focal encephalitis. Encephalitis signs may be manifested as neck stiffness, dizziness, ataxia, mental confusion and disorientation. Cranial nerve palsies may occur in about 20% of cases, but the absence of focal findings or seizures may be useful differential features to distinguish St Louis encephalitis from cases of focal encephalitis, such as herpes simplex. In more severe cases there may be midbrain involvement and progressively severe coma. Overall case fatality is approximately 9% of symptomatic cases, although in outbreaks it may reach 20%. The likelihood of encephalitis, and also its severity, is related directly to age, with case fatalities in the elderly during outbreaks reaching 30% (Monath, 1980).

Diagnosis

For rapid serological diagnosis of SLEV infection, the MAC-ELISA is the method of choice, using either serum or CSF. Cross-reactions may occur if other flaviviruses are active in the area, but this is not a major factor in North America. The immunofluorescence test on SLEV-infected cells is a useful alternative to the IgM ELISA for testing sera, and the HAI test may be used for surveys or diagnosis if acute and convalescent sera are available.

In regions where flavivirus activity is confined mainly to one virus, the HAI test would be a useful screening test, followed by the SLEV MAC-ELISA test to determine recent SLEV infection.

Control

Although Sabin developed an inactivated mouse-brain vaccine during the Second World War, no licensed vaccine is available at present because of the low priority accorded to the infection. Similarly, specific vector control programmes directed at SLEV are either impractical or thought not to be of sufficient urgency. Secondary measures to protect against mosquito bites, such as insect repellent and screening, may be of some benefit during reported outbreaks.

WEST NILE VIRUS

West Nile virus is one of the most ubiquitous of human arbovirus infections. The virus was first isolated from a febrile patient in the West Nile province of Uganda in 1937. Since then it was shown to be widely distributed throughout Africa, the Middle East, Asia, parts of Europe and Australia and since its invasion of the Western Hemisphere in 1999 has spread throughout the United States, southern Canada, South America and the Caribbean.

Viral Features and Host Range

According to NT tests, WNV is related to the other members of the JE serogroup of flaviviruses. At least two distinct lineages, lineage I and II, exist although a further three lineages have been proposed. Lineage I has initially been divided into three different sublineages. Lineage 1a consists of viruses from North Africa, the Middle East, Europe, and North and South America, 1b consists of Kunjin virus strains from Australia and 1c consists of strains from India. Lineage II consist mainly of viruses from Southern Africa and Madagascar although a single lineage II isolate has been associated with encephalitis in a goshawk fledgling in Hungary in 2004, suggesting that lineage II strains may be carried outside of this region by migratory birds (Bakonyi *et al.*, 2006; Beasley *et al.*, 2002; Burt *et al.*, 2002; Lanciotti *et al.*, 2002). Recently two new variants of WNV have been identified in *C. pipiens* mosquitoes in the Czech Republic (Rabensburg (97–103) and in *Dermacentro marginatus* ticks in the North-West Caucasus Mountain Valley of Russia (LEIV-Krnd88–190). Based on their distance to lineage I and II strains these two isolates have been proposed to represent two new lineages (lineages III and IV) (Bakonyi *et al.*, 2005; Lvov *et al.*, 2004). This led

to the re-evaluation of WNV phylogenetic clusters using both full genome and partial genomic sequences (921 nucleotides of the C-prM-E). Five distinct lineages that differ by 20–26% at the complete genome level have been proposed. Lineage I includes the lineage 1a and 1b sublineages, but the Indian strains that formerly formed sublineage 1c were reclassified as a separate cluster (lineage V); lineage II includes the Southern African strains and the strain from Hungary; lineage III includes the Rabensburg (97–103) strain as prototype and lineage IV includes strain LEIV-Krnd88–190 from Russia (Bondre *et al.*, 2007).

Since the late 1990s an increase in neurological disease has been noted in humans, horses and birds as a result of WNV infections in North Africa, Europe and the Middle East and since its emergence in the Western hemisphere in 1999 has become a major public health problem in the United States. Although initial speculation suggested that lineage I strains were more pathogenic than lineage II strains, phylogenetic analysis and mouse neuro-invasive experiments have shown that highly neuro-invasive and mild strains exist in both lineages and that the neuro-invasive phenotype is related to genotype not to lineage. The perceived virulence of WNV in recent epidemics probably reflects high medical alertness, active surveillance programmes and the emergence and re-emergence of existing strains of WNV in geographic locations with immunologically naive populations. The lineage I strain that was imported into North America in 1999/2000 has been demonstrated to be highly neuro-invasive in mice and its uniform spread across the continent may also account for a higher incidence of neuro-invasive disease (Beasley *et al.*, 2001; Burt *et al.*, 2002; van der Poel, 1999). Phylogenetic analysis suggests that the virus has remained highly conserved since its emergence in the United States; although two distinct populations have emerged, the maximum divergence of recent strains compared with the NY99 prototype is still only 0.4–0.5%. A small number of WNV isolates from the United States (Texas) and Mexico have been obtained that have an attenuated phenotype in mice which was associated with mutations in the NS proteins or loss of E protein glycosylation respectively (reviewed in Beasley, 2005).

The maintenance and amplification of WNV in nature is between birds, which is the major vertebrate host, and mosquitoes. In endemic countries the majority of bird species tested appears to be resistant to WNV disease. Susceptible birds sustain infectious viraemia for one to four days after exposure before developing lifelong immunity. In South Africa high titres of WNV antibodies were detected in 27 species of wild birds tested without isolating virus from any. Inoculation experiments demonstrated

high levels of viraemia that lasted three to four days in 13 common avian species found near Johannesburg with no illness or mortality (Jupp, 2001). Death has however been reported in young ostrich chicks in South Africa (Burt *et al.*, 2002). WNV-associated bird mortality has rarely been reported from Europe, although recent reports from Central Europe of an encephalitis outbreak in a flock of geese that resulted in a 14% death rate in six-week-old geese as well as a goshawk fledgling suggest susceptibility in young or non-endemic migratory birds (Bakonyi *et al.*, 2006).

It has been suggested that migratory birds are central in the transmission between continents. Various outbreaks have also been reported in storks and geese in Israel (Malkinson *et al.*, 2002; Steinman *et al.*, 2002). In contrast to endemic countries, major bird deaths have been recorded in the United States since 1999. Around 284 species of birds have been reported in the CDC mortality database. Vector competency indices suggested that the blue jay, common crackle, house finch and American crow and sparrow are the most important species involved in WNV amplification (www.cdc.gov/ncidod/dvbid/westnile/birdspecies.htm).

In addition to birds, the virus is able to infect a variety of domesticated animals (particularly equines) and wild animals, as well as humans and sub-human primates. The most significant outbreaks in animals have occurred in horses in particular in Europe, the Middle East and the United States (Steinman *et al.*, 2002; Trock *et al.*, 2001). Approximately 15 000 equine cases occurred in the United States during the 2002 season; however the introduction of an inactivated vaccine has dramatically decreased the number of cases in subsequent seasons. These are generally considered as dead-end transmissions due to a lack of significant viraemia in these hosts to facilitate further transmission. Isolations from a wide range of vertebrate hosts, including dogs, sheep, alpacas, a number of wild mammals, as well as crocodiles and the death of a harbour seal demonstrates the wide susceptible host range (reviewed in Beasley *et al.*, 2004).

The maintenance vectors of WNV consist of a variety of mosquitoes, especially of the genus *Culex*. The major *Culex* mosquito vector in Africa and the Middle East is *Culex univittatus*; in South East Asia, *C. tritaeniorhynchus*; and in France, *Culex modestus*. Although WNV has been identified in as many as 59 different mosquito species in North America, only 10 of these are considered to be the principal vectors. During the 1999 outbreak 57% of positive mosquito pools were *C. pipiens*, however as the virus spread westward, *C. tarsalis* became more common in 2003, while *C. quinquefasciatus* comprised 51% of positive pools in 2004 as the major outbreaks occurred in the south-west.

Epidemiology

The transmission cycle of WNV consists mainly of wild birds as the vertebrate host and ornithophilic *Culex* mosquitoes as the maintenance vector. The intensity of transmission appears to be determined by the abundance of competent vectors as well as the infection rate of these mosquitoes (reviewed in Hayes *et al.*, 2005).

Major epidemics of WNV have been reported in Israel during the 1950s, in France in 1962 and the largest epidemic ever recorded took place in South Africa in 1974, which involved tens of thousands of individuals. Epidemics have occurred characteristically in relatively localized areas, for example, close to Tel Aviv in the Israeli epidemic, in the Rhone delta in France and the semi-desert Karoo region and in and around major cities of the highveld of South Africa. The distribution of WNV in South Africa is predominantly in the inland plateau region, where it shares the same geographical distribution and ecology as Sindbis virus, which also produces a disease that is usually clinically indistinguishable from WNV. The presence of WNV in the United States was first recognized in 1999, and then spread extensively across the United States and the Caribbean as well as southern provinces of Canada, Mexico and South America. From 1999 to May 2007, 23 974 cases have been reported in the United States of which approximately 9849 were neuro-invasive disease with 962 fatalities (data from the USA CDC website, as of May 2007). Despite this large number of cases the infection rate in epidemics in the United States, Europe and the Middle East has been <5%. Such low infection rates will not reduce the frequency of epidemics through protective immunity (Hayes and Gubler, 2006). During major outbreaks in South Africa, high attack rates in humans have been observed, for example, in some of the worst-affected towns in South Africa, 50–80% of the human population were infected due to the high rate of feeding by *C. univittatus*. This mosquito is probably also responsible for sporadic cases in inter-epidemic periods. Seroprevalence in the 1950s to 1970s in South Africa ranged from 17% in the Karoo to 8% in the highveld and 2% in Natal outside of epidemics (McIntosh *et al.*, 1976). No recent serological data are available.

Outbreaks of WNV, as with many other arboviruses, have been governed by climatic conditions, such as heavy rainfall, particularly in early and late summer, and high summer temperatures. In the early stages of the epidemic in the United States, WNV infection was recognized in mid to late summer. In 2002 the virus was detected as early as May. Because viraemia is low in humans, epidemic activity is directly due to infection of mosquitoes from viraemic birds and human outbreaks are merely the 'spill-over' of extensive epizootic activity in birds—an

important factor which facilitates epidemiological surveillance. Furthermore, no human-to-human transmission occurs, although transmission reports of transfusion and organ donor infection has necessitated the screening of blood from donors in countries affected in the Western Hemisphere. A case of intrauterine transmission has also been reported. As is the case with JEV, human population immunity has no bearing on the suppression of epidemic activity itself, and susceptible individuals remain vulnerable irrespective of the proportion of immune individuals in the population.

Clinical Features

The majority of WNV infections are asymptomatic. Symptoms will develop in 20–40% of people infected with the virus, and most of these will present with a flu-like mild febrile illness (West Nile fever). The onset of disease is characteristically sudden, following a short incubation period of three to five days. Fever is usually the first sign, followed by headache, nausea and vomiting. Ocular pain is frequently reported, as is pharyngitis. Muscle pain occurs diffusely and there may be arthralgia.

During the first few days after onset, a maculopapular rash usually appears which is discrete, with each of the rash elements demarcated by a sharp halo. The rash usually first appears on the trunk and then spreads to the face and extremities, and may persist for a week. Unlike measles, there is no desquamation.

Convalescence is rapid in children but may be somewhat more prolonged in adults and characterized by weakness and malaise. The illness not infrequently recrudesces during the convalescent period. Although WNV is classified virologically within the JEV group of mosquito-borne encephalitis, involvement of the central nervous system was believed to be very rare, with 1% of cases resulting in meningoencephalitis. Since the mid-1990s an increase in cases of neuro-invasive disease and death was noted in the Middle East and Europe, and in the United States up to 41% of reported clinical cases showed some evidence of meningoencephalitis. Acute flaccid paralysis (AFP) attributed to Guillain–Barré syndrome has been associated with WNV infection, several cases having been reported in the United States (Centers for Disease Control and Prevention, 2002). Up to May 2007, approximately 4% of reported cases in the United States were fatalities. Although all ages may be affected by WNV, the frequency of neuro-invasive disease is significantly higher in elderly and immunocompromised patients. Although initial reports suggested that WNV neuro-invasive disease rarely occurs in children, from 2002 to 2004 more than a thousand cases have been reported in children younger than 19 years in the United States, and 30% of these were neuro-invasive (Davis *et al.*, 2006).

Rarely, cases of visceral involvement including severe hepatitis, occasionally with a haemorrhagic presentation, have been reported.

Diagnosis

The HAI, CF or NT tests can be used for serological diagnosis of WNV infection. The HAI test detects antibodies within a few days after onset, but the MAC-ELISA is recommended as the diagnostic test of choice for WNV infection. Cross-reactivity is not a problem in patients with no previous exposure to flavivirus infection or vaccination. The NT assay would be used to identify specific flavivirus antibodies.

Virus isolation may be readily achieved from blood from infected individuals, despite lower levels of viraemia. Suckling mice are particularly sensitive to intracerebral inoculation and, in addition, cell culture of mammalian origin as well as insect cell lines are commonly used for virus isolation. RT-PCR is a rapid method for the detection of WNV viral RNA. Because of the short viraemic period this is not the test of choice and will usually be combined with serological tests. Screening of blood donations for viraemic WNV patients is achieved by RT-PCR. Real-time RT-PCR that can reliably detect all lineages has been reported (Tang *et al.*, 2006).

Control

With the impact of WNV on human health in the United States, there has been increasing interest in the development of a vaccine: During outbreaks, vector control by insecticide spraying may be applied. Epidemiological surveillance makes use of sentinel animals, such as hamsters, goats, guinea-pigs or pigeons, to detect early warning signs of impending outbreaks. The introduction of an inactivated vaccine for use in horses has dramatically reduced the number of neuro-invasive cases in these animals since 2004.

MURRAY VALLEY ENCEPHALITIS

MVEV is a relatively uncommon cause of human disease—less than 1000 cases have been reported—all of them confined to Australia and New Guinea.

The disease was first recognized during two epidemics of a virulent encephalitis in Queensland and in the Murray Valley in 1917 and 1918. A number of epidemics were subsequently described until 1925, when there was an inexplicable gap until the 1950s. The last substantial epidemic took place in 1974 and since then only a few individual sporadic cases have occurred.

The infection is found in a patchy distribution from New Guinea through Darwin to the northern parts of Western Australia and down the east coast as far south as Brisbane, and in the basin of the Murray Darling River. The virus was reintroduced to central Australia in 2000 following a period of unusually high rainfall.

Viral Features and Host Range

The virus displays a close relationship with Kunjin virus and also JEV. Four distinct lineages can be demonstrated based on E protein sequencing: lineages I, II, III and IV. Lineage I contains mostly strains from Western Australia, as well as some strains from Queensland and Papua New Guinea. Strains from Papua New Guinea and Australia are the most divergent within this lineage with 94% nucleotide identity, while strains from Australia have a sequence identity of 96%. Lineage II consists only of strains isolated in Western Australia in 1971 and in 1995, and is more closely related to lineage III and IV strains (87% nucleotide identity) from Papua New Guinea than to lineage I strains (84% nucleotide identity). Lineages III and IV consist exclusively of two strains identified in Papua New Guinea in 1956 and 1966 respectively. Recent isolates of MVEV from the Western Province in Papua New Guinea were closer to Australian isolates of MVEV than to older isolates from Papua New Guinea in 1956 and 1966, providing evidence for the movement of flaviviruses between Papua New Guinea and Australia (Johansen *et al.*, 2007).

Epidemiology

The major maintenance vector is *Culex annulirostris* and a number of vertebrate hosts, chiefly wild birds, are involved in the transmission cycle. Domestic animals are infected, but they probably do not play any significant role as amplifying hosts. Outbreaks have characteristically occurred in the summer months.

Clinical Features

As with most other arboviruses, the vast majority of infections are asymptomatic, only about 1/800–1000 infections being clinically manifest (Anderson, 1954). Once clinical disease occurs, however, high case fatality rates of 18–42% have characterized the various outbreaks. The clinical features in symptomatic patients are a sudden onset of high fever (up to 40.6 °C), nausea, vomiting and severe frontal headache. Signs of encephalitis vary from mild neurological involvement with disturbances of consciousness and neck stiffness to rapid onset of coma with respiratory failure. Patients with severe neurological involvement and coma, who were kept alive on life-support

systems and subsequently survived, have all had remaining permanent and severe sequelae.

Diagnosis

Serology is generally carried out by HAI or ELISA tests. The RT-PCR assay may detect MVEV early after onset of illness, providing a rapid and specific diagnosis.

TICK-BORNE ENCEPHALITIS

Genetic analysis of the tick-borne flaviviruses suggests that these viruses can be assigned into three major groups (mammalian, seabird and Kadam tick-borne flavivirus groups). The mammalian tick-borne flavivirus group includes six human and animal pathogenic viruses, formerly known as the ‘tick-borne encephalitis serocomplex’. These include louping ill virus (LIV), TBEV, OHFV, Langat virus (LGTV), Kyasanur Forest disease virus (KFDV) and Powassan virus (POWV). All of these are encephalitic viruses, with the exception of OHFV and KFDV species, which cause haemorrhagic fever in humans. The recently identified haemorrhagic virus that appeared in Saudi Arabia in 1992, identified as Alkhurma haemorrhagic fever virus (AHFV), has been recommended for inclusion as a subtype of KFDV. No genetic link could yet be identified to viruses associated with haemorrhagic fevers (Grard *et al.*, 2007).

Although serological tests such as HAI and CF give considerable cross-reactivity with members of the flavivirus group, the tick-borne encephalitis subgroup of flaviviruses are far more closely genetically and antigenically related to each other. In contrast to many of their mosquito-borne arbovirus counterparts, the tick-borne encephalitis subgroup is found almost exclusively (with some exceptions, such as louping ill in the United Kingdom and Powassan in North America) in Asia and Eastern and Central and Western Europe. Within the subgroup is the entity of TBEV, which consists of three subtypes: TBE-Western European subtype, TBE-Far Eastern subtype and TBE-Siberian subtype, all transmitted mainly by *Ixodes* ticks. Other viruses within the tick-borne encephalitis subgroup are OHFV, KFDV and POWV, which will be considered separately.

Virological Features

On the basis of the recent availability of the complete genome sequences of all of the members of the mammalian tick-borne flaviviruses, certain changes have been proposed to the taxonomy of the TBEV. Grard *et al.* (2007) proposed that a single species of virus could be created namely TBEV, with four different types:

LIV, which includes Spanish, British and Irish subtypes and although infectious for humans, mainly causes encephalitis in sheep; western tick-borne encephalitis virus (W-TBEV); eastern tick-borne encephalitis virus including Far Eastern tick-borne encephalitis virus (FE-TBEV) and Siberian tick-borne encephalitis virus (S-TBEV) subtypes which are important human pathogens; and Turkish sheep encephalitis virus, including the Greek goat encephalitis virus subtype. They supported this taxonomic proposal by cut-off distances for species demarcation at 0.09 based on complete amino acid sequences and at 0.063 based on the complete NS3 protein (Grard *et al.*, 2007).

All subtypes of TBEV are transmitted by ticks in the *Ixodes* genus. The W-TBEV subtype are transmitted by *Ixodes ricinus*, while the FE-TBEV and the S-TBEV are transmitted by *Ixodes persulcatus*. The amplifying host are thought to be small rodents while wild animals (goat and deer) contribute indirectly through feeding of adult ticks thereby maintaining the tick population. *I. ricinus* species are distributed through Europe, Central Asia and parts of northern Africa, while *I. persulcatus* are found in Russia as well as northern Japan. Since both tick species are present in the Baltic countries, Latvia and Estonia, all three TBEV subtypes have been shown to co-circulate in both (Golovljova *et al.*, 2004; Lundkvist *et al.*, 2001). The western (European) subtype includes viruses isolated from Russia in the east through Finland and Sweden in the north, through Germany to France in the west and down to Italy, Greece and Yugoslavia in the south, encompassing the Central European countries in between. The eastern subtype includes the Far Eastern viruses isolated in northern Japan and the Siberian viruses isolated in the taiga region (the coniferous forest belt on the edge of the steppes and the tundra region of Siberia) and in western Siberia (reviewed in Suss and Klaus, 2006).

The TBEV are closely related to each other and are distinguishable serologically only by monoclonal antibodies or specialized techniques such as antibody adsorption tests. However, monoclonal antibody studies of the W-TBEV, especially those directed against glycoprotein domains, demonstrate a degree of antigenic complexity. Also, studies of different isolates of Far Eastern subtypes from different geographical locations have shown a heterogeneity of biological characteristics, such as mouse pathogenicity and plaque size. The viruses display clearly distinguishable biological differences from each other. The distribution of the infections closely follows that of their arthropod vectors—*I. ricinus* in the case of western subtypes and *I. persulcatus* in the case of Far Eastern and Siberian subtypes, although in countries in the Baltic region where both types of ticks occur, the western subtypes have been isolated from *I. persulcatus*. Recently reports of

isolations of Siberian and Far Eastern subtypes of TBEV have also been made in Europe.

The pathogenic potentials of the W-TBEV, S-TBEV and FE-TBEV subtypes also differ. Infection with the western subtype causes a biphasic febrile illness, characterized by a viraemic phase with fever, malaise, headache, myalgia, leukocytopenia, thrombocytopenia and elevated liver enzymes; this is followed by a one-week latent period, after which 25% of patients develop neurological disease, which may include meningitis or meningoencephalitis and poliomyelitis in a small number of cases. Although residual sequelae are observed in 25–50% of patients, less than 2% of these are fatal. W-TBEV has also been shown to induce a very much milder disease in experimentally infected sheep and monkeys than the Siberian and Far Eastern subtypes. In contrast, the Siberian and Far Eastern subtypes present as monophasic syndromes. Human infections reported in the East Asia are usually severe and are often associated with neurological signs with a fatality rate of 5–35%, although chronic cases are rare. In contrast, TBEV infections in Siberia causes less severe disease with fatality rates that range between 1 and 3%, although chronic forms are often reported. Recently eight fatal cases were reported in the Novosibirsk region of Siberia caused by Far Eastern strains that were associated with a pronounced haemorrhagic syndrome with massive gastrointestinal bleeding and multiple haemorrhages in mucosa and internal organs. Experimental data suggest that the Far Eastern strains have a clear tropism for neurons, which may account for the degenerative manifestations that are frequently associated with infection (reviewed in Charrel *et al.*, 2004).

Domestic animals, such as sheep, goats and cows, infected with TBEV excrete virus in their milk. The virus is also relatively stable to low pH and, experimentally, animals can rarely be infected by oral inoculation. In humans, milk-borne transmission of TBEV through ingestion of goat, sheep or cow's milk or dairy products made from them, such as cheese, is an important route of acquisition.

Epidemiology

W-TBEV, S-TBEV and FE-TBEV are endemic diseases with an increased seasonal incidence in the warmer months, April to November, related to climatic conditions of temperature and humidity, which affect tick activity. It is estimated that approximately 3000 cases of tick-borne encephalitis occur in Europe which translates to less than four cases per 100 000. The highest number of cases are reported in Latvia, where up to 199 cases per 100 000 population have been reported, although rates of 50–100 per 100 000 are more common. The incidence of tick-borne encephalitis has increased during the past

20 years, and the virus is now detected in previously unaffected areas. Changes in climate and vector distribution may account for the changes in tick-borne encephalitis incidence, although the decrease in disease in Sweden from 1984 onwards seemed to occur independently of the increase in recorded temperatures from 1989 (reviewed in Charrel *et al.*, 2004). In Russia an average of 12 cases per 100 000 population is reported. In China, TBEV is frequently detected in the Hunchun area, Jilin province and has been isolated from *Hymenocallis concinna* ticks. Antibody prevalence in humans in this region is as high as 10.9%. In the subtropical region of western Yunnan near the Burmese border, TBEV isolated from *Ixodes ovatus* was closely related to Russian spring summer encephalitis virus (RSSEV). Although data on tick-borne encephalitis morbidity are scarce, 3500 cases of the disease were reported in 1994 (reviewed in Suss and Klaus, 2006).

Infections occur predominantly in rural populations, especially farmers and forest workers. In addition, some 10–20% of W-TBEV infections are transmitted through ingestion of goat, sheep and cow's milk and dairy products. Seroprevalence studies of RSSEV have shown population prevalences of up to 50% in inhabitants of the taiga. Seroprevalence to W-TBEV depends on rural residence, occupation and age. Thus, in various studies in Central Europe, seroprevalence figures of 11–20% have been found in hunters, 5% in farmers and 1% in children (Gresikova *et al.*, 1973).

Infections with LIV are usually occupational, for example in sheep farmers, veterinarians and abattoir workers. A seroprevalence of up to 8% has been found in abattoir workers, suggesting asymptomatic infection. A large number of laboratory-acquired infections have been reported, which may indicate transmission by direct mucous or respiratory pathways. Tick-transmitted cases in humans are scarce (Charrel *et al.*, 2004).

Clinical Features

Disease caused by W-TBEV is relatively mild, with a low fatality of less than 5%. The incubation period is one to two weeks, followed by symptoms and signs of a non-specific febrile illness, headache, nausea, vomiting and lassitude; occasionally some signs of neurological disorders may appear, especially related to visual disturbances: blurring of vision and diplopia. This initial viraemic phase of the illness usually lasts some four to six days and is followed by a brief remission period.

The majority of individuals infected probably only experience a monophasic illness, which is rarely diagnosed specifically.

The second phase of the biphasic illness commences after a brief remission period, and is heralded in by a recrudescence of fever and signs of meningitis. The

most important signs of encephalitis are extrapyramidal and cerebellar syndromes, which may often persist for months after recovery. Localizing neurological signs, such as cranial nerve involvement, occur uncommonly and are usually mild. The mortality in various outbreaks that have been studied has varied (1–5%).

A more severe degree of encephalitis is usually seen with E-TBEV. The incubation period is similar but this is usually followed by sudden onset of fever and constitutional symptoms and, in the second phase of illness, a more intense meningitis. In some individuals an aseptic meningitis picture may be the sole clinical manifestation of disease. In others encephalitic signs and symptoms, such as disturbed consciousness, may lead to stupor, coma and death. A characteristic feature is lower motor neuron paralysis, which may resemble poliomyelitis but usually predominantly affects the upper limbs, spreading to the neck, and which may be followed by bulbar paralysis and death. The reported case fatality rates have varied (8–54%). In addition, residual paresis and atrophy of muscles of the upper limbs and neck may persist for long periods. Post-recovery epileptiform seizures may reflect permanent neurological damage.

The clinical symptoms of LIV in humans are similar to that of the biphasic meningitis typical of Western European TBEV. Following an incubation period of four to seven days, patients present with influenza-like illness with fever, headache, dizziness, retro-orbital pain, articular pain and myalgia. Patients usually then improve although in 50% of cases an encephalitic phase follows. A petechial rash is sometimes visible, with leukopenia in the first stage and leukocytosis in the second (Charrel *et al.*, 2004).

Diagnosis

MAC-ELISA on serum or CSF is the serological test of choice for diagnosis of TBEV infection. The HAI test is useful but a significant rise in antibody level must be demonstrated before a diagnosis can be made. Virus can be isolated from blood or CSF but specimens must be taken early after onset of symptoms. The virus may also be readily isolated from post-mortem tissues such as brain and also infected tick pools. The virus is readily isolated by intracerebral inoculation of suckling mice or cell cultures, such as Vero or chick embryo. RT-PCR assays are available, however because of the short viraemia period and low level of RNA present, virus isolation and RT-PCR is not often successful.

Control

Two commercially available vaccines are currently available and used widely in Central and Eastern Europe, namely new versions of Encepur (Chiron Vaccines,

Marburg, Germany) and FSME-IMMUN (Baxter Vaccines, Vienna, Austria). For paediatric applications, half the antigen dose in a 0.25 ml volume is available (FSME-IMMUN Junior). Both manufacturers' TBEV vaccines are considered safe and highly protective. The conventional vaccination schedule for both vaccines consist of three doses at day 0, months 1–3 and months 9–12 (or 5–12 months after the second dose). Rapid immunization schedules consisting of three doses at days 0, 7 and 21 are licensed for the historical and current versions of Encepur adults and Encepur children. First booster doses are given every 12–18 months then every five years in individuals ≤ 60 years and every three years in individuals > 60 years (reviewed in Beran, 2005).

Two licensed vaccines have been prepared from formaldehyde-inactivated, purified and concentrated Far Eastern subtype and Sofjin strains of TBEV, one called EnceVir (Virion, Tomsk, Russia), which has been available since 2001, and another produced at the Institute of Poliomyelitis and Viral Encephalitis (Moscow, Russia) since 1984. Both are certified for use in children. Up to 7 million doses have been used in Russia. The primary course of vaccination consists of three doses for both vaccines. Prevention has also been achieved though specific immunoglobulins, administered to tick-bitten people within three days of the tick bite. This therapy has a reported efficiency of 98% in a curative context and 100% in a prophylactic context (Charrel *et al.*, 2004).

OMSK HAEMORRHAGIC FEVER

Viral Features and Host Range

Omsk haemorrhagic fever virus was isolated in 1967 from the blood of a patient in western Siberia. It is closely related to TBEV and cannot be differentiated using polyclonal hyperimmune sera. They are differentiated on gel precipitation using cross-absorbed monospecific sera. The infection is conveyed by ixodid ticks, *Dermacentro reticulatus* and *D. marginatus*. A number of animal species are susceptible and the virus has been isolated from wild rodents. However, the most important vertebrate host is the muskrat (*Ondatra zibethica*), which is highly susceptible to infection, the virus usually producing a rapidly fatal haemorrhagic disease. The virus is excreted in the urine and faeces of sick animals and horizontal infection as well as arthropod infection is thought to play a role in transmission. The majority of human infections (60%) have occurred in hunters of muskrats, with transmission occurring as a result of direct contact during the skinning of animals. A further 28% of infections occur in adult family contacts of hunters.

Epidemiology

Infection has been limited to the Omsk region in the forest-steppe landscape of western Siberia, adjacent to tick-borne encephalitis endemic zones. The majority of cases were recorded between 1945 and 1949. Between 1945 and 1958, a total of 1488 cases were recorded. Occasional laboratory-acquired infections have been reported (Jelinkova-Skalova *et al.*, 1974). In recent years, most human cases have been related to direct contact with muskrats (*O. zibethica*), during the hunting season from September to October. A total of 165 cases of OHFV were recorded between 1988 and 1997. Of these, only 10 were transmission through tick bite while the rest were associated with exposure to muskrats. Muskrats were introduced into Siberia from Canada in 1928 and are therefore a relatively new host for the OHFV. Although the reason remains unknown, the OHFV endemic area is much smaller than the areas in which dermacentor ticks and muskrats are distributed (Charrel *et al.*, 2004).

Clinical Features

Clinically the disease presents with a sudden onset of fever, headache and myalgia. There is a recrudescence of fever followed by haemorrhagic manifestations, especially epistaxis, but also gastrointestinal bleeding and bleeding at other sites. Bronchopneumonia is a frequent complication and occasionally meningitis may occur with long-term complications, such as psychomotor retardation and depression.

Diagnosis and Control

Infection may be diagnosed by isolation of virus from patients' blood and intracerebral inoculation into suckling mice. Serological testing by ELISA, CF and NT are also available. Control measures to prevent infection involve the avoidance of ticks and care in handling muskrat carcasses in endemic areas, as well as laboratory safety measures. Because of extensive cross-reactivity, Central European encephalitis (CEE) vaccine would probably impart good protection. OHFV is classified as a biological safety level (BSL)-4 pathogen in most countries.

KYASANUR FOREST DISEASE

Viral Features and Host Range

The first isolation of KFDV was made in 1957 from a dead monkey found near the Kyasanur State forest in Kamataka (formerly Mysore) State in India. A few months previously a lethal epizootic amongst monkeys had been reported in the adjacent forested areas, with

human cases termed 'monkey disease' by the villagers. So far all human cases (on average, about 500 per year) have been limited to Karnataka State, in addition to a number of laboratory-acquired infections in both India and the United States. There is no evidence of the disease having existed prior to 1957.

Epidemiology

In addition to monkeys, a number of rodents are known to be infected, such as rats and shrews, as well as bats and other animals. The main tick vector is *Haemaphysalis spinigera*. Infection occurs predominantly in poor villagers working in forests.

Clinical Features

The disease is characterized by a sudden onset of fever after an incubation period of three to eight days. The fever may rise rapidly to 40 °C, associated with headache and severe myalgia reminiscent of dengue fever. Muscle pain is also predominantly found in the back and neck regions. A regular finding in patients in the acute stage is papulovesicular lesions on the soft palate. There is usually a cervical and axillary lymphadenopathy but occasionally this is generalized. Earlier reports of the disease laid great emphasis on the haemorrhagic manifestations, which occurred as early as the third day of illness. These consist of bleeding from the nose, gums and gastrointestinal tract. Associated with this there is a marked thrombocytopenia and neutropenia, but no evidence of bone marrow suppression or capillary damage. The cause of the haemorrhagic diathesis has more recently been thought to be autoimmune in nature (Pavri, 1989). Many of these earlier cases were reported in poor villagers, who were often infected with bacteria and parasites, and the associated raised interferon levels and IgE antibodies may also have contributed to the original clinical picture. Later studies of the disease, including those of laboratory-acquired infections, have rather put emphasis on neurological complications, such as severe headache, neck stiffness, coarse tremors, abnormal reflexes and mental disturbances. Mortality in Kyasanur Forest disease is approximately 5–10%.

Diagnosis and Control

The virus can be readily isolated from patients' blood using mice or cell culture and antibodies can be detected by HAI, CF, NT or ELISA tests. Vector control programmes have been carried out in the forest, especially spraying in the vicinity of dead monkeys when these are encountered. A formalin-inactivated vaccine has been prepared in India and immunization programmes of villagers in the affected areas have been carried out.

POWASSAN VIRUS

Viral Features and Host Range

Powassan virus is named after the town of Powassan in northern Ontario, where the first human virus isolate was made from a fatal encephalitis case in a five-year-old boy in 1958. The disease is rare, less than 50 cases having been reported worldwide. Case reports have come from Canada and the United States as well as Russia.

Epidemiology

A number of arthropod vectors have yielded isolates of the virus. In North America the major vector has been *Ixodes cookei*, with *Dermacentor andersoni*, *Ixodes marxi* and *I. spinipalpus* and, in Russia, *Haemaphysalis neu-manni*, *I. persulcatus* and *Dermacentor silvarum* occasionally being infected. In addition, infected mosquito species (*Aedes togoi* and *Anopheles hryanus*) have also been reported. Vertebrates infected with POWV have occurred mainly in mammals, but also birds, amphibians and reptiles.

Clinical Features

Clinical cases of POWV infection have presented with encephalitis, meningoencephalitis and aseptic meningitis. In some cases focal encephalitic signs have occurred and in one case from Russia the patient died following bulbar paralysis. In a series of 19 cases in North America, two deaths occurred in the acute illness phase. Serological diagnosis of POWV infection can be achieved by specific IgM antibody detection in acute serum or spinal fluid, or by IgG seroconversion. Because of cross-reactions with other flaviviruses, NT assays are required for confirmation.

² Department of Virology, National Health Laboratory Service Universitas, Faculty of Health Sciences, University of the Free State, Bloemfontein, South Africa

INTRODUCTION

At present, the family *Bunyaviridae* comprises approximately 300 animal viruses assigned to four genera: *Orthobunyavirus* (named after Bunyamwera virus), *Hantavirus* (named after Hantaan virus), *Phlebovirus* (named after phlebotomus/sandfly fever) and *Nairovirus* (named after Nairobi sheep disease virus). A further 41 inadequately characterized animal viruses are considered possible members of the family and there is a genus of plant viruses (Büchen-Osmond, 2006; Calisher, 1991; Calisher and Karabatsos, 1989; Karabatsos, 1985; Murphy *et al.*, 1995; Peters and LeDuc, 1991). Most of the animal viruses were discovered in the course of surveys on haematophagous arthropods or wild vertebrates, and the fact that new members of the family are constantly being encountered has been interpreted to indicate that many remain to be discovered (Peters and LeDuc, 1991). Some of the viruses are important pathogens of humans or livestock, but the majority have no known medical or veterinary significance. Sometimes a pathogenic role is discovered for a virus years after its initial isolation. Although most members of the family are thought to be arthropod-borne (i.e. arboviruses), transmission by vectors has been demonstrated conclusively in comparatively few instances. Members of the rodent-associated *Hantavirus* genus are not considered to be arthropod-borne.

The origins of the family can be traced to the initial detection of close antigenic relationships within certain groups of viruses, including one containing Bunyamwera virus (named for a place in Uganda) (Casals, 1957, 1961; Casals and Whitman, 1960, 1961). Subsequently

the demonstration of weak serological cross-reactions between the groups resulted in the viruses being included in a Bunyamwera supergroup (World Health Organization, 1967). The family *Bunyaviridae*, containing a single genus *Bunyavirus*, was erected when members of the supergroup and certain ungrouped viruses were found to have similar morphology (Fenner, 1976; Murphy *et al.*, 1973; Porterfield *et al.*, 1974), and subsequently *Phlebovirus*, *Uukuvirus*, *Nairovirus* and *Hantavirus* genera were added to the family as morphological and biochemical affinities between the viruses became evident (Bishop *et al.*, 1980; Matthews, 1981; Schmaljohn *et al.*, 1985). Later, the uukuviruses were included in the *Phlebovirus* genus since they were found to share coding and replication strategies with the phleboviruses, while the genus *Bunyavirus* was renamed as the genus *Orthobunyavirus* (Calisher, 1991; Murphy *et al.*, 1995; Simons *et al.*, 1990). Within genera, members were classified on the basis of antigenic affinities and arranged into serogroups, antigenic complexes, viruses (or serotypes), subtypes and varieties, in order of increasing relatedness, with serotypes being separable by definition only in cross-neutralization tests. However, classification of viruses by serotype is progressively being replaced by the definition of genotypes through nucleotide sequencing of the genome. This was initially applied particularly to agents which proved difficult to grow in laboratory culture systems, such as recently discovered hantaviruses, but is finding increasing application in phylogenetic studies of orthobunyaviruses, phleboviruses and nairoviruses (Ahmed *et al.*, 2005; Armstrong and Andreadis, 2006; Bird *et al.*, 2007; Briese *et al.*, 2004; Chamberlain *et al.*, 2005; Deyde *et al.*, 2006; Monroe

et al., 1999; Liu *et al.*, 2003; Xu *et al.*, 2007; Yandoko *et al.*, 2007).

THE VIRUS

Structure

The viruses of the family are spherical, 80–120 nm in diameter, and have a host cell-derived bilipid-layer envelope through which virus-coded glycoprotein spikes or peplomers project. The virions contain three major structural proteins: two envelope glycoproteins, G1 (G_n) and G2 (G_c), and a nucleocapsid protein N, plus minor quantities of a large or L protein (145–259 kDa) believed to be the viral transcriptase, an RNA-dependent RNA polymerase (Table 29.1) (Bishop, 1990; Calisher, 1991; Peters and LeDuc, 1991; Schmaljohn and Patterson, 1990). (Hazara virus of the genus *Nairovirus* is believed to have three glycoproteins.) Members of the family have a three-segmented, single-stranded RNA genome and each of the segments, L (large), M (medium) and S (small), is contained in a separate nucleocapsid within the virion. The sizes of the structural proteins and RNA segments vary with genus (Table 29.1). The genomic RNA is in the negative-sense (complementary to mRNA), but the S segment of the phlebovirus genome consists of ambisense RNA, that is, has bi-directional coding, a property which is shared only with the RNA of viruses of the family *Arenaviridae*. The first 8–13 nucleotide bases at the 3' ends of the RNA segments tend to have a sequence that is conserved within the viruses of each genus, with a complementary (palindromic) consensus sequence occurring at the 5' end; and the ends of the segments are noncovalently linked so that the RNA occurs in a loosely bound circular configuration within the nucleocapsids. The segmented nature of the genome suggests that the potential exists for reassortment to occur in co-infections, and it is thought that this mechanism may have contributed to the evolution of diversity in the family, but experimental evidence indicates that there are genetic restraints and

that reassortment occurs with facility only between members of genotypes (Bowen *et al.*, 2001; Briese *et al.*, 2006; Gerrard *et al.*, 2004; Peters and LeDuc, 1991).

The L RNA segment of the genome codes for the viral transcriptase, and the M segment for the G proteins, as well as a nonstructural protein NS_m in the *Orthobunyavirus* and *Phlebovirus* genera. The S segment RNA codes for the N protein, as well as a nonstructural protein NS_s in the bunyaviruses and phleboviruses. Nonstructural proteins have not been demonstrated in the nairoviruses or hantaviruses. The viral glycoproteins are responsible for recognition of receptor sites on susceptible cells, manifestation of viral haemagglutinating ability and for inducing protective immune response in the host. The N protein induces production of and reacts with complement-fixing antibody.

Biological Characteristics

Viruses that attach to receptors on susceptible cells are internalized by endocytosis, and replication occurs in the cytoplasm. Virions mature primarily by budding through endoplasmic reticulum into cytoplasmic vesicles which are presumed to fuse with the plasma membrane to release virus, but it appears that virus can also bud directly from the plasma membrane (Anderson and Smith, 1987). Most of the viruses have been isolated and propagated by intracerebral inoculation of suckling mice, but the hantaviruses produce chronic and inapparent infection of laboratory rodents. Members of the family can be grown in a variety of cell cultures (Vero cells have been used most commonly), but some of the viruses are noncytolytic so that their presence has to be demonstrated by immunofluorescence or similar means. Hantaviruses are difficult to grow *in vitro*, and some of the more recently discovered members of the genus have not yet been adapted successfully to cell cultures (Klempa *et al.*, 2006, 2007; Monroe *et al.*, 1999).

An abridged classification of the family, showing selected members known to cause infection of humans and livestock in relation to their vectors and distribution, is

Table 29.1 Major biochemical properties of members of the *Bunyaviridae*. Information derived from sources cited in the text

Viruses	Molecular weights of major structural proteins ($\times 10^3$)			Molecular weights of RNA species ($\times 10^6$)		
	G1	G2	N	L	M	S
Bunyaviruses	108–120	29–41	19–26	2.7–3.1	1.8–2.3	0.3–0.5
Sandfly fever group	55–70	50–60	20–30	2.6–2.8	1.8–2.2	0.7–0.8
Uukuniemi group	70–75	65–70	20–25	2.0–2.5	1.0–1.3	0.4–0.7
Nairoviruses	72–84	30–40	48–54	4.1–4.9	1.5–2.3	0.6–0.7
Hantaviruses	64–76	52–58	48–54	2.2–2.9	1.2–2.9	0.6–0.75

presented in Tables 29.2–29.4 (Büchen-Osmond, 2006; Calisher, 1991; Calisher and Karabatsos, 1989; Karabatsos, 1985; Peters and LeDuc, 1991). In addition, high prevalences of antibody to many other viruses have been found in particular human populations, but conclusive evidence of infection or disease association is lacking: antigenic cross-reactivity between viruses can complicate the interpretation of survey findings or render it difficult to arrive at a serological diagnosis in individual cases of disease.

There is a broad tendency for antigenic grouping and phylogenetic classification to correlate with geographic distribution and with the type of vector involved in transmission (Tables 29.2–29.4). Although a greater variety of arthropod-borne members occurs in tropical and subtropical countries of Latin America and Africa, many viruses including several important pathogens occur in temperate countries and the distribution of the family extends to the arctic region. Moreover, there are many instances on record of residents of temperate countries which lack indigenous disease, acquiring infection during travels abroad. Most of the viruses appear to be transmitted by culicine mosquitoes including aedines, but some are transmitted by anopheline mosquitoes. Simbu serogroup viruses are associated particularly with ceratopogonid midges (*Culicoides* spp.), while the sandfly fever serogroup of phleboviruses (apart from Rift Valley fever and a few other mosquito-borne viruses), are associated with phlebotomids (sandflies). The Tete serogroup of bunyaviruses, Uukuniemi serogroup of phleboviruses and the nairoviruses are associated with ixodid and argasid ticks. Some viruses have been isolated from more than one type of vector.

Transmission

It is characteristic of arthropod-borne viruses that they produce viraemia in at least one species of vertebrate to allow the infection to be acquired by biological vectors which take blood meals. During a so-called *extrinsic incubation period*, commonly lasting one to two weeks in dipterid vectors (mosquitoes, midges and sandflies), the virus replicates in the vector and spreads to produce infection of the salivary glands, thereby permitting transmission to occur to a second vertebrate host. Virus is thus maintained by circulation between the vector and a vertebrate host. The maintenance cycle may be cryptic, involving wild vertebrates which develop inapparent infection, with incidental spread of infection to susceptible domestic animals or humans which impinge on the cycle. It has been postulated that through selection pressure brought about by long association with the virus, natural maintenance hosts often develop transient viraemic infection without displaying susceptibility

to the pathogenic effects of the virus concerned. Small mammals and birds that occur in large numbers, breed prolifically to ensure a constant supply of non-immune individuals and are subject to periodic population explosions constitute ideal maintenance hosts for arboviruses. Species susceptible to disease may themselves serve to amplify circulation of virus through infecting vectors, but humans serve this purpose for members of the *Bunyaviridae* in few instances only (Oropouche, sandfly fever), and are usually ‘dead-end’ hosts. Domestic animals which develop disease or undergo inapparent infection may serve as link hosts between the natural cycle and humans, which in turn gain infection from contact with infected tissues of livestock or products such as milk, or from vectors infected by feeding on livestock (Rift Valley fever, Crimean–Congo haemorrhagic fever (CCHF).

Since the biting activity of arthropod vectors, and hence the infection of vertebrates, is seasonal, the fate of arthropod-borne viruses during winters or dry seasons of inactivity has long constituted a central enigma in the epidemiology of arbovirus diseases. Many plausible mechanisms for overwintering or hibernation of arboviruses have been described, including persistent infection of vertebrates, migration of infected birds or mammals, hibernation of infected adult vectors and continuous vector activity in tropical locations (Reeves, 1974). Transovarial transmission of infection in arthropod vectors, however, theoretically constitutes an ideal mechanism for ensuring the perpetuation of the viruses, and comparatively early in the history of the investigation of arbovirus diseases convincing evidence was produced to indicate that the phenomenon occurs in phlebotomids and ixodid ticks (Tesh, 1984). The evidence for mosquito-borne viruses long remained in doubt, but in recent years many investigators have demonstrated transovarial transmission of bunyaviruses, particularly members of the California encephalitis serogroup, as well as Rift Valley fever virus and members of the *Togaviridae* and *Flaviviridae* families in mosquitoes (Linthicum *et al.*, 1985; Peters and LeDuc, 1991; Swanepoel, 2003; Tesh, 1984). Even in the absence of transovarial transmission of infection, the overwintering of viruses transmitted by ixodid ticks can be explained by the long intervals that occur between the feeding of successive instars of the vectors.

In general, viruses transmitted by dipterid flies (mosquitoes, midges and sandflies) may cause sporadic infections, but are capable of causing explosive epidemics at irregular intervals of years when climatic conditions are particularly favourable for the breeding of vectors, or human manipulation of the environment results in large-scale juxtaposition of susceptible people or livestock and vectors. Viruses transmitted by ixodid ticks

tend to cause sporadic disease in locations where there is occupational or recreational exposure of humans to ticks, but human intervention can precipitate the occurrence of larger outbreaks of disease.

Clinical syndromes associated with members of the *Bunyaviridae* range from inapparent infections known from routine monitoring of laboratory workers, through moderate to severe influenza-like illness with or without a maculopapular rash and characterized by fever (often biphasic), headache, myalgia, arthralgia and malaise, to encephalitis or haemorrhagic disease with necrotic hepatitis, while the hantaviruses of Asia and Europe are associated with a group of diseases known collectively as haemorrhagic fever with renal syndrome (HFRS), and the hantaviruses of the Americas are associated with an acutely fatal respiratory disease known as hantavirus pulmonary syndrome (HPS). The information presented below on the epidemiology and disease associations of individual viruses is derived from a few collated sources, except where indicated otherwise (Calisher and Karabatsos, 1989; Gonzalez-Scarano and Nathanson, 1990; Karabatsos, 1985; McKee *et al.*, 1991; Peters and LeDuc, 1991; Porterfield, 1990).

LABORATORY DIAGNOSIS

The appropriate specimens and laboratory methods required for confirming diagnoses of the more important diseases are indicated in the relevant sections dealing with the individual infections below. Procedures developed and applied over decades for the isolation and identification of arthropod-borne members of the family, or for demonstrating immune responses, remain valid (Shope and Sather, 1979). However, there are residual problems concerning the sensitivity, specificity and rapidity with which certain infections can be diagnosed, and these are being solved through increasing utilization of newer serological and molecular biological techniques. Isolation and identification of virus remains the definitive way of making a diagnosis, and this is especially true for what is perceived as a novel or as an undifferentiated febrile illness: it is easier to arrive at a serological diagnosis in diseases which are recognizable from their clinical presentation or from the circumstances under which patients become infected, such as Oropouche fever, sandfly fever, CCHF, Rift Valley fever or HFRS. Sporadic undifferentiated febrile illnesses, in contrast, have usually been identified in the course of surveys, and the diagnosis of

^aVirus will be named when the rodent host or distribution is identified. HFRS, haemorrhagic fever with renal syndrome; HPS, hantavirus pulmonary syndrome.

individual cases requires clinical acumen and recourse to the services of a specialized laboratory able to screen for a range of viruses known or considered likely to occur in the area where the infection was acquired.

Virus Detection and Identification

Most members of the family were discovered through intracerebral inoculation of suckling mice, and this method is still widely used for isolating the viruses. A few of the viruses are also pathogenic for weaned mice or hamsters, some even by peripheral route, and this constitutes a useful screening method for preliminary identification of isolates, for example Rift Valley fever virus. Some viruses which are nonpathogenic for laboratory rodents, such as the hantaviruses (not known to be arthropod-borne), can nevertheless be isolated in rodents through demonstrating the presence of viral antigens in tissues. Many cytopathic, as well as noncytopathic viruses such as CCHF, can be isolated in mammalian cell cultures and detected by immunofluorescence. The method has the advantage that it is usually rapid, and therefore clinically useful, but it is not invariably more sensitive than the use of suckling mice for isolating viruses which are present in low concentrations in pathological specimens. Certain viruses which are nonpathogenic for laboratory mice, such as some of the neotropical phleboviruses, were only discovered because they proved to be cytopathic in mammalian cell cultures. Although it has not been proven for members of the *Bunyaviridae*, some arboviruses can be isolated most successfully by inoculation of mosquito cell cultures, which do not manifest cytopathic effect, or live mosquitoes, and in these instances the isolation of virus has to be demonstrated by immunological or molecular means.

In some diseases, such as Rift Valley fever or CCHF, rapid diagnoses can sometimes be achieved without culturing virus, by demonstrating the presence of viral antigens directly in infected blood or other tissues by enzyme-linked immunoassay, immunofluorescence, immunohistochemistry or a variety of other immunological methods. This approach was used in the discovery of hantaviruses in rodent tissues. In certain diseases, such as La Crosse encephalitis, it appears that virus is seldom present in blood or other tissues in infective concentrations at the time that the disease is recognized, while other viruses, such as the hantaviruses, appear to be present but may be extremely difficult to isolate and adapt to laboratory host systems. An alternative is to detect viral nucleic acids in tissue extracts or histological sections by hybridization with specific radiolabelled nucleic acid probes. A more sensitive technique, which has become a standard approach to the diagnosis of virus infections,

is the use of reverse transcription polymerase chain reaction (RT-PCR) to detect viral nucleic acids. This was used with notable success in the detection of novel hantaviruses in the blood and other tissues of human patients and rodents. Recent refinements of RT-PCR applied to the diagnosis of bunyavirus infections include the selection of consensus sequence primers which are specific for either individual viruses, groups of viruses or all potential members of a genus, and the use of pyrosequencing or hybridization of the PCR products to DNA microarrays to obtain rapid and accurate identification of the virus concerned (Ahmed *et al.*, 2005; Andreadis, 2006; Armstrong and Kramski *et al.*, 2007; Arthur *et al.*, 1992; Drosten *et al.*, 2002; Monroe *et al.*, 1999; Nichol *et al.*, 1993; Nordström *et al.*, 2004; Puthavathana *et al.*, 1992; Weidmann *et al.*, 2008; Xiao *et al.*, 1994).

Until recently, isolates were generally identified exclusively by serological means, and by definition viruses react most specifically with antisera in neutralization tests, but these are technically difficult to perform with some viruses, or may not yield results sufficiently rapidly to be clinically useful. Antisera tend to be more cross-reactive in other serological tests, such as complement fixation, haemagglutination inhibition, immunofluorescence and enzyme-linked immunoassay which appear to detect mainly the immunodominant nucleocapsid protein antigens (Briese *et al.*, 2004), but the problem can be overcome by use of monospecific monoclonal antibodies. In instances where potentially new viruses, or viruses associated with undifferentiated illnesses, have to be identified, cross-reactivity can be useful, and isolates may be subjected to preliminary screening with pools of antisera, or antisera which have deliberately been rendered cross-reactive by immunizing laboratory animals sequentially with several viruses. Morphological or partial biochemical characterization of isolates, by performance of electron microscopic examination or tests for sensitivity to ether and bile salts, for instance, may also facilitate the process of identifying a virus.

However, as indicated above, virus isolates are now usually identified by molecular biological techniques, including hybridization of viral nucleic acids with labelled DNA probes specific for individual viruses, by demonstrating specific endonuclease restriction enzyme digestion patterns with the nucleic acids, or more commonly by performing nucleotide sequencing of RT-PCR products or even whole viral genomes (Monroe *et al.*, 1999).

Serology

Serological diagnosis of infections is beset with the same problems of cross-reactivity which apply to antigenic identification of isolates, and the difficulties are compounded where patients have previously been infected

with an antigenically related virus: antibody response tends to be broadly cross-reactive within serogroups following sequential infections. Neutralizing antibody, which reacts most specifically for individual viruses, usually becomes demonstrable by day 7–10 of illness (earlier in Rift Valley fever) and after an initial post-convalescent decline in titre, tends to remain demonstrable for life, but the response is usually weak and difficult to demonstrate following nairovirus infections. Complement fixing antibody becomes demonstrable in the second or third week of illness, declines after several months, and tends to be group-specific with bunyaviruses and nairoviruses, but more specific among phleboviruses. Antibody demonstrable by haemagglutination inhibition, indirect immunofluorescence or enzyme-linked immunoassay becomes detectable at about the same time as neutralizing antibody, and after a post-convalescent decline in titre, remains demonstrable for a period of at least several years, and varies in specificity in different groups of viruses. Demonstration of IgM antibody activity in indirect immunofluorescence tests or enzyme-linked immunoassays is most useful for establishing a rapid diagnosis.

Antibody titres tend to be highest against the homologous infecting virus, so that problems of cross-reactivity can sometimes be overcome by screening patients' sera with a range of antigens prepared from all members of the virus serogroup known to occur in the area concerned, as is done with members of the California encephalitis serogroup. An alternative is the preparation of purified antigens which contain virus proteins or peptides that react specifically with serotype antibody, and this includes preparation of antigens by recombinant DNA technology (Feldmann *et al.*, 1993). The same effect may be obtained by selective capture of viral proteins with monoclonal coating antibody in enzyme-linked immunoassays.

GENUS ORTHOBUNYAVIRUS

Bunyamwera, Batai, Ngari, Ilesha, Germiston and Shokwe Viruses

Bunyamwera virus is widely distributed in Africa and has been isolated from aedines and other culicine mosquitoes, and/or human blood in Uganda, South Africa, Kenya, Nigeria, Central African Republic, Cameroon and Senegal. Antibody has been found in humans and/or domestic animals, rodents, bats and sub-human primates in the same countries as well as in Mozambique, Tanzania, Angola, Congo, Egypt and Tunisia. However, some of the antibody reactions recorded in surveys may have been due to infection with related viruses. Despite the widespread

occurrence of antibody, human disease has seldom been recognized and the few cases which have been described include several laboratory infections. Clinical findings included fever, maculopapular rash, arthralgia, neck stiffness, vertigo and temporary loss of visual acuity. Severe encephalitis occurred in experimental infection of a tumour patient. Infection was confirmed in patients by isolation of virus from blood or demonstration of an immune response. It seems likely that disease may be more common than at present realized.

Batai virus was first isolated from culicine mosquitoes in Malaysia in 1955. Antigenically related Calovo virus, isolated from anopheline mosquitoes in the former Czechoslovakia, Olyka virus isolated from mosquitoes in the Ukraine, and Chittoor virus isolated from anophelines in India, have all been confirmed to be strains of Batai virus (Briese *et al.*, 2006). The cluster of viruses has been isolated from anopheline and culicine mosquitoes in Malaysia, Thailand, Cambodia, India, former Yugoslavia, Austria, the former USSR and former Czechoslovakia. Recently, an unidentified virus which had been isolated from mosquitoes in Uganda in 1967 was also confirmed to be Batai virus (Briese *et al.*, 2006). Antibody to Batai virus has been found in the above countries, as well as in Sri Lanka, Romania, Hungary, Germany, Portugal and Finland in the sera of humans and/or birds, rodents, domestic ruminants and deer. The findings in seroprevalence studies suggest that human infection is seldom accompanied by overt disease, but febrile illness with malaise, myalgia, anorexia, and sometimes abdominal pain, tonsillitis, cough and dyspnoea (associated with lung infiltration), has been reported from former Czechoslovakia and Malaysia on the basis of serological diagnoses.

Ngari virus has been isolated from mosquitoes in Senegal, Burkina Faso and the Central Africa Republic, as well as from a sheep in Mauritania and the liver of a person who succumbed to cerebral malaria in Senegal. A mosquito isolate of Ngari virus reported from Madagascar may be Batai virus. A virus isolated from the blood of two human patients during the 1997–1998 Rift Valley fever epidemic in north-east Kenya and adjacent Somalia was thought to be a new bunyavirus and given the name Garissa virus, but was subsequently been found to be Ngari virus (Bowen *et al.*, 2001; Nichol, 2003). Later it was established that the nucleotide sequences of the L and M RNA genome segments of Ngari virus correspond to Bunyamwera virus sequences, and it was concluded that Ngari virus represents a reassortant between Bunyamwera virus and an unidentified M segment RNA donor (Gerrard *et al.*, 2004). Recently determined sequence homologies suggest that Batai virus is the most likely donor of the Ngari virus M RNA segment (Briese *et al.*, 2006). There

were many deaths from haemorrhagic disease which could not be confirmed as cases of Rift Valley fever in Kenya and Somalia in 1997–1998, and antibody to Ngari virus was found in a proportion of the patients (Bowen *et al.*, 2001; Gerrard *et al.*, 2004). Moreover, virus which had been isolated from two patients during an outbreak of febrile disease in Sudan in 1988 was recently shown to be Ngari virus, so it appears that Ngari virus could prove to be an important human pathogen.

Ilesha virus has been isolated from the blood of febrile humans in Nigeria, Uganda, Cameroon and the Central African Republic, and from anopheline mosquitoes in the latter country. In addition there is serological evidence that the virus occurs in Senegal and Ghana. Few cases of disease have been reported, and these consisted of undifferentiated febrile illness with a rash.

Shokwe virus has been isolated from mosquitoes, mainly aedines but also from other culicines in South Africa, Senegal, Ivory Coast and Kenya, and from rodents and the blood of a febrile human in Ivory Coast. Little is known of the pathogenic potential of the virus. Germiston virus has been isolated in South Africa, Zimbabwe, Mozambique, Kenya and Uganda from *Culex rubinotus*, a mosquito which selectively feeds on rodents, and from myomorph rodents (rats and mice) in Uganda. Antibody has been found in the sera of humans and/or cattle and rodents in South Africa, Botswana, Namibia and Angola. Two laboratory infections have been reported; one with undifferentiated febrile illness with rash, and the other with signs of mild encephalitis. Virus was isolated from the blood of the patients.

Cache Valley, Maguari, Fort Sherman, Tensaw and Wyeomyia Viruses

Cache Valley virus has been isolated from culicine and anopheline mosquitoes from widely separated locations in the United States and from Jamaica, and antibody has been found in the sera of humans and/or horses, sheep, cattle, wild rodents, raccoons, deer and monkeys in the United States, Canada, Trinidad and Guyana. A single case of fatal aseptic meningitis was diagnosed in a patient in North Carolina in 1995, and in 2003 a second, nonfatal, case of meningitis was diagnosed in Wisconsin, but the occurrence of human disease may be underestimated due to lack of awareness and failure to perform specific tests (Campbell *et al.*, 2006). Serological studies and pathogenicity trials, and the isolation of virus from a sentinel sheep, incriminated Cache Valley virus as the causative agent of an outbreak of congenital abnormalities (hydranencephaly–arthrogryposis syndrome) among sheep in Texas (Chung *et al.*, 1990a, 1990b). Maguari virus has been isolated from mosquitoes, mainly

aedines, in Brazil, Argentina, French Guiana, Colombia and Trinidad, and from horse blood in Guyana and Colombia. Antibody has been found in the same countries as well as in Peru, Surinam and Venezuela in the sera of humans and/or horses, cattle, sheep, water buffalo and birds. Human disease has not been reported, but the virus is suspected of causing disease in horses. Fort Sherman virus was isolated from the blood of a patient with fever, malaise, myalgia and sore throat in Panama, but no further information on the virus is available. Tensaw virus has been isolated from several species of anophelines in south-eastern United States, where antibody has been found in humans, dogs, cattle and raccoons. A single case of encephalitis was reported in 1973. Wyeomyia virus has been isolated from a range of culicine mosquitoes in Colombia, Panama, French Guiana and Trinidad, and antibody has been found in human sera in Panama and Trinidad. The virus has been isolated once from the blood of a patient with febrile illness in Panama.

Bwamba, Pongola and Nyando Viruses

Bwamba virus was originally isolated from blood samples from nine road workers with febrile illness in Uganda, and subsequently from eight febrile patients in Nigeria, three in the Central African Republic and one in Kenya, and from anopheline mosquitoes in Uganda, Nigeria and Senegal. In 1997, a large outbreak of infection with the mosquito-borne o'nyong-nyong virus (*Alphaviridae*) occurred in southern Uganda and adjacent Tanzania, and Bwamba virus was isolated from two patients and from mosquitoes collected during the outbreak, suggesting that Bwamba virus infection may be more common than realized (Lutwama *et al.*, 2002). Antibody has been found in human sera in Uganda, Tanzania, Mozambique, South Africa, Botswana, Angola, Congo, Nigeria and Guinea; generally with very high prevalence, up to 97% in some populations, and including both children and adults. Antibody was also found in donkeys and a bird in South Africa. Bwamba virus appears to be an important pathogen and the eight isolations in the Nigerian series represented 5% of all arbovirus isolations from febrile patients over a seven-year period, while 18 diagnoses (virological and serological) made in similar patients in the Central African Republic represented 25% of arbovirus infections diagnosed over a 13-year period. The patients suffered prostrating illness with fever, headache, conjunctivitis, rash, epigastric pain and myalgia, and many had meningeal signs.

There have been numerous isolations of Pongola virus from mosquitoes, mainly aedines and other culicines, in South Africa, Mozambique, Kenya, Uganda, Ethiopia, Central African Republic and Ivory Coast. There has been one isolation of the virus from a febrile patient with

headache and myalgia in Uganda (Kalunda *et al.*, 1985). Neutralizing antibody has been found in humans in South Africa, Mozambique, Botswana, Namibia and Angola, and in cattle, sheep, goats and donkeys in South Africa, but interpretation of the findings is complicated by the fact that there is unidirectional cross-neutralization of Pongola virus by antibody to its close relative, Bwamba virus. Moreover, the fact that most human isolates have reacted as Bwamba serotype while most mosquito isolates have reacted as Pongola serotype merits further investigation, particularly in view of a report that passage of a Bwamba isolate in mosquitoes led to selection of virus reacting as Pongola serotype (Johnson *et al.*, 1978).

Nyando virus has been isolated from anopheline and aedine mosquitoes in Kenya, Central African Republic and Senegal. Antibody has been found in human sera in Kenya and Uganda, and the virus was isolated from the blood of a single human patient with biphasic fever, myalgia and vomiting in the Central African Republic.

California Encephalitis, La Crosse, Snowshoe hare, Jamestown Canyon and Keystone Viruses

California encephalitis virus, which is distributed across the western United States and into Canada, was isolated from mosquitoes in the early 1940s and shortly thereafter serological evidence was produced to indicate that it causes encephalitis. However, from the mid 1960s onwards it became clear that most cases of what are loosely termed 'California encephalitis' are in fact due to infection with the La Crosse subtype of virus, and this agent is responsible for the majority of the approximately 100 cases of arbovirus encephalitis diagnosed in the United States annually, except in years when there are epidemics of St Louis encephalitis (a flavivirus). It must also be borne in mind that since its introduction into North America in 1999, the mosquito-borne flavivirus West Nile has been responsible for a major proportion of cases of encephalitis recognized each year, particularly in elderly or immunocompromised patients.

Most cases of disease due to La Crosse virus are recorded in the Mid-West states of Wisconsin, Iowa, Indiana, Minnesota and Ohio, but the virus is widely distributed and the infection is probably underdiagnosed elsewhere in the United States. Recent isolation of a distinct lineage of La Crosse virus from mosquitoes in Connecticut suggests that it has long been present in north-eastern United States (Armstrong and Andreadis, 2006). The principal vector of the virus is *Aedes triseriatus*, a tree-hole breeding mosquito, and accordingly the virus tends to be focally distributed in woodlands, but also occurs in suburban situations where water that collects in discarded containers such as motor vehicle tyres, affords mosquito breeding sites. The virus is passed transovarially in the

vector and overwinters in mosquito eggs; infection is amplified in the succeeding spring and summer in small mammals such as chipmunks and squirrels. The vector is a diurnal feeder and the infection is seen most commonly in forest workers, and children who enter woodlands for recreational purposes, but also occurs focally in rural and suburban residents. Males are more commonly infected than females, among both children and adults. Seroprevalence surveys and prospective studies indicate that most infections are inapparent or benign. Probably less than 1% of infected adults develop encephalitis, but the incidence may be up to four times greater in young children.

After an incubation period of three to seven days there is sudden onset of fever, headache, lethargy, nausea and vomiting, pharyngitis and sometimes respiratory illness. There is seldom a cutaneous rash. In mild cases of overt disease there may be transient meningismus and disorientation, and recovery within one week. In severe disease there may be greater disturbance of consciousness, aphasia, tremors, chorea, positive Babinski signs and other abnormal reflexes, and hemiparesis in about 20% of patients. Seizures may occur from the second day of illness onwards: in about half of severely ill patients there may be generalized, life-threatening convulsions, and in a further 25% there are focal convulsions associated with frontal or parietal brain lesions. Approximately one third of severely ill patients become comatose. There may be marked leukocytosis, and examination of cerebrospinal fluid (CSF) reveals elevated mononuclear and polymorphonuclear cell counts, but protein and glucose levels tend to remain normal. Electroencephalograms show generalized slow-wave activity or localized changes and sometimes epileptiform discharges. Treatment is symptomatic and includes monitoring and control of intracranial pressure, and vigorous anticonvulsant therapy as indicated. Less than 1% of patients with severe disease succumb and most are discharged from hospital after about two weeks of illness, but may remain irritable and emotionally labile for a few weeks. There are seldom residua, but patients who suffer seizures in the acute illness may have recurrent convulsions over a period of one or more years, and lasting hemiparesis occurs in about 1% of patients. Virus has not been isolated from throat swabs, blood, stools or CSF, and only with difficulty from brain specimens. Histopathological lesions are not pathognomonic and include cerebral oedema, perivascular cuffing and focal gliosis in grey matter. A variety of methods are used for making a serological diagnosis, but demonstration of IgM antibody activity by means of enzyme-linked immunoassay holds greatest promise as a rapid diagnostic technique. There is no vaccine.

Snowshoe hare is a mosquito-borne subtype of California encephalitis virus with a distribution extending from

north-western United States, across most of Canada to Alaska. The natural host appears to be the snowshoe hare, *Lepus americanus*, and serological evidence suggests that the virus is occasionally associated with encephalitis in children and adults.

Jamestown Canyon is a mosquito-borne virus which occurs widely in the United States, and high prevalence rates of antibody are found in white-tailed deer, and in humans where there are high concentrations of the deer. Serological evidence of an association with encephalitis in humans has been found from the early 1980s onwards (Grimstad *et al.*, 1986). Since antigens and tests commonly used for the serodiagnosis of 'California encephalitis' fail to allow response to Jamestown Canyon virus to be distinguished from response to other members of the serogroup, it is felt that the infection has probably been missed or underdiagnosed as a cause of encephalitis in the past, both in the Mid-West states and elsewhere where the deer occurs. In contrast to La Crosse virus, Jamestown Canyon appears to cause encephalitis more frequently in adults than in children, and nervous disease is often preceded by respiratory illness. Keystone virus is associated with swamp-breeding aedines and cotton rats and rabbits in south-eastern United States, and has been known to cause inapparent accidental infection in the laboratory.

Tahyna and Inkoo Viruses

Tahyna virus is widely distributed in countries of central Europe, including Yugoslavia, Germany and Italy, with antibody prevalence rates being particularly high in the Rhone Valley of France, the Danube basin in Austria, and in the southern Moravia region of the former Czechoslovakia, where up to 95% of adults may be immune in some communities. Viruses described as being Tahyna-like have been isolated in the former USSR, while Lumbo virus, which was isolated from saltwater-breeding mosquitoes on the coast of Mozambique, is considered to be indistinguishable from Tahyna virus. Antibody to Tahyna virus has also been found in southern China and Sri Lanka. It is not yet clear whether a single virus occurs throughout this range or whether, as seems more likely, a cluster of closely related viruses, subtypes or varieties is involved.

The epidemiology of the disease has been studied most intensively in Moravia where seasonal flooding of level woodlands provides extensive breeding sites for mosquitoes. The virus is transmitted transovarially in *Aedes vexans* which overwinters as eggs, and in *Culiseta annulata* which overwinters as larvae. Amplification of infection in spring occurs in small mammals such as hedgehogs, hares and rabbits, as well as in domestic animals such as horses. Hedgehogs may themselves serve as reservoir hosts for overwintering of virus in instances

where they undergo chronic infection during hibernation, with viraemia which persists for a few days after awakening. Once infection of vertebrates occurs in summer other species of mosquito also become infected and serve as vectors for transmission of the virus.

Seroprevalence surveys indicate that infection is much more common than overt disease in rural residents of Moravia. Nevertheless, the infection accounts for up to 20% of patients hospitalized with febrile illness in the region, including both adults and children. Patients may present with undifferentiated febrile illness with leukocytosis, but pharyngitis, cough and chest pain, and infiltration (demonstrable by X-ray imaging) may predominate, or gastrointestinal symptoms such as nausea, vomiting and abdominal pain may be dominant. Aseptic meningitis occurs in a minority of patients but fatal disease is unknown. Virus can be isolated from blood early in the illness, but the infection is usually diagnosed by demonstration of an antibody response. There is no vaccine.

Inkoo virus was isolated from aedine mosquitoes in Finland. Distribution of the virus extends to the Lapland region in the north of the country, and antibody occurs in the sera of humans, cattle, deer and hares. Antibody prevalence rates of up to 25% have been recorded in humans, and a few cases of febrile illness have been confirmed serologically.

Oropouche Virus

Oropouche virus was originally isolated from the blood of a febrile patient in Trinidad, but large epidemics involving thousands of people have occurred almost exclusively in northern Brazil over the past 20 years, with the most recent outbreaks being recorded in 2003 and 2004 (Azevedo *et al.*, 2007). In addition to humans, the virus has been isolated from a sloth, a few species of culicine mosquitoes plus the midge *Culicoides paraensis*, while antibody has been found in the sera of humans and/or monkeys and birds, in Brazil, Trinidad, Panama and Colombia. Virus is thought to be maintained in nature by circulation in forest primates, sloths or birds and an unidentified vector, and is introduced into urban settings by infected travellers or by extension from the sylvatic cycle. Humans serve as amplifier hosts in the urban cycle, and the vector is the *Culicoides* midge which breeds in decaying waste from tropical agricultural products. Epidemics occur when there are large concentrations of vectors and susceptible humans. Aerosol infection is suspected to have occurred in laboratory workers. The incubation period is four to eight days, and there is sudden onset of fever, chills, headache, myalgia, arthralgia and prostration. There may be a rash, and occasionally signs of meningitis or encephalitis, but there are no deaths or sequelae. Viraemia lasts from two to five days, as does illness, but myalgia persists for a

further three to five days, and strenuous exertion in early convalescence can precipitate a relapse of symptoms.

Caraparu, Apeu, Ossa, Madrid, Marituba, Murutucu, Nepuyo, Restan, Oriboca and Itaqui Viruses

These viruses occur in Central and South America and tend to be associated with tropical forests. They have all been isolated from the blood of febrile humans, and variously from sentinel monkeys, rodents, occasional marsupials and fruit bats, and from a range of culicine mosquitoes in Brazil, Surinam, French Guiana, Guatemala, Honduras, Trinidad, Panama or Mexico. Serological evidence suggests that some of the viruses may also occur in Venezuela, Colombia and Peru. Pairs of the viruses which are closely related antigenically may circulate in the same geographic location yet occupy separate ecologic niches. For instance, one virus circulates in arboreal monkeys and mosquitoes which feed in the canopy layer, while a closely related virus circulates in rodents and mosquitoes which feed at the level of the forest floor. Other pairs of closely related viruses coexist in the same habitat simply by utilizing different vectors. Sporadic infections occur in people who enter forests. No large outbreaks of disease have been reported, but disease is observed when susceptible outsiders such as military personnel enter endemic regions. Laboratory infections are relatively common. Disease, which lasts for up to a week and runs a benign course, is characterized by fever, rigors, headache, photophobia, conjunctivitis, tachycardia, myalgia, arthralgia, prostration, leukopenia and occasionally pain in the right upper quadrant of the abdomen and jaundice.

Guaroa, Guama, Catu, Tacaiuma and Turlock Viruses

Guaroa virus has been isolated from 12 febrile patients in Colombia and the Amazon region of Brazil, and from anopheline mosquitoes in Panama and Colombia. Antibody has been found in human sera in Colombia, Brazil, Argentina and Peru. Disease ascribed to infection with the virus was characterized by fever, headache, myalgia, arthralgia, prostration and leukopenia. Virus was isolated from the blood of the patients, and from a liver biopsy in one instance.

Catu virus has been isolated from sentinel monkeys in Brazil, febrile humans and forest rodents in Brazil and Trinidad, and from culicine and anopheline mosquitoes in the same two countries plus French Guiana. Guama virus has been isolated from febrile humans and sentinel monkeys in Brazil, and from rodents and/or culicine mosquitoes in Brazil, Trinidad, Surinam, French Guiana and Panama. The two viruses cause isolated cases of benign disease characterized by fever, headache, myalgia

and leukopenia, in people who enter tropical forests. Catu has also been associated with laboratory infection.

Tacaiuma virus was isolated from the blood of a sentinel monkey and from forest mosquitoes in the Amazon region of Brazil, as well as from mosquitoes in Argentina. Antibody has been found in humans in Brazil and French Guiana, and in horses, rodents, bats and birds in Brazil. The virus has been isolated once from the blood of a patient with febrile illness in Brazil.

Turlock virus was first isolated from *Culex tarsalis* mosquitoes in California in 1954. In 1995, the virus was isolated from the brain of an ostrich chick with ataxia in California, and antibody was found in a proportion of ostrich sera, but there has been no further reported association of the virus with disease in vertebrates (Shivaprasad *et al.*, 2002). There were slight quantitative differences in cross-neutralization tests between the ostrich isolate and prototype virus.

Akabane, Aino, Tinaroo and Shuni Viruses

Most members of the Simbu serogroup do not occur in the Americas, but are widely distributed in Africa, Asia and Australasia. Of these latter viruses, only Shuni has been marginally implicated in causing human disease, but a few have been incriminated as causative agents in large outbreaks of abortion, stillbirth and congenital defects (hydranencephaly–arthrogryposis syndrome) in domestic ruminants, particularly sheep and cattle, and the suspicion exists that most members of the serogroup have the potential for producing this type of disease. Akabane has been incriminated in outbreaks of the disease in Japan, Australia and Israel, Aino in Japan and Australia, Tinaroo in Australia, and Peaton virus has been shown to be teratogenic in experimental infections in Australia. Most recently, Akabane virus was incriminated on serological grounds of association with an outbreak of teratology in cattle in Israel in 2002, and the virus was isolated from mosquitoes collected in Vietnam in 2002–2004 (Brenner *et al.*, 2004; Bryant *et al.*, 2005). The main vectors of these viruses are believed to be species of *Culicoides* midges which breed in dung, independently of available surface water, but which are favoured by the humid conditions created by heavy rainfall. The natural hosts of the viruses are unknown, but antibodies have been found in wild herbivores. Infection is usually inapparent in domestic ruminants. However, if infection occurs in pregnant animals at critical stages of gestation, there may be embryonal or fetal death, or arrest of brain development (hydranencephaly), and the consequent lack of trophic effect of nervous stimulation on skeletal muscles of the fetus results in postural defects of the limbs, with joints locked in flexion (arthrogryposis). Once the stage of organogenesis in gestation is passed, fetuses are less susceptible to

the harmful effects of infection (the timing varies with length of gestation in different species).

Shuni virus has been isolated from cattle, sheep, midges and once from the blood of a febrile human in Nigeria, and from cattle and mosquitoes in South Africa. It was also isolated from the brain of a horse with histopathological lesions of meningoencephalitis, which was submitted for laboratory examination for suspected rabies in Zimbabwe (Foggin and Swanepoel, unpublished).

GENUS PHLEBOVIRUS

Sandfly Fever Naples, Sandfly Fever Sicilian and Toscana Viruses

Sandfly fever (also known as phlebotomus fever or papataci fever from the vector, *Phlebotomus papatasi*) has been known for at least two centuries as a febrile illness encountered by armies invading the Mediterranean basin. It was demonstrated shortly after the start of the twentieth century that the disease was caused by a virus transmitted by sandflies, but it was only during the Second World War that it was shown that there are in fact two distinct viruses and that there is no cross-immunity. Between them, the two viruses are known to occur in Morocco, Tunisia, Egypt, Sudan, Somalia, Italy, Greece, former Yugoslavia, Turkey, the former USSR, Israel, Saudi Arabia, Iraq, Iran, Pakistan, India and Bangladesh, and are probably present in many intervening countries. Throughout this range *P. papatasi* is the vector, and it breeds in moist soil in dark niches such as in rubble, drains, cracks in soil and in animal burrows, equally successfully in large cities as in remote rural locations. The viruses are transmitted transovarially in the vector, which overwinters in the larval stage, and adult flies emerge to assume biting activity in summer. High infection rates have been recorded in newly emerged sandflies and it is not known whether amplification in vertebrates is essential to ensure perpetuation of the viruses, but humans develop sufficiently intense viraemia to serve as source for the infection of the vector. No wild vertebrate hosts of the viruses are known, but antibody has been found in gerbils (whose burrows are utilized by the vector). Sandflies are nocturnal feeders, but will feed in dark rooms where they rest during daylight hours. Human infection rates recorded in outbreaks range from 3 to 75%, but the attack rate varies focally and is influenced by background immunity in the human population. Large epidemics have often occurred in association with socio-economic upheavals, wars or natural disasters such as earthquakes which create ideal breeding conditions for sandflies and/or lead to widespread exposure of susceptible humans to sandflies.

Experimental evidence suggests that most sandfly fever infections are symptomatic. Typically, there is sudden onset of fever of two to four days duration, severe headache, sore eyes and photophobia, myalgia, arthralgia, anorexia and malaise. Occasionally there may be sore throat, nausea and vomiting, abdominal pain and diarrhoea, epistaxis and dizziness. Patients may have injected conjunctivae and a flushed appearance, but there is seldom a rash, and meningeal signs are rare. The disease may be milder in children. Treatment is symptomatic. Recovery is complete and no deaths have been recorded. There appears to be lifelong immunity to the homologous virus. The diagnosis can be confirmed by detection of viral nucleic acid by RT-PCR or isolation of virus from blood taken in acute illness (Liu *et al.*, 2003; Weidmann *et al.*, 2008), or by demonstration of IgM antibody activity, or rising antibody titres in convalescence. Prevention of infection includes the use of insect repellants, but the treatment of walls (sandfly resting sites) with residual insecticides is highly effective.

Toscana virus was first isolated in 1971 in Tuscany, Italy, from *Phlebotomus perniciosus*, a sandfly which breeds in forest litter. Antibody was found to be common in the sera of rural and suburban residents of the region, and an association was established between the occurrence of aseptic meningitis and serological evidence of infection with Toscana virus. Since then the virus has come to be recognized as a major cause of meningitis and encephalitis each year in summer months in the Mediterranean region, including parts of Italy, France, Spain, Portugal and Greece (Charrel *et al.*, 2005; De Lamballerie *et al.*, 2007; Peyrefitte *et al.*, 2005). The virus is transmitted transovarially in the vector, *P. perniciosus*, which is widely distributed in Europe. No vertebrate maintenance host has been identified, but antibody has been found in rodent sera and the virus has been isolated from an insectivorous bat. The disease can sometimes be diagnosed by isolation of virus from CSF in acute illness, but usually by demonstrating IgM antibody activity or rising antibody titres in sera taken during convalescence.

Alenquer, Candiru, Punta Toro and Chagres Viruses

Alenquer and Candiru viruses were isolated from the blood of febrile patients in the Amazon region of Brazil, but otherwise little is known of their biology, and it is surmised that they are transmitted by phlebotomid flies. Punta Toro and Chagres viruses were isolated from febrile patients and from phlebotomids (*Lutzomyia* spp.) in Panama. These two viruses are known to be transmitted transovarially in phlebotomids, and antibodies to them have been found in primates, sloths, porcupines and other rodents. Disease thus far associated with all four viruses fits the description of classical sandfly fever, with the

difference that epidemics are unknown and only isolated cases have been seen in people who entered tropical forests for occupational or recreational purposes. Primers have been developed for use in RT-PCR for diagnosis of infection with these viruses (Liu *et al.*, 2003).

Rift Valley Fever Virus

The literature on Rift Valley fever has been reviewed extensively (Easterday, 1965; Flick and Bouloy, 2005; Henning, 1956; Meegan and Bailey, 1989; Peters and Meegan, 1981; Shimshony and Barzilai, 1983; Swanepoel and Coetzer, 2003; Weiss, 1957). It is an acute disease of domestic ruminants in mainland Africa and Madagascar, caused by a mosquito-borne virus and characterized by necrotic hepatitis and a haemorrhagic state, but infections are frequently inapparent or mild. Large outbreaks of the disease in sheep, cattle and goats are distinguished by heavy mortality among newborn animals and abortion in pregnant animals. Humans become infected from contact with tissues of infected animals or from mosquito bite, and usually develop mild to moderately severe febrile illness, but severe complications occur in a small proportion of patients. The virus recently escaped from the African region to cause a major outbreak of disease on the Arabian Peninsula in 2000–2001.

The disease was first recognized in the Rift Valley in Kenya early in the twentieth century, but the causative agent was not isolated until 1930. Since then large outbreaks of the disease have been recorded in Kenya, South Africa, Namibia, Mozambique, Zimbabwe, Zambia, Sudan, Egypt, Mauritania and Senegal, while lesser outbreaks, periodic isolations of virus or serological evidence of infection have been recorded in Angola, Botswana, Burkina Faso, Cameroon, Central African Republic, Chad, Gabon, Guinea, Madagascar, Malawi, Mali, Nigeria, Somalia, Tanzania, Uganda and Democratic Republic of the Congo. Epidemics may be extremely severe and, for example, it is estimated that 500 000 ewes aborted and a further 100 000 sheep died in the first outbreak of the disease to be recognized in South Africa in 1950–1951.

Prior to the 1970s, epidemics were seen only in eastern and southern Africa, where they tend to occur at irregular intervals of 5–15 years or longer when above-average rainfall favours the breeding of the mosquito vectors. Meteorological conditions conducive to the occurrence of epidemics usually prevail over large tracts of Africa, so there has been some tendency for outbreaks in adjacent territories such as Zimbabwe and Mozambique, Kenya and Tanzania, or South Africa and Namibia to coincide. The fate of the virus during inter-epidemic periods was unknown for decades, but on the basis of observations made in Uganda, Kenya and South Africa, it was widely accepted that the virus was endemic in indigenous forests

which extend in broken fashion from East Africa to the coastal regions of South Africa. The virus was thought to circulate in *Eretmapodites* spp. mosquitoes and unknown vertebrates in the forests, and to spread in seasons of exceptionally heavy rainfall to livestock-rearing areas where the vectors were believed to be floodwater-breeding aedine mosquitoes of the subgenera *Aedimorphus* and *Neomelaniconion*, which attach their eggs to vegetation at the edge of stagnant surface water. In contrast to other culicine mosquitoes, it is obligatory for the eggs of aedines to be subjected to a period of drying as the water recedes before they will hatch on being wetted again when next the area floods. Thus, the aedine mosquitoes overwinter as eggs which can survive for long periods in dried mud, possibly for several seasons if the area remains dry.

On the inland plateau of South Africa, where sheep rearing predominates, surface water gathers after heavy rains in undrained shallow depressions (pans) and farm dams which afford ideal breeding environments for aedines. On the watershed plateau of Zimbabwe, where cattle farming predominates, aedines breed in vleis, low-lying grassy areas which constitute drainage channels for surrounding high ground, and which are flooded by seepage after heavy rains. Vleis correspond to what are termed dambos in the livestock-rearing areas of central and eastern Africa. Sustained monitoring in Zimbabwe revealed that a low level of virus transmission to livestock occurred each year in the same areas where epidemics occurred. The generation of epidemics, therefore, was associated with the simultaneous intensification of virus activity over vast livestock-rearing areas where it was already present, rather than lateral spread from cryptic endemic foci. Comparison of the distributions of canopy forests and vleis in Zimbabwe, plotted from satellite images and aerial photographs, with the distribution determined for endemic Rift Valley fever, revealed remarkable overlap between the endemic areas and areas where vleis were common.

A major advance in the understanding of the epidemiology of the disease was made when the virus was isolated from unfed *Aedes mcintoshi* mosquitoes (= *Aedes lineatopennis* sensu lato) hatched in dambos on a ranch in Kenya during inter-epidemic periods in 1982 and 1984, confirming that the virus is endemic in livestock-rearing areas and indicating that it appears to be maintained by transovarial transmission in aedines. The available evidence suggests that in Zimbabwe, as in Kenya, *A. mcintoshi* is the most important maintenance vector of the virus while *Aedes dentatus* is probably also a maintenance vector; the same two species and possibly *Aedes unidentatus* and *Aedes juppi* are maintenance vectors on the inland plateau of South Africa. Heavy rainfall

and the humid conditions that prevail during epidemics favour the breeding of other biting insects besides aedine mosquitoes. Following extensive flooding of aedine breeding sites, significant numbers of livestock become infected and circulate high levels of virus in their blood during the acute stage of infection. Other culicines and anopheline mosquitoes then become infected and serve as epidemic vectors, particularly *Culex theileri* in southern Africa, and biting flies such as midges, phlebotomids, stomoxids and simuliids serve as mechanical transmitters of infection. Although contagion has been demonstrated on occasion under artificial conditions, nonvectorial transmission is not considered to be important in livestock, as opposed to humans. Epidemics generally become evident in late summer after there has been an initial increase in vector populations and in circulation of virus, and terminate in late autumn when the onset of cold weather depresses vector activity, or when most animals are immune following natural infection, or after there has been successful intervention with vaccine.

Antibody surveys and laboratory studies have failed to prove that the virus is maintained in transmission cycles in rodents, birds, monkeys, baboons or other wild vertebrates, although it is felt that wild ruminants could play a role similar to their domestic counterparts in areas where they predominate. It is also believed that the possibility of endemicity of the virus in forests cannot be dismissed entirely, and merits further investigation.

It was recognized from the time of the original investigations in Kenya that febrile illness in humans accompanied outbreaks of disease in livestock, and that some patients experienced transient loss of visual acuity, but the occurrence of serious ocular sequelae was first reported in the 1950–1951 epidemic in South Africa. Human deaths following natural infection were first recorded in South Africa during the epidemic of 1974–1976 when seven patients are known to have died of encephalitis and haemorrhagic fever associated with necrotic hepatitis. Subsequently deaths were also observed in Zimbabwe.

Outbreaks of Rift Valley fever were reported in the Sudan in 1973 and 1976. In 1977 and 1978 a major epidemic occurred along the Nile delta and valley in Egypt, causing an unprecedented number of human infections and deaths, as well as numerous deaths and abortions in sheep and cattle and some losses in goats, water buffaloes and camels. Estimates of the number of human cases of disease range from 18 000 to more than 200 000 with at least 598 deaths occurring from encephalitis and/or haemorrhagic fever. A severe epidemic occurred in 1987 in the Senegal River basin of southern Mauritania and northern Senegal. In Mauritania alone an estimated 224 human patients died of the disease, and there was a high rate of abortion in sheep and goats. Further outbreaks of Rift

Valley fever occurred in Mauritania in 1993 and 1998 with smaller numbers of human casualties, while a minor outbreak of disease in livestock occurred in Senegal in 1994–1995.

The outbreaks of Rift Valley fever which occurred in North and West Africa differed in many respects from the pattern of disease which had hitherto been observed in sub-Saharan Africa; in particular they occurred independently of rainfall in arid countries, apparently in association with vectors which breed in large rivers and dams. The presence of the virus in the Sudan and certain West African countries had long been known from antibody studies, and there had been periodic isolations of the virus in West Africa, where it was sometimes reported as Zinga virus, which is now known to be identical to Rift Valley fever virus. Various theories were advanced to account for the first known appearance of the virus in Egypt in 1977, including the carriage of infected mosquitoes from the Sudan at high altitude by prevailing winds associated with the intertropical convergence zone. The introduction of the virus through the transportation of infected sheep and cattle on the Nile or overland from northern Sudan to markets in southern Egypt was considered to have been the strongest possibility, and the movement of slaughter animals by sea could account for the evidence of infection detected in the northern and eastern coastal areas of Egypt. Although transportation on some routes would take a long time in relation to the course of the infection, Rift Valley fever virus has been shown to persist for prolonged periods in various organs of sheep, particularly the spleen, for up to 21 days after infection. The same could be true for goats and cattle, or even the camels brought in by overland caravan routes. It is believed that humans slaughtering or handling the tissues of such animals could have become infected and served as the amplifying hosts for the infection of mosquitoes since the main vector in the Egyptian epidemic, *Culex pipiens*, is known to be peridomestic and anthropophilic. In at least one instance there were indications that human infections centred on a location where introduced camels were slaughtered.

The occurrence of the epidemic in Egypt raised the spectre that Rift Valley fever could be introduced to the mainland of Eurasia, and the possibility was underscored by the fact that the virus is apparently capable of utilizing a wide range of mosquitoes as vectors. Extensive preventive vaccination of livestock was undertaken at the time in the Sinai peninsula and Israel. However, only isolated outbreaks of Rift Valley fever were recorded in Egypt in 1979 and 1980, and thereafter the country remained free of the disease for 12 years until ocular complications of the infection in humans, and abortions in cattle and water buffalo, were noted in the Aswan Governate in

May 1993. On this occasion there was not the same tendency for an explosive outbreak of the disease to occur as in 1977–1978, but by October 1993 infections of humans and livestock, including sheep, had been recognized across the length of the country in Sharqiya, Giza and El Faiyum Governates, and further infections were observed in 1994 (Arthur *et al.*, 1993; Botros *et al.*, 1997; World Health Organization, 1993, 1994).

From late October 1997 to February 1998, a large outbreak of Rift Valley fever occurred in north-eastern Kenya and adjoining southern Somalia, following the occurrence of heavy rains and extensive flooding in what is essentially an arid area where people had been receiving food relief owing to the extreme drought conditions that had prevailed in the preceding two years (Woods *et al.*, 2002; World Health Organization, 1998). There were heavy losses of livestock and an estimated 500 human deaths, but Rift Valley fever could not be confirmed in all instances. An agent isolated from human blood was thought to be a new bunyavirus and given the name Garissa virus, but was later found to be Ngari virus, originally isolated from mosquitoes in West Africa and recently shown to be a reassortant bunyavirus (Bowen *et al.*, 2001; Briese *et al.*, 2006; Gerrard *et al.*, 2004; Nichol, 2003). Antibody to Ngari virus was found in people in both Kenya and Somalia, but the importance of the virus as a human pathogen remains to be determined; many of the deaths could have been due to the appearance of malaria in an area not normally affected by this disease. It was subsequently established that extensive outbreaks of Rift Valley fever had also occurred elsewhere in Kenya and northern Tanzania following heavy rains in the region, and a few human deaths in southern Kenya were also ascribed to the disease. An outbreak of Rift Valley fever was again recognized in the North-Eastern Province of Kenya in November 2006 following the occurrence of heavy rains, and by the end of January 2007 it had also appeared in the Coastal, Central, Rift Valley and Eastern Provinces. A total of 684 human cases of the disease were recorded, with a 20% death rate. The disease also occurred in neighbouring Somalia with 114 cases and a 45% death rate being reported. Outbreaks were recognized in Tanzania in January 2007, but investigations revealed that livestock and human disease had occurred in late 2006, with a total of 191 cases and a 21% death rate being recorded. Following heavy rains an outbreak of Rift Valley fever occurred in October–November 2007 in White Nile, Gezira and Senar Provinces of Sudan, with 451 cases of the disease and an approximately 36% death rate being reported (World Health Organization, 2007a, 2007b). The high death rates reported in these outbreaks were estimated from cases which were diagnosed mainly on clinical grounds, without reference to mild or inapparent infections.

In September, 2000, Rift Valley fever broke out simultaneously in Jizan Province in south-west Saudi Arabia and in adjoining Yemen (Abdo-Salem *et al.*, 2006; Al Hazmi *et al.*, 2003; Madani *et al.*, 2003). The outbreaks lasted until early 2001, and resulted in 245 human deaths and the loss of thousands of sheep and goats. There had been heavy rains in the inland mountain range which runs parallel to the coast, with drainage from the mountains resulting in the creation of ideal mosquito breeding habitats (Jupp *et al.*, 2002). There was speculation that the virus may have been imported from Africa with slaughter animals, or carried from Africa by wind-borne mosquitoes in 2000, but there were no known epidemics in the Horn of Africa at the time. It is much more likely that infected animals were imported during the 1997–1998 epidemic in East Africa, and that infection had smouldered on the Arabian Peninsula until ideal circumstances for an epidemic occurred following heavy rains in 2000. Recent detection of IgM antibody in sentinel sheep suggests that the virus may have become endemic on the Arabian Peninsula (Elfadil *et al.*, 2006).

In contrast to the main vector in the Egyptian epidemic of 1977–1978, the principal mosquito vectors of Rift Valley fever virus in sub-Saharan Africa tend to be zoophilic and sylvatic, with the result that humans become infected mainly from contact with animal tissues, although there are instances where no such history can be obtained and it must be assumed that infection has resulted from mosquito bite. Occasional infections diagnosed in tourists from abroad who visited countries in Africa are also thought to have resulted from mosquito bite. Generally, people who become infected are involved in the livestock industry, such as farmers who assist in dystocia of livestock, farm labourers who salvage carcasses for human consumption, veterinarians and their assistants, and abattoir workers. There are numerous reports of humans becoming infected while investigating the disease in the field or laboratory, and the first known human fatality was recorded in 1934 in a laboratory worker, but since the infection was complicated by thrombophlebitis and the patient died from pulmonary embolism, the potential lethality of the virus for humans was overlooked until fatal infections were recognized during the 1974–1976 epidemic in South Africa. The results of surveys following epidemics in southern Africa indicated that 9–15% of farm residents became infected, with a slight pre-ponderance of adult males, although it appeared that housewives also gained infection from handling fresh meat.

No outbreaks of the disease have been recognized in urban consumer populations and it is surmised that the fall in pH associated with the maturation of meat in abattoirs is deleterious to the virus. Moreover, highest infection rates were found in workers in the by-products

sections of abattoirs in Zimbabwe and the implication is that the carcasses of infected animals which reach abattoirs are generally recognized as being diseased and are condemned as unfit for human consumption, and are then sterilized in the process of preparing carcase meal for fertilizers.

Human infection presumably results from contact of virus with abraded skin, wounds or mucous membranes, but aerosol and intranasal infection have been demonstrated experimentally and circumstantial evidence suggests that aerosols have been involved in some human infections in the laboratory, and in the field during the Egyptian epidemic. Many infections in Egypt are thought to have resulted from the slaughter of infected animals outside of abattoirs, and the fact that the mosquito vector was anthropophilic is thought to explain the high incidence of infection which occurred in people of all ages and diverse occupations. Low concentrations of virus have been found in milk and body fluids such as saliva and nasal discharges of sheep and cattle, and it appears that there may have been a connection between human infection and consumption of raw milk in Mauritania. In view of the intense viraemia which occurs in humans and the fact that virus has been isolated from throat washings, it is curious that there are no records of person-to-person transmission of infection.

Despite the sudden and dramatic change perceived in the nature of the human disease in the mid 1970s, it was deduced from the 598 reported deaths and 200 000 estimated cases of disease that Rift Valley fever had a case fatality rate of less than 1% in Egypt where a high prevalence of schistosomiasis may have predisposed the population to severe liver disease. The fatality rate may even have been lower in relation to total infections, since an antibody prevalence rate of 30% was detected and the human population estimated at 1 to 3 million in the areas affected by the epidemic. On the other hand, remarkably high estimates of 5 and 14% were made for case fatality rates in two separate populations in the 1987 epidemic in Mauritania, on the basis of the proportion of IgM antibody-positive people who actually reported illness considered to be compatible with Rift Valley fever, but it can be deduced that the fatality rates in terms of total IgM antibody-positive patients are much closer to the corresponding fatality rate in Egypt.

The majority of Rift Valley fever infections in humans are inapparent or associated with moderate to severe, non-fatal, febrile illness. After an incubation period of two to six days, the onset of the benign illness is usually very sudden and the disease is characterized by rigor, fever that persists for several days and is often biphasic, headache with retro-orbital pain and photophobia, weakness, and muscle and joint pains. Sometimes there is

nausea and vomiting, abdominal pain, vertigo, epistaxis and a petechial rash. Defervescence and symptomatic improvement occur in four to seven days in benign disease and recovery is often complete in two weeks, but in a minority of patients the disease is complicated by the development of ocular lesions at the time of the initial illness or up to four weeks later. Estimates for the incidence of ocular complications range from less than 1 to 20% of human infections, and possibly the differences stem from failure to record mild cases in populations where illiterate persons are less likely to report minor disturbances of vision. The ocular disease usually presents as a loss of acuity of central vision, sometimes with development of scotomas. The essential lesion appears to be focal retinal ischaemia, generally in the macular or paramacular area, associated with thrombotic occlusion of arterioles and capillaries, and is characterized by retinal oedema and loss of transparency caused by dense white exudate and haemorrhages. Sometimes there is severe haemorrhage and detachment of the retina. The lesions and the loss of visual acuity generally resolve over a period of months with variable residual scarring of the retina, but in instances of severe haemorrhage and detachment of the retina there may be permanent uni- or bilateral blindness.

Probably less than 1% of human patients develop the haemorrhagic and/or encephalitic forms of the disease. Underlying liver disease may predispose to the haemorrhagic form of the illness. The haemorrhagic syndrome starts with sudden onset of febrile illness similar to the benign disease, but within two to four days there may be development of a petechial rash, purpura, ecchymoses and extensive subcutaneous haemorrhages, bleeding from needle puncture sites, epistaxis, haematemesis, diarrhoea and melaena, sore and inflamed throat, gingival bleeding, epigastric pain, hepatomegaly or hepatosplenomegaly, tenderness of the right upper quadrant of the abdomen and deep jaundice. This is followed by pneumonitis, anaemia, shock with racing pulse and low blood pressure, hepatorenal failure, coma and cardiorespiratory arrest. Factors contributing to fatal outcome in the hepatic form of the disease include anaemia, shock and hepatorenal failure, with the kidney lesions possibly being as important as shock in producing anuria. A proportion of the less severely affected patients may make a protracted recovery without sequelae.

Encephalitis may occur in combination with the haemorrhagic syndrome. Otherwise, signs of encephalitis in humans may supervene during the acute illness, or up to four weeks later and include severe headache, vertigo, confusion, disorientation, amnesia, meningismus, hallucinations, hypersalivation, grinding of teeth, choreiform movements, convulsions, hemiparesis, lethargy, decerebrate posturing, locked-in syndrome, coma and death. A

proportion of patients may recover completely, but others may be left with sequelae, such as hemiparesis.

Abortion is the usual, if not invariable, outcome to infection of pregnant ruminants, but an attempt to relate the occurrence of abortion in humans to evidence of Rift Valley fever infection in Egypt produced inconclusive results. Diagnosis of the infection in a neonatal child in Saudi Arabia in 2000 implied that there had been vertical transmission of infection, but the mother was not tested (Arishi *et al.*, 2006).

By analogy with the course of events believed to follow natural infection with other arthropod-borne viruses, it can be surmised that the pathogenesis of the disease may involve some replication of virus at the site of inoculation, conveyance of infection by lymphatic drainage to regional lymph nodes where there is further replication with spillover of virus into the circulation to produce primary viraemia, which in turn leads to systemic infection, and that intense viraemia then results from release of virus following replication in major target organs. Wild Rift Valley fever virus, which has not been subjected to serial passaging in laboratory host systems, is described as being hepato-, viscerotrophic or pantropic, and immunofluorescence studies in laboratory animals indicate that replication occurs in littoral macrophages of lymph nodes, most areas of the spleen except T-dependent peri-arteriolar sheaths, foci of adrenocortical cells, virtually all cells of the liver, most renal glomeruli and some tubules, lung tissue and scattered small vessel walls, as well as in necrotic foci in the brains of individuals which develop the encephalitic form of the disease. These sites correspond to the lymphoid necrosis in lymph nodes and spleen, hepatic necrosis and adrenal, lung and glomerular lesions seen in humans and livestock, and the brain lesions in humans (encephalitis has not been described in natural disease of ruminants). Titration of infectivity in organ homogenates indicates that the liver and spleen are the major sites of virus replication. Cell damage is ascribed directly to the lytic effects of the virus, but the inflammatory response seen in human brain tissue suggests that there may also be an immunopathological element to the pathogenesis of encephalitis. The same may be true for ocular lesions. Recovery is mediated by nonspecific and specific host responses, and the clearance of viraemia correlates with the appearance of neutralizing antibody. No significant antigenic differences have been detected between isolates of the virus, although differences in pathogenicity for laboratory rodents have been demonstrated, and immunity appears to be lifelong.

The haemostatic derangement that occurs in Rift Valley fever has been investigated in rhesus monkeys, but the mechanisms involved remain speculative. Impairment of coagulation occurs even in benign infection of monkeys,

and moderate thrombocytopenia has been observed in benign infection in sheep, but haemostatic derangement is most severe in the fatal hepatic syndrome. It is postulated that the critical lesions are vasculitis and hepatic necrosis. Destruction of the antithrombotic properties of endothelial cells is thought to trigger intravascular coagulation, and the widespread necrosis of hepatocytes and other affected cells to results in the release of procoagulants into the circulation. Severe liver damage presumably limits or abolishes production of coagulation proteins and reduces clearance of activated coagulation factors, thereby further promoting the occurrence of disseminated intravascular coagulopathy, which in turn augments tissue injury by impairing blood flow. Vasculitis and haemostatic failure result in purpura and widespread haemorrhages.

Clinical pathology findings in humans are compatible with observations made in haematological and coagulation studies on monkeys, except that leukocytosis and anaemia may be more marked in severe human disease (Al Hazmi *et al.*, 2003). In most species there is an initial leukopenia followed by leukocytosis, and the same may be true for humans. Monkeys may have prolonged activated partial-thromboplastin times and prothrombin times even in benign infection, and in severe liver disease there may be depletion of coagulation factors II, V, VII, IX, X and XII, thrombocytopenia and platelet dysfunction, increased schistocyte counts and depletion of fibrinogen together with raised fibrin degradation product levels. Raised serum aspartate aminotransferase and alanine aminotransferase levels have been recorded even in benign disease in humans.

Treatment is essentially symptomatic, and supportive therapy in the haemorrhagic disease includes replacement of blood and coagulation factors. Results obtained in animal models suggest that the administration of immune plasma from recovered patients may be beneficial. The antiviral drug ribavirin inhibits virus replication in cell cultures and laboratory animals, and it has been suggested that it could be used even in benign disease in order to obviate the potentially serious complications which may occur in humans.

Specimens to be submitted for laboratory confirmation of the diagnosis include blood from live patients, and tissue samples, particularly liver, but also spleen, kidney, lymph nodes and heart blood of deceased patients. Tissue samples should be submitted in duplicate in a viral transport medium, and in 10% buffered formalin for histopathological examination.

Viral antigen can frequently be detected rapidly in tissues and/or blood by a variety of immunological methods, including immunodiffusion, complement fixation, immunofluorescence and enzyme-linked immunoassay, and viral nucleic acid can readily be detected by RT-PCR

(Bird *et al.*, 2007; Drosten *et al.*, 2002; Jupp *et al.*, 2002; Weidmann *et al.*, 2008). Viraemia lasts for up to a week. The virus is cytopathic and can be isolated readily in almost all cell cultures commonly used in diagnostic laboratories, and identified rapidly by immunofluorescence. Virus can also be isolated in suckling or weaned mice, or hamsters, inoculated intracerebrally or intraperitoneally, and antigen can be identified in harvested brain or liver by the immunological methods mentioned above. Definitive identification of isolates is achieved by performing neutralization tests with reference antiserum, or by nucleotide sequencing of RT-PCR products.

Histopathological lesions, particularly those in the liver, are considered to be pathognomonic, and are essentially similar in humans and domestic ruminants. The severity of the lesions varies from primary foci of coagulative necrosis, consisting of clusters of hepatocytes with acidophilic cytoplasm and pyknotic nuclei, multi-focally scattered throughout the parenchyma, to massive liver destruction in which the primary foci comprising dense aggregates of cytoplasmic and nuclear debris, some fibrin and a few neutrophils and macrophages, can be discerned against a background of parenchyma reduced by nuclear pyknosis, karyorrhexis and cytolysis to scattered fragments of cytoplasm and chromatin, with only narrow rims of degenerated hepatocytes remaining reasonably intact close to portal triads. Intensely acidophilic cytoplasmic bodies which resemble the Councilman bodies of yellow fever are common, and rod-shaped or oval eosinophilic intra-nuclear inclusions may be seen in intact nuclei. Icterus may be evident.

Antibody to Rift Valley fever virus can be demonstrated in complement fixation, enzyme-linked immunoassay, indirect immunofluorescence, haemagglutination inhibition or neutralization tests. Diagnosis of recent infection is confirmed by demonstrating seroconversion or a fourfold or greater rise in titre of antibody in paired serum samples, or by demonstrating IgM antibody activity in an enzyme-linked immunoassay.

Benign Rift Valley fever in humans must be distinguished from other zoonotic diseases such as brucellosis and Q fever, while the fulminant hepatic disease must be distinguished from the so-called formidable viral haemorrhagic fevers of Africa: Lassa fever, CCHF, Marburg disease and Ebola fever. The occurrence of HFRS associated with hantavirus infections, is also a theoretical possibility in Africa.

An inactivated and a live attenuated vaccine are available for immunization of livestock, but it is usually difficult to persuade farmers to vaccinate livestock during long inter-epidemic periods. The attenuated vaccine confers lifelong immunity in sheep, but is abortigenic and

teratogenic in a small proportion of pregnant ewes. The attenuated vaccine is poorly immunogenic in cattle and they are immunized annually with the inactivated vaccine. A formalin-inactivated cell culture vaccine produced in the United States is used on an experimental basis to immunize people such as laboratory and field workers who are regularly exposed to Rift Valley fever infection.

Uukuniemi Virus

Uukuniemi virus was originally isolated in Finland in 1960s from *Ixodes ricinus* ticks, which parasitize livestock but also bite humans. The virus has subsequently been isolated from ticks, birds and field mice in Finland, Norway, Poland, Lithuania and the former USSR and Czechoslovakia. Antibody to the virus has been found in human sera in Finland, Hungary and former Czechoslovakia, but no evidence has been presented to indicate that infection is associated with disease. The remaining members of the serogroup have been isolated from ticks associated with passerine or sea birds, and have no known medical or veterinary significance.

GENUS *NAIROVIRUS*

Crimean–Congo Haemorrhagic Fever Virus

The literature on CCHF is the subject of several comprehensive reviews (Chumakov, 1974; Hoogstraal, 1979, 1981; Watts *et al.*, 1989). A disease given the name Crimean haemorrhagic fever was first observed on the Crimean peninsula in 1944, and it was demonstrated through the inoculation of human subjects that the disease was caused by a tick-transmitted virus, but the virus itself was only isolated in laboratory hosts, namely mice, in 1967. In 1969, it was shown that the agent of Crimean haemorrhagic fever was identical to a virus named Congo which had been isolated in 1956 from the blood of a febrile child in Stanleyville (now Kisangani) in what was then the Belgian Congo (now Democratic Republic of the Congo), and since that time the two names have been used in combination.

The distribution of CCHF virus extends over Eastern Europe, Asia and Africa: the presence of the virus or antibody to it has been demonstrated in the former USSR, Albania, Bulgaria, Greece, Turkey, Hungary, former Yugoslavia, France, Portugal, Serbia, Kosovo, Macedonia, Kuwait, Saudi Arabia, Oman, Dubai, Sharjah, Iraq, Iran, Afghanistan, Pakistan, India, China, Egypt, Ethiopia, Mauritania, Senegal, Burkina Faso, Benin, Nigeria, Central African Republic, Democratic Republic of the Congo, Kenya, Uganda, Tanzania, Zimbabwe, Namibia, South Africa and Madagascar. However, the evidence for France

and Portugal is based on limited observations and needs to be confirmed.

In many instances virus or antibody was discovered in deliberate surveys, but in some countries of Eastern Europe and Asia the presence of CCHF first became evident in nosocomial outbreaks of disease, or in epidemics that arose in circumstances where humans were exposed to ticks and livestock on a large scale, such as in major land reclamation or resettlement schemes in Bulgaria and parts of the former USSR. Notable outbreaks of the disease in Eurasia during recent years have resulted from the exposure of people to blood and ticks from slaughter stock imported from Africa and Asia to Saudi Arabia in 1990, the United Arab Emirates in 1994–1995, and Oman in 1995, plus large scale exposure of war refugees to outdoor conditions in Kosovo in 2000 and Albania in 2001 (El Azazy and Scrimgeour, 1997; Khan *et al.*, 1997; Papa *et al.*, 2002a, 2002b; Scrimgeour *et al.*, 1996; Williams *et al.*, 2000). Prior to 1981, a total of 15 cases of the disease had been reported in Africa, eight of them laboratory infections, and only one patient had developed haemorrhagic manifestations and died. Since then sporadic cases of haemorrhagic disease and deaths have been diagnosed regularly each year in southern Africa, probably as a result of increased awareness among clinicians, and severe disease has also been recorded elsewhere in Africa.

Phylogenetic studies indicate that there is marked diversity between CCHF isolates from geographically distinct regions, and although the differences do not necessarily correlate with pathogenicity, they need to be taken into account in designing diagnostic assays and vaccines (Ahmed *et al.*, 2005).

The virus has been isolated from at least 29 species of ixodid ticks, but for most species there is no definitive evidence that they are capable of serving as vectors, and in some instances the virus recovered from engorged ticks may merely have been present in the bloodmeal imbibed from a viraemic host. Members of three genera of ixodid ticks, *Hyalomma*, *Dermacentor* and *Rhipicephalus*, have been shown to be capable of transmitting infection trans-stadially and transovarially, but *Hyalomma* is considered to be the principal vector, and with the exception of Madagascar the known distribution of CCHF virus coincides with the world distribution of members of this genus of ticks. Moreover, the prevalence of antibody to CCHF virus detected in the sera of wild vertebrates in southern Africa was highest in large herbivores known to be the preferred hosts of adult *Hyalomma* ticks, and in small mammals such as hares which are the preferred hosts of immature *Hyalomma* ticks. Mammals of intermediate size, and passerine and water birds, generally lacked evidence of infection, but antibody was found in ostriches which are known to be parasitized by adult *Hyalomma*

ticks. Virus or antibody has also been demonstrated elsewhere in the sera of small mammals of Eurasia and Africa, such as little susliks, hedgehogs, hares and certain myomorph rodents, and in some instances it has been shown that these hosts develop viraemia of sufficient intensity to infect ticks.

High prevalences of antibody occur in domestic ruminants in areas infested by *Hyalomma* ticks and the virus causes inapparent infection or mild fever in cattle, sheep and goats, with viraemia of sufficient intensity to infect ticks. It is doubtful whether transovarial transmission occurs with sufficient frequency in ticks to ensure indefinite perpetuation of the virus in the absence of amplification of infection in vertebrate hosts, and in particular, it is believed that the infection of small vertebrates constitutes an important amplifying mechanism which facilitates trans-stadial transmission of virus by adult ticks to large vertebrates.

Young ruminants generally acquire natural infection early in life and are viraemic for about a week. Humans become infected when they come into contact with the viraemic blood of young animals in the course of performing procedures such as castrations, vaccinations, inserting ear tags or slaughtering the animals. Animals that are raised under tick-free conditions and moved to infested locations later in life may acquire tick-borne diseases of livestock at the same time that they become infected with CCHF virus, and consequently humans become infected from contact with viraemic blood in the course of treating sick animals or butchering those that die. The available evidence suggests that the infection in humans is acquired through contact of viraemic blood with broken skin, and this accords with the fact that nosocomial infection in medical personnel usually results from accidental pricks with needles contaminated with the blood of patients, or similar mishaps. Common source outbreaks involving more than one case of the disease can occur when several people are exposed to infected tissues. Infection appears to be limited to those who have contact with fresh blood or other tissues, probably because infectivity is destroyed by the fall in pH which occurs in tissues after death, and there has been no indication that CCHF virus constitutes a public health hazard in meat processed and matured according to normal health regulations. Many human infections result directly from tick bite, and it has been observed that people can also become infected from merely squashing ticks between the fingers. Some patients are unable to recall contact with blood or other tissues of livestock, or having been bitten by ticks, but live in or have visited a rural environment where such exposure to infection is possible. Town dwellers sometimes acquire infection from contact with animal tissues or tick bite while on hunting or hiking trips.

The majority of patients tend to be adult males engaged in the livestock industry, such as farmers, herdsman, slaughtermen and veterinarians. Seroprevalence studies indicate that infection of humans is uncommon despite the widespread evidence of infection in livestock, and this may be explained by the facts that viraemia in livestock is short-lived, and of low intensity compared to that in other zoonotic diseases such as Rift Valley fever, and that humans are not the preferred hosts of *Hyalomma* ticks. The low prevalences of antibody generally found in populations at risk, and the paucity of evidence of inapparent infection encountered among the cohorts of cases of the disease, suggests that infection is frequently symptomatic.

Incubation periods are generally short, ranging from one to three days (maximum nine) following infection by tick bite, and are usually five or six days (maximum 13) in people exposed to infected blood or other tissues of livestock or human patients. Onset of the disease is usually very sudden. Patients develop fever, rigors, chills, severe headache, dizziness, neck pain and stiffness, sore eyes, photophobia, myalgia and malaise, with intense backache or leg pains. Nausea, sore throat and vomiting commonly occur early in the illness and patients may experience non-localized abdominal pain and diarrhoea at this stage. Fever is often intermittent and patients may undergo sharp changes of mood over the next two days, with feelings of confusion and aggression. By the second to fourth day of illness patients may exhibit lassitude, depression and somnolence, and have a flushed appearance with injected conjunctivae or chemosis. By this time, tenderness may be localized in the right upper quadrant of the abdomen, and hepatomegaly may be discernible. Tachycardia is common and patients may be slightly hypotensive. There may be lymphadenopathy, and enanthem and petechiae of the throat, tonsils and buccal mucosa.

A petechial rash appears on the trunk and limbs on days 3–6 of illness, and this may be followed rapidly by the appearance of large bruises and ecchymoses, especially in the antecubital fossae, upper arms, axillae and groin. Epistaxis, haematemesis, haematuria, melaena, gingival bleeding and bleeding from the vagina or other orifices may commence on day 4–5 of illness, or even earlier. Sometimes a haemorrhagic tendency is evident only from the oozing of blood from injection or venipuncture sites. There may be internal bleeding, including retroperitoneal and intracranial haemorrhage. Severely ill patients may enter a state of hepatorenal and pulmonary failure from about day 5 onwards and progressively become drowsy, stuporous and comatose. Jaundice may become apparent during the second week of illness. The mortality rate is approximately 30% and deaths generally occur on

days 5–14 of illness. Patients who recover usually begin to improve on day 9 or 10 of illness, but asthenia, conjunctivitis, slight confusion and amnesia may continue for a month or longer.

Changes in clinical pathology values recorded during the first few days of illness include leukocytosis or leukopenia, and elevated aspartate transaminase, alanine transaminase, gamma-glutamyl transferase, lactic dehydrogenase, alkaline phosphatase and creatine kinase levels, while bilirubin, creatinine and urea levels increase and serum protein levels decline during the second week. Thrombocytopenia, elevation of prothrombin ratio, activated partial thromboplastin time, thrombin time and fibrin degradation products, and depression of fibrinogen and haemoglobin values are also evident during the first few days of illness, indicating that the occurrence of disseminated intravascular coagulopathy is probably an early and central event in the pathogenesis of the disease. Changes are more severe in fatal than in nonfatal infections, and the occurrence of certain markedly abnormal clinical pathology values during early illness are predictive of fatal outcome (Ergonul *et al.*, 2006a; Swanepoel *et al.*, 1987, 1989).

It is surmised that peripherally introduced CCHF virus undergoes some replication at the site of inoculation, and that haematogenous and lymph-borne spread of infection occurs to organs such as the liver which are major sites of replication. Although it has not been shown conclusively that there is infection of endothelium, capillary fragility is a feature of the disease and there is evidence of formation of circulating immune complexes with complement activation, and this would contribute to damage of the capillary bed and the genesis of renal and pulmonary failure. Endothelial damage would account for the occurrence of a rash and would contribute to haemostatic failure through stimulating platelet aggregation and degranulation, with consequent activation of the intrinsic coagulation cascade. It is clear from the results of therapeutic administration of platelets to patients that they are consumed, and evidence of depression of thrombopoiesis in bone marrow has been reported. Widespread tissue damage in organs such as the liver would result in further release of procoagulants such as tumour necrosis factor into the bloodstream, and impairment of the circulation through the occurrence of a disseminated intravascular coagulopathy would contribute to further tissue damage. Damage to the liver would also impair synthesis of coagulation factors to replace those which are consumed.

Limited studies indicate that elevated serum levels of the pro-inflammatory cytokines tumour necrosis factor- α and interleukin-6 are significantly higher in patients with fatal outcome (Ergonul *et al.*, 2006b; Papa *et al.*, 2006). It is postulated that release of pro-inflammatory cytokines

by T-helper lymphocytes and macrophages triggers the occurrence of haemophagocytosis in bone marrow, and that endothelial damage associated with the occurrence of disseminated intravascular coagulopathy is caused by cytokine storms rather than directly by viral infection (Doganci, 2007; Fisgin *et al.*, 2008; Karti *et al.*, 2004).

Lesions in the liver vary from disseminated foci of coagulative necrosis, mainly mid-zonal in distribution, to massive necrosis involving over 75% of hepatocytes, and a variable degree of haemorrhage, with little or no inflammatory cell response. Lesions in other organs include congestion, haemorrhage and focal necrosis in the central nervous system, kidneys and adrenals and general depletion of lymphoid tissues. Fibrin deposits may be seen in small blood vessels in parenchymatous organs including the liver, and thrombus formation and infarction may contribute to the pathogenesis of the necrotic lesions in these organs.

Where possible, patients are treated by specially trained staff in institutions equipped for handling formidable viral haemorrhagic fevers, and barrier-nursing techniques are used for the protection of medical personnel. Therapy appropriate for disseminated intravascular coagulopathy, such as the use of heparin, may be contemplated early in the course of the disease by clinicians well versed in the treatment of haemostatic failure, but the procedure is considered to be risky, and generally only patients who acquire nosocomial infection come to medical attention at a sufficiently early stage. Standard treatment consists of replacement of red blood cells, platelets, other coagulation factors, protein (albumin) and intravenous feeding as indicated by clinical pathology findings. Immune plasma from recovered patients has been used in therapy, but there is no firm evidence from controlled trials of the value of the treatment, and there has been a lack of a uniform product with proven virus-neutralizing activity. Ribavirin has been found to inhibit virus replication in cell cultures, and in suckling mice, and preliminary results of a trial in human patients are promising.

On account of the propensity of the virus to cause laboratory infections, and the severity of the human disease, investigation of CCHF is generally undertaken in maximum security laboratories in countries which have biosafety regulations. Specimens to be submitted for laboratory confirmation of the diagnosis include blood from live patients and, in order to avoid performing full autopsies, heart blood and liver samples taken with a biopsy needle from deceased patients. During the acute phase of illness viral nucleic acid can be detected in blood by RT-PCR, viral antigen can be detected by enzyme-linked immunoassay, and virus can be isolated in cell cultures or mice (Burt *et al.*, 1998; Drosten *et al.*, 2002). Virus can be isolated from blood and organ suspensions in a wide

variety of primary and line cell cultures, including Vero, CER and BHK-21 cells, and identified by immunofluorescence. Isolation and identification can be achieved in one to five days, but cell cultures lack sensitivity and usually only detect high concentrations of virus present in the blood of severely ill patients during the first five days or so of illness. Intracerebral inoculation of suckling mice is more sensitive and can be used to demonstrate low concentrations of virus present in blood up to 13 days after the onset of illness.

Antibodies, both IgG and IgM, become demonstrable by indirect immunofluorescence from about day 7 of illness (slightly earlier by enzyme-linked immunoassay), and are present in the sera of all survivors of the disease by day 9 at the latest. The IgM antibody activity declines to undetectable levels by the fourth month after infection, and IgG titres may begin to decline gradually at this stage, but remain demonstrable for at least five years. Recent or current infection is confirmed by demonstrating seroconversion, or a fourfold or greater increase in antibody titre in paired serum samples, or IgM antibody activity in a single sample. Patients who succumb rarely develop a demonstrable antibody response and the diagnosis is confirmed by isolation of virus from serum, or from liver specimens, or by demonstration of antigen in liver sections by immunohistochemistry. Observation of necrotic lesions compatible with CCHF infection in sections of liver, provides presumptive evidence in support of the diagnosis.

The disease must be distinguished from the other so-called formidable viral haemorrhagic fevers: Lassa fever, Marburg disease, Ebola fever and HFRS (hantavirus infections), other febrile illnesses such as Rift Valley fever, Q fever and brucellosis which can be acquired from contact with animal tissues, as well as tick-borne typhus (*Rickettsia conorii* infection commonly known as tickbite fever), but many other conditions including bacterial septicaemias may resemble CCHF.

The control of CCHF through the application of acaricides to livestock is impractical, particularly under the extensive farming conditions which prevail in the arid areas where *Hyalomma* ticks are most prevalent. Pyrethroid preparations are available which can be used to kill ticks that come into contact with human clothing. Veterinarians, slaughtermen and others involved with livestock should be aware of the disease and take practical steps, such as the wearing of gloves, to limit or avoid exposure of naked skin to fresh blood and other tissues of animals. Inactivated mouse brain vaccine for the prevention of human infection has been used on a limited scale in Eastern Europe and the former USSR. Development of a safe and effective modern vaccine is inhibited by the limited potential demand for such a vaccine.

Nairobi Sheep Disease Virus

Nairobi sheep disease virus was first isolated from sheep blood in Kenya in 1910 and is known to be associated with disease of small ruminants, specifically sheep and goats, in a narrow band straddling the equator from Kenya in the east to Congo in the west. Antibody, but not disease, has also been found to the north of Kenya in Ethiopia and Somalia, and southwards along the east of the continent to Mozambique and Botswana. The virus can be transmitted trans-stadially by a range of ixodid ticks, including *Amblyomma variegatum*, but the endemic vector appears to be *Rhipicephalus appendiculatus*, in which transovarial transmission occurs. The disease in sheep and goats is characterized by fever, haemorrhagic gastroenteritis and abortion in pregnant animals. High mortality occurs when susceptible sheep or goats are introduced into an endemic area, but within such areas young animals appear to undergo benign infection as maternal immunity wanes, and there is a high prevalence of immunity in adult animals. Attenuated live and killed vaccines for sheep and goats are available in East Africa. Small antelope are susceptible to the disease, and rodents develop viraemic infection, but seroprevalence studies have failed to identify wild maintenance hosts of the virus. Larger ruminants such as cattle and buffalo are not susceptible to the disease. The virus has been isolated from human blood in association with febrile illness with arthralgia and malaise in Uganda, and laboratory infection has been recorded. Antibody prevalence rates of up to 20% have been found in humans in endemic areas.

Ganjam virus, first isolated from ixodid ticks in India in 1954, is considered to be identical to Nairobi sheep disease virus. It has been isolated from the blood of sheep and humans with febrile illness in India, where it is associated with ticks of the genus *Haemaphysalis*. There is speculation that the virus may have been translocated from India to Africa with ectoparasites on sheep and goats, which have been traded along sea routes for centuries.

Dugbe Virus

There have been approximately 600 isolations of Dugbe virus from ixodid ticks, mainly *A. variegatum*, in Nigeria, Central African Republic, Kenya and Ethiopia. The virus has also been isolated frequently from cattle blood in surveys, and from a giant rat (*Cricetomys gambianus*), aedine mosquitoes and *Culicoides* midges in Nigeria, and there is serological evidence of the occurrence of the virus in Senegal and Uganda. There have been seven isolations of the virus from the blood of patients with benign febrile illness in Nigeria and Central African Republic (including a laboratory infection). One patient

had mild meningitis and virus was isolated from CSF. Surprisingly, serosurveys have not revealed widespread human infection.

GENUS HANTAVIRUS

Hantaan, Dobrava, Seoul, Puumala, Sin Nombre and Related Viruses

Hantaviruses are associated with a range of nephrotic diseases in Asia and Europe known variously as haemorrhagic nephrosonephritis, Korean haemorrhagic fever, Songo fever, epidemic haemorrhagic fever and nephropathia epidemica (NE), but use of the generic term haemorrhagic fever with renal syndrome (HFRS) is advocated, while the term hantavirus pulmonary syndrome (HPS) is preferred for respiratory disease associated with hantaviruses in the Americas although some authors consider hantavirus cardiopulmonary syndrome (HCPS) to be more appropriate.

The existence of a febrile disease with haemorrhagic and renal manifestations has been recognized in Eurasia at least since the early years of the twentieth century and, in fact, descriptions of similar disease can be traced back to antiquity. A disease known by various names, including haemorrhagic nephrosonephritis, and which caused outbreaks among civilians and soldiers, was investigated independently in the far eastern region of the former USSR and in Manchuria prior to the Second World War, and by the early 1940s it was established that the condition could be transmitted to human volunteers by inoculation of filtrates of patients' blood or urine, or tissue extracts from *Apodemus* field mice (it had been observed that the incidence of disease was greatest at the end of summer when the mice were most numerous). At the same time, a febrile syndrome with abdominal pain, backache and renal manifestations was recognized in Scandinavia and numerous cases of this disease, later named nephropathia epidemica, were observed in soldiers during the Second World War.

Thousands of cases of a disease named Korean haemorrhagic fever were observed in soldiers and civilians during the Korean War of the early 1950s, and the disease continued to be seen after the war. In 1976 it was found that convalescent sera from patients in Korea could be used to demonstrate the presence of an antigen by immunofluorescence in the tissues of striped field mice (*Apodemus agrarius*) caught near the Hantaan river. The antigen was shown to be associated with a virus which could be subcultured in field mice. The virus, named Hantaan, was successfully grown in cell cultures in 1981, and shortly thereafter characterized as a member of the family *Bunyaviridae* and placed in a new genus *Hantavirus*.

The virus is widely distributed as the causative agent of HFRS in Asia, particularly in the eastern portion of the former USSR, China and Korea in association with *A. agrarius manichuricus* and *A. agrarius coreae*. A subtype of Hantaan virus, designated Amur virus, was isolated from *Apodemus peninsulae* (Korean field mice) in eastern Russia and subsequently shown to be associated with HFRS in China. Virus isolated from *A. peninsulae* in Korea and reported as Soochong virus, is probably synonymous with Amur virus (Baek *et al.*, 2006; Jiang *et al.*, 2007). Da Bie Shan, a further subtype of Hantaan virus isolated from Chinese white-bellied rats (*Niniventer confucianus*), is not known to be pathogenic for humans (Wang *et al.*, 2000). Virus associated with a severe form of HFRS in the Balkans (Albania, Greece, former Yugoslavia and Bulgaria) and found to be distinct from Hantaan virus, was independently isolated and described as Dobrava virus and Belgrade virus, and is currently designated Dobrava–Belgrade virus. It is associated with the yellow-necked field mouse, *A. flavicollis*. Subsequently, Saarema virus isolated from *A. agrarius agrarius* field mice in Europe, was found to be a subtype of Dobrava–Belgrade virus, but it causes milder disease.

Seoul virus was isolated in 1980s at Korea from the tissues of peridomestic rats, *Rattus rattus* and *Rattus norvegicus*, in association with human disease which occurred in urban as opposed to rural environments. It has been implicated in human disease in Japan, China and Korea, but has been isolated from rats in Egypt, the United States and elsewhere, and probably has a worldwide distribution. Isolation of the virus from rats led to speculation that hantaviruses in general may have been disseminated worldwide with ship-borne rodents. However, the distribution patterns of most hantaviruses within the interiors of continents, and the evolution of particular host relationships constitute evidence against recent spread of the viruses.

The last of the currently recognized hantaviruses associated with rodent hosts of the subfamily Murinae (Old World rats and mice), comprise Thailand virus isolated from bandicoots (*Bandicota indica*) in Thailand and Sangassou virus recently identified from partial genome nucleotide sequences obtained from tissues of African wood mice (*Hylomyscus simus*) in Guinea (Table 29.4) (Klempa *et al.*, 2006). Neither of these two viruses are known to be pathogenic for humans.

In the 1980s, the presence of the causative agent of nephropathia epidemica was demonstrated by immunofluorescence in the tissues of bank voles (*Myodes glareolus*) in Finland, and subsequently the agent, named Puumala virus, was grown in cell cultures and shown to be related to but distinct from Hantaan virus. Although evidence obtained in former Yugoslavia, Germany, Belgium,

France and Britain suggests that Puumala virus occurs widely in Europe, it is most prevalent at northerly latitudes, extending into the Arctic Circle in Scandinavia and the adjoining western portion of the former USSR, where highest concentrations of the bank vole occur. Muju virus, a subtype of Puumala virus recently identified from nucleotide sequences detected in *M. regulus* voles in Korea, is considered to be a possible cause of nephropathia epidemica-like infections in that country (Song *et al.*, 2007), while Hokkaido virus, associated with the red-backed vole (*Myodes rufocanus*) in Japan (Daud *et al.*, 2007; Kariwa *et al.*, 1999), is not known to be pathogenic for humans. Other hantaviruses associated with rodents of the subfamily Arvicolinae (voles, lemmings and muskrats) in Europe and Asia, and not known to cause human disease, include Topografov virus, Khabarovsk virus and Tula virus (Table 29.4). The findings in Asia and Europe prompted interest elsewhere, and as a result Prospect Hill virus, and later two other viruses, were isolated from voles in the United States, but no disease associations have been described for these viruses (Table 29.4).

In May 1993, an outbreak of an acute respiratory disease in adults, with a high fatality rate, was recognized in the Four Corners region of south-western USA where the borders of the states of Utah, Colorado, Arizona and New Mexico meet, but the initial occurrence of cases could be traced back to late 1992. Antibody cross-reactive with the antigens of known hantaviruses was found in the sera of patients, and by means of RT-PCR with consensus sequence hantavirus primers, it was possible to demonstrate the presence of nucleic acid of a novel hantavirus in the tissues of patients. The nucleotide sequence of the entire genome of the virus was determined even before it could be isolated and grown in cell cultures. The outbreak was apparently associated with a population explosion of the deer mouse *Peromyscus maniculatus* (a member of the Sigmodontinae subfamily of rodents), which is thought to be the natural host of the virus. Sporadic cases of similar disease were recognized elsewhere in the United States, some retrospectively, and by the end of 1993 a total of 53 cases had been confirmed (Bremner, 1994; Duchin *et al.*, 1994; Nichol *et al.*, 1993). After objections were raised to various names proposed for the new virus, Sin Nombre (Spanish for 'without name') was adopted, and the disease was referred to as hantavirus pulmonary syndrome (HPS).

Isolated cases and outbreaks of HPS were subsequently recognized beyond the distribution range of *P. maniculatus* in the United States, in Canada, and in several countries of South America. A succession of new hantaviruses was discovered in association with HPS, or in rodents tested speculatively in surveys (Table 29.4).

Thottapalayam virus, which had been isolated from suncid shrews in India in 1964, was found to be a distinct hantavirus, and recently nucleotide sequences of a putative new Tanganya virus were detected in a crocidurid shrew in Guinea (Table 29.4) (Klempa *et al.*, 2007).

Many of the new viruses were discovered through the detection of cross-reactive antibody activity to the antigens of existing hantaviruses, followed by the application of the PCR to detect viral nucleic acid, and genetic characterization. Adaptation to cell cultures followed the initial identification of the viruses, but *in vitro* culture has not yet been achieved in all instances. It is suspected that in addition to the hantaviruses currently known to be human pathogens, some of the remaining viruses may also prove to be associated with disease (Table 29.4) (Kanerva *et al.*, 1998; Monroe *et al.*, 1999; Schmaljohn and Hjelle, 1997; Schmaljohn *et al.*, 2002).

Serological classification of hantaviruses has lagged behind genetic characterization, primarily because the lack of *in vitro* culture systems for some of the viruses has prevented the performance of definitive cross-neutralization tests, but the extant information on antigenic affinities is in agreement with the genetic clustering of the viruses, which in itself conforms with the phylogeny of the rodent hosts (Table 29.4) (Puthavathana *et al.*, 1992; Arthur *et al.*, 1992; Chu *et al.*, 1994, 1995; Klein and Calisher, 2007; Kanerva *et al.*, 1998; Monroe *et al.*, 1999; Schmaljohn and Hjelle, 1997; Zeier *et al.*, 2005). In brief, all hantaviruses are antigenically related, with greatest affinities existing within clusters designated as Hantaan-like, Puumala–Prospect Hill-like and Sin Nombre-like, while Thottapalayam virus from shrews in India is more distantly related to the others. Viruses of the Hantaan-like group are associated with rodent hosts of the subfamily Murinae and with HFRS; Puumala–Prospect Hill-like viruses are associated with the subfamily Arvicolinae and with NE, and Sin Nombre-like viruses with the subfamily Sigmodontinae and with HPS (Table 29.4). Despite the fact that Seoul virus appears to be very widely distributed, incontrovertible evidence of disease associated with hantaviruses (detection of virus) has been obtained only for Asia, Europe and the Americas, while elsewhere there has only been inconclusive serological evidence of infection. However, Seoul, Hantaan and Puumala viruses have been encountered as contaminants of laboratory rodent colonies and are known to have caused infections in laboratory workers in the former USSR, Korea, Japan, Belgium, France and England. In one instance virus was inadvertently preserved for years in rat tissues kept in frozen storage. Hence, the potential exists for inadvertent dissemination of the viruses.

The distributions of the hantaviruses, insofar as they are known, tend to overlap, but conform to the distributions of the rodent hosts. Individual viruses have been isolated from more than one type of rodent, but each tends to have a particular association with a single species of rodent. The viruses appear to be apathogenic for their reservoir hosts. After the rodents become infected there is an initial viraemia followed by the persistence of infection, probably for life, in lungs, kidneys and possibly other organs, with chronic excretion of virus in urine, faeces and saliva, despite the occurrence of a demonstrable immune response. There does not appear to be intrauterine transfer of infection, and transmission between rodents is thought to occur by bite, aerosol or contamination of dust, food and other fomites with excreted virus. Gamasid mite parasites of rodents are suspected to be capable of transmitting infection, but transmission occurs in the laboratory in the absence of mites. Foci with very high infection rates are observed among rodents in nature.

Humans become infected by the same means as rodents, but airborne infection from dust contaminated with rodent urine and faeces appears to be the principal mechanism, and has been observed to occur even in people who briefly visited infected colonies of laboratory rodents. Infection occurs in three main situations: rural or sylvatic infection with Hantaan-like, Puumala-like or Sin Nombre-like viruses occurs in people who have occupational, residential or recreational exposure to rodent-infested buildings or to the outdoors, urban infection with Seoul virus occurs indoors in association with rat infestations, while all of the viruses may cause infections associated with laboratory rodents. Rodents are subject to periodic population explosions and crashes, and the incidence of human infection with Hantaan-like, Puumala-like and Sin Nombre-like viruses increases in years when the rodents are most numerous. Person-to-person spread of hantavirus infection has been observed in outbreaks of HPS caused by Andes virus in Argentina, but it has not been established whether transmission is associated with direct contact, droplets, aerosols or contaminated fomites (Wells *et al.*, 1997). Numerous cases of HPS have been reported in the Americas, and up to 200 000 hospitalized cases of HFRS are recorded in Eurasia each year, with more than half occurring in China (Monroe *et al.*, 1999; Schmaljohn and Hjelle, 1997).

Four clinical forms of HFRS are recognized and these vary in order of increasing severity from NE associated with Puumala virus infection, through mild or rat-borne HFRS associated with Seoul virus infection, to Far Eastern HFRS associated with Hantaan virus carried by

A. agrarius field mice, and so-called Balkan HFRS associated with Dobrava–Belgrade virus carried by *A. flavicollis* mice.

Far Eastern HFRS occurs in China, the eastern part of the former USSR and Korea, mainly in adult males with occupational exposure to the outdoors, such as farmers, forest workers and soldiers stationed in the field, and seldom occurs in children under 10 years of age. Most cases are seen in autumn and early winter when crops are harvested and the rodents are most numerous, and subsequently when the agricultural products are stored in proximity to homesteads. The incidence of asymptomatic infection is unknown, but it was noted that American soldiers participating in an exercise in Korea who seroconverted had all been ill, while in parts of Korea high-antibody prevalence rates without corresponding levels of disease have been observed.

The classical form of Far Eastern HFRS described in Korea has well-marked phases, but these may overlap and be obscured in mild cases (Lee, 1982). An incubation period of two to three weeks is followed by the abrupt onset of a febrile phase which lasts three to seven days and is marked by high fever, chills, malaise, myalgia, anorexia, headache, dizziness, ocular pain and abdominal and back pain, which is felt particularly in the renal area as a result of peritoneal and retroperitoneal oedema. Proteinuria is marked during this phase. Towards the end of the phase there is characteristic flushing of the face, neck and anterior chest, with the conjunctivae, palate and pharynx assuming an injected appearance, followed by the emergence of fine petechiae on the face, neck, soft palate and chest, together with conjunctival haemorrhages. Patients next enter a hypotensive phase which lasts hours to two days, and is marked by classical shock: tachycardia, narrowed blood pressure, cold and clammy skin, dulled senses and confusion. One third of fatal cases enter irreversible shock at this stage. There is marked proteinuria, microscopic haematuria, raised haematocrit levels (haemoconcentration), leukaemoid reaction and thrombocytopenia. Capillary haemorrhages are prominent. The patients then enter an oliguric phase which lasts three to seven days. Blood urea and creatinine levels increase, blood pressure begins to normalize, but hypertension may result from a hypervolaemic state. Bleeding tendencies increase markedly, and there may be epistaxis, conjunctival, cerebral and gastrointestinal haemorrhages and extensive purpura. There may be severe nausea and vomiting, lung oedema and symptoms referable to the central nervous system. Most deaths occur at this stage. A diuretic phase which follows may last days or weeks, and marks the start of clinical recovery. Diuresis of 3–6 l per day is common, but is influenced by dehydration, electrolyte imbalance or secondary infections. Severely ill patients are at risk in

this phase and may lapse into shock. A convalescent phase with progressive recovery of glomerular filtration rate, renal blood flow and urine-concentrating ability, may last two to three months. Mortality has been reduced from the 10–15% observed during the Korean War to 5%, with intensive supportive therapy and renal dialysis.

Balkan HFRS, associated with Dobrava–Belgrade virus, is also seen mainly in adult males, including woodcutters, shepherds and military personnel, but cases generally occur in spring and summer, possibly because there is not the same type of cereal crop farming as in the Far East, and the reservoir host is encountered in outdoor activities and at campsites during the warmer months of the year. The disease is essentially similar to Far Eastern HFRS, but is more severe, with a higher proportion of patients requiring renal dialysis, and with a greater tendency for the development of disseminated intravascular coagulopathy and haemorrhages. A case of the disease involving focal encephalitis with epileptic seizures and hemiparesis has been described (Cerar *et al.*, 2007). Reported death rates for Balkan HFRS range from 5 to 35%.

Natural outbreaks of mild or rat-borne HFRS, as opposed to outbreaks associated with laboratory rodent colonies, have been recorded in cities in Japan, China and Korea. The disease occurs in urban residents who have no contact with field rodents, and most cases are seen in spring and early summer. The disease is less severe and runs a shorter course than disease associated with Hantaan virus infections, and has less distinct clinical phases. There is also less tendency for haemorrhages and renal failure to occur, and frequently signs of liver involvement are dominant: abdominal pain, hepatomegaly and hepatic dysfunction. There are few deaths and mortality has been estimated at 1% or less.

Infection with Puumala-type virus occurs widely in Europe, but the disease, nephropathia epidemica, is recognized most frequently in Scandinavia and the neighbouring western region of the former USSR. The disease affects mainly adult males and infection appears to be associated principally with outdoor activities. It is seen most commonly in late autumn and early winter, but many cases occur in late summer following the traditional holiday season. Cases seen during the colder months are ascribed to the invasion of homes and barns by voles at the onset of winter. The incubation period is thought to be about one month, but a range of three days to six weeks has been reported. There is abrupt onset of fever, headache and malaise. By the third or fourth day of illness there is nausea, vomiting, and abdominal and lumbar pain. At this stage there may be azotemia, oliguria and proteinuria which peaks one week after the onset of illness and declines over the next three to six days. Patients

are extremely ill during the oliguric phase, and may manifest somnolence, restlessness, confusion and meningismus. Transient myopia or blurred vision is regarded as pathognomonic. Facial flushing and maculopapular rash of the neck and trunk are seen occasionally, as are hepatomegaly, cervical lymphadenopathy and haemorrhages such as epistaxis and gastrointestinal bleeding. Patients seldom require renal dialysis. The oliguria is followed by polyuria of 3–4 l daily for 7–10 days. At one stage it was thought that HFRS/NE and HPS were entirely distinct syndromes, but it is now recognized that there is some overlap, and in particular a proportion of NE patients may develop pulmonary infiltration similar to HPS, and some may even exhibit respiratory distress. Clinical improvement begins with the onset of polyuria, and two weeks after the onset of fever patients are subjectively well, but backache and lassitude may recur over weeks, and hyposthenuria may persist for months. Recovery is usually complete, and mortality is consistently less than 1%. The relatively high prevalence of antibody found in surveys suggests that inapparent infections may outnumber cases of overt disease by up to 20-fold.

It should be stressed that the hantaviruses overlap in distribution and in the severity of HFRS which they induce, and for instance, neither rural or urban domicile of patients, nor season of occurrence of disease, allow Hantaan and Seoul virus infections to be distinguished with certainty in Asia. Infections with Dobrava and Puumala-type viruses in the Balkans may be equally difficult to distinguish on occasion.

People who develop HPS are often healthy young adults, but may be of any age and either sex, although the disease occurs infrequently in children. Infection is acquired in similar manner to HFRS from occupational, residential or recreational exposure to the outdoors or rodent-infested buildings, and in many instances infected rodents have been found in the homes of victims. Incubation periods are similar to HFRS, generally falling into the range two to three weeks, but the disease is characterized by severe cardiopulmonary dysfunction rather than renal failure and haemorrhage, despite the facts that there is similar underlying capillary permeability and marked thrombocytopenia. Onset of the prodromal phase of the disease is marked by sudden development of fever, headache, severe myalgia and a cough which may be productive in some instances. Gastrointestinal manifestations in some patients include abdominal pain, nausea, vomiting and diarrhoea. After three to six days of illness there is progressive tachypnoea, tachycardia and hypotension preceding the onset of acute respiratory distress with pulmonary oedema. Patients are generally hospitalized at this stage, but some may die before they can be admitted. In addition to tachypnoea, tachycardia and hypotension,

on admission patients may be found to have proteinuria, leukocytosis with neutrophilia plus increased myeloid precursors and atypical lymphocytes, haemoconcentration, and thrombocytopenia, plus increased prothrombin and partial thromboplastin times, although there is no rash and seldom a tendency towards overt or internal bleeding. Within two days of being admitted to hospital most patients develop diffuse bilateral interstitial and alveolar pulmonary infiltration and pleural effusions demonstrable on radiographs, with hypoxaemia which has necessitated intubation, mechanical ventilation and oxygen supplementation in up to 88% of patients in some outbreaks. Renal insufficiency can occasionally follow prolonged hypoperfusion, but early renal insufficiency and increased serum creatine kinase levels (evidence of skeletal muscle inflammation) are not uncommon in infection with Andes, Bayou and Black Creek Canal viruses. Death generally occurs six to eight days after the onset of illness, often within 48 hours of admission to hospital, but can range from two days after the observed onset of illness to more than two weeks. Fatality rates often exceed 40%, and incurable shock and myocardial dysfunction may contribute to the high mortality. Autopsies reveal noncardiogenic pulmonary oedema and serous pleural effusions, with scant lymphoid infiltration of the lung tissue. Some survivors manifested transient diuresis, but otherwise they make an uneventful recovery without sequelae (Bremner, 1994; Duchin *et al.*, 1994; Kanerva *et al.*, 1998; Nichol *et al.*, 1993; Schmaljohn and Hjelle, 1997).

The underlying lesion in the pathogenesis of hantavirus syndromes appears to be vascular damage, and this is thought to be mediated by both viral invasion of endothelial cells and immunopathological mechanisms. Capillaries and small blood vessels dilate and there is extravasation of plasma and cellular elements into tissues, and the pathological changes observed in multiple systems all appear to be referable to the vascular damage (Borges *et al.*, 2006; Kanerva *et al.*, 1998).

Treatment of HFRS involves complex, phase-specific monitoring and support of homeostasis, including fluid and electrolyte balances. Trials of ribavirin for the treatment of the disease in China have been complicated by difficulties such as lack of uniformity of clinical status of patients at the time of protocol entry, but there are indications that use of the drug reduces mortality and leads to improvement of objective markers of patient well-being, and clinical pathology values. Epidemiological evidence suggests that there is lifelong immunity to hantaviruses, at least to the homologous serotype. There has been research on recombinant vaccines, but these are likely to find application only in Asia where suitable populations at risk can be identified. Inactivated vaccine has been used with some success in Korea (Cho *et al.*, 2002).

Investigation of hantavirus infections is usually undertaken in high security laboratories to minimize the exposure of staff to infection. Isolation and identification of hantaviruses is a notoriously difficult and time-consuming procedure, and is rarely successful on serum and urine specimens from patients. Demonstration of viral antigens in sera and urine is equally unsuccessful. Viral nucleic acids of hantaviruses can be detected in the tissues of human patients and experimentally and naturally infected rodents by means of real-time and conventional RT-PCR with appropriate primers (Arthur *et al.*, 1992; Grankvist *et al.*, 1992; Kramski *et al.*, 2007; Mertz *et al.*, 2006; Monroe *et al.*, 1999; Nichol *et al.*, 1993; Nordström *et al.*, 2004; Xiao *et al.*, 1992). Detection of IgM antibody by enzyme-linked immunoassay is also useful as a rapid diagnostic technique. Antibody activity appears to be present in the sera of HFRS patients from the time of hospitalization, and titres increase rapidly over the next two weeks. Owing to the antigenic cross-reactivity between hantaviruses, it may be difficult to determine the serotype of the virus responsible for the infection from antibody tests, but this can sometimes be inferred by using a range of antigens in enzyme-linked immunoassays (Feldmann *et al.*, 1993), or by performing neutralization tests with the full range of serotypes: antibody titres tend to be highest against the homologous infecting serotype. In attempts to diagnose infection by an unknown hantavirus, particularly in an locations where local viruses are unknown, it is advisable that antigens representative of all four antigenic types be included in the tests: Hantaan-like, Puumala-Prospect Hill-like, Sin Nombre-like and Thottapalyam viruses.

BUNYAVIRUSES UNASSIGNED TO GENUS

Bhanja, Kasokero, Bangui, Issyk-Kul, Tataguine and Wanowrie Viruses

Bhanja virus has been isolated from ixodid ticks of five genera –*Haemaphysalis*, *Amblyomma*, *Dermacentor*, *Boophilus* and *Hyalomma* –variously in India, the former USSR, former Yugoslavia, Bulgaria, Slovakia, Somalia, Central African Republic, Nigeria and Senegal. It has been suggested that the wide distribution of the virus could have resulted from the carriage of immature ticks on migrating birds, although birds do not themselves appear to be susceptible to the virus. Isolations of the virus have also been made from a hedgehog, ground squirrel and blood samples from cattle and sheep in Nigeria. Antibody has been found in cattle, sheep and goats parasitized by the ticks, and in human sera in Slovakia, former Yugoslavia, Italy and the Central African Republic. Mild febrile illness

was observed in two human patients who acquired laboratory infection, and serological evidence of infection was obtained in a patient who suffered meningoencephalitis in former Yugoslavia.

Kasokero virus was isolated from fruit bats in Uganda, and caused four laboratory infections marked by febrile illness, headache, myalgia, arthralgia, abdominal pain, diarrhoea, chest pain, cough, as well as hyperactive reflexes in one patient. Bangui virus was isolated from the blood of a patient with febrile illness, headache and rash in the Central African Republic, and antibody was found in the sera of local residents.

Issyk-Kul virus was isolated from several species of insectivorous bat and from argasid tick parasites of bats, birds and anopheline and aedine mosquitoes in the Central Asian Republics of the former USSR. It was demonstrated that aedine mosquitoes and argasid ticks are able to transmit the virus. Antibody was found in human sera and virus was isolated on at least 19 occasions from the blood of patients with febrile illness, headache, dizziness, cough, nausea and vomiting. The cases included laboratory infections. Keterah virus, isolated from argasid tick parasites of bats and from bat blood in Malaysia, has been shown to be closely related or identical to Issyk-Kul virus. It is difficult to be certain whether the natural vectors of Issyk-Kul/Keterah virus are argasid ticks or mosquitoes.

Tataguine virus has been isolated from anopheline mosquitoes in Senegal, Nigeria, Cameroon and Central African Republic. It appears to be a potentially important pathogen: antibody has been found in human sera in Senegal and Nigeria, and there have been at least 31 isolations of the virus from the blood of febrile humans in Senegal, Nigeria, Central African Republic and Cameroon. The infections were characterized by febrile illness with headache, rash and arthralgia.

Wanowrie virus has been isolated from *Hyalomma* ticks in India, Iran and Egypt. Little else is known about the virus except that it was isolated in Sri Lanka from the brain of a human patient who succumbed to febrile illness with abdominal pain, vomiting, haematemesis and passing of blood per rectum.

Arenaviruses

Colin R. Howard

University of London, Royal Veterinary College, London, UK

INTRODUCTION

The arenaviruses are a family of enveloped, single-stranded RNA viruses, the study of which has been pursued for two quite separate reasons. First, lymphocytic choriomeningitis virus (LCMV) has been used as a model of persistent virus infections for over half a century; its study has contributed a number of cardinal concepts to our present understanding of interactions between viruses and the host immune system. Although LCMV infections of humans are rare, there is significant evidence of LCMV associated with the keeping of pet rodents. LCMV remains the prototype of the *Arenaviridae* and was once a common infection of laboratory mice, rats and hamsters. Second, at least six certain arenaviruses cause severe haemorrhagic diseases in humans, notably Lassa fever in Africa, and Argentine haemorrhagic fever (AHF) in South America. Several other arenaviruses have been described from South America, two of which are associated with human infections (Guanarito and Sabia). In common with LCMV, the natural reservoir of these infections is a limited number of rodent species (Table 30.1). Although the initial isolates from South America were at first erroneously designated as newly defined arboviruses, there is no evidence to implicate arthropod transmission for any arenavirus. However, similar methods of isolation and the necessity of trapping small animals meant historically that the majority of arenaviruses have been isolated by workers in the arbovirus field. The discovery of hantaviruses as a cause of hantavirus pulmonary syndrome has led to a resurgence of interest in the link between zoonoses and persistent virus infections of rodents (see Chapter 29 for a description of the hantaviruses). This was particularly well illustrated in Argentina where virologists and clinicians specializing in AHF were in the

vanguard of national efforts linking respiratory disease with the discovery of new hantaviruses coexisting with arenaviruses in the same rodent populations.

With the current interest in emerging infections, the arenaviruses are an excellent illustration as to how environmental changes may result in an altered balance between humans and natural animal hosts, leading to unexpected diseases which can severely challenge local and national public health resources resulting from sporadic introduction into human populations outside of endemic areas. In addition, arenaviruses are classified as category A bioterrorism agents by the United States Centers for Disease Control and Prevention, thus heightening the need for public health vigilance.

There is a wide spectrum of pathological processes associated with these viruses that give useful insights into other zoonotic infections, particularly those with rodent reservoirs. The public health challenge is to recognize the likelihood of arenavirus infection as early as possible given the insidious onset of clinical disease. With new zoonotic infections emerging at least annually, the risk of new arenaviruses causing previously unknown human infections is high.

Nomenclature and Natural History

The members of the family currently identified are listed in Table 30.1. The various strains and isolates of LCMV are now considered to be a genus within the family *Arenaviridae*. A close serological relationship exists between LCMV, Lassa virus and other arenaviruses from Africa (LCMV-Lassa serocomplex). For this reason, they are loosely referred to as the 'Old World' arenaviruses, in contrast to those from the Americas, although LCMV can be found worldwide except in Australia. The 'New World'

Table 30.1 The arenaviruses: hosts, disease risk and geographical distribution

Virus	Natural host	Human disease	Distribution
LCMV-Lassa serocomplex (Old World)			
Ippy	<i>Arvicanthus</i> spp.	Not recorded	Central Republic African
Lassa	<i>Mastomys natalensis</i>	Lassa fever	West Africa
Lymphocytic choriomeningitis	<i>Mus musculus</i> , <i>Mus domesticus</i>	Aseptic meningitis	Worldwide except Australasia
Mobala	<i>Praomys jacksoni</i>	Infection possible	Central African Republic
Mopeia	<i>Mastomys natalensis</i>	Infection possible	Mozambique, Zimbabwe
Tacaribe serocomplex (New World)			
Clade A			
Allpahuayo	<i>Oecomys bicolor</i>	Not recorded	Peru
Bear Canyon	<i>Peromyscus californicus</i>	Infection possible?	California, USA
Catarina	<i>Neotoma micropus</i>	Not recorded	Texas, USA
Flexal	<i>Neocomys</i> spp.	Not recorded	Brazil
Paraná	<i>Oryzomys buccinatus</i>	Not recorded	Paraguay
Pichinde	<i>Oryzomys albigularis</i>	Not recorded	Columbia
Pirital	<i>Sigmodon alstoni</i>	Not recorded	Venezuela
Tamiami	<i>Sigmodon hispidus</i>	Not recorded	Florida, USA
Whitewater Arroyo	<i>Neotoma albigula</i>	Infection possible?	New Mexico, USA
Clade B			
Amapari	<i>Oryzomys gaedi</i> , <i>Neocomys guianae</i>	Not recorded	Brazil
Cupixi	<i>Oryzomys capito</i>	Not recorded	Brazil
Guanarito	<i>Zygodontomys brevicuda</i>	Haemorrhagic fever	Venezuela
Junín	<i>Calomys musculinus</i> , <i>Calomys laucha</i> , <i>Akadon azarae</i>	Haemorrhagic fever	Argentina
Machupo	<i>Calomys callosus</i>	Haemorrhagic fever	Bolivia
Sabiá	Unknown	Haemorrhagic fever	Brazil
Tacaribe	<i>Artibeus literatus</i> (bat)	Infection possible	Trinidad
Clade C			
Latino	<i>Calomys callosus</i>	Not recorded	Bolivia
Oliveros	<i>Bolomys obscurus</i>	Not recorded	Argentina

arenaviruses show varying degrees of serological relationships with Tacaribe virus, first isolated in Trinidad. For this reason, viruses from the Americas are frequently regarded as members of the Tacaribe serocomplex.

The arenaviruses take their name from the sand-sprinkled appearance when viewed in the electron microscope (Latin *harena* = 'sand'). With the exception of LCMV, all are referred to by names that reflect the geographical area in which they were isolated (Figure 30.1). Various strain designations are also commonly used, in particular for LCMV and human arenavirus isolates. There are increasing numbers of nonpathogenic arenaviruses being isolated from rodents in the Americas. Determining a causal link with human disease is often difficult, however, as is the discrimination of these new agents as new species distinct from other arenaviruses that may be variants of existing family members.

All but one of the 23 members of the *Arenaviridae* so far described have rodents as their natural reservoir hosts. The pre-eminent property of the arenaviruses is a capacity to establish long-term persistent infections in their principal host species. Although rodents are divided into over 30 families distributed worldwide, arenaviruses are predominantly found within two major families: Muridae (e.g. mice and rats) and Cricetidae (e.g. voles, lemmings, gerbils). Each arenavirus, except Tacaribe virus, is associated with a primary rodent host species, but seroprevalence studies indicate that virus is not uniformly distributed over the host's geographical range. Nearly all arenaviruses isolated from the South American continent are associated with cricetid rodents whose members frequent open grasslands and forest. Tacaribe virus was originally isolated from the fruit bat, *Artibeus literatus*, and, inexplicably, has never been recovered from wild rodents.

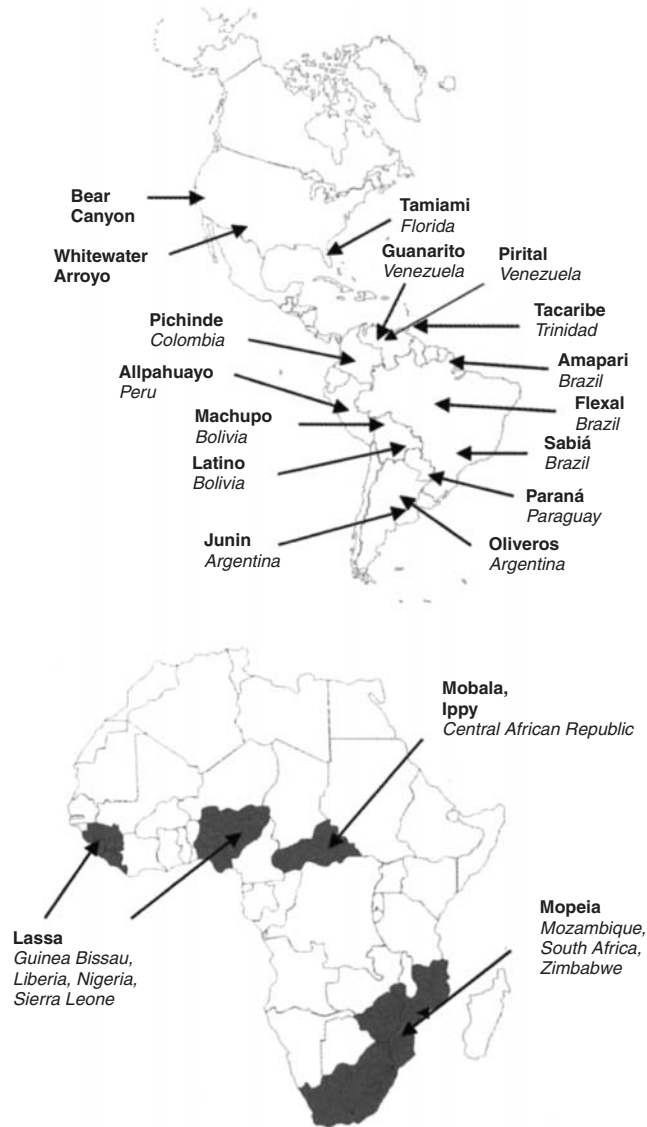

Figure 30.1 Geographical distribution of (a) New World and (b) Old World arenaviruses. Lymphocytic choriomeningitis virus (LCMV) can be found on all continents except Australasia.

The natural reservoirs of Lassa virus and the remaining Old World arenaviruses are members of the genus *Mastomys*. This is also a member of the Muridae and, in common with the host of LCMV, frequents human dwellings and food stores. The nature of the original reservoir for LCMV remains obscure, but it appears to be mainly in species of the Muridae which evolved in the Old World and subsequently spread to most parts of the globe. Interestingly, there is a wide range of tropism and virulence among those strains

of LCMV originally isolated from laboratory mouse colonies.

ULTRASTRUCTURE OF ARENAVIRUSES AND INFECTED CELLS

Negative-staining electron microscopy of extracellular virus shows pleomorphic particles ranging in diameter from 80 to 150 nm (Figure 30.2). The virus envelope

Figure 30.2 Electron microscopy of arenaviruses. (a) Negatively stained Lassa fever particle showing the whole surface covered in projections. Few particles are less than 100 nm, and many are twice this size, $\times 300\,000$. (b) Mopeia virus from southern Africa. Here the negative stain has disrupted the particle, the contents of which (x) have been extruded, $\times 150\,000$. (c) Lassa fever particles budding from an infected Vero cell. The thick arrow shows a mature particle, the thin arrow a maturing particle at the plasmalemma. Nucleocapsids and ribosomes line up immediately below the thickened membrane (white arrow), $\times 39\,000$. (Source: Micrographs courtesy of Dr D.S. Ellis.)

is formed from the plasma membrane of infected cells. A significant thickening of both bilayers of the membrane together with an increase in the width of the electron-translucent intermediate layer is characteristic of arenavirus maturation. Little is known about the internal structure of the arenavirus particle, although thin sections of mature and budding viruses clearly show the ordered, and often circular, arrangements of host ribosomes that are typical of this virus group and confer the 'sandy' appearance from which its name is derived. Distinct, well-dispersed filaments 5–10 nm in diameter are released from detergent-treated virus. Two predominant size classes are present, with average lengths of 649 and 1300 nm; these lengths do not show a close relationship with the two virus-specific L and S RNA species. Each is circular and beaded in appearance. Convolutated filamentous strands up to 15 nm in diameter can be seen in preparations of spontaneously disrupted Pichinde virus. These appear to represent globular condensations which arise from an association between neighbouring turns of the underlying helix. The basic configuration of the filaments shows a linear array of globular units up to 5 nm in diameter, probably representing single molecules of the viral polypeptide. These filaments progressively fold through a number of intermediate helical structures to produce the stable 15-nm-diameter forms (Young, 1987).

Arenaviruses replicate in experimental animals in the absence of any gross pathological effect. However, cellular necrosis may accompany virus production, not unlike that seen in virus-infected cell cultures. The variable pathological changes associated with arenavirus infections are further complicated by the occasional appearance of particles in tissue sections that react strongly with fluorescein-conjugated antisera. Granular fluorescence with convalescent serum in the perinuclear region of acutely infected Vero cells is often seen. In addition, intracytoplasmic inclusion bodies are a prominent feature in virus-infected cells both *in vitro* and *in vivo*. These usually appear early in the replication cycle and consist largely of single ribosomes which later become condensed in an electron-dense matrix, sometimes together with fine filaments (Murphy and Whitfield, 1975).

CHEMICAL COMPOSITION

Proteins

All arenaviruses contain a major nucleocapsid-associated (N) protein of molecular weight 60–68 kDa with two glycoproteins in the outer viral envelope. These envelope

glycoproteins are not primary gene products but arise by proteolytic cleavage of a larger, 75 kDa glycoprotein precursor polypeptide (GPC). Maturation and release of virus are not inhibited in the presence of tunicamycin, an inhibitor of glycosylation, but glycoprotein processing is essential for infectivity.

The major glycoprotein species (GP2) in the molecular weight range of 34–42 kDa represents the C-terminal cleavage product of the GPC envelope glycoprotein precursor. The first 59 amino acids at the N-terminus of GPC act as a signal sequence, containing two distinct hydrophobic domains that could function during glycoprotein transport and virus assembly. GP1 is cleaved from the N-terminus at a unique cleavage site conserved among all arenaviruses except Tacaribe. GP1 assembles into tetramers linked by disulfide bonds. GP2 forms tetrameric structures proximal to GP1 in the glycoprotein peplomer, penetrating the viral membrane to form electrovalent bonds with the underlying N-RNA nucleocapsids, possibly mediated by the Z protein.

A major antigenic site recognized by antibodies has been located between amino acids 390 and 405, and cross-reactive monoclonal antibodies bind epitopes in this region. The corresponding N-terminal product of GPC cleavage (GP1) is highly glycosylated with at least four antigenic domains. Neutralizing monoclonal antibodies to LCMV map to two of these regions where there is less sequence homology between the GP1 than between the GP2 molecules of different arenaviruses. Polyclonal neutralizing antibody appears to react predominantly with conformation-dependent structures within at least one of these domains.

The internal nucleocapsid-associated (N) protein accounts for over 70% of the protein present in purified virus and infected cells, and remains bound to the virus genome after solubilization of the virus to form the structures resembling a string of beads seen by electron microscopy. However, cleavage products of the N protein are a consistent feature of both virus and virus-infected cells. Cleavage is not noticeable in Vero cells; yields of arenaviruses are lower in these cells, perhaps due to reduced availability of N for packaging. N protein accumulates in the cytoplasm of infected cells and a fragment of the N protein often seen in the nuclei, the exact function of which is not clear. Molecular cloning studies have shown a surprisingly high degree of homology between the 558 and 570 amino acid N proteins of Old and New World arenaviruses with structural motifs and RNA-binding domains particularly conserved. This would account for the serological cross-reactions seen using certain monoclonal antibodies raised against such epidemiologically distinct viruses and may indicate precise functional roles in virus replication for specific domains of the N polypeptide.

A minor component with a molecular weight in excess of 150 kDa is observed in infected cells and is found with purified nucleocapsids. This L protein is coded by the larger RNA genome segment as shown by the study of reassortment viruses and represents the virus-specific RNA polymerase (Fuller-Pace and Southern, 1989; Lukashovich *et al.*, 1997). Amino acid sequences common to all RNA-dependent RNA polymerases are present along the open reading frame coding for the L protein owing to the conservation of certain functional domains. An additional two sequences are shared with the RNA polymerases of bunyaviruses. A small, 11 kDa viral polypeptide, the Z protein, is considered to play a role in controlling the replication and expression of the genome owing to its zinc-binding properties and interactions with cellular proteins. The Z protein may also modulate the interferon response to infection *in vivo* by binding to the nuclear promyelocytic oncoprotein PML (Djavani *et al.*, 2001).

Nucleic Acids

The genome of arenaviruses consists of two single-stranded RNA segments of different sizes, designated L and S, with S RNA being more abundant. Analysis of RNA is complicated by the presence of ribosomal 18S and 28S RNA, although these cellular RNA species are not essential for virus replication. The total ribosomal RNA content may in turn be influenced by the varying proportions of infectious to non-infectious particles present in virus stocks, particularly if cells are infected at a multiplicity above 0.1. In addition there are small quantities of both cell and viral low molecular weight RNA. One of these species, mRNA coding for the viral Z protein, may have a role in the initial stages of infection. There is no obvious role for host RNA molecules in either replication or the establishment of persistent infections (see section on Replication below).

Extracted virion RNA is not infectious and the detection of a viral RNA polymerase led to the belief initially that arenaviruses adopt a negative strand coding strategy with respect to viral protein synthesis. However, the actual coding strategy from the L and S RNA strands is not entirely in accord with all negative-strand RNA viruses as some genetic information can only be expressed by a genomic sense mRNA. This 'ambisense' strategy is also a characteristic of some bunyavirus genomes (see Chapter 29). Such a coding strategy allows for the independent regulation of arenavirus envelope and nucleocapsid proteins.

The S strand codes for the nucleoprotein (N) and the envelope glycoprotein precursor (GPC) in two main open reading frames located on RNA molecules of opposite polarity. The 3' half of the S RNA codes for the N protein by production of an mRNA with a viral-sense

sequence specific for the GPC protein. Thus expression of the genome is by synthesis of subgenomic RNA from full-length templates of opposite polarities. The reading frames for the two major gene products are separated by a hairpin structure of approximately 20 paired nucleotides. This intergenic region may act as a control mechanism for genome expression by forming stable stem-loop structures that in turn regulate transcription. The S RNA of Tacaribe and Junín viruses are predicted to form a second stem-loop structure.

The L RNA strand represents about 70% of the viral genome; reassortment studies with virulent and avirulent strains of LCMV have shown that the lethality of the disease in guinea-pigs is associated with the properties of the L RNA. The L protein is encoded by a large open reading frame covering 70% of the L RNA strand: it is expressed via mRNA complementary in sense to the viral genome. The mRNA for the Z protein is also expressed from the L RNA strand.

All arenavirus genomes have a conserved 3' terminus at the ends of the L and S RNA; this sequence is inversely complementary to the 5' terminus of the same RNA strand. There is evidence obtained by electron microscopy of intramolecular and intramolecular complexes promoted by this arrangement of 3' and 5' termini nucleotide complementarity.

Phylogenetic Analysis

Sequencing of polymerase chain reaction (PCR) products can give useful quantitative comparisons between newly discovered isolates and those already characterized, providing caution is exercised both in the choice of primer sets and the method of analysis. Bowen and colleagues (Bowen *et al.*, 1997) analysed at least one strain of all arenaviruses known at that time using maximum parsimony to generate an unrooted phylogenetic tree. The results confirmed that the distant relationship between Old World and New World arenaviruses are broadly consistent with the previously determined serological relationships using polyclonal and monoclonal antibodies. The New World arenaviruses are divisible into three lineages (Figure 30.3): clade A includes the viruses Pichinde, Tamiami, Paraná, Flexal and the newly described Whitewater Arroyo Virus; clade B the viruses Sabiá, Tacaribe, Amaparí, Guanarito and the human pathogens Machupo and Junín; and clade C consists of Oliveros and Latino viruses. Interestingly, Whitewater Arroyo Virus isolated in the United States appears closely related to Tamiami, for many years the only arenavirus reported from North America. However, full-length analysis of Whitewater Arroyo Virus S RNA strand has shown a quite separate ancestry for the nucleocapsid (N) and envelope (GP1, GP2) proteins, almost certainly the result of

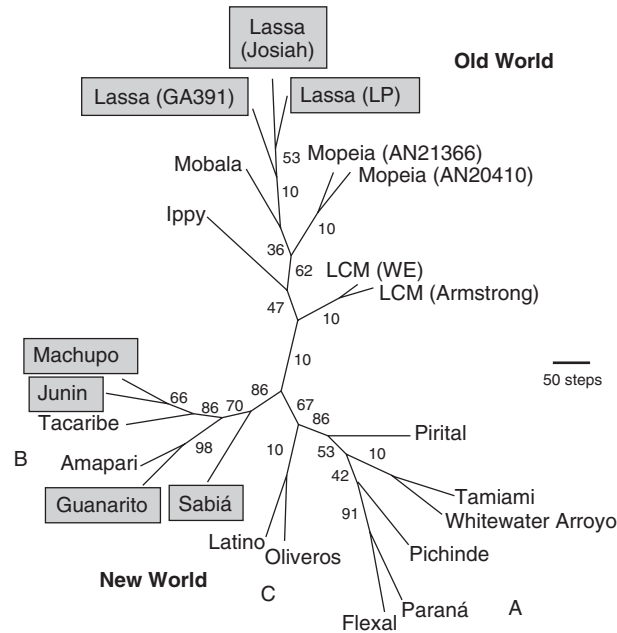

Figure 30.3 Phylogenetic analysis of Old and New World arenaviruses using nucleocapsid (N) gene sequences. The New World viruses are divisible into at least three clades. (Modified from Clegg, 2002.)

recombination between two ancestral arenaviruses. There is less variability among the Old World members. As may be expected from their natural history, Mopeia and Mobala viruses are closely related to Lassa fever virus. LCMV occupies the distinctive position of being closely related to the probable ancestral virus.

Nucleotide sequencing of isolates reveals a remarkable genetic diversity, not always correlated with geographical area and host. For example, Lassa virus may show over 25% nucleotide variability (Bowen *et al.*, 2000). Similarly, Guanarito virus isolates from clinical cases in Venezuela show a high degree of variability, the heterogeneity being greater among rodent isolates (Weaver *et al.*, 2000). Similar diversity has been reported among Whitewater Arroyo virus isolates collected from rodents captured in the same locality (Fulhorst *et al.*, 2002). It has been speculated that such diversity arises as a mechanism whereby the virus avoids the host immune response and thus persists within the rodent host.

The propensity to cause serious human illness appears to have evolved on two distinct occasions. The South American pathogens are all confined to clade B, suggesting these viruses have acquired the capacity to infect humans as a result of a common mutational event. Lassa fever virus, by contrast, has likely acquired its ability to cause serious haemorrhagic disease in humans by a quite separate series of evolutionary events.

REPLICATION

Arenaviruses replicate in a wide variety of mammalian cells, although either BHK-21 cells or monkey kidney cell lines are preferred for molecular studies (Howard, 1986). Arenaviruses can also infect a number of primary human cell lines and macrophages, including some members of the family that do not otherwise cause human infections. Most arenaviruses also grow well in mouse L cells but the simultaneous production of C-type retroviruses restricts the usefulness of such cells. The widely conserved cell protein α -dystroglycan has been identified as the cellular receptor for Old World arenaviruses, such as Lassa fever and Mobala, and the New World arenaviruses Latino and Oliveros in clade C (Cao *et al.*, 1998). Other cell surface proteins and cofactors may also be involved.

At low multiplicities of infection (i.e. below 0.1) the latent period is approximately 6–8 hours, after which cell-associated virus increases exponentially. The titre of extracellular virus reaches a maximum 36–48 hours after infection. The passage history of any particular virus stock is probably one of the most critical factors in determining the kinetics of arenavirus replication.

Infected cells undergo only limited cytopathic changes in the cell lines commonly employed, with little or no change in the total level of host cell protein synthesis; virus yields vary in different susceptible cell types.

Plaque assays are possible, but only under well-defined conditions. Cultures of persistently infected cells are readily established, with morphology and growth kinetics similar to those of uninfected cells.

The major feature of an ambisense coding strategy is that it allows for independent expression and regulation of the N and GPC genes from the S RNA segment. The N protein is expressed late in acute infection and continues to be expressed in persistently infected cells in the absence of glycoprotein production. This is explained by the production of a subgenomic mRNA from a negative polarity, virus-sense template. A control mechanism must therefore exist which determines the fate of nascent RNA of negative polarity, destined either for encapsidation or as a template for N protein-specific mRNA. In contrast, the template for glycoprotein-specific mRNA is of complementary sense to viral RNA and as such would not be required for nascent virus production. The lack of glycoprotein late in the replicative cycle or in persistently infected cells would therefore imply selective transcriptional or translational control of this gene product.

Both viral RNA and its complementary strand contain at least one hairpin sequence which may provide recognition points for termination of transcription by viral RNA polymerase. The nucleotide sequence in the hairpin region is of coding sense and may be transcribed, either as a discrete mRNA species or as a result of extended transcription of N or GPC messengers through this region. The reading frames for viral gene products transcribed from LCMV and Pichinde viral genomes would fit this hypothesis. In addition, a sequence for ribosomal 18S subunit binding is present on both mRNA molecules, although its significance remains uncertain.

DIAGNOSIS OF HUMAN ARENAVIRUS INFECTIONS

Early clinical signs are relatively nonspecific and therefore laboratory methods need to be used in order to reach a definitive diagnosis. A history of travel to a region where an arenavirus is endemic is also indicative. The importance of informing local public health officials as soon as an arenaviral case is suspected cannot be stressed too highly. Owing to the insidious onset and early influenza-like nature of the disease, there are a wide number of other causes which need to be excluded (Table 30.2). In the event that the patient presents with neurological signs, other causes of encephalitis or meningitis must be excluded.

Serology is often the only practical approach for making a differential diagnosis. Antibodies can be detected in the late acute phase and into early convalescence, but Old

Disease
Yellow fever
Malaria
Bacterial septicaemia
Enteric fevers (typhoid, paratyphoid)
Streptococcal pharyngitis
Typhus
Trypanosomiasis
Leptospirosis
Other viral haemorrhagic fevers

World arenaviruses are known to be immunosuppressive and thus caution needs to be exercised in interpreting negative results. The diagnosis of arenavirus infections ideally should be by virus isolation. Although arenaviruses can easily be grown in a variety of mammalian cell cultures, it must be remembered that clinical specimens from patients suspected as having a viral haemorrhagic fever should always be handled in biologically secure containment facilities. For this reason tests for antibody are more useful since inactivated viral antigens for serology can be prepared easily. For routine isolation, the E6 clone of Vero cells is the cell line of choice, although all arenaviruses grow well in primate and rodent-derived fibroblast cell lines. However, a cytopathic effect (CPE) is often difficult to see, and inoculated cultures often require examination by immunofluorescence (IF) or immunoperoxidase assay in order to detect viral antigens.

As a first step towards diagnosis, the use of PCR can be considered, provided primer sets have been rigorously tested beforehand and the temperature cycling conditions optimized. The need is often to give a first indication as to which of the various causes of viral haemorrhagic fever may be present, and thus it is often the case that PCR reactions need to be conducted in parallel using a range of primer sets specific for as many as six different agents, whether these be arenaviruses or other suspected causes, for example filoviruses. Drosten *et al.* (2002) have shown that this is possible; overcoming the common problems of low sensitivity and nonspecific amplification often associated with such multiplex PCR tests. The advantages of PCR include the opportunity to obtain sequence information of increasing relevance to the identification of new family members. Also PCR is useful for diagnosis in the early stages of disease when antibodies have yet to develop. The drawback, however, is that PCR does not discriminate between the presence of RNA fragments and infectious virus. Thus isolation of virus using cell cultures in a high-security facility should be attempted whenever possible.

Immunofluorescence-based specific viral antibody tests have been used successfully for the diagnosis of human arenavirus infections. In the case of Lassa fever, infected cell substrates are used that have been treated by ultraviolet (UV) light, acetone and cobalt irradiation to ensure safety. Drops of cell cultures dried onto glass slides can be prepared in a central laboratory and these preparations remain stable for many months. Most of the antigen detected within acetone-fixed infected cells represents cytoplasmic nucleocapsid protein. In the case of the New World arenaviruses, serological cross-reactions in the immunofluorescence test (e.g. with sera from patients with Bolivian (Machupo) and Argentine (Junín) haemorrhagic fevers) are found with fixed cultures. Substrates prepared from other members of the Tacaribe complex, which includes Junín and Machupo viruses, also react with sera taken from these patients during the acute phase and into early convalescence. Greatest cross-reactivity is seen between the closely related Junín and Machupo antigens, closely followed by Tacaribe virus-infected cells. Initially the use of enzyme-linked immunosorbent assay (ELISA) was restricted by the small amounts of antigen available for coating the solid phase but this has changed with the availability of recombinant antigens.

The difficulty in correlating the presence of hitherto unknown arenaviruses and human disease is illustrated by the emergence of Whitewater Arroyo virus. Initially fatal infections were considered as due to this virus on the basis that all three cases were found positive for Whitewater Arroyo virus RNA; however, virus was only isolated in one case and a specific diagnosis could not be confirmed in a second (Centers for Disease Control and Prevention, 2000). Until further cases come to light, assessing the zoonotic potential of this and similar newly described arenaviruses will remain challenging.

ANTIGENIC RELATIONSHIPS

Monoclonal antibodies are used to distinguish between virus strains because they can be prepared against epitopes that go unrecognized when polyclonal antisera are used. Buchmeier *et al.* (1981) summarized the patterns of reactivity with a panel of monoclonal antibodies directed against laboratory strains of the homologous LCMV, Lassa and Mopeia viruses. Antibodies directed against the smaller, GPC envelope glycoprotein cross-reacted by immunofluorescence with all substrates examined, whereas antibodies directed against the larger GP1 glycoprotein were either strain-specific or reacted with only a subset of the strains examined, presumably by binding to previously unrecognized epitopes. Certain of these broadly cross-reactive antibodies also reacted with Pichinde virus,

suggesting that epitopes on surface envelope structures among Old World and New World arenaviruses are conserved. A similar comparison has also been undertaken with monoclonal antibodies to Lassa tested against the Mopeia and Mobala viruses from Africa. Again, various degrees of cross-reactivity were observed, with reagents specific for the GP2 external glycoprotein. Mobala virus from the Central African Republic, however, appears to be distinct, as several cross-reactive monoclonal antibodies originally prepared against LCMV failed to recognize Mobala-infected cells.

The plaque-reduction neutralization test is highly specific for all members of the *Arenaviridae*; it is notable that the few examples of cross-reactivity were obtained with high-titre animal antisera raised against Junín, Tacaribe and Machupo viruses. However, the ease with which neutralizing antibodies can be quantified varies greatly. No cross-reactions have been observed between Junín and Machupo viruses in plaque reduction tests with human convalescent sera despite sharing a close antigenic relationship. A similar marked specificity of neutralization has been demonstrated with LCMV and Lassa sera, although neutralizing antibodies to Lassa virus are difficult to detect. The sensitivity of the neutralization test for LCMV can be increased by incorporating either complement or anti-gammaglobulin into the test system.

CLINICAL AND PATHOLOGICAL ASPECTS

Immune Response

Lymphocytic choriomeningitis virus infection of adult mice is the classic example of virus-induced immunopathological disease in which intracerebral inoculation causes severe disease and death. In contrast, if mice are infected before or shortly after birth they develop a nonpathogenic lifelong carrier state. The newborn mouse is immunologically immature and the virus does stimulate an immune response; in these circumstances the virus causes no illness. The immunologically mature mouse mounts an immune response following LCMV infection and a fatal choriomeningitis results, but without evidence of neuronal damage (Lehmann-Grube and Lohler, 1981). Immunosuppression, either by neonatal thymectomy or by use of anti-lymphocytic serum, protects adult mice against fatal LCMV infection; the pathological damage thus appears to be immune-mediated.

The immune responses are best understood in acute infection of mice. Intraperitoneal injection of adults gives rise to an asymptomatic acute infection of two to three weeks' duration. Studies of such infections have resulted in a number of findings with implications beyond

the field of arenavirus research. First, the description by Rowe (1954) of the immune-mediated pathology of acute LCMV infection was the seminal demonstration that the pathogenicity of the viruses may not be solely related to their cytolytic effects. The observation that LCMV-infected cells were lysed by cytotoxic T cells led to the understanding that recognition of a target cell requires the presence of both viral antigen and class I antigen of the host's major histocompatibility complex (Zinkernagel and Doherty, 1997). Second, the persistence of virus in mice infected shortly after birth has provided a model for both host and viral factors involved in the establishment and maintenance of chronic infection. The finding of virus antigen-antibody complexes in persistently infected animals shows that B-cell tolerance is not involved.

Activation of natural killer cell activity early in acute infection, which coincides with the production of interferon, has helped increased our knowledge of innate immunity against virus infection.

The direct demonstration of virus replication in lymphocytes is of substantial importance for understanding arenavirus pathogenesis, as these cells provide a continued source of virus entering the circulation. These cells play a key role in the temporal and quantitative control of the immune response (Murphy and Whitfield, 1975). Viral antigen is present in the cells of the lymphatic system in mice persistently infected with LCMV. Most of the virus in the blood of carrier mice is associated with approximately 2% of the total circulating lymphocyte population. Precursor or immature lymphocytes may support the replication *in vitro* of LCMV when stimulated to proliferate by phytohaemagglutinin, in agreement with the general finding that arenaviruses grow best in actively dividing cells. Such clonal expansion may be triggered *in vivo* by viral antigen binding to appropriate lymphocyte receptors.

Key to understanding LCMV outcome is T-cell immunosuppression or 'tolerance'. Immunocompetent mice induce a marked adaptive immune response that rapidly controls the acute infection and results in virus elimination. The effector CD8⁺ T cells directly lyse infected cells and this function is augmented by the production of interferon- γ and tumour necrosis factor, which further limit the extent of virus replication. Virus heterogeneity also plays a role: a normally cytolytic isolate of LCMV will produce persistence after intracerebral inoculation of newborn mice, but during the course of chronic infection clones can be obtained from lymphoid organs with a different phenotype characterized as being able to induce persistent infection. Passage of this virus results in persistence owing to the absence of a functioning cytolytic CD8⁺-mediated T-cell response. Comparison of

these isolates has shown that acquisition of the persistence phenotype correlated with a change in sequence along the GPI surface glycoprotein (Sevilla *et al.*, 2000), with the consequence that virus binds with higher affinity to α -dystroglycan, a receptor molecule found predominantly on the surface of cells in lymphoid tissue. Here there is a similarity with Lassa virus which also binds α -dystroglycan with high affinity, leading to dendritic cell activation and downstream immunosuppression (Mahanty *et al.*, 2003). Interleukin (IL)-10 plays a critical role in this process of T-cell suppression as mice deficient in IL-10 production fail to become chronically infected with LCMV.

Interferon

Interferon is induced early in acute LCMV infection of mice, and its appearance correlates with the appearance of infectious virus in the blood. There have been few studies of the levels of α -interferon in acute human arenavirus infection. Elevated levels can be detected in the early stages of AHF, and these coincide with the onset of fever and backache. Although there is no correlation between the titres of interferon and circulating virus, Levis *et al.* (1984) suggested that at least some of the clinical signs may be directly attributable to interferon, particularly the depression of platelet and lymphocyte numbers resulting from Junín virus infection of leukocytes and macrophages.

The role of natural killer cells in controlling arenavirus infection is not clear, although many are found in the blood and spleen of LCMV-infected mice as early as one day after infection. This response declines rapidly, however, until by the fourth day almost all the cytolytic immune activity is H-2 restricted.

Antibodies

Antibodies against the nucleocapsid can be detected early in the acute phase of most arenavirus infections. Infectious virus-antibody complexes can be detected four days after LCMV infection of mice but there is no evidence that B-cell responses play a role in the pathology of the acute infection. Immunity to arenaviruses appears in general to be type-specific; an infection with one member of the family does not necessarily confer protective humoral or cellular immunity against arenaviruses that can be distinguished by neutralization tests *in vitro*. However, cross-reactive antibodies may confer some degree of protection in some instances. For example, immunization of guinea-pigs with Tacaribe virus protects against subsequent challenge with the normally virulent Junín virus. These responses are clearly different from the secondary immune responses that may be induced as a result of antigenic similarities between the nucleocapsid proteins of the two viruses concerned.

Cellular Immunity

The role of cellular immunity during acute LCMV infection is manifested by a cytotoxic T-cell response associated with the clearing of virus; for example, CD8⁺ T cells cultured and cloned *in vitro* and injected intravenously reduce the amount of virus 100-fold in the spleens of acutely infected mice. Cytotoxic T-cell responses are restricted by the need for activated T cells to recognize both viral antigen and host cell proteins encoded by the H-2 region, a concept developed in LCMV-infected mice which, as referred to above, has radically altered our concept of how the infected host clears virus from infected tissues. The generation of specific cellular toxicity is related to the replication of the virus in target organs; inoculation with live virus appears necessary as a primary cytotoxic T-cell response is not seen if the virus is inactivated. This has implications for the development of inactivated arenavirus vaccines should the stimulation of cellular immunity prove essential for protection, as many workers believe. T-cell clones from mice infected with the Armstrong strain of LCMV lyse a wide range of LCMV strains. This finding demonstrates that cytotoxic responses to arenaviruses are haplotype-restricted but show a broad cross-reactivity for conserved viral determinants. Some of these determinants have now been mapped to an immunodominant domain of GP2 between amino acids 278 and 286 (Whitton *et al.*, 1988). Such T-cell clones can discriminate between cells infected with a given strain of virus containing only a single amino acid substitution in this region; this implies that mutations in this region of the genome may lead to selection of a virus variant with altered pathogenicity.

In contrast to LCMV, the role of cellular immunity in Lassa virus infection seems to play only a minor role. The human host is clearly restricted in its ability to clear the virus and preventing virus replication in tissues. The poor neutralizing antibody response and the high degree of viraemia contrast sharply with those in patients with South American haemorrhagic fevers, with neutralizing antibodies developing rapidly during acute infection and in whom there is little viraemia.

The release of pro-inflammatory mediators and cytokines is a cardinal feature of viral haemorrhagic fever in humans, yet there is suppression in patients with Lassa fever of both antibody and cytotoxic T-cell responses. Mahanty *et al.* (2003) have provided insight into this paradox by showing that Lassa virus productively infects macrophage-derived dendritic cells. The result is that dendritic cells do not become activated and thus the two arms of the immune response are blocked. The apparent contradiction that macrophages and endothelial cells are strongly activated would suggest the differentiation of inflammatory responses between cell

populations and their microenvironments. Whatever the mechanism, the prospects for immunotherapy at first sight seem poor but there is some encouragement in that antibodies directed against immunoregulatory components, for example IL-10, can 'restore' effector CD8⁺ cells in mice chronically infected with LCMV, leading to virus clearance (Barber *et al.*, 2006).

LCMV infection in mice shows the complexity of this process: interferon- γ , a key effector in inhibiting virus replication, has been shown by Whitmire *et al.* (2005) to enhance T-cell help but is not required for functional development. Thus immunosuppression in Lassa virus infection may be due to factors other than the direct activation of effector T cells.

PERSISTENT INFECTION

Antibodies

Mice persistently infected with LCMV produce antibodies to all the major structural proteins. This finding was contrary to the view previously held that viral persistence is established or maintained *in vivo* as a result of an absence of specific B-cell responses to some or all viral antigens. As viral proteins continue to be produced in the tissues of such animals, circulating antigen-antibody complexes are formed which can be detected by binding Clq. Antibodies in the sera of such animals bind to the surface of virus-infected cells, but are unable to mediate complement-dependent cytolysis, suggesting that viral antigens at the plasma membrane may be either masked, thereby preventing further immune reactions, or removed by antigenic modulation. This notion would imply that persistently infected mice are deficient in viral antibody of the complement fixing subclass of IgG, but this has not been proven.

Cell-mediated Immunity

Mice persistently infected with LCMV are expected to mount a normal T-cell response to unrelated immunogens, indicating a state of tolerance only to specific antigens. However, it has been difficult to distinguish T-cell suppression from an absence of virus-specific T-cell clones. Here it is pertinent to mention that persistence of LCMV in mice infected at birth or *in utero* was one of the important observations made by Burnet and Fenner to support the concept of tolerance to 'self' antigens. The time of infection is critical, as LCMV infection induced 24 hours after birth results in a cytotoxic T-cell response typical of acute disease. The failure of mice infected before this time to mount an adequate cytotoxic response is presumably related to maturation of T-cell function; it appears

to be virus-specific because adult carrier mice challenged with other unrelated arenaviruses mount normal cytotoxic T-cell responses. Thus the block appears to be either in recognition of infected cells, or in their expression of type-specific antigenic determinants. The relationship between the virus and the host immune response may be more complex than hitherto believed, however, as there is evidence for arenaviral RNA being transcribed into complementary DNA, presumably mediated by endogenous retroviral reverse transcriptase (Klenerman *et al.*, 1997). This would imply that long-term persistence of viral gene sequences as retroviral elements results in continual low-level expression of viral proteins. Thus immune responsiveness is maintained by the continued presentation of viral sequences as major histocompatibility complex (MHC)–peptide complexes.

PATHOLOGY OF ARENAVIRUS INFECTIONS: GENERAL FEATURES

Haemorrhagic fevers due to arenaviruses are characterized by a rapidly progressing febrile phase accompanied by capillary leakage, the latter giving rise to subcutaneous haemorrhages sometimes accompanied by haemorrhages at mucosal surfaces. It appears to be more likely that disease is caused by direct damage of cells by the virus although disease severity often appears out of proportion to the damage evident by histology. Post-mortem studies on patients who died from Junín virus infection have shown generalized lymphadenopathy, endothelial swelling both in the capillaries and arterioles of almost every organ, abnormalities accompanied by a depletion of lymphocytes in the spleen. Junín virus first replicates in lymphoid tissue, from whence it invades the reticuloendothelial system and those cells concerned in generating the humoral and cellular immune response. Fatal illness is invariably associated with capillary damage, leading to capillary fragility, haemorrhages and irreversible shock (Johnson *et al.*, 1973). Disseminated intravascular coagulation is not a typical feature. Although Lassa fever is often regarded as being hepatotropic, the extent of hepatic damage is insufficient to account for the severity of the infection, serum transaminase values often remaining within normal limits except in more severe cases. Studies of Lassa virus-infected rhesus monkeys have shown that changes in vascular function may play a much greater role in pathogenesis, as a result either of viral replication in the vascular epithelium or secondary effects of virus activity in different organs. Platelet and epithelial cell functions fail immediately before death and are accompanied by a drop in the level of prostacyclin; these functions rapidly return to normal in surviving animals

(Fisher-Hoch *et al.*, 1987). Impairment of vascular epithelial functions in the absence of histological changes appears to be a common feature of the final stages of viral haemorrhagic diseases. Parallel infection of dendritic cells may in turn lead to impairment of immune responses and the release of pro-inflammatory cytokines. There is no general agreement on this point, however, since some work has shown that the virus may actually stimulate dendritic cells when infected *in vitro*.

The pathogenesis of AHF has been studied in guinea-pigs infected with Junín virus, regarded as a suitable model of human disease. There is the pronounced thrombocytopenia and leukopenia characteristic of human infections, and animals die of severe haemorrhagic lesions. Bone marrow cells are destroyed with release of proteases and both acid and alkaline phosphatases into the blood; this leads to consumption of the C4 complement component. These effects may lead in turn to progressive alterations in vascular permeability and platelet function (Rimoldi and de Bracco, 1980). The most extensive histopathological studies have been made on tissues from patients with Lassa fever (Walker and Murphy, 1987). However, there are many similarities in the pathological lesions found in human Junín and Machupo virus infections. Focal non-zonal necrosis in the liver has been described in all three conditions, with hyperplasia of Kupffer cells, erythrophagocytosis and acidophilic necrosis of hepatocytes. Councilman-like bodies can be observed together with cytoplasmic vacuolations and nuclear pyknosis or lysis. As with many organs, there is little evidence of cellular inflammation. Lesions in other organs have been described, including interstitial pneumonitis, tubular necrosis in the kidney, lymphocytic infiltration of the spleen and minimal inflammation of the central nervous system (CNS) and myocardium (Walker and Murphy, 1987). The hepatic changes may range from mild, focal necrosis to extensive zonal necrosis involving up to 50% of hepatocytes. These changes are consistent with a direct cytolytic action of the virus; nevertheless, the simultaneous presence of Lassa virus and specific antibodies during the later stages of the acute disease suggests that antibody-dependent cellular immune reactions may also occur. Microscopic changes in the kidneys are minimal, although it is not clear whether the functional impairment is due to the deposition of antigen–antibody complexes.

Lymphocytic Choriomeningitis

Clinical and Pathological Features

The incubation period is 6–13 days. Infection is often inapparent but may present as an influenza-like febrile illness, as aseptic meningitis or as severe

meningoencephalomyelitis. Up to 20% of patients develop neurological signs, and in such cases the incubation period may extend to 21 days. The great majority of LCMV infections are, however, benign. In the influenza-like illness there is fever, malaise, muscular pains and bronchitis. LCMV infection is biphasic, the first phase being characterized by leukopenia followed by lymphocytosis. In general, the mean value of mononuclear cells is approximately $600 \text{ cells mm}^{-3}$, although counts of up to 3000 mm^{-3} have been recorded. A coryza together with retro-orbital pain, anorexia and nausea are common. During the acute phase a large number of mononuclear cells are present in the cerebrospinal fluid (CSF) as part of a pleocytosis, although the absolute number varies with time after onset.

CNS involvement becomes apparent in the second phase after a short period of remission. As with all CNS diseases, the CSF is at increased pressure, with a slight rise in protein concentration, normal or slightly reduced sugar concentration, and a moderate number of cells, mainly lymphocytes ($150\text{--}400 \text{ mm}^{-3}$). It has been noted that the majority of such patients have a history of influenza-like illness immediately prior to the onset of meningitis. The meningeal form is more common; the same symptoms may remain mild and be of short duration and patients recover within a few days, but there can be a more pronounced illness with severe prostration lasting two weeks or more. Chronic sequelae have been reported on occasion, including parotitis and orchitis. Other symptoms include continuing headache, paralysis and personality changes. The few deaths reported have followed severe meningoencephalomyelitis. In this most severe form, patients may rapidly develop a bilateral papilloedema, confusion and paralysis of the extremities over a one-week period. An erythematous rash followed by haemorrhage and death has also been reported. Virus can be isolated from blood, CSF and, in fatal cases, from brain tissue.

The mechanism of transmission of the virus to humans is not fully understood but is likely to involve dust contaminated by urine, the contamination of food and drink, or via skin abrasions. Intrauterine infection is possible, the fetus being at risk of developing hydrocephaly or microcephaly.

Epidemiology

Humans are usually infected through contact with rodents. In the past, these have been acquired in laboratories, where LCMV may be a contaminant in laboratory colonies of mice and hamsters. In particular, virus is shed from the urine of persistently infected animals, resulting in contamination of skin and working surfaces. Hamsters kept as pet animals have also played a role in human

infection. Human cases of LCMV infection are rare, despite there being widespread evidence of infection among peridomestic rodents, although it must be stated the prevalence of chronic infection in wild mice varies between geographical regions. When human infections do occur, these tend to be benign or asymptomatic. This is consistent with the few reported seroprevalence studies that have shown low numbers (<5%) of adults with have demonstrable anti-LCMV antibodies. Of concern are reports of LCMV transmission by organ transplantation where the donor has a history of keeping rodents as pets. In a study of two clusters of infection, one of these was traced back to a donor who had been exposed to virus from an infected pet hamster (Fischer *et al.*, 2006).

A variant of LCMV has been isolated from captive New World primates. The histopathology in infected marmosets and tamarins is remarkably similar to that seen in Lassa virus infection in humans. It is suspected that these animals acquired the virus from infected *Mus musculus* rodents (Montali *et al.*, 1995; Stephensen *et al.*, 1991).

Diagnosis of Bolivian and Argentine Haemorrhagic Fevers

Although the clinical features of Bolivian and Argentine haemorrhagic fevers are similar, the laboratory diagnosis of these diseases is approached in a somewhat different manner. In the case of Junín, virus can be recovered consistently from the blood from the third to the eighth day of illness; in contrast, direct recovery of Machupo virus from acutely ill patients is much more difficult. In both instances, however, serological methods are more useful.

Antibodies may be detected sufficiently early in both cases, providing suitable paired sera are available or the capability exists for the detection of virus-specific IgM antibodies. Early use of immunofluorescence techniques for the diagnosis of AHF showed that specific antibodies could be detected by the indirect method approximately 30 days after onset of symptoms. Specific staining is generally seen as a bright, granular fluorescence, evenly distributed over the cytoplasm of the fixed infected cell substrate. The titre of immunofluorescent antibodies increases from the 12th to the 20th day of illness and is a mixture of IgG and IgM antibodies.

Neutralizing antibodies to both Machupo and Junín viruses persist for many years at high titre, appearing simultaneously with IgG antibodies. The sensitivity and specificity of neutralization tests for detecting immunity to Junín virus has proven to be of value retrospectively in the detection of subclinically infected individuals. The test may be carried out in Vero cell monolayers by varying virus dilution in the presence of a fixed concentration of

serum. Antibody titres are then expressed as an index calculated by subtracting the logarithmic differences between the virus titre in control and experimental reactions. Inapparent infections have been shown in approximately 20% of laboratory workers handling known or presumptively positive specimens by this method.

Argentine Haemorrhagic Fever (Junín Virus)

Clinical and Pathological Features

Argentine haemorrhagic fever has been known since 1943 and Junín virus, the causative agent, was first described in 1958. The virus causes annual outbreaks of severe illness, with between 100 and 3500 cases, in an area of intensive agriculture known as the wet pampas in Argentina. Mortality in some outbreaks has ranged from 10 to 20%, although the overall mortality is generally 3–15%. After an incubation period of 7–16 days, the onset of illness is insidious, with chills, headache, malaise, myalgia, retro-orbital pain and nausea; these are followed by fever, conjunctival injection and suffusion, a pharyngeal enanthema and erythema and oedema of the face, neck and upper thorax. A few petechiae may be seen, mostly in the axilla. There is hypervascularity and occasional ulceration of the soft palate. Generalized lymphadenopathy is common. Tongue tremor is an early sign, and some patients present with pneumonitis. In the more severe cases the patient's condition becomes appreciably worse after a few days, with the development of hypotension, oliguria, haemorrhages from the nose and gums (Figure 30.4), haematemesis, haematuria and melaena. Oliguria may progress to anuria and pronounced neurological manifestations may develop. There is a suggestion that disease severity correlates with the inhibition of platelet aggregation (Cummins *et al.*, 1990). Laboratory findings have included leukopenia with a decrease in the number of CD4⁺ cells, thrombocytopenia and urinary casts containing viral antigen. Patients recover when the fever falls, followed by diuresis and rapid improvement. Death may result from hypovolaemic shock. Subclinical infections also occur. Person-to-person transmission has not been observed.

Epidemiology

Argentine haemorrhagic fever has a marked seasonal incidence, coinciding with the maize harvest between April and July, when rodent populations reach their peak. Agricultural workers, particularly those harvesting maize, are, not surprisingly, the most commonly affected. The main reservoir hosts of Junín virus are *Calomys* field voles that live and breed in burrows under the maize fields and in the surrounding grass banks (Figure 30.5). Other rodent species may also be infected. *Calomys* spp.

Figure 30.4 Bleeding from the gum margin in a case of Argentine haemorrhagic fever. (Source: From Howard, 1986.)

Figure 30.5 The habitat for the rodent *Calomys* sp. in the wet pampas of Argentina. (Source: From Howard (1986).)

have a persistent viraemia and viraemia, and virus is also present in considerable quantities in the saliva. The mode of transmission of Junín virus to humans has not been conclusively established. The virus may be carried in the air from dust contaminated by rodent excreta or may enter by ingestion of contaminated foodstuffs.

Therapy

In contrast to Lassa fever, antibodies play a major role in recovery from Junín infection. Controlled trials of immune plasma collected from patients at least six months into convalescence have shown a dramatic reduction in mortality if plasma is given within the first eight days of illness. The efficacy of this therapy is directly related to the titre of neutralizing antibody in the plasma; as a result a dose of no less than 3000 'therapeutic units' per kg body weight has been recommended (Enria *et al.*, 1984). The late development of a neurological syndrome is seen in up to 10% of patients treated with immune plasma; it

is often benign and self-limiting but points to the possible persistence of viral antigens on cells of the CNS well into convalescence. Treatment with immune plasma also restores the response of peripheral blood lymphocytes to antigenic stimuli, suggesting that administration of plasma somehow modulates cellular immunity. Interestingly Tacaribe virus infection of mice can be abrogated by injection of CpG oligodeoxynucleotides which stimulate an increase in virus-specific antibodies, again indicating antibody production may play a pivotal role in virus recovery from infection (Pedras-Vasconcelos *et al.*, 2006).

Prophylaxis

There have been attempts to produce a vaccine against AHF. The XJC13 strain of virus grown in the brains of suckling mice is relatively nonpathogenic and was administered to 636 volunteers between 1968 and 1970. Over a period of three years, 70 cases of Junfñ virus infection occurred among the population but there were no cases amongst those immunized. However, the vaccine often induced a mild febrile reaction or a subclinical infection, and its use was discontinued despite the fact that over 90% of vaccinees maintained neutralizing antibody for up to nine years. There have been renewed attempts to develop a new vaccine strain sufficiently attenuated for human use and meeting modern day requirements as to derivation, manufacture and potency. Several clones have been prepared from the original XJ isolate, one of which exhibits less neurovirulence than the XJC13 strain yet protected rhesus monkeys against challenge with wild-type Junfñ virus (McKee *et al.*, 1993). This 'Candidate 1' vaccine has been tested in a double blind study in volunteers.

Bolivian Haemorrhagic Fever (Machupo Virus)

Clinical Features

Bolivian haemorrhagic fever was first recognized in 1959 in the Beni region in north-eastern Bolivia with 470 reported cases in the years up to 1962. The disease continued in that region more or less annually for a number of years in the form of sharply localized epidemics. Its incidence has decreased considerably since the late 1960s and human infections are now rarely reported. It is worth noting that the discovery of a common morphology and serological cross-reaction between Machupo and LCMV led to the concept of the arenavirus family. The mortality in individual outbreaks varied from 5 to 30%. The most notable outbreak affected 700 people in the San Joaquin township between late 1962 and the middle of 1964. The mortality was 18%. In July 1994, a fresh outbreak occurred in north-eastern Bolivia, with at least seven deaths. These were the first recorded since 1971; for reasons that

are obscure, this outbreak did not appear linked to any major changes in rodent numbers or behaviour.

The clinical disease is similar to AHF. The incubation period ranges from 7 to 14 days and the onset is insidious, beginning with an influenza-like illness accompanied by malaise and fatigue. This is followed by abdominal pain, anorexia, tremors, prostration and severe limb pain. About one-third of patients show a tendency to bleed, with petechiae on the trunk and palate, and bleeding from the gastrointestinal tract, nose, gums and uterus. Almost half the patients develop a fine tremor of the tongue and hands, and some may have more pronounced neurological systems. The acute disease may last two to three weeks and convalescence may be protracted, generalized weakness being the most common complaint. Clinically inapparent infections are rare. Machupo virus, the responsible agent, is readily isolated from lymph nodes and spleen taken at necropsy. Isolation of the virus from acutely ill patients has proved difficult, with the best results being obtained from specimens taken 7–12 days after onset.

Epidemiology

The rodent reservoir of Machupo virus is the field vole *Calomys callosus*; over 60% of animals caught during the San Joaquin epidemic were found to be infected. The distribution of cases in the township was associated with certain houses and *C. callosus* was trapped in all households where cases occurred. Transmission to humans is probably by contamination of food and water or by infection through skin abrasions. Human transmission is unusual but a small episode took place in 1971, well outside the endemic zone. The index case, infected in Beni, carried the infection to Cochabamba and, by direct transmission, caused five secondary cases, of which four were fatal.

Abnormally low rainfall, combined with an increase in the use of insecticide, led to a rapid decline in the numbers of cats, with the result that the population of Machupo-infected rodents increased dramatically, thus increasing the opportunity for human contact with contaminated soil and foodstuffs. Once this balance was restored, the number of reported cases declined rapidly.

Treatment

As with AHF, treatment is largely supportive. Although attempts have been made to use convalescent immune plasma from survivors of Machupo infection, a combination of a lack of facilities in Bolivia suitable for treating collected plasma and the absence of a controlled trial as to the efficacy of its use means that the treatment of patients with immunoglobulin remains speculative. Ribavirin has been administered during the 1994 outbreak, but again

there is no certain indication that ribavirin is effective against Machupo infection.

Lassa Fever

History

In 1969 Lassa virus made a dramatic appearance in Nigeria as a lethal, highly transmissible disease. The first victim was an American nurse who was infected in a small mission station in the Lassa township in north-eastern Nigeria, whence the virus and the disease derive their names. The origin of the infection was never determined, although it is thought to have been acquired through direct contact with an infected patient in Lassa. When the nurse's condition steadily deteriorated she was flown to the Evangel Hospital in Jos, where she died the following day. While she was in hospital she was cared for by two other American nurses, one of whom also became infected by direct contact, probably through skin abrasion. This nurse became unwell after an eight-day incubation period and died following an illness lasting 11 days. The head nurse of the hospital, who assisted at the post-mortem of the first patient, fell ill seven days after the death of the second patient for whom she had cared, and from whom she probably acquired the infection. This third case was evacuated to the United States by air. After a severe illness under intensive care she slowly recovered. A virus, subsequently named Lassa, was isolated from her blood by workers at the Yale Arbovirus Unit. One of these virologists became ill but improved after an immune plasma transfusion donated by the third case. Five months after this infection, a laboratory technician in the Yale laboratories, who had not been working with Lassa virus, fell ill and died. The manner in which this infection was acquired has never been determined. This trail of events not unnaturally earned for Lassa virus a formidable notoriety, which was sharply enhanced by two more devastating hospital outbreaks—one in Nigeria, the other in Liberia.

The fourth outbreak was seen in Sierra Leone in October 1972. In sharp contrast to the previous outbreaks, this one was not confined to hospitals, although hospital staff were at considerable risk and several became infected. Most of the patients acquired their illness in the community and there were several intrafamilial transmissions. This led to a revision of the initial view—formed from experience of nosocomial infections—of Lassa fever having a high mortality.

Lassa fever has since continued to occur in West Africa, usually as sporadic cases (Monath, 1987). For example, between 1969 and 1978 there were 17 reported outbreaks affecting 386 patients, among whom the mortality was 27%. Eleven of the episodes were in hospitals, where

the case fatality rate reached 44%; two were laboratory infections, two were community-acquired outbreaks, and two were prolonged community outbreaks. Eight patients were flown to Europe or North America. One of them was evacuated with full isolation precautions and the remainder, of whom five were infectious, travelled on scheduled commercial flights as fare-paying passengers. Fortunately, no contact cases resulted.

Clinical Features

Lassa virus causes a spectrum of disease ranging from subclinical to fulminating fatal infection. Although sharing many features with those seen in patients with the South American arenaviruses, neurological involvement in Lassa fever is minimal or absent. Studies in Sierra Leone show that most patients present with only a mild form of the disease and this is resolved by good primary healthcare. The incubation period ranges from 3 to 16 days and the illness usually begins insidiously. Importantly, given that Lassa virus is endemic in West Africa, the disease is difficult to distinguish in the early stages from other systematic febrile illnesses, most notably malaria, septicaemia and yellow fever. The most reliable clinical signs on presentation are a sore throat, myalgia, abdominal and lower back pains, accompanied by vomiting. Occasionally a faint maculopapular rash may be seen during the second week of illness on the face, neck, trunk and arms. Cough is a common symptom, and light-headedness, vertigo and tinnitus appear in a few patients. The fever generally lasts 7–17 days and is variable. Convalescence begins in the second to fourth weeks, when the temperature returns to normal and the symptoms improve. Most patients complain of extreme fatigue for several weeks. Loss of hair is common and deafness afflicts one in four patients, and there may be brief bouts of fever.

In a significant number of cases the symptoms suddenly worsen after the first week, with continuing high fever, severe prostration, chest and abdominal pains, conjunctival injection, diarrhoea, dysphagia and vomiting. One important physical finding is a distinct pharyngitis; yellow-white exudative spots may be seen on the tonsillar pillars together with small vesicles and ulcers. The patient appears toxic, lethargic and dehydrated; the blood pressure is low and there is sometimes a bradycardia relative to the body temperature. Patients in whom the disease is eventually fatal not uncommonly have a high sustained fever. There may be cervical lymphadenopathy, an encephalopathy, and coated tongue, puffiness of the face and neck, and blurred vision. In approximately 25% of cases there is marked involvement of the CNS, manifested by disorientation, ataxia and seizures. Progression to severe haemorrhaging occurs in around a fifth of patients and it

is among such patients that mortality exceeds 50%. Death is due to shock, anoxia, respiratory insufficiency and cardiac arrest. Lassa fever is particularly severe in pregnant women. A study of 75 women in Sierra Leone showed that 11 of 14 deaths were the result of infection during the third trimester; a further 23 patients suffered abortion in the first and second trimesters.

Epidemiology

Lassa virus has been repeatedly isolated from the multimammate rat *Mastomys natalensis* in Sierra Leone and Nigeria. This rodent is a common domestic and peridomestic species, and large populations are widely distributed in Africa south of the Sahara. During the rainy season it may desert the open fields and seek shelter indoors, thus infection rates peak during the summer months. Some genetic variation has been shown in *Mastomys* populations inhabiting different ecological niches; however, there appears to be no difference in the prevalence of antibody and virus in at least two of the karyotypes found in West Africa. The animals are infected at birth or during the perinatal period. Like other arenaviruses, Lassa virus produces a persistent, tolerant infection in its rodent reservoir host with no ill-effects and without any detectable immune response. The animals remain infectious during their lifetime, freely excreting Lassa virus in urine and other body fluids. The correlation between the prevalence of antibody in a community and the degree of infestation by infected rodents, however, is poor.

Studies of the ratio of clinical illness to infections confirm that Lassa fever is endemic in several regions of West Africa. In contrast to the early studies, it has been estimated that only 1–2% of adult infections are fatal—substantially lower than the figures of 30–50% originally associated with the early nosocomial outbreaks. However, there may still be up to 300 000 infections per year with as many as 5000 deaths (McCormick *et al.*, 1987). The seroconversion rates among villagers in Sierra Leone vary from 4 to 22 per 100 susceptible individuals per year; up to 14% of febrile illness in such population groups is due to Lassa virus infection. There is a marked variation as to the severity of the disease according to different geographical regions. However, this may in part be due to genotypic variation of Lassa virus, or dose and route of infection, or a combination of these factors (Fisher-Hoch, 1993). There is a relatively high rate of asymptomatic and mild infections in endemic areas. One reason for this may be the frequency of reinfections; although about 6% of the population lose antibody annually, rises in antibody titre are also often observed. It is not clear if reinfection results in clinical disease. A frequent finding of incomplete immunity after

infection would have profound implications for the use of a vaccine.

There may be secondary spread from person to person in conditions of overcrowded housing and particularly in rural hospitals. There is a particularly high risk to staff and patients on maternity wards as Lassa fever is a major cause of spontaneous abortion. Medical attendants or relatives who provide direct personal care are most likely to contract the infection; as noted above, accidental inoculation with a sharp instrument and contact with blood have resulted in transmission in a few cases. Air-borne spread may take place, as well as mechanical transmission. Although in Sierra Leone there has been no evidence of air-borne spread in hospital outbreaks, one of the 1970 outbreaks in Nigeria is believed to have been caused by air-borne transmission from a woman with severe pulmonary infection.

Lassa fever is a major cause of spontaneous abortion in West Africa. The virus is readily recovered from the blood and placenta of aborted fetuses. Women generally recover quickly, showing a dramatic decline in viraemia, partially due to massive bleeding at the time of abortion (A. Demby, personal communication). Paediatric Lassa fever is known to occur more commonly in male children for unknown reasons. Presenting as an acute febrile illness, the case fatality rate may approach 30% in children, with widespread oedema, abdominal distension and bleeding.

Diagnosis

The diagnosis of Lassa fever is confirmed by isolation of the virus or demonstration of a specific serological response. Infection in the early stages can be confused clinically with a number of other infectious diseases, particularly malignant malaria (Table 30.2) (Woodruff, 1975). The two most reliable prognostic markers of fatal infections are the titres of circulating virus and of aspartate aminotransferase (AST). Patients in whom the titre of virus exceeds 10^4 TCID₅₀ per ml accompanied by AST levels above 150 IU have a poor prognosis, and fatality rates approach 80%. In contrast, patients with virus and enzyme levels below these values have a greater than 85% chance of survival (Johnson *et al.*, 1987). This demonstration of an association between the degree of viraemia and mortality is unique for virus infections and contrasts with the difficulty in predicting the outcome in patients with other arenaviral haemorrhagic fevers. Although Lassa fever can be diagnosed accurately from the presence of IgM antibodies on admission, there is no correlation between the time of appearance, the titre of specific antibodies and clinical outcome.

Lassa virus grows readily in Vero cell culture and virus can usually be isolated within four days. Virus can be cultured from serum, throat washings, pleural

fluid and urine; it is excreted from the pharynx for up to 14 days after the onset of illness and in urine for up to 67 days after onset. Lassa infection can be diagnosed early by detection of virus-specific antigens in conjunctival cells using indirect immunofluorescence. The use of reverse transcription polymerase chain reaction (RT-PCR) is possible, although these techniques require careful use and standardization in endemic areas.

The most sensitive serological test for the detection of Lassa antibodies is indirect immunofluorescence and ELISA; antibodies can be detected by these methods in the second week of illness. Occasionally antibodies are not detected despite the presence of virus. Neutralizing antibodies are difficult to measure *in vitro*, in sharp contrast to infections by the South American arenaviruses, for reasons that are unclear.

Therapy

Although the passive administration of Lassa immune plasma may suppress viraemia and favourably alter the clinical outcome, it does not always do so, particularly if the patient has a high virus burden (McCormick and Fisher-Hoch, 2002). Failure may be due to either the difficulty in assessing accurately the titre of viral neutralizing antibodies in the plasma, the late and non-uniform nature of this response in convalescence, or antigenic variation. The widespread occurrence of human immunodeficiency virus (HIV) infections in West Africa precludes at present the use of immune plasma from convalescent individuals in this region. This is in marked contrast to the benefit of immune plasma in the treatment of Junín infections. This may be due either to the high titre of neutralizing antibodies that develops soon after the acute phase or to the lesser importance of antibody in resolution.

Greater success has been achieved with antivirals. In one study of patients with a poor prognosis, treatment for 10 days with intravenous ribavirin (60–70 mg/kg per day) within six days after the onset of fever showed a reduced case fatality rate of 5% (McCormick *et al.*, 1986). In contrast, patients treated seven or more days after the onset of fever had a case fatality rate of 26%. In the Sierra Leone study, viraemia of greater than $10^{3.6}$ TCID₅₀ per ml on admission was associated with a case fatality rate of 76%. Patients with this risk factor who were treated with intravenous ribavirin within six days of the onset of fever had a case fatality rate of 9% compared with 47% in those treated seven days or more after the onset of illness. Oral ribavirin is less effective. A difficulty with its use, however, is that ribavirin can induce haemolytic anaemia in over 40% of patients.

The introduction of vaccines against Junín virus has stimulated the expectation that a vaccine could also

be developed for the prevention of Lassa virus infections. However, the perceived necessity for a strong cell-mediated response would dictate the development of an attenuated vaccine; this raises concerns as to a possible reversion to virulence of any attenuated Lassa virus vaccine. Given these technological difficulties and the limited numbers globally at risk of infection, it is unlikely that such a vaccine will be developed in the near future.

Control

Containment of Lassa fever depends upon the strict isolation of cases, rigorous disinfection, rodent control and effective surveillance. Nosocomial transmission presents a considerable risk and patient isolation—in isolators if available—is an absolute must. Strict procedures for dealing with body fluids and excreta need to be enforced. Disinfection with 0.5% sodium hyperchlorite or 0.5% phenol in detergent is recommended for instruments and surfaces. Given the higher virus burden in cases of Lassa fever compared with patients with Junín or Machupo infections, surveillance of those having been in contact with Lassa fever patients is also a high public health priority. WHO recommends that those who have been in noncasual contact with cases should be observed for as long as three months after their last contact with the patient. This follow-up should consist of taking body temperature measurements twice daily. Infection should be suspected if the body temperature exceeds 38.3 °C and the contact immediately hospitalized.

Rodent control is frequently difficult, although much can be done to minimize the risk of virus transmission by isolating foodstuffs, preventing rodent entry into dwellings and reducing the chance of inhabitants coming into contact with rodent excreta. The greatest risk factors are housing quality, the presence of rat burrows and external sanitation (Bonner *et al.*, 2007). Minimizing rodent densities in the immediate domestic environment together with improved housing standards could do much to reduce the incidence of infection.

OTHER ARENAVIRUS INFECTIONS

Venezuela Haemorrhagic Fever (Guanarito Virus)

Between May 1990 and March 1991 an outbreak occurred among residents of Guanarito municipality on the central plains of Venezuela. Originally mistaken as dengue fever, a total of 104 cases were recorded with a mortality rate of around 25%. The Guanarito virus was subsequently isolated from the spleens of such cases at autopsy. The principal rodent hosts of this virus have been identified (Table 30.1) (Tesh *et al.*, 1994).

The disease has a clinical profile similar to that of AHF, with patients manifesting a thrombocytopenia, haemorrhaging and neurological signs. Pharyngitis has been observed and deafness reported in convalescent patients. Although initial reports suggest a high mortality for this infection, antibody prevalence rates of up to 3% have been found among healthy individuals and up to 10% of household contacts have anti-Guaranito virus antibodies.

During the course of studying the extent of the natural host for Guaranito virus, a second arenavirus was discovered within the same geographical region; Pirital virus causes chronic infection in the cotton rat (*Sigmodon alstoni*), a species which occupies a separate ecological niche to the main host for Guaranito virus (Fulhorst *et al.*, 1999). Although not a cause of haemorrhagic fever in humans, Pirital virus infection of Syrian golden hamsters has been exploited as a model of human arenaviral haemorrhagic fevers (Xiao *et al.*, 2001).

Brazilian Haemorrhagic Fever (Sabiá Virus)

This arenavirus was isolated in 1990 from human cases at autopsy (Lisieux *et al.*, 1994). The source of this infection was uncertain but is likely to have been acquired by exposure to infected rodents in an agricultural setting in an area immediately outside São Paulo. As a continuing reminder of the potential severity of these infections, a laboratory worker in the United States became critically ill after having been accidentally exposed to an aerosol containing Sabiá virus. This laboratory-acquired infection was characterized by a febrile illness accompanied by leukopenia and thrombocytopenia. There is little information regarding the epidemiology of this virus, although the extensive liver necrosis seen in the first case is a warning that this and other haemorrhagic fevers may on first examination be mistaken for yellow fever.

Oliveros Virus

This new agent has been isolated from a small rodent, *Bolomys obscurus*, within the endemic region of AHF (Bowen *et al.*, 1996). With a rodent host distinct from that of Junín virus, approximately 25% of captured *B. obscurus* have been found to contain antibodies to this virus. At present, there is no indication that this virus causes human infections (Mills *et al.*, 1996).

Whitewater Arroyo Virus and Other Isolates from the United States

As a consequence of the 1993 hantavirus outbreak on the Colorado Plateau in the United States, there followed intensive study of rodent populations in order to gauge the extent of Sin Nombre Virus distribution and

the risk posed by infected rodents to rural populations. During one such study, an unexpectedly high level of arenavirus antibodies was found in pack rats (*Neotoma* spp.) caught in the Whitewater Arroyo of New Mexico (Kosoy *et al.*, 1996). Members of the *Neotoma* genus are ubiquitous throughout the south-western part of the United States. Independently Fulhorst and colleagues (Fulhorst *et al.*, 1996) described the isolation of a hitherto unknown arenavirus from trapped examples of the white-throated woodrat, *Neotoma albigula*. The virus causes chronic infection when passed from dam to progeny, thus infected adults are likely to shed virus into the environment, particularly around isolated human dwellings and in recreational areas. The importance of these findings became evident when in 1999 and 2000 three female patients residing in California presented with symptoms subsequently suggested to be due to infection with the same arenavirus. Although there was no obvious link between the three cases, each presented with nonspecific febrile symptoms and acute respiratory distress. Two developed a lymphopenia and thrombocytopenia, and two showed also signs of liver failure and haemorrhage. All three died within one to eight weeks of onset. Virus was recovered in one and all three gave PCR products that were 87% identical with Whitewater Arroyo virus. Doubt remains, however, as to the zoonotic potential of Whitewater Arroyo virus.

Yet further new isolations have been made recently. A virus closely related to but distinct from Whitewater Arroyo virus has been isolated from the California mouse *Peromyscus californicus*. Infectious virus was recovered from 5 to 27 animals caught in the Santa Ana Mountains of southern California, close to the Bear Canyon trailhead. It cannot be ruled out that the tentatively dubbed Bear Canyon virus represents an additional arenavirus that has yet to be associated with human disease. Catarina virus is a distinct arenavirus found associated with the southern plains woodrat (*Neotoma micropus*) found in southern Texas (Cajimat *et al.*, 2007) but there is no evidence as yet that Catarina virus infects humans.

SUMMARY

The increasing numbers of human infections due to arenaviruses is beginning to require a greater vigilance on the part of public health workers. Arenavirus aetiology for febrile illnesses in individuals residing in endemic areas should be considered, particularly those who are likely to have come into regular contact with rodents by virtue of their lifestyle or occupation.

There is increasing evidence for human arenavirus infection in North America, in part due to a greater awareness of the potential for emerging infections among clinicians and microbiologists, particularly in geographical

areas where the last decades have seen clearance of woodland, forest and scrub in advance of extensive changes in agricultural practices. This potential has been augmented by changing or abnormal weather patterns, these serving to promote behavioural, if not also numerical, changes in rodent populations. Particularly in the Americas, arenavirus investigations have progressively become interleaved with studies on hantavirus distribution, especially in endemic zones where a particular species of rodent may be infected with either a hantavirus or an arenavirus. The only certainty is that the number of arenaviruses identified hitherto will increase as more becomes known regarding the natural history of these agents.

Filoviruses

Susan P. Fisher-Hoch

Division of Epidemiology, University of Texas Houston School of Public Health, Brownsville, Texas, USA

INTRODUCTION

Human infections with filoviruses are rare, and outbreaks both dramatic and mysterious. The first filovirus hit the headlines as the 'Andromeda strain' or 'green monkey disease' following the outbreak in 1967 in Marburg, Germany. It was not until 1990, however, after an outbreak in imported monkeys, that filoviruses, particularly Ebola, hit news headlines, bestseller shelves and the big screen. Some media accounts took over-dramatization to new heights, heavily marketing the fear factor. Media excesses did not serve science or public health well, and included much misinformation. To those closely involved the true stories had drama enough, with many of the best qualities of adventure movies and science fiction. A case of truth being stranger than fiction.

The existence of filoviruses was first recognized in Marburg in 1967 (Martini, 1971). Thirty-one people in this provincial German city were infected: laboratory technicians, medical personnel, animal care personnel and their relatives. Seven died. Those working in Marburg at the time described the fear as palpable whenever the ambulance sirens were heard in the streets. Primary cases had been exposed to tissues and blood from African green monkeys imported into Germany and former Yugoslavia from Uganda; hence the name 'green monkey disease'. Many monkeys also died, but despite efforts the real source of the infection remained obscure (Henderson *et al.*, 1971). A novel virus isolated from patients and animals was found by electron microscopy to be unique among mammalian pathogens, having a strange looped and branched filamentous form, hence the name filovirus (*filo* = 'thread'; Figure 31.1) (Kissling *et al.*, 1968).

The disease then vanished until 1976 when epidemics of a haemorrhagic disease with very high mortality (up to

90%) broke out simultaneously in a remote area of northern Zaire (now the Democratic Republic of the Congo (DRC)) and southern Sudan (World Health Organization, 1978a, 1978b). Again the fear was overwhelming, with abandoned hospitals and fleeing patients, but this time the outbreaks were found to be due to two separate but antigenically related filovirus strains, distinct from the Marburg virus. These new viruses were grouped under the name Ebola virus, after a river in Zaire (Kiley *et al.*, 1982; McCormick *et al.*, 1983).

Over the next 10 years rare, sporadic cases of Marburg infections in Africa were the only continuing evidence of the existence of filoviruses (Gear *et al.*, 1975; Smith *et al.*, 1982). Though the natural host and its ecology remained elusive, evidence pointed to filoviruses being exclusively African, occurring principally in Zaire, Sudan, Uganda and Kenya (Figure 31.2). The mystery of their origin deepened further in 1989 when a filovirus was isolated near Washington, DC, from sick and dying cynomolgus monkeys. These monkeys and other shipments had been imported into the United States from the Philippines (Brown, 1997; Fisher-Hoch *et al.*, 1992a; Jahrling *et al.*, 1990). No epidemiological link with Africa could be found so this virus has to be considered Asian. A few human infections were serologically identified, but in sharp contrast to the previous outbreaks in Africa and Germany, no-one became sick and no-one died.

Later in the 1990s things changed. In 1994 news broke from DRC of a fresh, large outbreak of disease caused by the original Zaire strain of filovirus (Khan *et al.*, 1999). Thereafter came a considerable increase in the filovirus outbreaks and the numbers of patients involved. A series of outbreaks in Gabon were mostly associated with handling of dead chimpanzees (Georges *et al.*, 1999). Later a massive die-off of great apes (chimpanzees and

Stars are in vacuoles also seen in Ebola-infected liver ($\times 8400$). (Source: Both courtesy of C. Goldsmith.)

gorillas) associated with Ebola infection moved through the Gabon and the Republic of Congo (Leroy *et al.*, 2004). Later in the decade (1998–2000) Marburg infections were found to be associated with mining in eastern DRC (Bausch *et al.*, 2006), and in 2004/2005 a very large outbreak of Marburg disease affected northern Angola (World Health Organization, 2005b). Filovirus outbreaks were here to stay.

New classifications within the filoviridae family allow common use of acronyms, which for consistency will be used throughout the remainder of this chapter: The ‘Ebola-like virus’ genus includes Ebola Zaire (Zaire ebolavirus (ZEBOV)), Sudan virus (Sudan ebolavirus (SEBOV)), Ebola Ivory Coast (Cote d’Ivoire ebolavirus (CIEBOV)) and Ebola Reston (Reston ebolavirus (REBOV)). The ‘Marburg-like virus’ genus includes at present only one strain, Lake Victoria marburgvirus (MARV).

EPIDEMIOLOGY

Epidemics: Marburg Haemorrhagic Fever

In 1967, a fulminating haemorrhagic fever struck a number of laboratory workers in Marburg and Frankfurt, Germany, and Belgrade, Yugoslavia (Martini, 1971). The virus name was that of the German city where most of the cases occurred. There were 31 human cases, 25 of which were primary infections with seven deaths (Table 31.1). None of six secondary cases died. Twenty primary cases were in Marburg, four in Frankfurt and one in Belgrade. All primary cases had handled blood or tissues from shipments of African green monkeys (*Cercopithecus aethiops*) soon after they had been imported from Uganda. Twenty out of 29 people with monkey blood contact became infected, and four of thirteen who were exposed to tissue culture. Among the primary human cases in Marburg, ten had assisted in autopsies and three had trephined monkey skulls. One of the laboratory staff had dissected kidneys, one had handled tissue culture from the monkeys, one broke a test tube which had contained contaminated material, and five had cleaned contaminated glassware. One physician accidentally inoculated herself with a needle through a rubber glove. None of the animal attendants who had had no contact with blood were infected, nor were any of the laboratory personnel who had used precautions, such as protective gloves and clothing. There were no further primary cases following the institution of compulsory wearing of protective clothing with gloves and masks for work with monkeys with stringent cleaning procedures and use of disinfectants. Six secondary cases resulted from person-to-person contact at home or in hospital. One was the wife of a veterinarian who became ill several weeks after her husband recovered. Marburg virus was later isolated from his semen. In Belgrade, the single primary case, a veterinarian, performed autopsies towards the end of the monkeys’ six-week quarantine. His wife fell ill 10 days after nursing him at home. Despite the death of a total of 99 animals during quarantine in Belgrade, these were the only two human infections.

About 400–600 animals originating from four shipments reached Europe from Uganda over a three-week period. Frankfurt received only 40–60 animals from two shipments, and Belgrade about 300 animals from three shipments. The remainder went to Marburg. All spent 60–87 days in a holding facility in Uganda before being shipped to London, Heathrow, where they spent between 6 and 36 hours in an animal hostel prior to being forwarded to Germany. In Marburg, monkeys were housed in separate rooms with no recirculation of ‘air-conditioned’ ventilated air. Published data are unclear as to whether ongoing enzootics were observed inside Germany or the

Figure 31.2 Map of Africa showing approximate locations and dates of Ebola and Marburg epidemics and origins of known index cases.

details of animal movements. Data on the Belgrade enzootics are, however, well recorded. Three shipments of monkeys from the same source in Uganda were received, two of which were in transit at London, Heathrow airport. The third arrived directly via Munich. Unusually high mortality during six weeks' quarantine was noted in all three shipments: 46/99 animals died from the first shipment, and 20 and 30 from the second two. The Belgrade epizootic was clearly characterized by ongoing transmission with daily death of one or more animals (Figure 31.3) (Martini, 1971).

Epidemiological studies after the 1967 epidemics concluded that two or three infected monkeys would have been sufficient to initiate the epizootic and all three outbreaks of human disease. It was stated at the time that evidence clearly pointed to transmission between monkeys in quarantine facilities by direct contact with equipment. Direct contact with blood and tissues was documented for all human cases and there was significant evidence ruling out transmission to humans by air. No evidence was

ever produced that supported the hypothesis that the monkeys were infected in transit in London from any number of a wide range of mammals and birds also temporary lodgers at the airport hostel. Furthermore, no evidence could be found of epizootics in Uganda, but later some indirect, controversial information emerged that there had, at the time of the outbreak, been excess deaths in monkey colonies in islands near Lake Kyoga, north of Lake Victoria, to the east of Mount Elgon in Kenya. In Uganda, monkeys were captured in this area and placed in holding facilities, reportedly in single cages (Henderson *et al.*, 1971). They were then transported to Entebbe. Here they were held for at least three days before shipment. At the time of the outbreak the trade had expanded considerably and holding times had been reduced, and it may be imagined that some crowding may have ensued. During July and August 1967, 1772 *C. aethiops* were housed in Entebbe, and 1290 exported, the majority to Germany and Yugoslavia (Henderson *et al.*, 1971).

Table 31.1 Cumulative reported human cases and deaths from filovirus infections between 1967 and August 2007.

Virus	Year	Place of infection	Total cases	Deaths	Mortality
Marburg	1967	Marburg, Germany	31	7	31%
Marburg	1967	Belgrade, Yugoslavia	2	0	—
Marburg	1975	Zimbabwe/South Africa	2	1	—
Marburg	1980	Mount Elgon, Kenya	2	1	—
Marburg	1998–2000	Durba, DRC (Zaire)	154	128	83%
Marburg	2004/2005	Angola (Uige Province)	252	227	90%
Marburg	2004/5	Angola (Uige province)	374	329	88%
<i>Total Marburg</i>			443	364	54%
Ebola Zaire	1976	Yambuku, Zaire	318	280	88%
Ebola Zaire	1976	England (laboratory infection)	1	0	—
Ebola Zaire	1977	Tandala, Zaire	1	1	—
Ebola Zaire	1980	Nzoia, Kenya	1	0	—
Ebola Zaire	1994	Kikwit, Zaire	315	242	77%
Ebola Zaire	1994/1995	Gabon	49	30	61%
Ebola, Zaire	1996	Gabon	60	45	75%
Ebola, Zaire	2000/2002	Gabon	30	22	73%
Ebola Zaire	2000/2002	Republic of Congo	92	80	87%
<i>Total Ebola Zaire</i>			745	598	80%
Ebola Sudan	1976	Maridi, Sudan	284	151	53%
Ebola Sudan	1979	Maridi, Sudan	34	22	65%
Ebola Sudan	1999	Uganda (Gulu district)	425	224	53%
<i>Total Ebola Sudan</i>			743	995	54%
Ebola Reston	1990	Richmond, Virginia	4	0	—
Ebola Reston	1990	Manila, Philippines	12	0	—
<i>Total Ebola Reston</i>			16	0	—
Total cases			3431	2952	

Data are from multiple sources and are approximations. Many cases are not laboratory confirmed, and many other cases may not have been reported.

Figure 31.3 Histogram depicting the epizootic of Marburg virus infections in monkeys imported into Belgrade in 1967. (Source: Constructed from published data (Stojkovic *et al.*, 1971).)

For two decades only three further, isolated primary human Marburg infections and only two secondary cases were observed. These were adventurous tourists or expatriate residents. One was a hitchhiker in Zimbabwe who reported an insect bite while waiting for a ride

on the roadside. (It now (2007) appears he had visited bat-infested caves in Zimbabwe.) The two others had both visited the Kitum Cave in the Mount Elgon region of western Kenya, not far from the shores of Lake Victoria (Gear *et al.*, 1975; Smith *et al.*, 1982; Teepe *et al.*, 1983).

The Kitum Cave, a popular tourist destination, is heavily populated with a wide range of exotic species, particularly bats. One of the Marburg victims was a 12-year-old boy, an amateur geologist, who collected specimens in the cave. Extensive epidemiological investigations in Zimbabwe and in the Kitum Cave revealed no clues to the origin of the infections. Medical facilities are limited in these areas, and isolated cases in local residents probably went unnoticed unless dramatic epidemics supervened.

Between 1998 and 2000, Marburg disease re-emerged in the east of the DRC, in a mining community in and around Durba (Feldmann, 2006). This was the first community outbreak of Marburg haemorrhagic fever. A total of 154 cases were identified, 48 of whom were laboratory confirmed. In this outbreak, mortality of 83% contrasted with the 23% in the original outbreak in the city of Marburg. This sharp difference in mortality has not yet been explained by differences in viral strains or other biological factors, but the DRC patients certainly did not have access to quality supportive care. A very difficult investigation was conducted in what was essentially a war zone in a state of anarchy. Cases were found to be associated with illegal working of a partially flooded gold mine infested with all manner of wildlife (Bausch *et al.*, 2003). There appeared to have been a series of primary cases going back many years among these illegal miners rather than as had been seen before, a point source epidemic, with secondary cases in hospitals and households. Genetic analysis of isolates confirmed that, indeed, this outbreak was quite different, with multiple genetically distinct isolates from a series of index cases, most if not all of whom had worked illegally in the same abandoned mine (Bausch *et al.*, 2006). The outbreak stopped abruptly in 2000 when that mine became entirely flooded and no longer accessible.

In 2004/2005 a further, large outbreak of Marburg haemorrhagic fever occurred in northern Angola, in Uige province, which borders southern DRC (Centers for Disease Control and Prevention, 2005). This outbreak was large with 252 cases and 227 deaths (mortality 90%) (Towner *et al.*, 2006). The high reported mortality is consistent with that of the Durba 1998–2000 outbreak. This outbreak was also distinguished by there being many paediatric cases, mostly hospitalized infants (Feldmann, 2006). Molecular analysis of strains from this outbreak indicated it may have been a point source introduction by one index case, with spread in hospitals and the community (Towner *et al.*, 2006).

Epidemics: Ebola Haemorrhagic Fever

It was not until nearly a decade after the Marburg outbreak, in 1976, that simultaneous outbreaks of another lethal haemorrhagic fever struck suddenly in northern

Zaire and southern Sudan (Figure 31.2) (World Health Organization, 1978a, 1978b). Among 318 probable or confirmed cases in Zaire, there were 280 deaths (mortality 88%) (World Health Organization, 1978b). Though initial suspicions were that the outbreaks were linked, it was soon shown that there were no observable or even potential epidemiological connections between the two outbreaks. Mortality in the Sudan outbreak was also lower (53%) than in Zaire (World Health Organization, 1978a). Both outbreaks centred in and around local hospitals, where conditions existed for person-to-person spread. New filoviruses were isolated from specimens from patients from both epidemics.

The excellent and detailed reports of these two outbreaks define the classic filovirus outbreak, with little new knowledge having been added in more recent reports (World Health Organization, 1978a, 1978b). In Yambuku, Zaire, the index case may have been a traveller recently in the northern Equateur region of Zaire. This individual apparently attended the outpatient clinic of the mission hospital in Yambuku for treatment of acute malaria, where he received an injection of chloroquine. It remains unclear whether this man was the source of the epidemic or whether he was infected by his injection, since another patient with a similar illness was admitted to the hospital at about the same time. The subsequent nine cases, however, had all received treatment for other diseases at the hospital. Though all ages and sexes were affected, the highest incidence was in women aged 15–29 years, mostly those who had attended antenatal and outpatient clinics at the hospital. The major risk factor was receiving an injection at this hospital. The hospital was simply run, mostly by Belgian nuns, providing the only medical care in the region. Needles were in short supply, and not sterilized between use. Clearly the medical staff had no concept of what was going on, since 11 of the 17 staff members of the hospital died. The outbreak only terminated four weeks after it began when the hospital was closed. Though transmission was focused in the outpatient clinics of the hospital, there was subsequent dissemination in surrounding villages to people caring for sick relatives, or attending childbirth. The overall secondary attack rate was about 5%, but nearer 20% in close relatives of a case. Illness-to-infection ratios in one village exceeded 10 to one. Ebola virus antibody in people not ill and without contact with cases during the epidemic was only conclusively identified in four individuals. Interestingly, though not reported in the scientific literature, final control of the epidemic was probably achieved by the local village chiefs who, with the recent experience of smallpox eradication, placed their own 'cordon sanitaire' around each village, preventing anyone entering or

leaving (Close, 1995). The outbreak only came to international attention when a nurse infected with Ebola virus fled to the capital Kinshasa, and died in a hospital there.

The following year, 1977, a single fatal case was identified in Tandala, also in northern Zaire (Table 31.1). There was no ensuing epidemic, but serological and epidemiological investigations uncovered two possible cases dating back to 1972, and 7% prevalence of immunofluorescent assay (IFA) antibody in the local population (Heymann *et al.*, 1980). Unfortunately, nonspecific reactions to the Ebola virus antigens make interpretation of serological data uncertain.

At the same time as the 1976 Yambuku epidemic in Zaire, an outbreak of a similar disease occurred in southern Sudan (Figure 31.2) (World Health Organization, 1978a). This outbreak was strongly associated with an index case who worked in a cotton weaving factory. There were 151 deaths among 284 cases identified (case definition not stated). The focus of the infection was in the town of Nzara where the factory was located, and spread was to close relatives (67 cases). The epidemic was augmented by high levels of transmission at nearby Maridi hospital following transfer of one of the Nzara patients, and further cases were transferred to Juba and Khartoum. There were 203 cases in Maridi, 93 of whom were probably infected in the hospital, and 105 in the community. Forty-one staff members died, and at the height of the epidemic all wards contained patients with overt haemorrhage. The highest attack rates were associated with nursing a patient, but not with sleeping in the same room. In 1979 there was a second outbreak originating from an index case working in the same Nzara cotton factory. This time 22 of 34 infections (65%) were fatal (Baron *et al.*, 1983). From the 1976 and 1979 outbreaks two new filovirus strains were isolated, (ZEBOV and SEBOV) (Johnson *et al.*, 1977). It was quickly realized that these two viruses are quite different (Kiley *et al.*, 1982), but the two Sudan virus strains from 1976 and 1979 were identical (Cox *et al.*, 1983).

Between 1979 and 1994 only one case of human Ebola infection was recorded (Teepe *et al.*, 1983). In 1994 all this changed when there was a large, hospital-based outbreak in Kikwit, DRC, resulting in the deaths of 242 of 315 cases. Again a hospital was the amplifying focus of the outbreak, with many needle-borne transmissions. The virus then spilled over into the community with cases among close contacts of the sick (Khan *et al.*, 1999; Reiter *et al.*, 1999). The probable source was traced to a single forest worker (Garrett, 1996), but intensive studies failed to reveal the primary host.

Soon afterwards the first of three epidemics caused by Ebola virus emerged in Gabon (Georges *et al.*, 1999). The index cases may have been gold panners or hunters in the forest. One outbreak resulted from finding and handling

the carcass of a dead chimpanzee in the forest. In this outbreak all the primary cases handled the uncooked meat at some stage. People who ate the cooked meat did not get sick.

The Sudan virus did not reappear until October 2000, and when it did it was by way of a massive epidemic in Uganda (Okware *et al.*, 2002). The origins of this outbreak are obscure, but it appeared to originate in the inaccessible northern part of the country where rebel fighting was ongoing. The epidemic was centred in northern Uganda, in the Gulu district, and was not brought under control until mid January 2001. There were a total of 425 cases and 224 deaths countrywide (case fatality 53%). Attack rates were calculated to be between 4.5 and 12.6/10 000 depending on the case definition (Okware *et al.*, 2002).

Infections of Ebola virus appeared again in Gabon and the neighbouring Republic of Congo in 2000 and continue to date. As of 30 December 2002, WHO had reported 30 confirmed cases (14 laboratory confirmed and 16 epidemiologically linked), including 22 deaths, in Gabon and neighbouring villages across the Congolese border. Epidemics in the Republic of Congo appear to be closely associated with epizootics in great apes (details in the section on Ecology, below). As of 27 May 2005, there were 11 confirmed and many probable cases of Ebola haemorrhagic fever in the Cuvette Ouest Region of the Congo (World Health Organization, 2005a). These outbreaks are proving difficult to detect and control because of the remoteness of the area, the association with the ongoing great ape epizootic and the fears and resistance of the communities affected. These fears were sufficient in one community for a schoolteacher to be attacked and killed following accusations of being the cause of the epidemic.

Epizootics: Reston Virus

In 1989 and early 1990 a filovirus (REBOV) closely related to ZEBOV was isolated from cynomolgus monkeys in quarantine facilities in Reston, Virginia, in Texas and in Pennsylvania (Centers for Disease Control and Prevention, 1989; Jahrling *et al.*, 1990). The monkeys had recently been imported into the United States from the Philippines. The first shipment arrived via Amsterdam, and exhaustive inquiries ruled out a link with African animals during transit. Early the following year more shipments of monkeys from the same source arrived, this time directly from the Philippines, over the Pacific Ocean, and several more REBOV isolations were made from sick and dying monkeys (Centers for Disease Control and Prevention, 1990a). No link with Africa or African animals could be identified in the Philippines, and in the absence of such evidence, REBOV must be considered

an Asian filovirus. Pathogenicity in the outbreak animals was uncertain because of a high rate of co-infection with simian haemorrhagic fever virus (SHFV), a DNA virus which is a known severe simian pathogen unrelated to the *Filoviridae* (Palmer *et al.*, 1968). This co-infection added enormously to the complexity of this episode (SHFV also produces haemorrhagic disease though it does not apparently infect humans). In the first reported SHFV epizootic, 223 of 1050 exposed animals died, with increased handling a risk factor for disease and death. The natural host and geographical distribution are also unknown, though the infected monkeys (*Macaca mulatta*) apparently originated in India (Palmer *et al.*, 1968).

In 1990 concern about the risk to humans led to a temporary ban on importation into the United States of cynomolgus, rhesus and African green monkeys. Evidence for ongoing epizootics and transmission was sought in the Philippine export facilities which had provided the monkeys (Hayes *et al.*, 1992). Antigen-detection enzyme-linked immunosorbent assay (ELISA) assays on liver homogenates revealed that 85/161 (53%) of monkeys that died there over a period of less than three months were positive for filovirus antigen, as were 7% of monkeys tested in an initial serological survey. Incidence was calculated to be 24.4/100 animals, or 0.6/100 monkeys per day of follow-up, similar to the reports from Belgrade in 1967 (Figure 31.3). Documented case fatality at this institution was 82.4%, and survivors developed high-titre IFA antibody. Average duration of viraemia was 5.6–2.4 days. Diarrhoea and respiratory problems were the most frequently recorded manifestations. In the 73% of monkeys positive for filovirus by IFA at this facility the geometric mean antibody titre was 145. A protective factor was the presence of antibody to filovirus at the time of entry to the facility (Hayes *et al.*, 1992). As in the United States, many of the filovirus-infected monkeys were co-infected with SHFV, which means data from these epizootics are difficult to interpret and conclusions are open to question.

Epidemiology: Reston Virus

In the Philippines 186 people were studied who lived in wildlife collection areas or worked in four primate export facilities in Manila (Miranda *et al.*, 1991). Twelve (6%) were filovirus antibody positive by IFA, and in the facility experiencing the epizootic 22% were positive, significantly higher than the other export facilities (relative risk 5.6, 95% confidence interval 1.09–24.14) (Hayes *et al.*, 1992). In that facility the workers in the animal hospital had the highest titres: three of five had titres of >256. However, there was no illness in any of the positive individuals, and no association between seropositivity

and other risk factors, such as bites, scratches or eating monkey meat (a local delicacy). In the facility at Reston, Virginia, five animal handlers had a high level of daily exposure to infected and dying animals (Centers for Disease Control and Prevention, 1990b, 1990c, 1990d). Though four of these had serological evidence of recent infection by IFA, and three were observed to seroconvert during the period of the epizootic none reported any illness. One cut his finger while performing a necropsy on an infected animal.

ECOLOGY

Until the early 1990s outbreaks of human disease had been unusual because transmission from the natural reservoir to humans is rare. Searches for evidence of virus infection in many species of animals captured in Central African countries failed to provide any clues as to the possible reservoir. The original ecological setting of Marburg and Ebola appeared to centre around Central and south Central Africa (Figure 31.2). Surveys of wild monkeys from the Lake Kyoga area in northern Uganda in the 1970s where the original Marburg-infected group originated failed to yield virus, but about 10% of sera reacted with crude Marburg antigen in a complement fixation test, and in at least three animals neutralizing antibody could be demonstrated. The 1987 Marburg disease case was a boy who had spent considerable time in Kitum Cave, collecting minerals and other items, near to the sugarcane factory where the 1980 Marburg disease case had worked. Extensive searches for the reservoir in the area around the sugarcane-processing factory and around Kitum Cave were unsuccessful. The cave contained enormous numbers of bats, and was visited by a wide range of mammals, birds, reptiles and insects. Sentinel animals and other means of searching for the virus failed to identify bats (or any of a number of wild mammals) as the ultimate source. Similarly, because of the history of an insect bite, a thorough study of insects and mammals along the trail of the 1975 traveller in Zimbabwe did not produce evidence of the source of infection.

Bats as the Reservoir

Bats have always been highly suspect, since they were directly implicated in the Kitum Cave cases. In Sudan in 1976 and 1979 both index cases had worked in the same storeroom in a cotton factory where the roof was heavily infested with bats. Antibody could not be detected in sera from six bats captured in 1976, and no virus was isolated from bat tissues in either investigation, but limited sampling could have missed infected animals. (Serological studies in bats and other exotic species presented a

serious challenge in terms of species specific reagents. Similarly all isolation attempts involved tissue culture, since the more sensitive polymerase chain reaction (PCR) methods were not yet available.)

In the 1990s, a heroic laboratory study involving a menagerie of exotic species experimentally infected with ZEBOV was conducted by Swanepoel and co-workers in South Africa in the Pretoria BSL4 suit laboratory. Though technical difficulties led to premature termination of the ZEBOV-infected snake arm of the study, the remainder of the data showed that ZEBOV can replicate in fruit bats without causing disease (Swanepoel *et al.*, 1996). The fruit bats used were *Epomophorus wahlbergi*, a widely distributed species native to the tropical rainforest, home to ZEBOV outbreaks. This was further evidence that bats could carry a silent infection which is a prerequisite for maintaining the virus in a wild population over time. Other suggestions, such as rodents and even plants as primary hosts have never been substantiated. If this were a rodent virus, the ubiquity of most rodents would mean that primary infections in humans would be much more frequent, as is the case with Lassa fever, so rodents are unlikely as hosts. There is no precedent for a plant virus infecting humans.

Fruit bats remained prime suspects, not only because of epidemiological evidence, but because the rarity of human exposure to a canopy-feeding animal would explain the rarity and sporadic nature of primary infections, as well as the association with bat-infested caves and buildings. The evidence, however, remained circumstantial until Leroy *et al.* reported identification of ZEBOV in bats by PCR in Gabon around sites where outbreaks of disease had occurred in great apes and in humans (Leroy *et al.*, 2005). These studies implicated silent infection in three species of fruit bat native to the distribution of known Ebola index cases. The ranges of the bat species identified, *Hypsignathus monstrosus*, *Epomops franqueti* and *Myonycteris torquata*, overlies with precision the known range of ZEBOV primary infections. Captured animals were PCR-positive for seven different RNA fragments from the ZEBOV genome. Studies a few months later at the same sites showed serological evidence of infection in some bats but no PCR-positive animals. Since no animals were simultaneously PCR-positive and serologically reactive, the idea was raised that the infection is not only silent, but transient in bats. This limited window of infectivity in the natural host is also consistent with rarity of human index case infections. Sequencing of the fragments showed them all to be closely related to one another and to locally isolated strains from humans and great apes, and also to the original ZEBOV strains, but more distantly to SEBOV and MARV (Leroy *et al.*, 2005). More recently common ZEBOV ancestry has been demonstrated in bat

reservoirs (Biek *et al.*, 2006). These data are compelling in themselves, but more so since the report in August 2007 that Marburg virus has been identified in four of 1100 fruit bats (*Rousettus aegyptiacus*) captured in two sites in western Gabon (Towner *et al.*, 2007). The distribution of this cave-dwelling species encompasses most of equatorial and southern Africa, including all the known Marburg primary sites. Three of the four infected bats had evidence of both antibody and virus, indicating this time a persistent infection. However, prevalence in this sample was extremely low (0.36%), suggesting that infection is either a rare or a transient event. The infected bats were apparently healthy and active, and no virus could be isolated, which argues for very low titre infection. Isolation of viruses from wild-caught fruit bats would provide an important key to understanding viral dynamics in this reservoir.

Involvement of the Great Apes

Ebola epizootics among great apes in Central Africa have become of great concern to conservationists, to the extent that the virus, combined with intense bush meat hunting, is now threatening chimpanzees and lowland gorillas with extinction. Since the 1990s, large apes, specifically chimpanzees and gorillas have also become increasingly implicated in transmission to humans (Georges *et al.*, 1999). The catastrophic decline in great ape populations is illustrated by a 99% drop in nest groups between 1998 and 2000 in Gabon near Minkébé, an area where there had been a human epidemic (Walsh *et al.*, 2003). In Mekambo, in neighbouring Congo, many ape carcasses have been found, and in Lossi, a population of 143 individually identified gorillas has been reduced to seven. The epizootic has been gradually making its way south and west, and in 2006, the deaths of 5000 gorillas has now been attributed to ZEBOV infection (Bermejo *et al.*, 2006). With such high mortality these apes must be, like humans, an accidental end-host. Ecological disturbances have been hypothesized as an underlying reason for transmission, but it has now been shown that social behaviour among apes facilitates transmission (Walsh *et al.*, 2007).

The question of how the virus is introduced into human populations is now partially resolved. It is known that non-human primates, particularly chimpanzees, will eat any smaller animal they can catch, which could be a bat or an intermediate, canopy-dwelling species, such as a small monkey. Molecular sequencing of strains from dead apes shows infections with differing strains so that, however it happens, there are multiple virus introductions. This also argues against the primates as a natural host (Leroy *et al.*, 2004).

Use of Modelling Techniques

Further light has been cast on these questions by the use of ecological niche modelling (Peterson *et al.*, 2004a). This technique includes large numbers of variables in models, encompassing terrain, climate, flora and fauna. Data from known or suspected primary infection locations are fed into the model, and used to predict where future outbreaks might be expected based on the theory that the natural host will occupy similar ecological locations. Using this approach Peterson *et al.* predicted the geographical distribution of ZEBOV to overlie the distribution of the tropical broadleaf rainforest. This also coincides with the range of the fruit bats described by Leroy *et al.* Using the same model to identify potential hosts produced a dauntingly long list of candidates (Peterson *et al.*, 2004b).

Of great interest were predictions for wider distribution of MARV, mostly in savannah-type regions, including many countries where no cases had ever been seen. One of these was Angola, with a predicted distribution pinpointing Uige province where the MARV outbreak started later in 2004, six months after publication of the model (Centers for Disease Control and Prevention, 2005). At least two MARV cases among miners in Uganda in the summer of 2007 also fall geographically within this model (World Health Organization, 2007). Peterson *et al.* have now updated their model of the geographic distribution to include the Uige province of Angola, and a probably more accurate estimation of the single index case from Zimbabwe (the Sinoia caves). Though the model has limitations, particularly the small number of precise localities in the sample, it predicts a much larger area over which MARV infections should be expected, broadly distributed across the arid woodlands regions of Africa (Peterson *et al.*, 2006).

TRANSMISSION AND RISK FACTORS

With few exceptions, transmission of filoviruses among humans has been the result of lax medical procedures or unwise behaviour (Fisher-Hoch, 1993; World Health Organization, 1978b). Person-to-person spread has been the major mode of transmission in epidemics. But unprotected direct contact with blood or secretions from patients ill with Ebola is the most important factor in determining risk of illness. Other risk factors associated with human-to-human transmission are infection from contaminated materials, particularly sharps, preparation of victims for burial or, occasionally, sexual contact (World Health Organization, 1978a). Injury or injection with a contaminated needle carries the highest risk, and the highest likelihood of death (World Health Organization, 1978b). Close

contact with blood or tissues of infected monkeys is also important, historically in the laboratory (Martini *et al.*, 1968), and currently in the wild (Georges *et al.*, 1996). The virus enters through mucous membranes or skin lesions. Medical personnel who do not take simple, barrier nursing precautions, however, are particularly at risk, as are their uninfected patients who may become exposed during treatment. Indeed, the history of filovirus outbreaks has been one of massive amplification of the epidemic in poorly operated medical facilities (Khan *et al.*, 1999; World Health Organization, 1978b). Outbreaks have been abruptly terminated when blood and/or needle transmission were interrupted (Fisher-Hoch, 1993; World Health Organization, 1978b).

Epidemiological studies in Zaire and Sudan rule out spread through casual contact or by aerosol transmission (World Health Organization, 1978a, 1978b). A formal study of risk factors for virus transmission in the Sudan epidemic in 1979 showed that caring for an ill patient carried a relative risk five times greater than in people with a lesser degree of physical contact. No cases occurred in people who entered the room of an ill patient but had no physical contact (Baron *et al.*, 1983). These data confirm that Ebola is not an air-borne disease.

The most significant risk factor for the monkeys infected in the REBOV epizootic in the Philippines was being an occupant of a gang cage (Hayes *et al.*, 1992). REBOV has been identified at high titre in respiratory secretions in monkeys, and respiratory transmission at close quarters may be a factor in epizootics with this virus. However, the evidence for monkey-to-monkey transmission by reuse of needles for routine procedures, such as tuberculin testing or antibiotic administration cannot be ignored.

The outbreak of MARV in 1967 was caused by infection of individuals handling fresh monkey tissues or contaminated equipment without gloves or other protective clothing (Martini *et al.*, 1968). Otherwise there has only been one reported laboratory-acquired infection (needlestick) with Ebola virus in 1976 (Emond *et al.*, 1977). Because of its lethal potential, Ebola has been a candidate for biological warfare. Little information is available, but it has been handled extensively in biological research, and further accidental infections may have occurred, specifically in the former Soviet bloc. The key to safe laboratory handling of filoviruses is extreme care in avoiding accidental inoculation.

CLINICAL SPECTRUM

The incubation period for Marburg disease is three to nine days (Martini *et al.*, 1968) and for Ebola virus about

10 days; five to seven days for needle transmission and 6–12 days for person-to-person spread (Baron *et al.*, 1983; World Health Organization, 1978a, 1978b). The incubation period for the Ebola-related virus from Sudan may be slightly longer than for the more lethal ZEBOV strain, and appears to be dose-dependent. The illness-to-infection ratio for Marburg and Ebola viruses is very high. Using molecular techniques a few asymptomatic infections have been observed (Leroy *et al.*, 2000b). Serological studies generally reveal few people who have recovered from ZEBOV or MARV infections, even after a large epidemic (Bausch *et al.*, 2003). SEBOV-infected patients are more likely to survive, and attack rates are lower. REBOV in all individuals documented to have been infected was uniformly asymptomatic (Table 31.1) (Centers for Disease Control and Prevention, 1990e; Miranda *et al.*, 1999).

The human disease caused by the African viruses is dramatic (Figure 31.4) (World Health Organization, 1978a, 1978b). The onset is abrupt, with fever, severe headache (usually periorbital and frontal), myalgia, arthralgia, conjunctivitis and extreme malaise. Sore throat is a common symptom, often associated with severe swelling and dysphagia, but no exudative pharyngitis. A papular, eventually desquamating rash may occur in some patients, especially on the trunk and back, and morbilliform rash has been observed on white skins. In non-human primates petechiae are striking. Gastrointestinal symptoms develop in most patients on the second or

third day of illness, with abdominal pain, and cramping followed by diarrhoeal and vomiting. Jaundice is not a feature of Marburg or Ebola disease. The bleeding begins about the fifth day of illness and is most commonly from the mucous membranes: gastrointestinal tract, gingiva, nasopharynx and vagina. The persistence of vomiting and the onset of any signs of mucosal bleeding carry a high risk of fatal outcome, which is associated with hypovolaemic shock. Bleeding is insufficient to account for death.

Infection in pregnancy results in high maternal fatality and virtually 100% fetal death. Central nervous system involvement has led to hemiplegia and disorientation, and sometimes frank psychosis. Even in convalescence, patients show prolonged weakness, severe weight loss, and in a few survivors serious but reversible personality changes are recorded, namely confusion, anxiety and aggressive behaviour. Ocular involvement is also seen, and may be persistent (Kibadi *et al.*, 1999).

LABORATORY DIAGNOSIS

General

Care should be taken in both drawing and handling blood specimens since virus titres may be extremely high, and the virus is stable for long periods even at room

Figure 31.4 Frequency of symptoms and signs in Ebola haemorrhagic fever. (Source: Constructed from published data (World Health Organization, 1978b).)

temperature (Elliott *et al.*, 1982). Gloves should be worn at all times, and discarded directly into freshly made disinfectant. All sharps (instruments, needles, syringes) should be discarded in a puncture-resistant container with a lid, as is recommended for HIV-infected specimens (Centers for Disease Control and Prevention, 1988). In Africa where resources are limited, discard of sharps into freshly made chlorine is recommended. All discarded materials should be burned in a deep pit (World Health Organization, 1985).

Clinical laboratory observations are limited to the Marburg outbreak. No acute-phase investigations were performed during the care of the one Ebola laboratory infection in England. Data from non-human primate studies have been very useful. Thrombocytopenia is invariable, and profound lymphopenia early in disease is followed by marked neutrophilia. Aspartate transaminase (AST) and alanine transaminase (ALT) are raised, but the rise in AST is disproportionately higher than ALT, as was described in the early Marburg cases, (AST : ALT ratios 7 : 1) and is important in distinguishing viral haemorrhagic fevers from hepatitis viruses clinically (Fisher-Hoch *et al.*, 1985; Martini, 1971).

Virus-Specific Diagnosis

For virus isolation, antigen detection and serology a blood specimen should be taken without anticoagulant and serum separated. For PCR assays, separation of buffy coat may be preferred. Specimens may be safely handled for immunological tests by inactivating with γ -irradiation, or heating to 60 °C for 30 minutes (Elliott *et al.*, 1982). Denaturing chemical reagents used in PCR reactions can also be considered to inactivate the virus, though definitive studies are needed to establish this principle.

The indirect IFA is the original basic diagnostic serological test for acute infections evaluated for the diagnosis of human Ebola virus disease (Wulff and Johnson, 1979). Though less sensitive than the ELISA techniques which later superseded it, the IFA has the advantage of being simple enough to perform in the field anywhere a fluorescent microscope is available, with the added advantage that visualization of the infected cells allows experienced observers to make some assessment of specificity. In acute infections a rising filovirus-specific IFA titre (fourfold) in paired serum, or a high IgG titre (>64) and presence of IgM antibody with a clinical illness compatible with haemorrhagic fever are consistent with the diagnosis of filovirus infection (Ksiazek *et al.*, 1992). In the absence of a history of filovirus-like illness, MARV antibody is usually specific, but Ebola virus serology in the absence of a history of recent disease has consistently been plagued by low-titre, nonspecific reactions. ELISA assays using recombinant nucleoprotein (NP) are now the most broadly

reactive and the most sensitive assays (Groen *et al.*, 2003). Use of other proteins as antigens, for example, recombinant VP35, results in a strain-specific assay, but is less sensitive (Ksiazek *et al.*, 1992, 1999).

ZEBOV and MARV are readily isolated from serum, blood or tissue specimens, stored at -70 °C, in Vero E-6 cells. Biological safety level 4 containment facilities are recommended for any procedure such as isolation where virus will be amplified. Blood specimens unrefrigerated for up to 10 days have yielded virus strains. Primary isolation of ZEBOV is more difficult and success may depend on blind passage of cultured cells or guinea-pigs monitored for febrile response. Specimens including throat washing, urine, various soft tissue exudates, semen and anterior eye fluid may also contain virus. Virus identification is made generally by direct immunofluorescence of the tissue culture using monoclonal antibodies or by electron microscopy (Elliott *et al.*, 1993; Wulff *et al.*, 1978). Impression preparations made from a post-mortem liver biopsy may be probed with monoclonal antibodies by IFA for presence of virus antigen which is abundant in liver and spleen. Immunohistochemistry has been widely used for histological studies, but for studies of pathophysiology electron microscopy is much more precise.

An antigen-detection ELISA system in serum has been extensively used, employing monoclonal antibodies (Ksiazek *et al.*, 1992). This assay has been used extensively in human and epizootic outbreaks. One study showed that a positive antigen test was obtained in symptomatic patients, but once symptoms had resolved in survivors, the test became negative (Baize *et al.*, 1999). Most of these assays have been superseded by the PCR, which is now universally used on blood and all other body fluids and tissues. It is rapid, highly sensitive and specific and can be conducted safely in the field (Grolla *et al.*, 2005; Leroy *et al.*, 2000a).

PATIENT MANAGEMENT

Supportive Care

Fluid, electrolyte, respiratory and osmotic imbalances should be managed carefully. Patients may require full intensive care support, including mechanical ventilation, along with blood, plasma or platelet replacement. The maintenance of intravascular volume is a particular challenge but every effort is justified since the crisis is short-lived, and complete recovery can be expected in survivors. Pregnant patients may present with absent fetal movements, and maternal survival may depend on aggressive obstetric intervention. Heparin has been advocated but remains controversial and potentially dangerous. The

only experience has been the therapy of two individuals with Marburg disease in South Africa. However, both of these patients were secondary Marburg infections, and none of 10 known secondary patients with Marburg infection have died (Gear *et al.*, 1975).

Approaches to Antiviral Therapy

The current lack of effective antiviral therapy has led to the development of innovative approaches such as experimental use of RNA interference. Post-exposure prophylaxis with vaccines and molecular approaches have shown some promise in animal models. A single dose of a live-attenuated recombinant vaccine 20–30 minutes after challenge protected four of eight rhesus monkeys (Feldmann *et al.*, 2007). Treatment of guinea-pigs immediately before and after challenge with iRNA targeting the viral polymerase (L) shows some protection (Geisbert *et al.*, 2006). For the future, inhibition of the NP35 suppression of the immune system is a target of interest (Kash *et al.*, 2006), as may be inhibition of apoptosis.

PAST INFECTION AND PERSISTENCE

Humans and non-human primates with documented acute infection with ZEBOV, SEBOV or REBOV seroconvert to high-titre IFA to antigens prepared from all three viruses. Low-titre antibody may be associated with filovirus infection in the past, and also with immunity, but this remains to be demonstrated, though MARV has been isolated from semen seven months after acute infection (Martini, 1973) and from the anterior chamber of the eye two months after acute infection (Gear *et al.*, 1975). A systematic study of the potential of the Ebola filovirus strains to persist in non-human primates failed to detect persistent filovirus. This was despite intensive efforts, including laparotomy to obtain serial specimens, co-cultivation and use of PCR (Fisher-Hoch *et al.*, 1992b).

VIROLOGY

The filoviruses still retain some of the great mysteries of virology. At first filoviruses were thought most to resemble rhabdoviruses, but it is now clear that they form a family of their own, designated *Filoviridae* on account of their filamentous appearance (Kissling *et al.*, 1968). Nucleotide sequence analyses place the family in the order Mononegavirales, which also includes the *Paramyxoviridae* and *Rhabdoviridae* families (Pringle, 1999). Within the *Filoviridae* family are two genera: ‘Ebola-like

viruses’ and ‘Marburg-like viruses’. The ‘Ebola-like’ genus includes the African viruses ZEBOV, SEBOV and CIEBOV and the Asian virus, REBOV. These viruses are of varying pathogenicity in patients and non-human primates, with ZEBOV being the most virulent, and REBOV essentially apathogenic in humans and demonstrating low, but variable pathogenicity in non-human primates depending on the primate species (Fisher-Hoch *et al.*, 1992a). The ‘Marburg-like’ genus includes at present only one strain, MARV, with high pathogenicity in humans and non-human primates. Though still considered a single strain, isolates now include a large number of MARV strains distinguishable genetically, antigenically and phenotypically (Reed and Mohamadzadeh, 2007; Towner *et al.*, 2006).

Filoviruses undergo rapid, lytic replication in the cytoplasm of a wide range of host cells. The nucleocapsids acquire the envelope with its surface projections by a process of extrusion of cell membrane rather than a discrete orderly budding, which may account for the striking pleomorphism of these viruses (Johnson *et al.*, 1977). Filoviruses are among the largest known viruses, with highly variable length (up to 14 000 nm), apparently due to concatamerization (Regnery *et al.*, 1980). The virions are of uniform 80 nm diameter, with a nucleocapsid consisting of a central axis 20–30 nm in diameter, surrounded by a helical capsid 40–50 nm in diameter, with 5 nm cross-striations. A host cell membrane-derived layer with 10 nm projections in regular array surrounds the nucleocapsid and the terminal windings of nucleocapsid at one end of the particle. The virions contain a single negative-strand RNA genome ranging from 4×10^6 (MARV) to 4.5×10^6 Da (EBOV). The RNA is a template for seven polypeptides; an NP, a surface glycoprotein (GP), an RNA-directed RNA polymerase (L) and four other proteins (VP40, VP35, VP30 and VP24) (Elliott *et al.*, 1985).

Aided by the development of reverse genetics, the functions of some of the filovirus proteins are now becoming understood (Volchkov *et al.*, 2001). The surface GP has been studied in most detail. Regions of the GP have been identified which bear antibody and T-cell epitopes (Dowling *et al.*, 2007). The GPs of most ‘Ebola-like viruses’ are cleaved to produce two molecular species, one a soluble truncated protein (sGP) which is secreted from infected cells, and the other the full-length glycoprotein. The sGP is a disulfide-linked homodimer, for which an anti-inflammatory function has been described (Falzarano *et al.*, 2006). Since MARV does not produce an sGP (Feldmann *et al.*, 1999), this molecule is an unlikely candidate for virulence. The ZEBOV GP, when cleaved, yields yet another small, soluble protein, the Δ -protein, whose function is unknown. In all filoviruses

the full-length GP is further proteolytically cleaved to form two heavily glycosylated subunits, GP1 and GP2, which together form the surface spikes seen by electron microscopy. The GP2 is a transmembrane protein and bears a fusion site (Freitas *et al.*, 2007), and has been shown to modify permeability of the plasma membrane (Han *et al.*, 2007). The GP1 is involved in viral attachment and entry, the latter associated with critical conserved sequences (Mpanju *et al.*, 2006). During entry and assembly and budding, viral proteins including GP1 have been shown to associate with lipid rafts on the cell surface, and released viruses, including virus-like particles (VLPs), incorporate raft-associated host molecules (Bavari *et al.*, 2002). Using VLPs, it has also been shown that a heavily glycosylated mucoid domain on the GP is able to stimulate human dendrite cells through NF- κ B and MERK pathways (Martinez *et al.*, 2007).

The VP30, VP35, NP and L proteins are necessary and sufficient for *in vitro* replication. VP30 is a nucleocapsid-associated transcription factor which interacts directly with viral RNA, and is thought to stabilize the nascent molecule (Hartlieb *et al.*, 2007; John *et al.*, 2007). VP35 is capable of targeting several pathways of antiviral interferon systems (Feng *et al.*, 2007; Cardenas *et al.*, 2006). It is an RNA-binding protein which acts as an interferon antagonist. It works by blocking the activation of interferon regulatory factor 3 which is responsible for facilitating interferon-associated gene expression. VP35 has further been shown to block the host iRNA responsible for RNA silencing. This silencing is part of the host innate antiviral activity, and is analogous to the activity of the HIV-Tat protein (Haasnoot *et al.*, 2007). It has also been shown to be capable of blocking α -interferon-induced antiviral activities and inhibition of the β -interferon promoter. The NP is associated with the nucleocapsid, serving as a scaffold (Noda *et al.*, 2002), and binding with VP40 is important for its incorporation into the virion during assembly (Noda *et al.*, 2007). The L protein is the RNA-directed RNA polymerase.

The VP24 protein, an abundant but poorly glycosylated protein, is believed to be a secondary matrix protein. It is associated with assembly and budding, and appears to localize to the plasma membrane and the perinuclear region (Han *et al.*, 2003). It has been shown to be capable of budding from mammalian cells as lipid-bound VLPs (Licata *et al.*, 2003). There is some evidence in a mouse model that VP24 and NP are associated with virulence and may also interfere with the host cell antiviral interferon response (Ebihara *et al.*, 2006).

ANIMAL MODELS

African green monkeys recently imported from Uganda were the source of the original Marburg outbreak (Henderson *et al.*, 1971; Martini *et al.*, 1968), and South East Asian cynomolgus monkeys were the source of the newly described Asian filovirus (Centers for Disease Control and Prevention, 1989; Jahrling *et al.*, 1990). Both are important species imported for medical and other research, and non-human primates have been the most successful animal used for the study of the pathogenesis of filoviruses (Fisher-Hoch and McCormick, 1999; Simpson *et al.*, 1968). The ability of filoviruses to kill guinea-pigs is variable. ZEBOV kills guinea-pigs consistently after several adaptive passages; the Sudan strain and MARV do not. Only the Zaire virus was found to be lethal for suckling mice (McCormick *et al.*, 1983). A lethal mouse model has also been developed and used in protection and pathophysiology studies (Bray *et al.*, 1999).

Rhesus monkeys inoculated intraperitoneally with 10^3 – 10^4 guinea-pig infectious units of ZEBOV become febrile on the third to fifth day after inoculation, and develop a petechial rash on the forehead, face, limbs and chest between the fourth and fifth days. Severe prostration with diarrhoea and bleeding leads to rapid death in almost all animals. Though similar in onset, the disease in non-human primates caused by SEBOV is characterized by lower viraemia, enzyme and immune disturbances, and some survivors, and is not pathogenic in mice (Figure 31.5). Petechiae are rarely seen, and then only in dying monkeys. Viraemias and liver enzymes do not reach the levels seen in ZEBOV filovirus infections, but as the illness progresses severe thrombocytopenia, neutrophilia and lymphopenia developed with very high AST and lactate dehydrogenase (LDH). Monkeys are obviously very sick, including the survivors, but haematological and biochemical parameters return essentially to normal by day 20, and recovery is rapid and complete. Though systematic comparisons have not been made MARV infection in monkeys apparently resembles SEBOV infection. However, African green monkeys experimentally inoculated with the virus soon after the 1967 outbreak all died, regardless of route of inoculation, but progression to death was slowed if the inoculum titre was reduced (Hass and Maass, 1971).

REBOV was first identified in an epizootic in an animal-handling facility, where transmission and a high death rate were observed in cynomolgus monkeys but these animals were co-infected with SHFV so that observations on filovirus pathogenesis are inconclusive (Centers for Disease Control and Prevention, 1989; Jahrling *et al.*, 1990). Using purified REBOV inoculate, free of SHFV, it has been shown that REBOV infected

Figure 31.5 Comparison of viraemia and outcome in 31 monkeys challenged with filoviruses. Solid lines denote mean viraemia in monkeys challenged with ZEBOV and dashed lines those infected with REBOV. Numbers of deaths are shown by dark bars for ZEBOV-infected animals and open bars for REBOV-infected animals.

non-human primates have lower viraemia, delayed onset of enzyme and immune disturbances, and lower mortality than those infected with African viruses (ZEBOV or SEBOV) (Fisher-Hoch *et al.*, 1992b). It is clear that the host genetics also contribute, in that African green monkeys are less susceptible to severe or fatal disease due to SEBOV or REBOV than cynomolgus monkeys. ZEBOV infection, however, seems uniformly fatal in all species so far challenged (Fisher-Hoch and McCormick, 1999).

SEROLOGICAL STUDIES

The 'Ebola-like' viruses cross-react immunologically with one other, but not with MARV, which is serologically distinct (Elliott *et al.*, 1985). Serosurveys of village populations in epidemic areas have shown the presence of low-titred Ebola and Marburg antibodies, with antibody prevalence to Ebola virus in Zaire reported as high as 37%, which is at variance with the high mortality (nearly 90%) reported during known outbreaks. The problem is that specificity of responses to 'Ebola like' viral antigens has been a continuing issue, with positive responses, albeit at low titre, in highly improbable populations, such as Alaskan Eskimos (Stansfield *et al.*, 1988). Specificity is not improved by use of Western blot techniques, since nonspecific antibody to several proteins is variably seen. This problem appears to be unique to Ebola virus (EBOV, SEBOV and REBOV), and is not encountered

with MARV. Lack of correlation of serology with history of disease supports the conclusion that the titres are non-specific and results should be interpreted with caution. Possible explanations are cross-reactions with host proteins, or some common probably silent, but as yet unidentified human virus. Though some technical advances have reduced nonspecific reactions they continue to be a problem in interpretation of serological survey data (Elliott *et al.*, 1993).

PATHOGENESIS AND IMMUNOLOGY

Pathogenesis and immunology need to be discussed together since they are inextricably linked, and some of the major manifestations of disease are immunopathological in origin. In humans and non-human primates these processes reflect a complex, poorly adapted host/parasite relationship with extensive disruption of the host immune response in fatal infections (Baize *et al.*, 2000, 2002; Leroy *et al.*, 2001). Other factors such as infecting dose, route of infection and host genetics also undoubtedly play major roles.

At autopsy both Marburg and Ebola-infected humans and primates show widespread haemorrhagic diathesis into skin, membranes and soft tissue. There is focal necrosis in liver, lymph nodes, ovaries and testis. Most prominent are eosinophilic inclusion bodies in hepatocytes (Councilman-like), without significant inflammatory

response (Baskerville *et al.*, 1985). Focal necrosis is observed in many organs, including liver, lymphatic organs, kidney, testes and ovaries, but usually not sufficient to produce organ failure, and there is little infiltration of inflammatory cells in areas of tissue damage. Though REBOV is markedly less pathogenic, virus particles have been observed embedded in the basement membrane of lung alveoli (Ikegami *et al.*, 2002).

Among the long-established facts are that high titres of virus are found in serum and tissues taken at autopsy, and particles may be seen in large numbers with some obvious tropism for reticuloendothelial cells (Baskerville *et al.*, 1985; Fisher-Hoch *et al.*, 1992a). The most profound physiological alteration, invariably associated with death, is shock. Several years before the discovery of cytokines and other cellular messenger profound disruption of biochemical integrity of the endothelial cell was proposed without destruction of the cell itself by lytic replication (Baskerville *et al.*, 1985). More recent studies show that endothelial cells are indeed not primary targets and though permissive for EBOV replication *in vitro*, no significant cytopathic changes are observed, and there is insignificant cell activation. The conclusion is that damage to endothelial cells is likely triggered by immune-mediated mechanisms (Geisbert *et al.*, 2003c). On the other hand, coagulation abnormalities are now thought to involve increase in tissue factor (TF) expression stimulated by macrophage/monocyte activation, and leading to dysregulation of the coagulation cascade (Geisbert *et al.*, 2003b).

Until 2000 very little was understood about the immunology of Ebola virus infections. Dendritic cells, monocytes and macrophages are now recognized as the primary targets (Geisbert *et al.*, 2003a; Hensley *et al.*, 2005b). Filoviruses are also known to utilize a number of host molecules for viral entry such as DC-SIGN and various lectins (Hensley *et al.*, 2005a), and VP35 and VP24 both act as interferon antagonists (Cardenas *et al.*, 2006; Ebihara *et al.*, 2006; Feng *et al.*, 2007). Application of reverse genetics techniques has shown potent induction of TNF- α pathway and NF- κ B genes. Downregulation of many coagulation and acute-phase proteins is also reported, including toll-like receptors (Kash *et al.*, 2006).

Studies in humans are rare and very difficult to do, but intensely revealing. Baize and Leroy have published the only series using specimens from patients collected and processed in Gabon. They have shown the immune system to be playing a very important role in patients in both pathogenesis and protection (Baize *et al.*, 1999). Fatal infections are characterized by monocyte/macrophage activation associated with defective inflammatory and anti-inflammatory responses, culminating in massive intravascular T-cell apoptosis (Baize *et al.*, 1999, 2002;

Leroy *et al.*, 2000b, 2001). In a small number of patients (seven) who were asymptotically infected with ZEBOV, an early, orderly inflammatory immune response was observed. Control of virus replication and elimination of virally infected cells was shown to be associated with a prompt inflammatory response which was rapidly down-regulated. T-cell activation was subsequently associated with clearance of infected cells, followed thereafter by development of IgG antibodies (Leroy *et al.*, 2000b). Interestingly, IgG3 and IgG1 subclasses predominated, and it was hypothesized that these are responsible for containment of persistent virus in privileged sites, such as the uvea and semen.

CONTROL

Containment

It now appears that bat-infested environments and bat guano should be considered potential sources of infection, as should sick or dead apes in the rainforest. Prompt identification of active cases is critical, and is in great part dependent on an accurate and detailed history (Centers for Disease Control and Prevention, 1988). Interruption of person-to-person spread of the virus is essential to control. The most important issue is that of awareness in the medical community that these diseases exist and they may result in extensive nosocomial spread if not recognized early and if appropriate isolation of the patient is not achieved. Thus early institution of safe and orderly care of the ill can be set up with effective surveillance of high-risk contacts and prompt isolation of further cases. This has been shown to ensure rapid control of an epidemic.

The experience from Uganda provided the only unique data showing the value of a national approach to control combined with strong community participation (Okware *et al.*, 2002). This extensive outbreak presented major logistic problems threatening to spread throughout the country. The Ugandans set up a series of task forces at different administrative levels including a District Talk Force in each district of the country. Programmes included public education, mobilization of communities, training for healthcare workers and village volunteers, and timely dissemination of information using radio, mobile phones and foot and motor patrols. Scouts were recruited for active case finding. Isolation wards were set up and a temporary field laboratory. One of the major obstacles was lack of laboratory facilities. Burial teams were established for safe burial, since it soon became clear that the preponderance of female cases was associated with ritual cleansing of the dead. In the Angolan outbreak of Marburg disease, church organizations were successfully used to reach

the community and educate people to avoid spreading the disease.

Contacts

High-risk contact is associated with direct contact with blood or body fluids from acutely infected humans or animals, or sexual contact with a convalescent case. Laboratory accidents must be treated seriously, with careful review of level of risk. If this is thought to be high, isolation for the incubation period (17 days is adequate) and tracing and surveillance of any further potential contacts such as family members are necessary. If the risk is low, simple surveillance of the individual by daily telephone contact for fever during the incubation period suffices. It must be remembered that biocontainment facilities do not protect against injury with needles or other sharps. There is no evidence for or against the use of passive antibody in prophylaxis. Suitably screened and stored material is in any event unavailable.

Hospital Containment

The key to prevention of transmission in both endemic and non-endemic areas has consistently been good hospital and laboratory practice, with strict isolation of febrile patients and rigorous use of gloves and disinfection. Intensive care, surgery and air transport should not be denied. Patient isolators are not recommended since the hazard to contacts is not aerosol, but direct inoculation of virus in blood or other material. Isolators induce loss of manual dexterity and fatigue, inhibit intensive care procedures and communication, do not protect against sharp instrument injury and have no provision for resuscitation. The 1988 Centers for Disease Control and Prevention guidelines for the management of patients with viral haemorrhagic fever recommends routine patient isolation in a single room, preferably but not necessarily with negative air pressure gradient from the hallway, through an anteroom to the patient room (Centers for Disease Control and Prevention, 1988). Staff education and strict supervision, use of gloves, gowns, masks and rigorous disinfection with fresh liquids are mandatory. The recommendations issued for management of AIDS patients are also adequate for containment of filoviruses. Since most cases occur in hospitals in more remote parts of Africa, common sense, and careful use of good techniques and disinfectants by trained staff is the best approach.

Vaccines

There are now candidate vaccines for filoviruses, though the potential target population for a vaccine is small (Bukreyev *et al.*, 2007; Geisbert and Jahrling, 2003; Geisbert *et al.*, 2002; Jones *et al.*, 2005; Sullivan *et al.*, 2003).

Filoviruses do not induce classical neutralizing antibodies, making an effective killed vaccine unlikely. Neutralizing mouse monoclonal antibodies have been produced and shown to protect mice, but they do not protect non-human primates (Oswald *et al.*, 2007). Rodents and primates clearly handle filoviruses quite differently, as is borne out by the failure to protect monkeys of several candidate vaccines which protected mice and/or guinea-pigs (Geisbert *et al.*, 2002). The most promising candidate is currently a vesicular stomatitis virus recombinant expressing EBOV and MARV glycoproteins (Jones *et al.*, 2005). Currently the only vaccine in phase I clinical trials is an adenovirus recombinant vaccine (Martin *et al.*, 2006).

PERSPECTIVE

At the time of writing (August 2007) another large, unconfirmed, outbreak of suspected haemorrhagic fever with more than 100 deaths is reported on ProMed in the DRC near the Angolan border. It is likely that there will be more outbreaks, given the increase in human population density in the endemic area, and the ubiquity of the natural hosts. Nevertheless, there have been recent, major advances in understanding filoviruses. These include the identification of fruit bats as the reservoir, which now allows us to envisage specific control measures, or at least recommendations to avoid bat-infested areas. Bats occupying roofs in larger buildings in Africa can be removed. We are also beginning to understand the highly complex immunopathology of this disease. Because of the high mortality, particularly in non-human primate models, filoviruses are excellent models for understanding such complex processes in small numbers of animals. The introduction of reverse genetics and the identification of functions of the viral proteins also takes us further in understanding how the virus works, and by what means it might be thwarted. Effective treatment and safe vaccines can be anticipated as the outcomes of this knowledge. However, the main obstacle to prevention is the poverty and lack of education of most of the victims, and the degradation and invasion of the habitats of the natural reservoir. We shall need political as well as scientific solutions to control filoviruses.

Rabies and Other Lyssavirus Infections

Mary J. Warrell

Centre for Tropical Medicine, John Radcliffe Hospital, Oxford, UK

INTRODUCTION

Rabies is a zoonosis of a variety of mammalian species in different areas of the world. The domestic dog is the most important vector, mainly in Asia and Africa, and canine viruses are responsible for >99% of human infections. Sylvatic or wildlife rabies is endemic in Asia, Africa, the Americas, Australia and most of Europe. Classical rabies, genotype I, viruses cause most infections, the remainder being due to the six genotypes of rabies-related lyssaviruses. With one recent exception, the disease has been fatal in unvaccinated people. Despite attempts at intensive care treatment over 30 years, only a few previously vaccinated patients have survived, and all but one had profound neurological deficits. The combination of pre- and post-exposure rabies immunization is 100% effective in preventing this fatal infection.

In English, rabies is also known as hydrophobia, lyssa and mad dog bite; in French, *la rage* or *l'hydrophobie*; in Italian, *la rabbia*; in Spanish *la rabia*; in Portuguese, *a raiva* or *hidrofobia* and in German, *die Tollwut*.

HISTORY

Rabies in dogs and the importance of saliva in its transmission may have been recognized in pharaonic times and in China seven centuries BC (Théodoridès, 1986). Aristotle (322 BC) described rabies in animals but seemed to deny that humans could be infected or could die from the disease. Celsus in 'De medicina' (first century AD) described hydrophobia in afflicted humans and recognized

that the disease was spread by saliva. In the sixteenth century, Fracastoro strengthened the concept of rabies as a contagious disease. A scientific or experimental approach to rabies was delayed until 1793, when John Hunter suggested that the transmission of rabies should be studied by inoculating saliva from rabid animals and humans into dogs and that attempts should be made to inactivate the 'poison' in the saliva. These ideas may have inspired the animal experiments on transmission by Zinke, and Magendie and Breschet (Théodoridès, 1986).

Galtier found that rabbits could be infected with rabies and were more convenient experimental animals than dogs. In 1881, he first demonstrated specific immunization against the disease (Théodoridès, 1986). Pasteur adopted the use of rabbits in his studies of rabies, beginning in the 1880s. He was the first to recognize that the major site of infection was the central nervous system (CNS). Pasteur was able to protect dogs from challenge by immunizing them with a virus attenuated in desiccated rabbit spinal cord and in 1885 he used this as a vaccine for the first time in Joseph Meister and Jean-Baptiste Jupille, boys who had been severely bitten by rabid dogs. The reputation of modified forms of Pasteur's vaccine increased during the first half of the twentieth century, but its efficacy remained uncertain. The bite of a mad dog caused rabies in only about 30% of untreated patients, although with wolf bites the risk was higher. In Iran, treatment of bites by rabid wolves with classical Semple brain tissue vaccine only reduced the case fatality about 10% compared with unvaccinated patients. A dramatic natural experiment in 1954, when a rabid wolf invaded a village and bit 29 people, demonstrated the protective

value of passive immunization in patients with severe bites (Baltazard and Bahmanyar, 1955). This led to a general recommendation that immunoglobulin should be included in rabies post-exposure prophylaxis as well as vaccine.

In 1903 Negri described his diagnostic inclusion body which allowed the post-mortem laboratory diagnosis of rabies. The introduction of the more specific and sensitive immunofluorescence method in 1958 has since replaced Seller's stain for Negri bodies. Remlinger, in 1903, showed that rabies was caused by a filterable agent. It was not until 1936 that the size of the virus was established, and it was first seen by electron microscopy in 1962 (Théodoridès, 1986).

Improvements in Pasteur's vaccine were achieved by Semple and Fermi who killed the virus rather than attenuated it, and by Fuenzalida and Palacios who developed a suckling mouse brain vaccine which carried a lower risk of neuroparalytic complications. Growth of rabies virus in tissue culture was achieved in the 1930s, leading to the development, by Wiktor and his colleagues, of the first tissue culture vaccine for human use. This human diploid cell vaccine (HDCV) was licensed in 1974. Since then other substrates including chick embryo and vero cells have been used to facilitate production and reduce the cost.

CLASSIFICATION

The family *Rhabdoviridae* (*rhabdos* meaning 'rod' in Greek) includes several genera of viruses found in plants, arthropods, fish, birds, reptiles and mammals. Almost all of those known to infect humans belong to two morphologically similar genera: *Vesiculovirus* and *Lyssavirus*. Members of the genus *Vesiculovirus* cause vesiculostomatitis of cattle and horses. In humans, influenza-like symptoms occur occasionally, and two cases of encephalitis have been reported (Quiroz *et al.*, 1988). The genus *Lyssavirus* (*lyssa* meaning 'rage' or 'frenzy' in Greek) comprises seven genotypes: genotype 1 causes classical rabies; genotype 2 Lagos bat virus; genotype 3 Mokola virus in shrews and cats, genotype 4 Duvenhage virus in bats; genotypes 5 and 6 are European bat lyssaviruses (EBLV) found in insectivorous bats and genotype 7 Australian bat lyssavirus (ABLV) in flying foxes (fruit bats) and insectivorous bats. All these rabies-related viruses have been associated with human disease except for Lagos bat virus (see Table 32.1, Figure 32.2 and section on Human infections with rabies-related viruses below). There is serological evidence of rabies-related lyssaviruses in bats in the Philippines, Thailand, Cambodia, Bangladesh and China.

The Lyssavirus genus has been divided into two phylogroups as a result of serological and genetic analyses (Badrane *et al.*, 2001). Phylogroup I includes all genotypes except Mokola virus and Lagos bat virus, which form phylogroup II. All phylogroup I genotypes have caused fatal rabies-like encephalitis in humans, whereas Mokola virus probably caused three known human infections, one of which was a fatal encephalitis without typical features of rabies. Experimentally, phylogroup II viruses are less pathogenic, and there is little if any cross-neutralization with the phylogroup I lyssaviruses. Four as yet unclassified lyssaviruses have been found in bats in the Russian Federation and Central Asian Republics (Table 32.1).

VIRUS STRUCTURE

The bullet-shaped rabies virions measure 180×75 nm. The genome is a nonsegmented strand of negative-sense RNA of 11.9 kb, which bears five structural genes. In the core of the virion the RNA is in a tight helical coil incorporating a nucleoprotein (N) a phosphoprotein (P) and an RNA-dependent RNA polymerase (L), forming the ribonucleoprotein (RNP) complex. A layer of matrix (M) protein covers this cylindrical structure. The outermost lipoprotein envelope is composed of a host-derived lipid bilayer and virus-coded glycoprotein (G) bearing spikes projecting 8.3 nm above the virion surface. Each projection is a trimer of G molecules with a distal knob. The envelope covers all except the flat end of the virion, resulting in the characteristic bullet shape.

The viral nucleoprotein has 450 amino acids, (~57 kDa) and is an integral component of the RNP complex. It is the most conserved protein throughout the Lyssavirus genus, and so its antigens are employed diagnostically both for genus-specific simple immunofluorescent antibody (IFA) techniques and genotype-specific monoclonal antibody and polymer chain reaction (PCR) assays. N protein encapsidates viral RNA, protecting it from ribonucleases, and has a role in regulating RNA transcription. It also bears T helper cell epitopes. The lyssavirus N is phosphorylated, unlike all other rhabdovirus nucleoproteins. Nascent N molecules rapidly aggregate together or combine with molecules of viral P protein, often in large accumulations of filamentous matrix forming the diagnostic Negri bodies (Figure 32.1), which may also include other proteins.

The phosphoprotein has 297 amino acids (~40 kDa), and is the most diverse rabies protein. It exists in different phosphorylated forms and truncated P products which maybe intranuclear. It has previously been known as M1, membrane-associated 1 and NS, nonstructural protein. Its

Table 32.1 The *Lyssavirus* genus

Genotype	Source	Known distribution
Phylogroup I		
1 Rabies virus	Dog, fox, raccoon, skunk, bat and others.	Widespread
4 Duvenhage	Insectivorous bat (<i>Nycteris thebaica</i>)	South Africa, Zimbabwe (very rarely identified)
5 European bat lyssavirus	1a bats, for example, <i>E. serotinus</i> 1b bats, for example, <i>E. serotinus</i>	Northern and Eastern Europe Western Europe (see text)
6 European bat lyssavirus	2a <i>M. dasycneme</i> bats <i>M. daubentonii</i> bats 2b <i>M. daubentonii</i> bat	Netherlands, Germany (see text) UK Switzerland (very rare)
7 Australian bat lyssavirus	Flying foxes (<i>Pteropus</i> sp.) Insectivorous bats	Australia
Phylogroup II		
3 Mokola	Shrews (<i>Crocidura</i> spp.), cats, dog ^a	South Africa, Nigeria, Cameroon, and Ethiopia (rare)
2 Lagos bat virus	Bats, cats, water mongoose ^a , dog ^a . Has not been detected in humans	Africa (rare)
Unclassified		
Irkut	<i>Murina leucogaster</i> bat	<i>Siberia</i>
Aravan	<i>Myotis blythi</i> bat	<i>Kyrgyzstan</i>
Khujand	<i>Myotis mystacinus</i> bat	<i>Tajikistan</i>
West Caucasian bat virus	<i>Miniopterus schreibersi</i> bat	<i>Russia</i>

^aSingle isolates only.

Figure 32.1 A Negri body (arrow) in a cerebellar Purkinje cell. (Source: Courtesy of F.A. Murphy.)

Figure 32.2 World distribution of rabies. Rabies-free areas are white; red indicates terrestrial rabies genotype 1, and countries with only bat lyssaviruses are green. No rabies-related lyssaviruses have been found in the Americas.

functions include binding to nascent N and so preventing its polymerization, and nonspecific binding to cellular RNA. P protein also forms a stabilizing complex with L protein and is a cofactor in genome transcription and replication. P protein has been shown to interact with a light chain (LC8) component of dyenin and myosin V molecular motors. Possible involvement in the intracellular transport of rabies virus fragments remains to be proved (Warrell and Warrell, 2004) (see section on Pathogenesis). The P protein also inhibits interferon transcription and signalling at three different stages (Finke and Conzelmann, 2005; Vidy *et al.*, 2007).

The viral RNA-dependent RNA polymerase is the largest protein (hence the designation L), containing approx 2142 amino acids (~244 kDa). It contains groups of highly conserved residues. This RNA polymerase starts the transcription of the primary genomic RNA. Other functions of L protein include replication, polyadenylation and protein kinase activities.

The matrix protein, M, has 202 amino acids (~25 kDa), and covers the RNP complex. It has several functions including: the compacting of the loose helical core structure; regulation of viral RNA transcription (Finke and Conzelmann, 2005); inhibiting translation of host cell proteins; and interacting with the lipid bilayer and the G protein to enable budding of virus from the cell membrane. M protein can also induce apoptosis experimentally.

The surface glycoprotein is *N*-glycosylated with branched chain oligosaccharides which show microheterogeneity within the virion. It has 505 amino acids (~65 kDa). The external domain of the G molecule is a trimeric spike connecting via a transmembrane anchor to a cytoplasmic domain, which is closely

associated with the M protein. The distal knob on the surface projection is important in pathogenesis as it bears binding sites for cellular receptors, and effects pH-dependent fusion with endosomal membranes. A reversible change in conformation of the protein into an activated hydrophobic state initiates membrane fusion. Single amino acid replacements, notably arginine 333, at antigenic site III on the ectodomain can radically reduce the virulence of the virus (Dietzschold *et al.*, 1983). The G molecule also promotes the passage of virus from cell to cell, is involved in axonal transport, and is essential for trans-synaptic spread (see section on Pathogenesis below). G epitopes are most important as they are the only inducers of protective rabies neutralizing antibodies. They can also induce helper and minimal cytotoxic T-cell responses. At high expression levels, G is associated with induction of apoptosis (Finke and Conzelmann, 2005).

REPLICATION

Entry of virus into a cell occurs via coated pits or by cell receptor-mediated adsorptive endocytosis into an endosome (see section on Pathogenesis below) (Wunner, 2007). The surface viral glycoprotein enables low pH-dependent fusion with the endosomal membrane, uncoating and liberating the nucleocapsid (or RNP complex) into the cytoplasm. Catalysed by the viral L protein, the primary genomic negative-strand RNA is transcribed, beginning with a short leader RNA and followed by 5' monocistronic positive-strand mRNAs and later the full length anti-genome replicative RNA. The amount of

mRNA produced is greatest from the 5' end, in the order of N, P, M, G and L. Protein synthesis proceeds in the cytoplasm on host cell ribosomes. The unstable nascent nucleoprotein and phosphoprotein encapsidate and stabilize the progeny negative-strand genomic RNA by binding to its 5' end, or they may aggregate to form localized masses which accumulate and become inclusions. The viral polymerase is incorporated into the strand of nucleoprotein, which forms a tight helical coil aided by the action of the viral matrix protein. The resulting RNP complex migrates to the cell membrane where the nascent viral glycoprotein has become concentrated and inserted into the lipid membrane. The matrix protein interacts with the cytoplasmic domain of the glycoprotein, and promotes budding of the bullet-shaped virion. The membrane at the flat-ended base bears no G protein. Viral maturation can occur intracellularly by budding through endoplasmic reticulum, as seen especially in neurons (Iwasaki et al, 1985). Unlike vesicular stomatitis virus, rabies virus replication requires the presence of the nucleus in the host cell.

INACTIVATION OF VIRUS AND STABILITY OF VACCINE ANTIGEN

Rabies virus in a phosphate-buffered saline (PBS) solution is rapidly inactivated by heat: at 56 °C the half-life is less than a minute; at 37 °C the half-life is prolonged to about 3 hours in moist conditions and at 4 °C to three or four days. The stabilizing presence of serum or other buffer solutions enhances survival. The lipid coat of the virion renders it vulnerable to disruption by detergents and simple 1% soap solution. About 45% ethanol, iodine solutions (with 1 in 10 000 available iodine), 3% sodium hydroxide, 1% benzalkonium chloride, 3% formalin, neat chloroform and acetone all inactivate the virus (Kaplan *et al.*, 1966). Hypochlorite and glutaraldehyde solutions are suitable for laboratory use with the normal precautions, but phenol is not an effective virucidal compound.

Although benzylkonium chloride and other quaternary ammonium compounds are virucidal experimentally, they are not recommended for cleaning rabies-infected wounds at the concentrations in normal clinical use because they are inactivated by the presence of soap (Kaplan *et al.*, 1966). Soap is recommended as first aid treatment of animal bites.

The potency and immunogenicity of lyophilized cell culture vaccine is retained after tropical ambient temperatures for 11 weeks (Nicholson *et al.*, 1983). In reconstituted liquid form, however, the potency may fall significantly after a week or two. It is therefore unwise to keep an open vial for several days because of the risk

of microbial contamination causing denaturing of antigen, loss of potency and possible infection of the recipient.

EPIZOOTIOLOGY AND EPIDEMIOLOGY

Rabies is transmitted within populations of relatively few species of mammals, principally within the domestic dog population. The vectors of sylvatic, or wildlife, rabies vary in different parts of the world and the virus circulates within the species group, but in South Africa a virus type is related to a geographical area and occurs in several vector species. As a result of the geographical compartmentalization of rabies within a mammalian species, there has been a tendency for adaptation and divergence of virus strains. This is identified by monoclonal antibody tests and genetic analysis. There is occasional overspill between these intraspecies cycles, for example, when a rabid raccoon bites a fox in North America. Transmission outside the cycle occurs more commonly to non-vector mammalian species, for example, when a cow or sheep is bitten by a rabid red fox in Europe, and all human infections.

Rabies is enzootic in terrestrial mammal species in most of the world, but in a few countries rabies-related lyssaviruses are found in bats alone (Figure 32.2). Areas of the world which have been reported to be free of rabies include: Ireland, Iceland, Finland, Sweden, Norway, Portugal, Italy, Greece, the Mediterranean islands (except the Balearic islands, where there is European bat lyssavirus), New Zealand, New Guinea, Japan, Taiwan, Hong Kong islands (but not the New Territories), Singapore, peninsula Malaysia, Sabah, Sarawak, some islands of Indonesia, islands of the Pacific and Indian Ocean (except Madagascar); some Caribbean islands (e.g. Barbados, Bahamas, Jamaica, St Lucia, Antigua and so on); and Antarctica. Some countries are generally free but infected animals occasionally cross their land borders. The epizootiology is constantly changing, so local advice should be sought for detailed information.

Rabies is spread between mammals by bites; by contamination of scratches or intact mucosal membranes by virus-laden saliva; by ingestion of infected prey; transplantally; and possibly by inhalation of aerosols (in heavily populated bat caves). The principal reservoir or vector species in different geographical areas are listed below.

Europe

- Red fox (*Vulpes vulpes*)—Germany, Poland, Hungary, Croatia, Serbia, Slovenia, Romania and then eastwards to include the Russian Federation.

- Arctic fox (*Alopex lagopus*)—northern Russian Federation.
- Raccoon dog (*Nyctereutes procyonoides*) (not an established reservoir)—the Baltic States, Poland, Belarus, Ukraine and the Russian Federation.
- Wolf (*Lupus lupus*)—from Poland east to the Russian Federation
- Domestic dog (*Canis familiaris*)—dominant vector in Turkey. Cases also found in the Baltic States, Poland, Slovakia south to Croatia and eastwards to the Russian Federation. These are likely to be due to infection from foxes or other wildlife.
- Insectivorous bats—harbour the rabies-related European bat lyssaviruses (Amengual *et al.*, 1997). Transmission to terrestrial mammals has very rarely been found; to date only in five sheep in Denmark and a stone marten in Germany.
- Genotype 5, EBLV-1a—found mainly in serotine bats, *Eptesicus serotinus*, in the Netherlands, Denmark, Germany, Poland, Hungary, the Russian Federation and a single case in France. (Isolates also from the Slovak Republic and Czech Republic but typing not available. Seropositive bats found in Belgium.)
- EBLV-1b—usually found from the Netherlands down to Spain. The host is *E. serotinus* in the Netherlands, France and a single bat in Poland; also several bat species in Spain, and rarely in unidentified bats in Germany.
- Genotype 6—rare. EBLV-2a was isolated eight times in the United Kingdom: from a Scottish patient in 2002 and from seven infected Daubenton's bats (*Myotis daubentonii*) first from Newhaven in 1996, then from Lancashire, Surrey, Oxfordshire and Shropshire. The seroprevalence in that species is 2–3% (Fooks *et al.*, 2006). EBLV-2a was found in *Myotis dasycneme* (pond bats) in the Netherlands; also rarely from Germany and a doubtful isolate in the Ukraine.
- EBLV-2b was isolated from *M. daubentonii* in Switzerland and from the Swiss or Finnish human case (see section on Human infections with rabies-related viruses below and Table 32.1).

Middle East

- Dominant vectors are the fox and the wolf. Dogs maybe infected from wildlife.
- Other vectors include golden jackals (*Canis aureus*) in Israel.

Asia

- Domestic dog (*C. familiaris*) is the dominant vector.

- Frugivorous and insectivorous bats in the Philippines, Cambodia, Thailand, Bangladesh and China are seropositive for lyssavirus.

Africa

- Domestic dog (*C. familiaris*) rabies is predominant throughout the continent and in Madagascar.
- Black backed jackals (*Canis mesomelas*)—southern Africa
- Yellow mongoose (*Cynictis penicillata*)—southern Africa
- Bat-eared fox (*Otocyon megalotis*)—southern and East Africa
- Frugivorous and insectivorous bats—Duvenhage virus very rarely found (see section on Human infections with rabies-related viruses below).

For more on Africa see Nel and Rupprecht, 2007.

North America

- Arctic fox (*A. lagopus*)—Alaska, north-western Canada
- Red fox (*Vulpes fulva*)—western Canada and north-eastern United States.
- Grey fox (*Urocyon cinereoargenteus*)—Texas, Arizona.
- Striped skunk (*Mephitis mephitis*) and other species—Texas, central United States, California, also western Canada.
- Raccoon (*Procyon lotor*)—eastern coastal states of United States from Florida to the Canadian border, and adjacent regions of Canada.
- Insectivorous bats—in all continental states of United States, e.g. Mexican free-tailed bat (*Tadarida brasiliensis mexicana*), red bat (*Lasiurus borealis*), big brown bat (*Eptesicus fuscus*), hoary bat (*Lasiurus cinereus*), silver-haired bat (*Lasionycteris noctivagans*), eastern pipistrelle (*Pipistrellus subflavus*).

Caribbean

- Vampire bat—Trinidad, Tobago and Isla de Margarita.
- Mongoose (*Herpestes* species)—Puerto Rico, Granada, Cuba, Dominican Republic and probably Haiti.

Central and South America

- Domestic dog rabies—in Mexico and areas of Central and South America, except the Southern Cone.

- Grey fox (*Urocyon cinereoargenteus*)—in Colombia, Mexico.
- Vampire bat (*Desmodus* species)—causing bovine paralytic rabies from Mexico south to the northern parts of Argentina and Chile.
- Insectivorous bats—widespread

Australia

- Flying foxes or fruit bats (*Pteropus* species) and rarely insectivorous bats in Eastern coastal regions harbour ABLV (Warrilow, 2005) (see section on Human infections with rabies-related viruses below, Table 32.1 and Figure 32.2).

Vampire bat rabies has serious economic effects for farmers. The bats feed on the blood of large mammals, particularly cattle, transmitting, in the process, a form of paralytic bovine rabies. The disease causes an estimated loss of 50 000 head of cattle each year in Brazil. Outbreaks have been reported from Ecuador and Peru.

All bat rabies in the Americas is due to genotype 1 virus, whereas bats in the rest of the world harbour only the rabies-related lyssaviruses: EBLV, ABLV or Duvenhage virus.

Cyclical epizootics of rabies, such as the fox epizootic in Europe, result from an uncontrolled increase in the population of the key reservoir species. This epizootic started in Poland at the end of the Second World War and spread to France. In Western Europe it has been controlled by vaccination (see section on Control below).

Many other species of domestic and wild mammals may develop rabies due to infection by known local vector species.

INCIDENCE OF HUMAN RABIES

The true global incidence of human rabies has been obscured by underreporting, and is not reflected in official figures. Canine rabies virus is the cause of more than 99% of human infections. A large study in Asia and Africa (Knobel *et al.*, 2005) estimated an annual mortality of 55 270 or 1.38 per 10 000 population. Data suggest that only 3% of human cases are recorded by central health authorities and 80% occur in rural areas. The highest annual mortality is 20 000 in India, 2–3 per 100, 000 population, and deaths rates are high in Bangladesh and Pakistan. Human cases have been mounting for a decade in China, with a reported increase of 30% in one year, to 3209 cases in 2006. Rabies encephalitis is often misdiagnosed; among 26 children dying of presumed cerebral malaria in Malawi, 3 (11%) proved to have rabies infection at post-mortem (Mallwela *et al.*, 2007).

In Latin America, mortality from canine rabies is reported from Brazil, El Salvador, Mexico, Bolivia, Haiti and Venezuela (Schneider *et al.*, 2007). In the United States an average of two to three deaths occur annually. More than 80% are indigenous infections and 90% of these are due to bat rabies viruses, usually the silver-haired bat or the eastern pipistrelle type. Less than 40% of patients had recognized a bat bite. It has been suggested that rabies is underdiagnosed in the United States (Messenger *et al.*, 2002).

In Europe 62 human deaths have been reported in the last six years, mainly from Russia and also Ukraine, Eastern European states plus imported cases in Western Europe. In Great Britain 10 people have died of rabies since 1980s, nine of whom were infected abroad. After a century of freedom from indigenous rabies, a man died of EBLV-2a infection in Scotland in 2002.

PATHOGENESIS

Entry of Virus into the Nervous System

Bites by rabid animals may inoculate virus-laden saliva through the skin into muscle. Local replication of virus in striated muscle occurs experimentally and might account for the long incubation periods often observed (Charlton *et al.*, 1997). Virus has been detected at local motor or sensory nerve endings (Murphy, 1977). Direct invasion of neurons has also been shown after peripheral inoculation. The mechanism of infection from superficial skin lesions inflicted by bats is unknown.

The rabies virus infects a great variety of cell types *in vitro* and *in vivo*, and viral attachment has been demonstrated to several types of cell surface receptor including carbohydrates, phospholipids and sialylated gangliosides. This binding is not specific and there is no evidence yet that these receptors are important *in vivo*, but it might explain the diversity in the tissue culture cell lines that will support rabies infection.

Specific binding occurs at neuromuscular junctions where it co-localizes with the nicotinic acetylcholine receptor (Jackson, 2007b; Lentz *et al.*, 1982). Binding at this post-synaptic site is competitive with cholinergic ligands, including the snake venom neurotoxin alpha bungarotoxin, which shows sequence homology with rabies virus glycoprotein. The varied susceptibility of different species to rabies infection could be related to the quantity of nicotinic acetylcholine receptors in muscle tissue (Baer *et al.*, 1990).

Viral attachment occurs *in vitro* to the neural cell adhesion molecule (NCAM), found on susceptible cell lines (Thoulouze *et al.*, 1998). *In vivo*, NCAM is in

neuronal membranes especially at presynaptic terminals. Its presence enhances infection, but is not essential. Another *in vitro* G protein-binding site is to the neurotrophin receptor p75 (p75^{NTR}) (Langevin *et al.*, 2002) found on selected neurons. Again it contributes to but is not essential for infection, suggesting that a variety of receptors are involved in rabies, perhaps at different stages of the pathogenesis. Virus entry via coated pits or receptor-mediated endocytosis into a vesicle occurs and pH-dependent fusion of the viral glycoprotein with the endosomal membrane may release the RNP complex into the cytosol.

Transport of Virus to the Brain

Rabies antigen can be found along the nervous pathways from a peripheral site of infection towards the brain during the incubation period. The migration of virus from a wound in a peripheral nerve to the CNS occurs within motor axons via the retrograde fast axonal transport system (Finke and Conzelmann, 2005; Jackson, 2007b). Its progress can be blocked by sectioning nerves or by metabolic inhibition with locally applied colchicine, which disrupts the axon microtubular system. The rate varies experimentally but an *in vitro* estimate is 50–100 mm per day; it can be considerably faster *in vivo*. Viral transport is not affected by the presence of extracellular neutralizing antibody (Tsiang, 1993). Since rabies virus has strictly retrograde axonal movement, it has been used as a tracer to identify neural pathways (Ugolini *et al.*, 2006). Attachment to the dyenin axonal motor molecule is assumed to be essential for this retrograde transport, but the means of viral binding remains speculative (Warrell and Warrell, 2004). The rabies P protein associates with LC8, a component of a cytoplasmic dynein LC, suggesting a means of attachment of the viral RNP complex to the retrograde dyenin axonal motor (Jacob *et al.*, 2000; Raux *et al.*, 2000). Further studies show that binding of viral proteins to the LC8 molecule is not essential for pathogenesis (Mebatsion, 2001), and that the viral G protein alone promotes retrograde microtubular transport (Mazarakis *et al.*, 2001). Viral replication is intracytoplasmic. Interneuronal spread is dependent on the presence viral G protein (Etessami *et al.*, 2000; Wickersham *et al.*, 2007) and budding of virus at synapses directly into an adjacent axon is the most likely mechanism (Iwasaki *et al.*, 1985). Contact with the extracellular environment is thereby avoided.

Effect of Infection on the Brain

Rabies progresses rapidly through the spinal cord and brain, with massive viral replication and accumulation of

viral proteins resulting in inclusion formation and eventually Negri bodies (see section on Virus structure above). Infected glial cells have rarely been observed in humans, and they are not a significant route of dissemination of virus. Infection of the limbic system affects the behaviour of the host which, in a vector species, increases the chance of transmitting the disease.

The areas of maximum inflammatory change in the human brain do not correlate with the distribution of Negri bodies. Electroencephalogram (EEG) evidence of pathology is greater in animal infections with attenuated virus than virulent street strains (Tsiang, 1993) and neuronal death is not a prominent feature at post-mortem. Rabies infection may have surprisingly little visible pathological effect on the brain. Pathogenic strains of virus cause less viral glycoprotein expression and neuronal apoptosis than avirulent ones, so that apoptosis only appears at a terminal stage of infection (Dietzschold *et al.*, 2001).

The cause of the gross neuronal dysfunction of living cells remains elusive but it may be associated with altered activity at a variety of neurotransmitter-binding sites (Jackson, 2007b; Tsiang, 1993). Rabies infection of neurons alters cellular gene expression. Although infection downregulates host cell gene expression overall, a few genes are upregulated, not only in infected cells, but probably also in uninfected neurons, including ones associated with synaptic vesicle function (Prośniak *et al.*, 2001; Dhingra *et al.*, 2007). The depletion of metabolic pools may limit cell survival (Dietzschold *et al.*, 2001). Changes in the functional expression of some channels, and attenuation of inhibition of others, have been shown *in vitro* (Iwata *et al.*, 2000). The suggestions that nitric oxide might have neurotoxic or beneficial effects remain unproven (Jackson, 2007b).

Centrifugal Spread of Virus from the Brain

There is a final phase of diffuse centrifugal spread by axonal transport of virus from the brain by many nerve pathways including the autonomic nervous system. Virus has been isolated from human tissues such as peripheral nerve, skeletal and cardiac muscle, kidney, lung, skin, salivary, lacrimal and adrenal glands (Helmick *et al.*, 1987). Rabies antigen has been detected in nerves and ganglia adjacent to these organs and the gastrointestinal tract, and extraneurally in tongue tissues, often without an inflammatory reaction (Jackson *et al.*, 1999; Metzke and Feiden, 1991). Viraemia has very rarely been detected, only in animals, and is not thought to be involved in pathogenesis or spread. Virus is shed from human salivary and lacrimal glands, respiratory tract and rarely in urine (Helmick *et al.*, 1987) and possibly in milk.

The predominant site of replication changes as the virus reaches the salivary gland. In contrast to neural cells

there is profuse production of extracellular virus from acinar cells. Viral budding occurs into the gland lumen or intercellular canniculae with secretion into the saliva where it is available to infect a new host.

IMMUNOLOGY

Immune Responses to Rabies Virus

Following a rabid bite, no immune response can be detected until after the development of symptomatic rabies encephalitis. Viral antigens are not recognized by the immune system during the incubation period. Rabies neutralizing antibody, which is only induced by glycoprotein epitopes, is protective against rabies following challenge in animals. *In vitro*, this antibody impairs viral attachment and penetration of cells, and reduces cell-to-cell spread of virus. Although the presence of neutralizing antibody is the best available indicator of protective immunity, the level does not correlate with protection in all experiments, so other immune mechanisms are also involved. N protein-induced immunity can contribute to protection experimentally. N antigens are more cross-reactive with other strains, including rabies-related viruses, than G antigens. There is evidence that N acts as a weak super-antigen, but any effect on the course of infection remains elusive. An immunosuppressive effect of rabies infection has been shown experimentally to rabies antigens and also unrelated viral antigens (Camelo *et al.*, 2001). Rabies P suppresses interferon induction (Finke and Conzelmann, 2005; Vidy *et al.*, 2007). CD8⁺ T cells do not seem to have a significant rôle in rabies encephalitis.

Survival of infection in animals is associated with a strong immune response, shown by cell membrane expression of G, neutralizing antibody induction, and upregulation of MHC class II mRNA expression in the CNS early in infection (Irwin *et al.*, 1999). Infected neurons undergo T cell-mediated apoptosis. Paralytic disease develops with subsequent neurological deficit in survivors (Lafon, 2005).

During infection of mice by virulent virus, immune CD3 T cells migrate into the CNS, but they are destroyed on contact with infected neurons, due to Fas ligand-mediated apoptosis (Lafon, 2005). Neurons remain intact. Infected human brains show remarkably little apoptosis, which is in keeping with experimental findings.

Response in Human Encephalitis

In unvaccinated humans with encephalitis, neutralizing and other antibodies appear in serum about seven days after the first symptom, and later in the cerebrospinal fluid (CSF) (Anderson *et al.*, 1984). Patients may die before

these antibodies are detectable, but in patients whose lives are prolonged by intensive care antibody titres may rise to very high levels. A low level of rabies-specific IgM is sometimes detectable in serum and CSF, but it does not appear earlier than the IgG response (Warrell *et al.*, 1988).

A minimal lymphocyte response is detected histologically in brain, blood and CSF (Warrell *et al.*, 1976), and there is no pleocytosis in 40% of patients in the first week of illness, or in 13% in the second week (Anderson *et al.*, 1984). Evidence of cell-mediated immunity by specific lymphocyte transformation tests was found in six of nine furious encephalitis patients, but not in seven with paralytic disease (Hemachudha *et al.*, 1988).

It has long been recognized that the rabies incubation period is shorter than average in patients who were inadequately vaccinated and develop rabies. Although high levels of neutralizing antibody are protective, low levels can accelerate the terminal phase of the illness, resulting in the 'early death' phenomenon (Prabhakar and Nathanson, 1981). The effect can be produced in mice by adoptive transfer of antibody or immune B lymphocytes during the incubation period.

Interferon- α prevents rabies viral replication *in vitro*, but only very low levels have been found in the serum and CSF of one-third of patients with encephalitis (Merigan *et al.*, 1984). Mice die of rabies despite high levels of interferon- α and - β in the brain, and high doses of intravenous and intrathecal interferon- α after the onset of symptoms of human rabies encephalitis have not proved to be effective therapy in humans (Merigan *et al.*, 1984; Warrell *et al.*, 1989). In contrast, the early appearance of interferon- γ in infected rodent brain was associated with survival or delayed mortality (Koprowski and Dietzschold, 1997).

Immune Response to Rabies Vaccine

Despite the anergy seen in patients with encephalitis, rabies virus proteins are highly immunogenic when given as vaccine. Neutralizing antibody usually becomes detectable in serum between 7 and 14 days after starting a primary course of vaccine. Antibody production is accelerated if the dose of tissue culture vaccine is given in multiple sites, either by increasing the intramuscular dose or by dividing a single dose between several intradermal sites (Suntharasamai *et al.*, 1987; Turner *et al.*, 1976). The early IgM component of the antibody response does not protect against rabies experimentally, has low affinity for viral antigens and is confined to the vascular system. It is unlikely to be important in immediate post-exposure prophylaxis (Turner, 1985).

No antibody or T lymphocyte function test predicts protection against disease, but the level of neutralizing

antibody induced by rabies G protein gives the best correlation available, and should be used to evaluate vaccines. The cumbersome mouse serum neutralization test has been replaced by tissue culture methods. The rapid immunofluorescent focus inhibition test (RIFFIT) (Smith *et al.*, 1996) takes 24 hours. The similar fluorescent antibody virus neutralization (FAVN) test (Cliquet *et al.*, 1998), which is easier to read and automate, takes 40 hours. The results are expressed in International Units (IU/ml), compared with an International Standard serum. An arbitrary minimum neutralizing antibody level of 0.5 IU/ml indicates unequivocal seroconversion and is taken to be the minimum adequate response after a pre- or post-exposure course of vaccine.

Other antibody tests employing killed virus antigen are more convenient but detect a variety of non-neutralizing antibodies, whose titres show less correlation with protection from disease. A commercially available enzyme-linked immunosorbent assay (ELISA) method gives the best correlation with neutralization to date (Feysaguet *et al.*, 2007). Cell-mediated immune responses following vaccination do not correlate with neutralizing antibody titres.

The amount of antibody induced by a vaccine depends on host factors. Lower titres were found in people over 50 years old. Immunosuppression due to drugs, human immunodeficiency virus (HIV), cirrhosis or other disease can also impair the response. Genetic effects have been demonstrated in animals, and 3% of people only produce low antibody levels (Strady *et al.*, 2000).

ROUTES OF INFECTION

Human infection usually occurs by inoculation of virus-laden saliva through the skin by the bite of a rabid dog or other mammal. Broken skin and intact mucosae can admit the virus, and scratches, abrasions and previous open skin lesions can be contaminated with infected saliva. Intact skin is an adequate barrier to the infection. The following are very unusual routes of human infection:

- Human to human transmission: This has only been documented in recipients of transplanted tissue. Six virologically proven cases have been reported in which infected corneas were transplanted from donors who had died of unsuspected rabies. Two further cases resulted in clinically diagnosed rabies in India. Seven organ transplant recipients recently succumbed to a mysterious encephalitis in Texas and in Germany. Liver, kidney, pancreas and even an iliac artery graft transmitted rabies virus from two donors aged 20 and

26 years old, who both died of undiagnosed neurological disease. Subsequent histories elicited a previous bat bite in the United States and contact with a dog in India (Burton *et al.*, 2005; Rabies Bulletin Europe, 2005). Rare reports of infection by human bite or kissing (Fekadu *et al.*, 1996) have been persuasive, but infection from another source could not be excluded. Despite these anecdotal cases, thousands of people dying of rabies have been nursed in poverty-stricken homes, yet their relatives in intimate contact with saliva and tears have not developed rabies. This indicates that the infection is not easily transmitted from human to human.

- Inhalation: This has been reported from the United States where there were two laboratory accidents involving the inhalation of fixed virus during vaccine preparation (Centers for Disease Control and Prevention, 1977; Winkler *et al.*, 1973). Air-borne rabies virus was assumed to be the cause of death of two people who had visited caves densely populated with insectivorous bats in Texas 50 years ago. Aerosol transmission of rabies virus was demonstrated in caves experimentally, presumably from infected bats' nasal secretions and possibly urine (Winkler, 1975). However, no similar human cases have been reported, and infection can also be due to unnoticed physical contact with a bat (Gibbons, 2002; Messenger *et al.*, 2002).
- Vaccine-induced rabies ('*rage de laboratoire*'): Incomplete inactivation of virus in human vaccine should no longer be a problem but in the worst incident 18 people developed paralytic rabies in Fortaleza, Brazil in 1960.
- Transplacental infection: This has occurred in animals but only once documented virologically by antigen detection in brain tissue of a mother and infant in Turkey. Many women with rabies encephalitis have been delivered of healthy babies.
- Oral infection: This has been shown in animals, although high titres are needed. The transmission of rabies from mother to suckling infant via the breast milk has been suspected in at least one human case and is said to occur in animals. However, there have been no documented cases of transmission of rabies by ingestion of milk from an infected animal. Boiling and pasteurization inactivate rabies virus. Transmission of virus is theoretically possible from ingestion of raw milk, but it is not a criterion for post-exposure immunization. Nevertheless, in the United States people who had drunk milk from rabid cows were given rabies prophylaxis (Centers for Disease Control and Prevention, 1999).

CLINICAL FEATURES OF RABIES IN ANIMALS

In domestic dogs, the incubation period ranges from 5 days to 14 months, but is usually 3 to 12 weeks. It is under four months in 80% of cases. Prodromal symptoms include change in temperament, fever and, as in many humans, intense irritation at the site of the infecting bite. The familiar picture of a 'mad dog' with furious rabies is seen in only 25% of infected animals. The commoner, paralytic or dumb presentation is less dramatic and more dangerous as it may not be recognized. The clinical features of furious canine rabies include irritability, convulsions, dysphagia, laryngeal paralysis causing an altered bark, hypersalivation, trembling, snapping and extreme restlessness, causing the animal to wander for miles. Dogs with furious rabies attack and swallow inanimate objects, often breaking their teeth and injuring their mouths in the process. Dogs with paralytic rabies may be reclusive and exhibit paralysis of the jaw, neck and hind limbs, dysphagia and drooling of saliva. Virus may be excreted in the saliva seven days before the appearance of symptoms and the animal usually dies within 7 to 10 days of onset. Among other species, signs are usually furious in horses, cats, mustelidae and viverridae, and usually paralytic in foxes and bovines. Although rabid animals are commonly unable to swallow, they do not exhibit hydrophobia.

Recovery From Infection and Chronic Rabies in Dogs, Vampire Bats and Other Mammals

Rabies is not a universally fatal disease in mammals. The pathogenicity of rabies viruses can vary greatly when tested in another mammal species. Dogs, cats, bats and most often mice have recovered from experimental infection with street rabies virus. It is conceivable that a low dose of virus inoculated in the wild could immunize without causing disease. Although the fox is one of the most susceptible species to rabies, about 3% of animals survive the infection and become immune. Animals of several species have been found to be seropositive and so are assumed to have recovered from rabies. These include the natural rabies vectors: mongooses in Granada; foxes and raccoons in Alabama; hyenas in Tanzania; insectivorous bats in America and, very rarely, stray or unvaccinated dogs in Ethiopia and Nigeria (Ogunkoya *et al.*, 1990; Sérié and Andral, 1962; Warrell and Warrell, 2004); similarly, rabies-related lyssaviruses in bats in Europe, Australia and across South East Asia.

Vampire bats have long been considered chronic carriers of rabies virus, and some bats carried rabies in their saliva for more than two months before death; but there is now doubt about the validity of these reports (Jackson, 2007b). Some bats recover from infection but there is no evidence of excretion of virus following recovery

and experimental inoculation has failed to induce a carrier state.

The repeated shedding of rabies virus in the saliva of apparently healthy dogs is a cause for great concern. This chronic infection is apparently exceptionally rare (Jackson, 2007b), but it has been reported in an Indian dog, and in Ethiopian and Nigerian dogs. Thorough searching in other areas has not revealed any chronically infected animals. The incidence of chronic rabies is presumed to be so low that it has not influenced recommendations for human post-exposure treatment.

In Tanzania 37% of spotted hyenas were found to be seropositive and rabies was detected by reverse transcription polymerase chain reaction (RT-PCR) in 13% of saliva samples from seropositive animals, and occasionally from brain. Attempts at virus culture failed, and infection was not associated with disease or decreased survival. The virus strain was distinct from those of other local species and may be of low virulence. It is assumed that prolonged and perhaps repeated infection occurred with a strain of low virulence (East *et al.*, 2001).

Infection of apparently healthy bats by EBLV-1 (genotype 5) has been found in wild *Myotis* and other species of Spanish insectivorous bats and bats in a Dutch zoo, with an antibody prevalence up to 20% in some populations. EBLV-1 was detected by RT-PCR in brain and other tissues of healthy-looking bats (Wellenberg *et al.*, 2002) and in oropharyngeal swabs of live bats (Echevarria *et al.*, 2001). To date there has been no isolation of virus from these asymptomatic persistently infected bats.

CLINICAL FEATURES IN HUMANS

Incubation Period

The extreme incubation range recorded is four days to 19 years (Gavrila, Iurasog and Luca, 1967): a deep shoulder bite by a rabid dog may have inoculated virus directly into the brachial plexus, explaining the shortest reported incubation period of four days. It is between 20 and 90 days in more than 60% of cases however, and much longer incubation periods of four and six years have been well documented in immigrants to the United States (Smith *et al.*, 1991). Others have reported incubation over one year in from 4 to 6.8% of cases, but in those studies the possibility of a second more recent exposure could not be excluded (Lancet, 1991).

Incubation periods tend to be shortest with severe bites on the face, head and neck, especially in children and in experimental animals injected with large doses of virus. Average incubation for bites on the head and neck are 25–48 days; for the extremities 66–69 days; for the

upper limb 46 and for the lower limb 78 days. However, the virus may remain quiescent until activated by some kind of stress, which has been shown experimentally and suspected clinically (Smith *et al.*, 1991). The incubation appears to be shorter in patients who have received (unsuccessful) post-exposure treatment than in those who have not (Hattwick, 1974).

Prodromal Symptoms

A vague feverish illness associated with a change in mood may precede, by up to about a week, the appearance of definite signs of rabies encephalomyelitis. The patient becomes anxious, agitated, apprehensive, restless, irritable and tense and may suffer from nightmares, insomnia, loss of concentration and depression. Physical symptoms include vague malaise, anorexia, headache, other aches and pains, weakness, tiredness, fever, chills, sore throat and other symptoms suggestive of upper respiratory tract infection, influenza or gastroenteritis. This wide range of misleading symptoms has encouraged inappropriate referral to psychiatrists, otolaryngologists, gastroenterologists and other specialists. Itching, tingling, burning, pain, numbness or some other paraesthesia at the site of the healed bite wound is experienced by about half the patients and may be associated with trembling, fasciculations, muscle contractures or weakness of the bitten limb. Most of the patients infected by corneal transplants noticed pain behind the grafted eye. Although local paraesthesia is suggestive of imminent rabies encephalomyelitis, this symptom is also surprisingly common in healthy victims of animal bites who fear that they are developing rabies. It might be the result of trauma by the bite or by vigorous local infiltration of rabies immunoglobulin. Pruritis is, in the author's experience, by far the commonest local prodromal symptom. Neuritic pain is also reported. Itching may be so intense that the patient excoriates large areas of skin by scratching.

Clinical Presentations of Rabies Encephalomyelitis

Human rabies can take two clinical forms. In the more familiar type, furious or agitated rabies, the brainstem, cranial nerves, limbic system and higher centres bear the brunt of the infection, while in dumb or paralytic rabies the medulla, spinal cord and spinal nerves are principally involved. The predominantly but not exclusively paralytic picture seen in human victims of vampire bat-transmitted rabies and other evidence from experimental rabies infection in animals suggests that the virus strain or size of infecting inoculum may contribute to the pattern of CNS infection. Host factors may also modify the pattern of the disease; the frequency of the paralytic form of rabies varies from species to species (it is common in bovines

but rare in cats) and paralytic rabies may be more likely to develop in those who have received antirabies vaccine (Hattwick, 1974).

Many different clinical features and patterns of presentation of human rabies have been described over the past 100 years and, since the recognition of strains of classical rabies lyssavirus genotype I and rabies-related lyssaviruses, clinicians have been interested in attempting to associate distinctive clinical patterns with these various viruses. This is premature. Even the use of the term 'classical rabies' for a clinical presentation has become misleading as it has been applied to the furious form of the disease (Jackson, 2007a), but also to both furious and paralytic forms to distinguish them from hypothetical atypical patterns (Hemachudha *et al.*, 2002).

Furious (Agitated) Rabies

This is the more familiar and probably the commoner presentation in humans. Without intensive care most patients with furious rabies die within a week of their first prodromal symptom and within a few days of developing hydrophobia. This short and hectic clinical course is characterized by hydrophobia, aerophobia and periods of extreme excitement alternating with lucid intervals, features of autonomic system dysfunction and finally by unconsciousness and complete paralysis. Hydrophobia (from the Greek 'dread of water') is a reflex series of forceful jerky inspiratory muscle spasms provoked by attempts to drink water and associated with an inexplicable terror (Figure 32.3). Driven by thirst to confront this terror, the patients attempt to drink but, even before the liquid has reached the lips, a rapid succession of violent inspiratory gasps is provoked. forcible contractions of the diaphragm depress the xiphisternum and contractions of the accessory muscles of inspiration, particularly the sternocleidomastoids, are visible during these spasms. There is usually no evidence of laryngospasm and most patients deny pain in the neck or retrosternal region. A draught of air on the skin produces a similar reflex response—'aerophobia'.

Initially, the spasms (also known as 'phobic spasms') affect mainly the inspiratory muscles, but a generalized extension response may be produced ending, not infrequently, in opisthotonos and generalized convulsions with cardiac or respiratory arrest. The hydrophobic response may be reinforced by unpleasant consequences of the inspiratory spasms, such as aspiration of water up the nose or into the trachea. However, the first attack may occur without preceding difficulty in swallowing and with no opportunity for the establishment of a conditioned reflex. The hydrophobic response may eventually be produced merely by the sight, sound, mention or thought of water; by touching the palatal mucosa; by splashing water on the skin; by loud noises, bright lights or by attempts to speak.

Figure 32.3 The terror of furious rabies in an 18-year-old Nigerian, bitten on the temple by a dog. After 13 days he developed classical hydrophobic spasms. Periods of lucidity were interspersed with episodes of extreme agitation, violent struggling, shouting and terrifying hallucinations. (Source: Courtesy of D.A. Warrell.)

There may be associated excitement, agitation and aggression and many patients develop generalized convulsions and die during a hydrophobic spasm.

Cardiac tachyarrhythmias and ECG evidence of myocarditis may be observed during this phase of the disease (Jackson *et al.*, 1999; Warrell *et al.*, 1976). There is transient hypertension during the hydrophobic spasms and the violent inspiratory spasms may result in pneumothorax (Warrell *et al.*, 1989). Pneumomediastinum may result from alveolar rupture or tears in the lower oesophagus. If the patient survives this phase of the disease and sinks into coma, hydrophobia is replaced by a variety of respiratory arrhythmias (cluster or Biot's breathing and Cheyne—Stokes respiration) with long apnoeic periods.

Pathophysiology of Hydrophobia

There is some clinical evidence that the inspiratory spasms of hydrophobia may be an exaggeration of reflexes which normally protect the respiratory tract from foreign bodies (Warrell *et al.*, 1976). These include sneezing, coughing, the neonate's aspiration reflex and perhaps the immersion reflex, all of which have a powerful inspiratory contraction as their main motor effect. In furious rabies there is a selective brainstem encephalitis which damages cells in the region of the nucleus para-ambiguus (where the inspiratory motor neurons are situated) and in the limbic system. These lesions could disinhibit the respiratory tract protective reflexes and explain the associated terror of hydrophobia. The responses could be reinforced by conditioning, resulting in the heightened reaction to a variety of sensory stimuli which provoke spasms.

Other Features of Furious Rabies

Alternating phases of extreme arousal and calm, lucid intervals are typical of furious rabies. Physical findings include meningism, cranial nerve lesions (especially III, VII, VIII), upper motor neuron lesions, muscle fasciculations and involuntary movements. However, conventional neurological examination may fail to disclose any abnormality unless a hydrophobic spasm is observed. Evidence of autonomic stimulation includes lacrimation, hypersalivation and excessive sweating, piloerection, high fluctuating body temperature and blood pressure, pupillary abnormalities and Horner's syndrome. Involvement of the amygdaloid nuclei and limbic system may explain the increased libido, priapism and spontaneous orgasms/ejaculations in a small minority of patients. These symptoms are reminiscent of Klüver—Bucy syndrome which can be induced experimentally in rhesus monkeys and by surgical treatment for temporal lobe epilepsy in humans (following bilateral temporal lobectomy). Evidence of an extensive axonal neuropathy was found in two patients with furious rabies in the second week of intensive care. The normal progression of furious rabies is to coma and death within a week of the first symptom, but some patients have been kept alive for several months in intensive care units. In these cases a variety of other complications can develop (Table 32.2).

Paralytic Rabies

Paralytic rabies is less likely to be recognized than furious disease, and this contributed to its being apparently less common in humans. The patients may become literally dumb ('*rage muette*'), because their laryngeal muscles

Table 32.2 Complications of rabies

Cardiovascular	Arrhythmias, hypotension and cardiac failure
Respiratory	Asphyxiation (hydrophobic spasm) Pneumonia Respiratory failure Pneumothorax, Pneumomediastinum
Neurological	Adult respiratory distress syndrome Convulsions Diabetes insipidus Syndrome of inappropriate anti-diuretic hormone Hypo- or hyper-pyrexia Cerebral oedema
Gastrointestinal	Stress ulcers Mallory—Weiss syndrome Haemorrhage

are paralysed, but the term ‘dumb rabies’ also describes the quieter symptoms and more insidious and protracted clinical course exemplified by its other French name, *rage tranquille*.

There was a famous outbreak of paralytic rabies in Trinidad involving 20 people, mostly children, between 1929 and 1931. After prodromal fever and headache, burning, tingling, numbness, cramp or weakness developed in one foot followed by a gradually ascending hypoaesthesia and paralysis, eventually affecting respiratory and deglutitive muscles. Constipation, urinary retention, high fever and profuse sweating were common. Some patients survived for three weeks and only one showed terminal hydrophobic spasms. Vampire bats were eventually implicated. Paralytic rabies was seen in patients with post-vaccinal rabies (due to defective inactivation of vaccine) and in two patients who inhaled a vaccine strain of virus.

Neurological signs include quadriparesis with predominant involvement of proximal muscles, loss of deep tendon reflexes and progressive paralysis. In most patients sensation is intact, but in some there is evidence of ascending myelitis with loss of pinprick and joint position sense and fasciculations. Myoedema has been claimed to be a distinguishing feature of paralytic rabies (Hemachudha *et al.*, 2002). However, this transient local mounding of muscle in response to percussion, which was used historically to lateralize pulmonary tuberculosis, is unlikely to be a helpful sign as it is associated with a variety of pathological conditions (wasting, myxoedema, hyponatraemia) and may also be found in healthy people (Jackson, 2007a). Fasciculation in the muscles becoming involved in the ascending paralysis was mentioned

in the original description of paralytic rabies by Gamaleia in 1887. Cranial nerve involvement may result in ptosis, external ophthalmoplegia, paralysis of the tongue and deafness. Most patients with paralytic rabies do not experience hydrophobia, but in a few it may be represented by some terminal respiratory spasms. The course of the disease is less acute and stormy than furious rabies. Even without intensive care, patients may survive for up to 30 days before they succumb to bulbar and respiratory paralysis.

Differential Diagnosis of Rabies and Infections by Rabies-related Viruses

In a rabies endemic area, the diagnosis of furious rabies may be obvious in a patient with hydrophobic spasms who has a history of being bitten by a dog within the previous few weeks or months. However, exposure to a mammal bite or scratch may not be remembered, as in the majority of cases of genotype 1 insectivorous bat-transmitted rabies in the United States (Noah *et al.*, 1998). Although hydrophobia is a pathognomonic sign of furious rabies, it may be misdiagnosed as a laryngopharyngeal or even a psychiatric problem. Some of the reported misdiagnoses and differential diagnoses of furious and paralytic rabies are listed in Table 32.3. Rabies phobia, an hysterical response to the fear of rabies, differs from true rabies in its shorter incubation period which may be only a few hours after the bite, exaggerated aggressive and dramatic

Table 32.3 Differential diagnosis of rabies

Furious rabies	Hysterical pseudo-hydrophobia (Cephalic) tetanus Other brain stem encephalitides (e.g. complicating serum sickness) Other causes of muscle spasms: (e.g. phenothiazine dystonia, tetany, strychnine poisoning) Delirium tremens Porphyria Cerebrovascular accident, epilepsy
Paralytic rabies	Post-vaccinal encephalomyelitis Paralytic poliomyelitis Other causes of acute ascending paralysis (e.g. acute idiopathic inflammatory polyneuropathy—Guillain-Barré syndrome) Drug abuse Cercopithecine herpesvirus (B virus) encephalomyelitis (after monkey bites) Creutzfeldt—Jakob disease

symptoms and its excellent prognosis. Severe (cephalic) tetanus, involving the cranial nerves, is distinguished by its shorter incubation period, the presence of trismus, the persistence of muscular rigidity between spasms and the absence of pleocytosis.

In the few remaining countries where nervous tissue vaccines are still used, post-vaccinal encephalomyelitis (PVE) is the commonest differential diagnosis of paralytic rabies. In PVE, symptoms usually develop within two weeks of the first dose of vaccine, but no clinical or laboratory features reliably distinguish the two conditions while the patient is still alive, save for the absence of demonstrable rabies virus in skin biopsies, saliva or CSF. Cercopithecine herpes virus (B virus) encephalomyelitis, transmitted by monkey bites, has a much shorter incubation period than rabies (three to four days). Vesicles may be found in the monkey's mouth and at the site of the bite. The diagnosis can be confirmed virologically and the patients treated with acyclovir.

Clinical Investigations in Human Rabies

Haematological and Biochemical Tests

Routine haematological and biochemical tests are initially normal, apart from neutrophil leukocytosis. Later, hypernatraemia or hyponatraemia may reflect diabetes insipidus or the syndrome of inappropriate antidiuretic hormone (ADH) secretion respectively. In a majority of patients there is a lymphocytic pleocytosis and sometimes an elevated protein concentration in the CSF. Hypoglycorrhachia has been reported (Roine *et al.*, 1988).

Neurological Investigations

The EEG may be normal or may show the expected wide range of nonspecific changes, including evidence of seizure activity. Electromyography has revealed evidence of primary axonal neuropathy.

Most reported computed tomographic (CT) scans in rabies have been normal, especially in the early stages. Hypodensities of the basal ganglia and of cortical lesions have been described.

Reports of magnetic resonance imaging (MRI) (Jackson, 2007a) have mainly been in patients with paralytic rabies although, surprisingly, both paralytic and encephalitic rabies patients are said to show a similar distribution of ill-defined, mildly T2-weighted hyperintensity of the brainstem, hippocampus, hypothalamus, deep and subcortical white matter and deep and cortical grey matter (Hemachudha *et al.*, 2002). Minimal gadolinium enhancement, indicating mild inflammation, may be seen in the later stages of the clinical course. Similar changes in the

spinal cord, suggestive of myelitis, might indicate a diagnosis of paralytic rabies. None of the MRI changes reported to date would be diagnostic of rabies infection.

Recovery from Rabies

Animals of several species have recovered from rabies (see above). Humans with paralytic rabies can survive for several weeks, especially with intensive care, but the illness progresses relentlessly. Six patients over the last 40 years have been claimed as survivors of rabies encephalitis. Five received some rabies vaccine before the onset of symptoms. No virus or viral antigen was detected in any patient and so the diagnoses were based on finding high rabies neutralizing antibody levels in the CSF.

Two of the patients were treated post-exposure with rabies vaccines of nervous tissue origin. In Argentina, in 1972, a 45-year-old woman was bitten by her clinically rabid dog and began a course of suckling mouse brain vaccine 10 days later (Porras *et al.*, 1976). Three weeks after the bite she had paraesthesiae of the bitten arm, with tremors, myoclonic spasms, ataxia and other signs of cerebellar dysfunction. She recovered but, following booster doses of rabies vaccine, relapsed twice. Clinical features included hypertonia, tetraparesis, dysphonia, dysphagia, varying levels of consciousness and a cardiac conduction defect, with slow resolution over a year. The CSF and serum neutralizing antibody levels were very high. The clinical features typical of rabies were the apparently subjective paraesthesiae of the bitten limb, the cardiac conduction defect (if it was a new finding) and the high-antibody level. Cerebellar signs have rarely been reported in rabies. A possible diagnosis of post-vaccinal encephalitis cannot be excluded.

The second patient was a six-year-old boy in Ohio, USA in 1970, who was bitten on the thumb by a proven rabid big brown bat (*E. fuscus*). He began treatment with duck embryo vaccine four days later (Hattwick *et al.*, 1972). Twenty days after the bite he developed a meningitic illness progressing to encephalitis with unilateral weakness maximal in the bitten arm. Focal seizures, paralysis, cerebral oedema and coma ensued, lasting more than a week. He also had an atrial arrhythmia. Prolonged intensive care resulted in complete recovery in six months. The CSF and serum rabies antibody levels were high. Features suggesting rabies were the dominant signs in the bitten limb, a cardiac arrhythmia and the high antibody level. Now, over 30 years later, the patient lives a normal life.

The third case was a 32-year-old laboratory worker in New York in 1977 who was thought to have inhaled an aerosol of a fixed strain of rabies (SAD) virus (Centers for Disease Control and Prevention, 1977). He had had pre-exposure prophylaxis with duck embryo rabies vaccine, with a neutralizing antibody titre of 1 : 32 six months

before exposure. Fever, encephalitic symptoms, spastic hemiparesis, myoclonus, impaired consciousness and respiratory arrest developed over two weeks, and the rabies neutralizing antibody titres were high in the serum and CSF. A gradual improvement was followed by onset of a personality disorder and dementia. Two and a half years later he still had profound neurological deficits.

A Mexican boy severely bitten on the head by a proven-rabid dog was given a course of vero cell vaccine, starting the following day, but no rabies immunoglobulin (RIG) treatment (Alvarez *et al.*, 1994). Nineteen days later he developed encephalitis with fever and convulsions. Intracranial hypertension and coma ensued. He improved over three weeks, and reacted to painful stimuli, but quadriplegia persisted, he became blind and deaf, and eventually died within four years (Jackson, 2007a). High titres of rabies antibody appeared in the CSF and the serum. A second boy with similar clinical features survived at least nine months.

Another case of survival was reported from India (Madhusudana *et al.*, 2002). A six-year-old girl was severely bitten by a stray dog which died four days later. The wound was not cleaned but she was given purified chick embryo cell (PCEC) rabies vaccine (see section on Human rabies prophylaxis below) on days 0, 3 and 7 after the bite. Sixteen days later she would not drink and developed fever, hallucinations and impaired consciousness which progressed to coma with excessive salivation and focal seizures. Rabies antibody titres rose to very high levels in serum and CSF. After three months of coma, improvement began very slowly but after 18 months she had spasticity, tremors and involuntary limb movements, and she died after two years. Neurological illnesses following tissue culture rabies vaccines has been reported rarely (see below) but have been relatively mild.

The most recent and surprising report is reminiscent of the second case. A 15-year-old-girl, bitten on a finger by a bat in Wisconsin in 2004, had no rabies prophylaxis (Willoughby *et al.*, 2005). A month later she developed tingling and numbness of the bitten hand. Neurological signs including V1th nerve palsy, slurred speech, nystagmus and tremors, with lethargy, fever and hypersalivation. MRI and magnetic resonance angiography (MRA) scans were normal, but she had a mild lymphocytic pleocytosis. Rabies antibody was detected on the sixth day of illness, but no virus or antigen was detected. Treatment comprised coma induction, ketamine, ribavirin and amantadine. The neutralizing antibody rose to high levels. She was extubated after a month, and made a slow motor recovery over two years. She has returned to independent normal life, albeit with some neurological deficits. The effect of multiple antiviral treatments cannot be evaluated in a single case. Her symptoms were of paralytic rabies with evidence of

an early immune response. Her treatment possibly maintained her vital functions until the spontaneous specific immunity eliminated infected neurons.

This case is similar to the second patient, the boy from Ohio. Both were infected by American bat rabies viruses which differ from canine rabies experimentally: infection is slower to evolve and progress; virus replication is not restricted to neurons and histopathological changes are milder with very little apoptosis. This suggests that the genotype 1 bat viruses are less pathogenic, and could explain the earlier induction of immunity.

Rabies virus was not isolated nor was antigen identified in any of these patients. Diagnostic samples were taken when there was already a high titre of antibody, probably masking virus or antigens. For the three patients given tissue culture vaccines, the term 'survival' is more appropriate than 'recovery', as all had profound residual neurological deficits. Severe impairment of nervous function was irreversible before the infection was controlled, presumably by the immune response.

Human Infections with Rabies-related Viruses

Mokola (Lyssavirus Genotype 3)

Two cases of Mokola virus infection occurred in girls admitted to University College Hospital, Ibadan in 1968 and 1971. The first was a three and half year old who presented with a febrile convulsion, and had a temperature of 105 °F and a sore throat. She recovered. Virus was isolated from CSF, but no specific complement fixing antibodies were detected. A similar strain of Mokola, isolated from a shrew, was being handled in the laboratory at the same time (Familusi and Moore, 1972). The second case was a six-year-old girl admitted after six days of feverish illness. Initially she had a cough and vomited but later became drowsy, confused and weak. She died three days after admission. Mokola virus was isolated from brain tissue, and a Coxsackie A virus isolated from a rectal swab. (Familusi *et al.*, 1972). A laboratory worker recovered from a mild Mokola virus infection (Crick, 1981).

Duvenhage (Lyssavirus Genotype 4)

This virus was named after a 31-year-old white South African man who had been bitten on the lip by a bat of unknown species (Meredith *et al.*, 1971). One month later he noticed headache, dizziness and aching in the neck and back. He began to sweat profusely, suffered involuntary spasms of the face and limbs, became progressively more confused, irritable and aggressive, had nightmares and noticed difficulty in swallowing. He had typical hydrophobia, agitation, aggressive episodes and

had involuntary spasms of the neck and back. He died within a week.

In 2006, another infection appeared in South Africa in a 77-year-old man, scratched on the face by an insectivorous bat. He received no treatment and 27 days later developed classical features of rabies encephalitis. He died after 14 days of illness, and Duvenhage virus was isolated from saliva and brain tissue (Paweska *et al.*, 2006). A third patient, a 34 year old unvaccinated dutch woman visiting Kenya was scratched on the nose by a bat. She died of a rabies-like encephalitis after 14 days of illness, and Duvenhage virus was identified by PCR of skin biopsy.

European Bat Lyssaviruses

Genotype 5, EBLV-1 Three human deaths from rabies following bat bites have been reported from Russia in 1977 and 1985 (Selimov *et al.*, 1989) and in 2002 from the Ukraine. None of them received rabies vaccine. One month after being bitten on the hand, a 15-year-old girl became unwell with fever, anxiety and paraesthesia of the bitten hand. She developed an acute ascending paralysis, encephalitis and myocarditis and died five days later. An 11-year-old girl was bitten on the lip by a bat in Belgorod. Three weeks later she became unwell with pain in the bitten cheek, weakness and drowsiness. She developed typical furious rabies and died six days later. No rabies antigen was detected in brain impression smears by the immunofluorescent test, but virus was isolated in suckling mice and proved to be an EBLV-1a. A 34-year-old Ukrainian developed clinical rabies with hydrophobia six weeks after a bat bite, but there was no laboratory confirmation (Botvinkin *et al.*, 2005).

Genotype 6, EBLV-2 Two human infections due to EBLV-2 virus have been documented. An unvaccinated 30-year-old Swiss zoologist visiting Finland who studied bats had been bitten several times by bats in Malaysia and Switzerland over five years (Roine *et al.*, 1988). Then, in southern Finland, he was bitten by a sick Daubenton's bat (*M. daubentonii*) and 51 days later developed numbness of the palm of his right hand and pain in the neck radiating to his right cheek. He became unable to walk, was feverish, weak with numbness of the right arm and neck and retrosternal pain. Myoclonic twitching of the feet, trismus and typical hydrophobic symptoms of furious rabies ensued. Delirium, muscle spasms, convulsion, respiratory failure and diabetes insipidus followed. He died 23 days after his first symptoms. No rabies antibody was detected, but EBLV-2b was isolated from brain tissue. As EBLV-2b has only been found in Switzerland, it is possible that his infection originated there.

The second patient, a 55-year-old unvaccinated bat conservationist, had been bitten by bats on several

occasions in Scotland, most recently in Angus in 2002 on the left hand, about four months before his illness. He developed pain, paraesthesiae and diminished sensation in the left arm. He received nonsteroidal anti-inflammatory drugs and, five days later, had acute haematemesis attributable to these drugs. He was feverish, disinhibited, dysarthric, with nystagmus and ataxia. Touch sensation was diminished over the left arm. There was no meningism or pleocytosis. He became suddenly confused, aggressive and agitated and deteriorated with a pneumothorax, respiratory failure, decreased consciousness and hypersalivation. Neither aerophobia nor hydrophobia was observed. He became comatose. There was electrophysiological evidence of a peripheral, predominantly motor, axonal neuropathy. He died 19 days after the first prodromal symptom (Nathwani *et al.*, 2003). EBLV antigen was identified ante-mortem by RT-PCR, and from the brain post-mortem by immunofluorescence and isolation of EBLV-2a.

Australian Bat Lyssavirus (ABLV) (Lyssavirus Genotype 7)

First discovered in Australian bats in 1995, ABLV is more closely related to genotype 1 rabies than any of the other rabies-related lyssaviruses.

There have been two reported human fatalities from ABLV infection in Queensland. The first was a 39-year-old woman who cared for bats and had been scratched by bats during the previous 30 days. After a few days of left shoulder pain, dizziness, vomiting, headache, fevers and chills, she developed arm weakness, ataxia, cerebellar signs, slurred speech, diplopia, dysphagia, bilateral facial palsies, progressive quadriplegia and a fluctuating level of consciousness. She died 20 days after the start of her illness. Rabies antibody was detected and the CSF was PCR-positive (Samaratunga *et al.*, 1998). The insectivorous bat (*Saccolaimus* spp.) variant of ABLV was isolated from post-mortem brain.

The second case was a 37-year-old woman who had been bitten on her left hand by a flying fox or fruit bat (*Pteropus* spp.) (Hanna *et al.*, 2000). Twenty-seven months later she presented at hospital with a five-day history of fever, vomiting, anorexia, pain around the left shoulder girdle, paraesthesiae of the dorsum of the left hand, sore throat and difficulty in swallowing. She was feverish, unable fully to open her mouth, was drooling saliva and had difficulty speaking. There was increased muscle tone, painful spasms provoked by examination of the throat. She also had a neutrophil leukocytosis. She became agitated with dysphagia, dysphonia and increasingly severe frequent muscle spasms which were uncontrollable by medication, and she died 19 days after the first symptom. ABLV was detected by PCR in saliva. A post mortem

revealed diffuse pancarditis, and virus was isolated from the brain.

DIAGNOSIS

Intra Vitam Diagnosis of Human Rabies Encephalitis

The laboratory diagnosis of rabies is rarely attempted in developing countries. However, confirmation of the diagnosis is possible within a day or two and is important to guide the appropriate management of the patient, relatives and staff, prevent unnecessary investigations and allow characterization of the virus (Table 32.4). Routine haematological and biochemical tests are likely to be normal initially, but a plasma neutrophil leukocytosis may be present. A mild CSF pleocytosis is only seen in 60% of patients in the first week (Anderson *et al.*, 1984).

The diagnosis can be made by virus isolation, identification of antigen or, in unvaccinated people, antibody detection, and taking serial samples for all tests will enable most rapid detection of the infection. The success of tests depends on the quality of sample-taking. For example, a throat swab is no substitute for a saliva sample.

Isolation of Rabies Virus

Culture of the virus from saliva, throat, tracheal or eye swabs, brain biopsy samples, and rarely the CSF is most successful during the first week of illness (Anderson *et al.*,

1984) and in seronegative patients. The isolation of virus is best attempted in murine neuroblastoma cells, which yields results in only a few days, whereas suckling mouse inoculation takes one to three weeks.

Antigen Detection

The most rapid diagnosis of rabies during life can be made by direct IFA identification of antigen in a skin biopsy (Noah *et al.*, 1998; Trimarchi and Nadin-Davis, 2007). A full-thickness biopsy, preferably taken with a disposable biopsy punch, must include the bases of hair follicles. It is taken from a hairy area, usually the nape of the neck, and in addition near the original bite wound, if there is an adjacent proximal hairy area. Vertical frozen sections through hair follicles indicate rabies antigen in the nerve twiglets around the base of the follicles, in a characteristic pattern (Bryceson *et al.*, 1975) (Figure 32.4). Careful controls of specificity are needed. For a reliable result, more than 20 sections including hair follicles are compared with sections stained with an adsorbed negative control conjugate. The method is 60–100% sensitive (Blendon *et al.*, 1986; Warrell *et al.*, 1988), and false positives have not been reported. Antigen detection by IFA in the corneal smear test is too insensitive to be useful (Anderson *et al.*, 1984; Warrell *et al.*, 1988) and false positives have occurred. Brain biopsy samples are ideal for antigen detection (see section on Animal diagnosis below) or culture, but biopsies are very rarely indicated in life.

Table 32.4 Human rabies diagnosis

Sample	Aim	Test
Intra vitam		
REPEAT until a diagnosis is made		
Skin punch biopsy ^a	Antigen detection	IFA test on frozen section RT-PCR
Saliva, tears, CSF	Virus isolation	Tissue culture Mouse inoculation test
Serum	Antigen detection Serology	RT-PCR Antibody test Unvaccinated, test immediately Vaccinated, save for comparison later
CSF	Serology	Test immediately with serum
Post-mortem		
Brain ^a : Needle biopsy (see text) or brainstem and cerebellum	Antigen detection	IFA test on impression smear
	Virus isolation	RT-PCR Tissue culture Mouse inoculation test
Serum	Serology	Antibody test

^aCollect in small moistened container, keep cool during transport. Do not freeze. IFA, immunofluorescent antibody; RT-PCR, reverse transcription polymerase chain reaction; CSF, cerebrospinal fluid.

Figure 32.4 Vertical section through a skin biopsy, shows a hair (small arrow) surrounded by its follicle. The bright fluorescence (large arrow) indicates rabies antigen in neurons surrounding the follicle, and is a rapid means of diagnosing rabies during life. (Source: Copyright M.J. Warrell.)

RT-PCR techniques differ between laboratories, but they have become a popular means of diagnosis and genetic identification of rabies strains. Rabies RNA may be found in saliva, CSF, skin biopsy tissue and urine. Nested PCR techniques enhance the sensitivity. Real-time PCR methods are being evaluated (Trimarchi and Nadin-Davis, 2007).

Antibody Detection

In unvaccinated patients, the diagnostic appearance of rabies antibody, using any specific technique, often occurs during the second week of illness, but it may take longer. Antibody may be detectable in the CSF a few days later (see section on Immunology above). A low level of rabies-specific IgM has been detected in the serum and occasionally in the CSF of rabies patients, but it did not appear earlier than IgG, and IgM has also been found in post-vaccinal encephalitis patients (Warrell *et al.*, 1988). In vaccinated people, very high levels of antibody in the serum, and especially in the CSF, have been considered diagnostic (Hattwick *et al.*, 1972).

Post-mortem Diagnosis in Humans

Post-mortem diagnosis can be made by any of the above tests but rabies virus is most readily detected in the brainstem and cerebellum. Brain tissue can, however, be obtained without a full post-mortem examination. Needle necropsies are taken with a Vim—Silverman or other long biopsy needle via the medial canthus of the eye through the superior orbital fissure; via the nose through the ethmoid bone; by an occipital approach through the foramen magnum or through burr holes or open fontanelles in children. The IFA test for antigen takes about 3 hours to perform on brain impression smears. Viral isolation from brain by inoculation of murine neuroblastoma cells or suckling mice may be successful even if the IFA staining is negative. A retrospective diagnosis using formalin-fixed brain specimens is possible by protein digestion and antigen detection by IFA or enzymatic techniques. Genomic and mRNAs can also be analysed by *in situ* hybridization (Trimarchi and Nadin-Davis, 2007; Warner *et al.*, 1997). Rabies-related viruses may give a weak or negative reaction in the IFA test.

Diagnosis in the Biting Mammal

Suspect rabid animals should be euthanased immediately and their brains tested for rabies infection (Trimarchi and Nadin-Davis, 2007; World Health Organization, 1997). In practice this is often impossible if the animal escapes, or if laboratory facilities are not available. Observation in captivity is potentially dangerous and uncertain. Animal brain samples should include brainstem and cerebellum, but tissue can be obtained without craniotomy, via the occipital foramen. The diagnosis can be confirmed by a direct IFA test on acetone-fixed brain impression smears. A rapid enzyme immunodiagnosis kit will detect rabies antigen in a suspension of brain tissue. This is useful for laboratories without a fluorescence microscope, although the method is slightly less sensitive than the IFA test. No single laboratory method is sufficiently accurate for this crucial diagnosis. The IFA test has been found to be about 2% less sensitive than virus isolation in tropical dog rabies endemic areas, while false positive results are rare. Culture of virus should be attempted in antigen-negative samples. The sensitivity of detection, especially on decomposing samples, can be further increased by RT-PCR, and genotyping can also identify the vector species and geographical origin of the rabies or rabies-related virus. The diagnosis can also be made on formalin-fixed brain specimens (see section on Diagnosis in humans above).

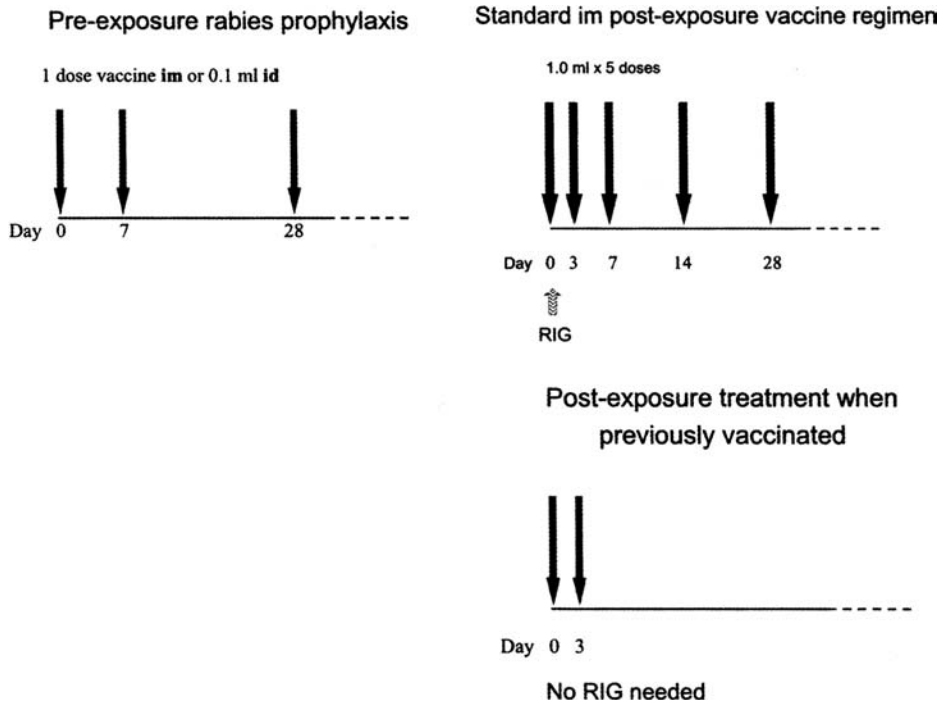

Figure 32.5 Rabies vaccine regimens. Pre-exposure: the final dose may be advanced towards day 21 (see text). RIG, rabies immune globulin; id, intradermal; im, intramuscular.

MANAGEMENT OF HUMAN RABIES

The mortality from rabies in patients infected by canine rabies viruses is 100%. Despite many attempts at intensive care treatment over 35 years, only two patients have recovered, and both were infected by bat bites (Hatwick *et al.*, 1972; Willoughby *et al.*, 2005). Their survival may have been due to the reduced pathogenicity of the American bat rabies viruses (see section on Recovery from rabies above). Intensive care may be appropriate for similar patients who are seropositive at presentation. Life can be prolonged, but many complications arise (see Table 32.2). Heavy sedation and analgesia should be given to relieve the agonizing symptoms. Ketamine, an anaesthetic agent and a noncompetitive antagonist of the *N*-methyl-D-aspartate (NMDA) receptor, has specific antirabies activity (Lockhart *et al.*, 1992), but the human therapeutic dosage is unlikely to give adequate concentrations, and it proved ineffective therapeutically in mice (Jackson, 2007a, 2007b). Immunosuppressive drugs including corticosteroids, rabies immunoglobulin, antiviral agents such as vidarabine, cytosine arabinoside, ribavirin (Centers for Disease Control and Prevention, 1984; Warrell *et al.*, 1989) and interferon- α (Merigan *et al.*, 1984; Warrell *et al.*, 1989) have not proved useful.

For canine rabies virus infections, until any new specific therapy has been evaluated, palliative care is recommended. Patients and their relatives should be advised that although intensive therapy may prolong life there can be no expectation of survival without severe permanent neurological disabilities (Jackson *et al.*, 2003).

PATHOLOGY

Rabies causes an acute nonsuppurative meningoencephalomyelitis, usually accompanied by diagnostic intracellular inclusions called Negri bodies (Figure 32.1). These are masses of dense eosinophilic material in neuronal cytoplasm. Electron microscopy shows they are composed of disorganized filaments in an amorphous matrix, largely consisting of rabies ribonucleoprotein. The inclusions described by Negri contained a basophilic inner body which may include fragments of cellular organelles and occasional virions, probably mechanically trapped by the fusion of smaller inclusions. Negri bodies are found in about 75% of patients and are most numerous in the hippocampus, Purkinje cells, medulla and ganglia (Perl, 1975). Inclusions with no internal structure were called 'lyssa bodies' by Goodpasture.

These contain the nucleoprotein alone, and are usually smaller than Negri bodies.

By the time the patient dies, cerebral congestion with some petechial haemorrhages is usual, but without gross oedema (Tangchai *et al.*, 1970). Inflammation with perivascular mononuclear cell infiltrate is common, with neutrophils seen only at an early stage. Neuronophagia, microglial reaction, ganglion cell degeneration, foci of demyelination and perineural infiltrates (Babes' nodules) (Perl, 1975) are less frequent. All changes may be widespread and are most pronounced in the grey matter of the brainstem and spinal cord and in paralytic rabies, spinal cord pathology may predominate. Children often show meningeal inflammation (Perl, 1975). The degree of histopathological change in rabies encephalitis may depend upon the strain of virus, and varies from absence of any inflammation (Iwasaki *et al.*, 1985; Tangchai *et al.*, 1970) to complete disruption of neuron structure in a patient treated with intensive care for several weeks. Peripheral nerve changes include axonal degeneration of myelinated and unmyelinated nerve fibres with leukocyte infiltration and degeneration in dorsal root ganglia, especially in the region of the site of the bite.

Extraneural changes include focal degeneration of salivary and lacrimal glands, liver, pancreas, adrenal medulla and lymph nodes and ocular tissues. An interstitial myocarditis with round cell infiltration has been described (Metze and Feiden, 1991; Warrell *et al.*, 1976) and tissue in the myocardium is also affected, which may account for associated cardiac arrhythmias.

HUMAN RABIES PROPHYLAXIS

Rabies Vaccines

Two rabies vaccines are now licensed for use in the United Kingdom and United States: HDCV (Sanofi Pasteur) and PCEC vaccine (Rabipur[®] Novartis). Both are in 1 ml dose vials. Elsewhere, purified vero cell vaccine (PVRV) (Verorab, Sanofi Pasteur) is widely available. The single-dose vial contains 0.5 ml.

Pre-exposure Prophylaxis

No rabies deaths have been reported in those given pre-exposure prophylaxis with post-exposure boosting. Pre-exposure immunization is indicated for residents of or visitors to areas where dog rabies is endemic, and all those at occupational risk of contact with a rabid animal or rabies virus, in quarantine facilities, customs departments, zoos, laboratories or hospitals. Those staying in rural areas of foreign countries where rabies is enzootic in other

mammals (foxes, jackals, wolves, coyotes, mongooses, bats, etc.) should seek advice about the risk.

Subsequent post-exposure treatment will be simplified and much cheaper after a prophylactic course. Pre-exposure immunization is especially important for children, and the high cost of vaccine is the only constraint to widespread immunization. Official recommendations on the need for pre-exposure rabies vaccine use a risk assessment analysis to define a length of stay in the endemic area, but as rabies is a fatal disease and a primary vaccine course is only required once, prophylaxis should be encouraged for all those visiting endemic areas.

Pre-exposure Vaccine Regimens

One dose of HDCV, PCEC or PVRV is given intramuscularly into the deltoid on days 0, 7 and 28 (the last dose can be advanced towards day 21 if necessary, but the antibody level may wane more rapidly) (Figure 32.5). An economical but effective alternative, recommended by the World Health Organization (1997, 2005) is to give the vaccine intradermally if more than one person is to be immunized. The dose of 0.1 ml of any of these vaccines is injected intradermally over the deltoid to raise a papule. If the injection is too deep, withdraw the needle and repeat the procedure. Opened ampoules should be stored in the fridge and used the same day because they do not contain preservatives and are not registered as multi-dose vials (World Health Organization 1997). The level of antibody may be lower following intradermal vaccination, but the quality of the secondary immune response to a booster dose is similar for intradermal and intramuscular injections. Chloroquine antimalarial chemoprophylaxis may inhibit the induction of rabies antibody after intradermal vaccination, so the larger dose must be given intramuscularly. All vaccinees must keep a record of their immunisation.

Booster Doses of Vaccine

A booster dose intramuscular or intradermal one year later enhances and prolongs the immune response, which lasts more than 10 years in 96% of people (Strady *et al.*, 1998). The neutralizing antibody level after three years has been used to decide whether to give a booster dose every 3 years, or every 10 years (Strady *et al.*, 2000). If no serology is available, or affordable, doses may be given every 5 to 10 years to those at continued risk of infection. In the United States, frequent serology and boosters are recommended only for those at high risk, but no boosters are given after the primary course for travellers assuming that vaccine will be available promptly after exposure (Centers for Disease Control and Prevention, 2008). A neutralizing antibody test should be performed six monthly for rabies

laboratory staff and when appropriate to avoid unnecessary treatment. A booster dose is given if the titre is <0.5 IU/ml. Measurement of antibody levels after vaccination is necessary only if immunosuppression is suspected, for example, in patients with acquired immune deficiency syndrome (AIDS). Those with a low CD4⁺ count may fail to produce antibody, even to repeated doses of vaccine.

Post-exposure Treatment

Post-exposure treatment is in increasing demand especially where dog rabies is endemic. According to World Health Organization data, over 13 million people are treated with vaccine annually, but many other patients remain untreated.

Any bite or close contact with an animal in a rabies endemic area is a potential exposure to rabies virus. Evaluation of the risk of infection depends on the history and clinical features of both the patient and the biting animal, and information about the local vectors and epidemiology of rabies.

The Site of Infection?

The virus gains access through any bite, scratch or contamination of broken skin or mucous membrane by animal's saliva, but intact skin is an adequate barrier against infection. The risk of infection is greatest from bites on the head, neck and hands, and multiple bites carry a higher risk than single bites. Other routes of infection are very rare.

The Animal Species and Behaviour?

An unprovoked attack by a known local rabies vector (see section on Epidemiology above), or an animal which may have been in contact with a vector species, suggests a high risk of exposure. Abnormal behaviour, either excitability or partial paralysis, is typical of rabies. Wild animals can appear unusually tame. Vaccination of domestic animals is not always protective. About 20% of proven rabid dogs in Bangkok had been vaccinated.

To Confirm Exposure

Every effort should be made to obtain a virological diagnosis, by examining the animal's brain for rabies antigen, and other tests if appropriate (see section on Diagnosis of biting animal above).

If rabies exposure is suspected or proven, post-exposure prophylaxis must be started as soon as possible. The greater the delay in starting treatment the greater the risk of virus entering a peripheral nerve where it becomes inaccessible to immune attack. If in doubt vaccinate; it is worth giving prophylaxis even if months have elapsed. Treatment can be stopped or converted to a pre-exposure regimen if the cat or dog is alive 10 days after the bite. The recommended criteria for treatment are shown in Table 32.5.

Table 32.5 The decision to give post-exposure treatment^a

Category	Type of contact with a suspect or confirmed rabid domestic or wild ^b animal, or animal unavailable for observation	Recommended treatment
I	Touching or feeding of animals	None, if reliable case history is available
II	Nibbling of uncovered skin Minor scratches or abrasions without bleeding Licks on intact skin	Administer vaccine immediately Stop treatment if animal remains healthy throughout an observation period ^c of 10 days or if animal is killed humanely and found to be negative for rabies by appropriate laboratory tests
III	Single or multiple transdermal bites or scratches. Contamination of mucous membrane by animals' saliva	Administer rabies immunoglobulin ^d and vaccine immediately. Stop treatment if animal remains healthy throughout an observation period ^c of 10 days or if animal is killed humanely and found to be negative for rabies by appropriate laboratory tests

^aThis table is a simplification of the WHO recommendations (World Health Organization, 1997, 2005).

^bExposure to rodents, rabbits and hares seldom, if ever, requires specific antirabies treatment.

^cThis observation period applies only to dogs and cats. Other domestic and wild animals suspected as rabid should be killed humanely and their tissues examined using appropriate laboratory tests. An exception may be made for animals of threatened or endangered species.

^dIf previously vaccinated against rabies, RIG is probably not needed, see text.

Primary post-exposure treatment For those who have not had a previous course of vaccine, the treatment consists of three parts: wound treatment, active immunization with vaccine and passive immunization with RIG.

Treatment of wounds The recommendation for all animal bite wounds is immediate vigorous washing, scrubbing and flushing with soap or detergent and water. This can be 50% effective in preventing rabies experimentally. Local infiltration, proximal to the wound, with procaine hydrochloride 1% in saline for pain may also have some antiviral action (Kaplan and Cohen, 1962). Then apply either 70% ethanol or povidone iodine. Avoid or postpone suturing the wound. Tetanus prophylaxis may be needed. Consider giving a prophylactic antimicrobial agent for serious bites or those on the hands (co-amoxycylav, doxycycline or erythromycin for dog or cat bites).

Vaccine regimens A course of five intramuscular injections of HDCV or PCEC vaccine are given into the deltoid on days 0, 3, 7, 14 and 28 (Figure 32.5) (Centers for Disease Control and Prevention, 2008; World Health Organization, 2005). Economical intradermal post-exposure treatment has been used for 15 years in Asia (see below). Although an intradermal regimen may have some advantages, it is not officially recommended in Europe and North America where full intramuscular treatment is freely available. If immunosuppression is suspected, due to diseases such as AIDS or to drugs, the antigenic stimulus might be increased by doubling the initial dose of intramuscular vaccine (one intramuscular dose into each deltoid) or by dividing a whole single dose between multiple intradermal sites (see below). A shortened course of intramuscular treatment, requiring four instead of five doses of tissue culture vaccine, is occasionally used outside the United Kingdom. Two doses are injected on the first occasion, one into each deltoid muscle, then one dose is given on days 7 and 21 (Vodopija *et al.*, 1988), but the antibody level wanes more rapidly than with the conventional regimen (Lang *et al.*, 1998; Suntharasamai *et al.*, 1987). Pregnancy is not a contraindication to rabies vaccination.

Rabies immune globulin (RIG) Rabies immune globulin should be given with every primary post-exposure treatment. It is most important for severe exposure to infection: bites on the head, neck or hands or multiple bites. Passive immunization provides some protection for the 7–10 days before vaccine-induced immunity appears. RIG apparently neutralizes virus in the wound. The dose of 20 units/kg body weight of human RIG (or 40 units/kg equine RIG, outside Europe and North America) should be infiltrated deep under and around the wound. If this is anatomically impossible, for example, in a bitten finger, give the rest by intramuscular injection at a site remote

from the vaccine, but not into the gluteal region. For multiple bites the RIG can be diluted two- or threefold in saline to ensure infiltration of all wounds. The recommended dose of RIG must not be exceeded as this will impair the immune response to the vaccine. Serum sickness has not been reported with human RIG. As there are problems of production and supply of RIG worldwide, efforts to find alternative products continue, including the use of a mixture of monoclonal antibodies.

Post-exposure treatment in previously vaccinated patients Treatment of animal bites, including immediate wound cleaning, is always urgent. Provided that a complete pre- or post-exposure course of a tissue culture vaccine has been given previously, or if a serum rabies neutralizing antibody level of >0.5 IU/ml has been recorded, an abbreviated course of only two doses of vaccine may be used. It is injected intramuscularly into the deltoid on days 0 and 3 (Figure 32.5). RIG treatment is not necessary (Centers for Disease Control and Prevention, 2008; World Health Organization, 2005) If there is any uncertainty about past immunization, the full post-exposure regimen and RIG must be used.

How effective is post-exposure treatment? The untreated mortality from proven rabid dog bites in India was 35% and 57% in separate studies more than 35 years ago. Optimal modern post-exposure treatment started on the day of the bite in healthy recipients is practically 100% effective. 'Failures of treatment' are due to not delivering the three components correctly and promptly, or failure of the patients' immune response. Examples are: if there is delay in starting treatment; failure to clean the wound; failure to complete the course of vaccine; injections of vaccine or RIG into the buttock; failure to infiltrate the wound with RIG, or immunosuppression by drugs, HIV, cirrhosis or other illness. There has been no suggestion that treatment has failed because the potency of the recommended vaccines was low; nor that the vaccine virus strain did not protect against the infecting virus. Deaths have been documented very rarely following complete prompt treatment with modern products (Hemachudha *et al.*, 1999; John and Patnaik, 2005). Nevertheless if wounds are extensive and severe, especially from wolf bites, primary post-exposure treatment cannot ensure survival.

Efficacy against rabies-related viruses Tissue culture vaccines do afford some protection against European bat lyssaviruses (genotypes 5 and 6), but they are probably less effective than they are against the genotype 1 rabies strains and ABLV (genotype 7). Vaccine is less protective against Duvenhage (lyssavirus genotype 4) and gives

little or no protection against Mokola virus (genotype 3) (Badrane *et al.*, 2001; Nel, 2005).

Side Effects of Tissue Culture Vaccines

There is very wide variation in the incidence of side effects in different groups of recipients. Mild erythema and pain at injection sites are reported in 7–64% of HDCV recipients, and local irritation is more common (13–92%) after intradermal injections. Generalized symptoms of headache, malaise and fever occur in 3–14%, (World Health Organization, 1997) and up to 3% reported a ‘rash’ distant from the injection site. There are similar data for PCEC and PVRV vaccines.

Rare case reports of neurological illness temporally associated with tissue culture vaccine treatment have described a Guillain—Barré-like syndrome (Bernard *et al.*, 1982; Chakravarty, 2001; Bøe and Nyland, 1980; Knittel *et al.*, 1989) a relapsing mild hemiplegia (Tornatore and Richert, 1990) or in two patients, symptoms restricted to an arm (Gardner, 1983). The incidence of neurological disease after these rabies vaccines is no more than after other commonly used vaccines.

Late booster doses of HDCV were followed, 3 to 13 days later, by a systemic allergic reaction in 6% of vaccinees in the United States (however, reaction rates were not evenly distributed between the groups of volunteers) (Dreesen *et al.*, 1986). The urticarial rash, angioedema and arthralgia responds to symptomatic therapy. It is possibly caused by an IgE-mediated reaction to β -propiolactone-modified vaccine components (Warrington *et al.*, 1987). Repeated booster doses of vaccine for people at continued risk of infection can be avoided by serological testing to confirm the need.

Human RIG has a very low reaction rate (Suwansrinon *et al.*, 2007).

What to do if Bitten in a Rabies Endemic Area

If bitten by a mammal in a rabies endemic country (or if any direct contact with a bat in the Americas), immediately wash the wound thoroughly. Seek advice on the local epidemiology. If there is a risk of rabies infection, start post-exposure treatment without delay. Tissue culture vaccines are too expensive for worldwide use, and so nervous tissue vaccines, Semple (sheep brain) or suckling mouse brain vaccines, are still produced in several developing countries. Their potency is variable and they are associated with allergic encephalomyelitis. Nevertheless, if only locally produced animal brain vaccine is available it might be reasonable to begin treatment immediately, and change to one of the European vaccines as soon as possible. If RIG is not available initially, it should be given up to seven days after starting vaccine. Equine RIG,

usually used in Asia and Africa, causes reactions in 1.8% and serum sickness in 0.7%, but anaphylaxis is exceptional (Suwansrinon *et al.*, 2007). If the risk of rabies exposure seems high it is worth curtailing a holiday to seek a recommended vaccine and RIG.

Two other post-exposure treatment regimens are recommended by the World Health Organization (1997). They are economical multi-site intradermal regimens which use only 40% of the amount of vaccine needed for the standard intramuscular course. The eight-site regimen gives an accelerated antibody response: on day 0 use a whole 1 ml vial to inject about 0.1 ml of PCECV or HDCV intradermally at eight sites (deltoids, thighs, suprascapular, lower anterior abdominal wall), on day 7 give 0.1 ml intradermally at four sites (deltoids, thighs) and on days 28 and 91, 0.1 ml intradermally at one site (Warrell *et al.*, 1985). This regimen is not suitable to use with PVRV, which contains 0.5 ml per ampoule.

The two-site intradermal post-exposure regimen has been used widely in Asia, usually accompanied by RIG. It was designed for use with PVRV (Chutivongse *et al.*, 1990), with an intradermal dose of 0.1 ml per site. If PCECV or HDCV (1.0 ml ampoule) are used, each intradermal dose must be 0.2 ml. On days 0, 3 and 7, give one intradermal dose at two sites (deltoids); on days 28 and 91 give one intradermal dose at one site (deltoid).

The two intradermal regimens use the same amount of vaccine, and aseptic techniques are essential when sharing ampoules. Opened ampoules should be used the same day. A comparative study shows that the eight-site method induces neutralizing antibody more rapidly and to higher levels than the two-site regimen, which is important when RIG is not available (Madhusudana *et al.*, 2001).

Difficulties with the current intradermal regimens have inhibited their use. A new variation, a four-site intradermal method has proved at least as immunogenic as the standard intramuscular regimen (Warrell 2008). On day 0, a whole ampoule of vaccine is divided between four intradermal sites (deltoids, thighs), 0.1/0.2 ml (depending on the vaccine used) is given intradermally at two sites on day 7 and one site on days 28 and 90. It is applicable with vaccine of any volume, has all the advantages of the eight-site method, uses the same amount of vaccine, and could replace both the present regimens, simplifying the confusing range of options.

CONTROL OF ANIMAL RABIES

The ability to control animal rabies depends on: the prevalence and host range of rabies in wild and domestic mammals in the region; the effectiveness of the local rabies surveillance network; the mode of transmission of

infection; the suitability of animal rabies vaccines; the social and cultural attitudes of the population to the vector species and the financial resources to implement a control programme.

Canine Rabies

Enzootic rabies is widespread in domestic and stray dogs. Muzzling, vaccinating and restricting the movement of owned dogs and reducing the number of strays was effective in eradicating rabies from some islands and peninsulas. In several large cities in South America intense mass vaccination programmes were dramatically effective in reducing the incidence of canine rabies and eliminating human disease (Schneider *et al.*, 2007). The size of urban dog populations, as with wild species, is determined by availability of food, water and shelter. Attempts to eliminate stray dogs by shooting and poisoning are difficult, unpopular and inefficient as fertility increases, restoring the numbers. Oral rabies vaccines for stray dogs have not proved very effective or easy to distribute; but methods of clearing rubbish to reduce the food supply, with parenteral vaccination and fertility control of strays can be successful in localized areas (Reece and Chawla, 2006). The support of the residents is essential. The role and influence of traditional methods of rabies prophylaxis must be taken into account and tactfully overcome by discussion and education.

Vaccination of owned dogs and cats should be mandatory in these areas. Facilities for viral diagnosis, disease surveillance and pre- and post-exposure vaccination of humans are also necessary. Countries free of rabies should prevent reinvasion by controlling the importation of mammals and by enforcing strict quarantine regulations from areas with canine rabies.

Sylvatic (Wildlife) Rabies

Attempts to reduce populations of vector species such as foxes and skunks have not been effective in the long term. Live attenuated rabies virus vaccines and a live vaccinia recombinant vaccine expressing rabies glycoprotein proved immunogenic by the oral route for foxes and raccoon dogs, and they are apathogenic in other local species. Since 1978, these oral rabies vaccines, disguised in baits, have been distributed over the countryside by hand or by aeroplane. The massive repeated control campaigns in 14 countries have proved very successful in Western Europe. Fox rabies has been eliminated in seven countries (Cliquet and Aubert, 2004). Long-term vaccination and surveillance are planned to prevent resurgence. In North America vaccinia recombinant vaccines have also been used to eliminate coyote rabies, and for control in raccoons and foxes. Raccoon rabies has been spreading north

along the eastern coastal states of the United States, and into Ontario despite an intensive campaign of oral vaccination. New vaccines are being developed for skunks, mongooses and jackals. Despite much work on developing DNA vaccines for rabies, none has yet proved suitable for use in animals or humans. Experimental plant-derived oral vaccines have induced rabies immunity. A single human vaccinia infection from a recombinant rabies vaccine has been reported in a pregnant woman with a chronic skin condition, epidermolytic hyperkeratosis (Rupprecht *et al.*, 2001).

In Latin America, vampire bat rabies is a major cause of death in cattle, with disastrous economic consequences. Specific control methods include vaccination of cattle or treating them with anticoagulants, to which the bats, but not cattle, are highly sensitive.

No attempts have been made to control rabies in some vector species despite their potential to infect humans. Insectivorous bats in North America and Europe are examples, due to their inaccessibility. Practical measures to avoid contact with bats, and a low threshold for giving post-exposure treatment are the only means of preventing human infection (Centers for Disease Control and Prevention, 2008). In rabies endemic areas, people should be educated to avoid unnecessary contacts with wild and domestic carnivores and to seek medical advice immediately if they are bitten or scratched.

Papillomaviruses

Dennis McCance

Centre for Cancer Research and Cell Biology, Queen's University, Belfast City Hospital, Belfast, Northern Ireland

INTRODUCTION

The genus *Papillomavirus* is one of the two genera of the family *Papovaviridae*. However, the viruses belonging to this group are quite different from those of the other genus, *Polyomavirus*, both in genome size, organization and pathogenesis.

The papillomaviruses (Latin: *papilla* = 'nipple'; *oma* = 'tumour') produce in their host benign skin tumours (papillomas), containing variable amounts of infectious virus. The lesion has been recognized since the fifth century BC. Common hand and plantar warts are the most frequent skin papillomas of humans and until recently the viruses responsible have generated little clinical or scientific interest since the typical lesions were a cosmetic nuisance and the viruses were not thought to be involved in serious disease. However, 25 years ago the first papillomavirus isolated from invasive carcinoma of the cervix was described (Durst *et al.*, 1983) and since then papillomaviruses have been linked with other squamous cell carcinomas (SCCs) of mucosal and cutaneous epithelia. This has stimulated interest in these viruses, resulting in significant advances in our understanding of the natural history and pathogenic process.

CLASSIFICATION

At present papillomaviruses are classified into five supergroups: A (genital human papillomaviruses (HPVs)), B (associated with epidermodysplasia verruciformis (EV)), C (ungulate fibropapillomaviruses), D (bovine papillomaviruses (BPVs) causing true papillomas) and E (animal

and human cutaneous papillomaviruses). There are 11 groups under supergroup A, 2 under B and C and one group under both D and E. The classification results from the deduced evolutionary relationships among the papillomaviruses as judged by the sequence similarity of their genomes. For example, A9 contains the commonly isolated virus HPV-16 and the related viruses HPV-31, -33, -35, -52 and -58. Table 33.1 breaks down the classification. Note that two of the animal viruses, rhesus monkey and pygmy chimpanzee papillomaviruses, are grouped with the human genital isolates in groups A9 and 10, respectively.

PHYSICAL AND CHEMICAL PROPERTIES

Structure

The capsids of the papillomaviruses have icosahedral symmetry containing 72 capsomeres with a diameter of 52–55 nm (Figure 33.1).

Genome

The HPV virion contains a double-stranded DNA molecule of 5×10^6 Da molecular weight with an average of 7900 bp. The DNA, when in the virion, has a supercoiled circular configuration.

The molecular organization of the papillomavirus genome is well conserved between viruses of various species and an example of one of the common genital isolates is shown in Figure 33.2a. In this figure the genome is represented as a linear molecule with the boxed areas indicating the open reading frames (ORFs)

Table 33.1 Classification of the papillomavirus subfamily

and for convention it is divided into two areas coding for early (E) and late (L) proteins. Because of the overlapping nature of the ORFs, the mRNAs transcribed are complex and it is not always clear which proteins

each transcript codes (Figure 33.2b). All the ORFs are transcribed from the same strand and so are read in the same direction, remembering that transcription is in the 5' to 3' direction. HPV-16 codes for 5 early and

Early Transcripts

Figure 33.2 (a) Schematic of the HPV-16 genome organization. The early genes are solid grey and the late genes are speckled. The base pairs of the open reading frames are shown and the ATG start codon is shown in italics. E4 is spliced to the N-terminal of E1 (E1^{E4}) since it has no ATG of its own. The poly(A) + signals for the early and late mRNA are shown (pA). The origin (Ori) of replication and the upstream regulatory region (URR) or the main early promoter region are indicated. (b) Determination of mRNA species detected in many cases by RT-PCR, so some of the 5' and 3' ends are uncertain. E4 is always expressed as a function of E1^{E4}.

Table 33.2 Molecular weights of HPV-16 proteins

Protein	Molecular weight (kDa) ^a
E1	70
E2	45
E4	17
E5	8
E6	16
E7	11
L1	55
L2	50

^aMolecular weight on SDS-PAGE gels may be different, e.g. E7 runs at 15–16 kDa because of charged amino acids in the N-terminus of the protein, but codes for a protein of 11 kDa and L1 runs at 75 kDa.

3 late proteins. There is an upstream regulatory region which contains the major early promoter at base 97 and enhancer elements for transcription of early genes and also contains the origin of replication. A late promoter for the transcription of the capsid protein mRNA has been identified and lies in the E7 ORF at 670, although start sites for some of the late transcripts may initiate at different bases around this nucleotide.

Viral-Coded Proteins

There are five proteins coded for by the early region of the HPV genome and three late proteins. Because there are differences in the pathogenesis of various HPV types this is reflected in some of the functions of the early proteins. For brevity, therefore, a short summary of the functions of HPV-16 (Figure 33.2) early (E prefix) and late (L prefix) proteins is presented and their molecular weights are shown in Table 33.2.

Three of the early proteins, E6, E7 and E5, have properties that are consistent with the virus having to stimulate the infected cells into S phase so that the viral DNA has the cell's replicative machinery available for propagation of the genome. It has to be remembered that the virus is attempting to replicate in cells that are programmed to differentiate and so will have little or no replicative enzymes available to the virus. Both E6 and E7 are important for the efficient immortalization of human keratinocytes and have functions that disrupt the normal control of G₁ to S phase progression. E6 has been shown to bind a number of other cellular proteins (McMurray *et al.*, 2001), but the biological consequences of the binding to many of these proteins is unclear. For instance, E6 has also been shown to bind to a Ca²⁺-binding protein called E6BP, which has homology to a cellular protein ERC-55 of unknown function (Chen *et al.*, 1995), but the biological outcome

of this interaction is unknown. There are two proteins interactions of E6, which have been shown to be important for the pathogenesis of the high-risk, cancer-inducing viruses. E6 has been shown to bind the human p53 protein and cause its rapid degradation through the ubiquitin proteolysis pathway (Scheffner *et al.*, 1990). The viral protein also binds to proteins with a PDZ domain, such as membrane-associated guanylate kinase (MAGUK) homologues, which are found at the membrane and are thought to be involved in intra- and intercellular interactions (Thomas *et al.*, 2001). Mutants of E6 unable to bind and degrade p53 or PDZ-binding proteins are unable to cooperate with E7 to immortalize primary human keratinocytes and have reduced ability to replicate (Lee and Laimins, 2004; McMurray and McCance, 2004; Shai *et al.*, 2007).

E7 binds another cellular protein, the retinoblastoma gene product (pRb, (Dyson *et al.*, 1989)) and de-represses the inhibitory activity of Rb for transcription factors that are important for expression of genes whose products are essential for DNA synthesis. Repression of transcription may be due to the binding by Rb of a histone deacetylase protein (Brehm *et al.*, 1998), which functions to condense chromatin and restrict the access of transcription factors to DNA. Whether E7 competes for the binding site of the deacetylase on Rb or has an effect on the enzymatic activity of the deacetylase is unclear at present. Both p53 and pRb are negative regulators of the cell cycle and so interference with their normal function may allow cells to divide in an uncontrolled manner. E7 has also been shown to bind to other cellular proteins such as various members of the AP-1 family of transcription factors and upregulate their activity (Antinore *et al.*, 1996) as well as some members of the basal transcription machinery such as TATA-binding protein (TBP) (Phillips and Vousden, 1997).

E1 and E2 are involved in the replication of the HPV genome (see section on Viral replication below). E2 has additional functions in that it can positively and negatively regulate transcription from the early promoter. The full-length E2 protein contains a transactivation domain at the 5' end and a DNA-binding domain in the 3' half, and the active complex is a dimer. Negative regulation of the HPV early promoter is due to the fact that one of the E2-binding sites lies next to the TATA box of this promoter and so E2 binding sterically inhibits binding of the TATA-binding protein and therefore inhibits initiation of the early transcripts.

E5 is a membrane-associated hydrophobic protein with transforming activity for rodent fibroblasts. The E5 protein inhibits the acidification of endosomes (Straight *et al.*, 1995) by binding to the smallest subunit (16 kDa)

of the vacuolar ATPase, a multi-component proton pump (Conrad *et al.*, 1993). In human keratinocytes this results in the delay of the epidermal growth factor receptor (EGFR) degradation and a hyper-stimulated cell. Since the EGFR is the major growth factor receptor on keratinocytes, this activity may be important for stimulating cells into S phase for viral DNA replication. E5 can transform rodent fibroblasts and in the presence of the epidermal growth factor there is an increase in the efficiency of transformation (Leechanachai *et al.*, 1992).

The late proteins L1 and L2 are the major and minor capsid proteins, respectively, of the virion. The DNA and amino acid sequences are highly conserved between HPV types, especially in the L1 protein. The amino acid homology can be as high as 76% between HPV-16 and -33 (group A9). However, even within groups of papillomaviruses type-specific conformational epitopes predominate, so it is possible to differentiate between types on a serological basis (see section on Serology below).

The mRNA for the E4 protein is spliced, with the 5' portion coded for by the first few base pairs of E1 and then spliced to the E4 ORF. This is referred to as E1^E4. The message and protein are detected late in infection, although it has the prefix of an early gene. E1^E4 interacts with cellular microfilaments, causing them to collapse (Doorbar *et al.*, 1991), but the motive for this interaction is not clear. It has been suggested that this might allow the virions to be more easily released from the differentiated keratinocyte after transfer to a new susceptible host. It has also been shown to arrest cells in G₂/M by modulating cyclin/kinase complexes (Davy *et al.*, 2005; Knight *et al.*, 2006).

There are host coded histone proteins H2a, H2b, H3 and H4 associated with the viral DNA within the virion.

SEROLOGY

The expression of the major capsid protein, L1, in yeast and insect cells results in the folding and production of virus-like particles (VLPs). This has permitted serological studies on the relatedness of HPVs and to determine serological responses in infected patients (Kirnbauer *et al.*, 1992). Virus-like particles can also be produced which contain both the major (L1) and minor capsid protein (L2). The latter appears to stabilize the icosahedral structure and also has been shown to possess neutralizing epitopes. Antiviral antibodies have been produced to virions of HPV-11 and -16 and these antibodies recognize virus-like particles of the L1 protein from HPV-11 and -16, respectively (Rose *et al.*, 1994), but do not

cross-react. Therefore, virus-like particles are recognized by antibodies raised to infectious virus particles, and vice versa. The antibodies to virus-like particles or virions detect conformational epitopes, unlike earlier serological studies, where disrupted particles, or fusion proteins of L1 or peptides of regions of L1 were used either as targets or to raise antibodies to the L1 protein, and produced extensive cross-reactivity. This cross-reactivity was so complete that antibodies to disrupted BPV-1 particles recognized linear epitopes in most HPV types. Therefore, it was only with the production of virus-like particles that the serological differences between HPVs, even those closely related, became apparent. For example, within one group, say A9, containing HPV-16, -31 and -33, polyclonal antibodies only react well with the type to which the antibodies were raised, although some cross-reactivity has been observed. The level of cross-reactivity is very low and is probably not biologically relevant for cross-protection. This does limit the spectrum of cross-protection induced by the HPV types contained in the vaccine (see section on Vaccination below). Monoclonal antibodies to virions or virus-like particles have shown that there are predominantly type-specific epitopes, although in closely related viruses such as HPV-6 and -11, where L1 is are over 80% homologous at the amino acid level, cross-reactive epitopes have been observed. While there is little cross-reactivity at the antibody level, there appears to be more at the T-cell receptor level as lymphoproliferative assays show some cross-reactivity between types such as HPV-6 and -16.

VIRAL REPLICATION

Infection of tissue culture cells with papillomavirus particles and subsequent propagation of infectious virus has not been achieved. The major problem is that HPV virion production depends on terminally differentiating epithelial cells and by their nature these cells do not grow *in vitro*. However, it has recently been possible to transfect human keratinocytes, the natural host cell, with HPV-31 DNA, select stable cell lines containing episomal copies of HPV-31 DNA, and then differentiate the cells using the raft culture system and show that virus particle production occurs in a few cells in the upper most part of the differentiated epithelium (Frattini *et al.*, 1996). HPV-11 DNA has also been replicated in keratinocytes by the same laboratory, although because HPV-11 is unable to immortalize human keratinocytes the cells senesce and so the replicating DNA is lost over time. The distribution of the virus particles is the same as that observed in infected epithelium (Figure 33.3). The level of virus production is very

Figure 33.3 A section of biopsy containing CIN 1, showing nuclear staining of HPV-16 L1 antigen using a monoclonal antibody, followed by alkaline phosphatase-tagged anti-mouse secondary antibodies. Note that the dark-staining nuclei are found in the outer, differentiated part of the epithelium.

low and not enough to produce virus particles for serological or infectivity studies. However, propagation of HPV types has been successful in a nude mouse kidney capsule system (Kreider *et al.*, 1985) and in human skin grafts onto the epithelium of severe combined immunodeficient (SCID) mice (Bonnez *et al.*, 1998). In the former system human foreskin tissue fragments are mixed with a viral

suspension of HPV and then the tissue is transplanted under the kidney capsule of a nude mouse. Over the next 60 days the tissue fragments grow and produce infectious HPV virus. Both HPV-11 and -16 have been propagated in this animal model, but, the system is obviously complex, requiring skills and animal facilities not available to all. In the alternative method, the tissue fragments are placed under the skin of the immunocompromised SCID mouse and so the growth of the tissue can be monitored. While the surgical skills are less demanding, the latter model is not a routine one.

The origin of replication of HPV-11 and -31 (Frattoni and Laimins, 1994; Lu *et al.*, 1993) has been mapped extensively and the region is conserved in other HPV types. The mapping has been achieved by cloning the origin region into a bacterial vector and transfecting mammalian cells along with plasmids expressing the E1 and E2 proteins of the respective virus. The E1 and E2 proteins are the only HPV-specific products necessary for the replication of the origin-containing plasmid. The origin region of the DNA has been mapped to a region at the 3' end of the upstream regulatory region (Figure 33.2a) and both E1 and E2 have specific DNA-binding sites at the origin. In addition to binding at the origin, E1 and E2 can bind together and E1 has been shown to have ATPase and helicase activities, which are typical of viral proteins, such as SV40 large T antigen, that are involved in the initiation of viral DNA replication.

NATURAL HISTORY OF HPV INFECTIONS

HPVs infect and replicate in squamous epithelium on both keratinized and mucosal surfaces. Most people are

infected with certain cutaneous viruses, such as the ones causing hand and foot warts (HPV types 1, 2, 3, 4), during childhood and adolescence. A small group of individuals with the rare autosomal recessive disease epidermodysplasia verruciformis (EV) harbour a number of virus types not often isolated from normal people (Table 33.1, groups B1 and 2). Two common presentations in EV patients are multiple warts, which may be so numerous as to produce coalescent areas and dry, scaly flat lesions. These may be red or heavily pigmented and although not having a wart-like appearance, may contain many of the unusual types of HPV in groups B1 and 2. SCC develop in nearly one-third of patients with EV, usually in areas of skin exposed to the sun (face, neck and hands being most commonly affected); HPV-5 and -8 are commonly found in these lesions while types 14, 17 and 20 (Table 33.3) account for a smaller number. While the viruses found in EV patients are not isolated from normal individuals, some types, such as 5 and 8, have been detected in SCC in allograft recipients. The disease EV is rare but since some of the EV-associated HPVs have been isolated from transplant patients this suggests that these viruses must be circulating in the community, infecting normal individuals perhaps without any associated clinical lesions.

As mentioned earlier, there are mucotropic HPVs, which mostly infect the genito-urinary tract. Common isolates like HPV-6 and -11, which cause benign condyloma, can also infect the oral cavity, particularly the larynx. Infection of the larynx is rare, but it usually requires several episodes of surgery or laser treatment to remove recurrent lesions. Frequent recurrences may be due to the fact that only the visible lesions are treated, but healthy-looking areas of mucosal tissue may harbour HPV genomes. The oral cavity is also infected with other HPV types associated with oral warts and hyperkeratosis.

Transmission is thought to occur from one epithelial surface to another in exfoliated cells containing infectious virus, rather than free virus particles. Therefore direct contact is the most efficient way to transmit infection. Direct contact through sexual intercourse is the most important mode of transmission of genital viruses. However, an infected mother may transmit virus to her neonate during delivery through the birth canal. This route of infection is thought to be a major cause of laryngeal warts in babies and young children. It is possible that other modes of transmission occur for the genital viruses, since a number of studies have detected DNA in the genital and perianal regions of young children. However, the routes of transmission, apart from those mentioned above, are unclear.

Infection of the genital mucosa is common and in the United Kingdom involves hundreds of thousands of new cases each year, usually among sexually active

individuals. The 18- to 30-year-olds have the highest incidence (cf. common hand warts). It is estimated that a sexually active woman has a 70–80% chance of being infected with a genital HPV type over her lifetime. Most of these infections will lead to transient disease which will spontaneously regress with the virus removed by the immune response. It is the women who have a persistent infection with high-risk HPV types that are at most risk of developing clinical disease and eventually cancer if the lesion is not detected in time. The transmission rate between partners was first described back in the 1970s when Oriel (Oriel, 1971) showed that 64% of partners of individuals with genital warts developed warts. Subsequent studies have shown that up to 90% of male partners have shared common HPV types with their partner's cervical isolates. Therefore, transmission of HPV types is common in a relatively stable partner setting. However, it is still unclear how frequent transmission is during casual sex with different partners.

As mentioned above, infection with certain of the genital HPV types increases the risk of malignant disease, especially of the cervix, and in the next section there will be a discussion of the pathogenesis of the genital HPV types.

PATHOGENESIS

HPVs cause benign and malignant changes in epithelial cells. It is the latter property that will be dealt with in this section since certain HPV types are the most important component of the aetiology of genital cancers and worldwide cervical cancer is one of the most common causes of cancer-related death in women.

Oncogenic Potential of Papillomaviruses

Until recent epidemiological and laboratory-based studies, most of the evidence for an oncogenic potential of HPVs came from research with animal papillomaviruses. Work in the 1930s showed that the cottontail rabbit papillomavirus (CRPV) produced benign tumours in this animal, its natural host, and that in 25% of cases these benign tumours would become malignant after 12 months. Benign tumours produced in domestic rabbits became malignant more frequently and within a shorter time. Also, application of hydrocarbons or tar produced a higher and more rapid malignant conversion in both animal species. The viral DNA was detected in both the benign and the malignant lesions. These results suggested that the CRPV produced the benign lesion, but other factors, genetic and environmental, were necessary for production of malignant disease. More recently, oesophageal, intestinal and bladder papillomas produced by BPV-4 were

shown to become malignant when cattle were fed on a diet of bracken. In this case the BPV-4 DNA was detected only in the benign lesion and was not detectable after malignant conversion. Recently a rhesus monkey papillomavirus type 1 has been isolated from a lymph node metastasis of a penile carcinoma. This virus is sexually transmitted and is associated with both penile and cervical cancers. This animal virus may serve as a good, if expensive model, to investigate the natural history of papillomavirus infections.

In humans, one-third of patients with EV develop squamous cell carcinoma, usually in sun-exposed areas. Over 30% of these lesions contain HPV DNA, most commonly types 5 or 8. This suggests that given the right environmental or genetic conditions, benign HPV-associated lesions may develop into carcinoma. Other evidence of a helper function associated with malignant conversion concerns laryngeal papillomas, where a high rate of malignant disease was observed in patients who were treated with X-irradiation some 50 years ago. With the increase in the number of allograft recipients there has been an increase in reports of SCC at many different sites. The cutaneous cancers are associated with those viruses isolated from similar lesions in EV patients and the genital cancers harbour the viruses found in similar cancers in immunocompetent individuals. The increased incidence of disease in immunosuppressed individuals, such as transplant patients, suggests that the immune response is important in controlling infectious and tumour development.

It is the genital papillomaviruses that are responsible for the most common HPV-associated cancer and these types will be discussed in more detail in the following sections.

Genital Cancers Associated with HPV

While the association between the genital cancers, especially cervical cancer, is now known to be causal rather than casual, not everyone infected with an oncogenic HPV type will develop cancer. In fact, it appears that people can be infected and have disease which spontaneously regresses, or perhaps have no obvious lesions resulting from infection. It is not clear why the outcome from infection can be so varied, but the immune response may play an important role as well as other less well-described factors, such as genetic background and response of the epithelial cells to infection.

HPV Infection and the Normal Cervix

It has been observed for some time that HPV DNA could be detected in cervical cells from women with a normal cervix as assessed by normal cytology and absence of a visible lesion upon colposcopic examination. What

is not clear, however, is whether the cervix epithelium is really normal or if there are micro-lesions present which harbour the virus. So far, no histologically normal section of the cervical epithelium has been shown to harbour the DNA of a high-risk HPV type, although viral DNA has been detected in cells from an apparently normal cervix. These infected cells probably emanate from undetectable micro-lesions. The rate of detection of HPV DNA in cervical cells varies dramatically depending on the method used to detect the DNA and the age and demographics of the group studied. Using polymerase chain reaction (PCR), longitudinal studies have shown a very high lifetime risk (70–80%) of HPV infection. However, there is variation in isolation rate depending on the age and lifestyle of the individuals studied. For instance, in one of the earliest studies of young women between the ages of 18 and 25, up to 46% had detectable HPV DNA by PCR in epithelial cells from a normal cervix over a four-year period (Bauer *et al.*, 1991). HPV types 16 and 18, which are commonly found in malignant disease, accounted for about one-third of the viruses detected. This infection rate has been observed in other populations of young, sexually active women. While similar studies on large populations of males have not been carried out, it is clear from smaller studies that males are infected at similar rates, a finding to be expected with a sexually transmitted disease. Therefore, a large number of young women may be infected with HPV types which cause malignant disease. It is clear that while many individuals will develop transient premalignant disease, only a small number will ever develop malignant disease. However, recognizing those at subsequent risk is not possible at present. HPV detection decreases in older women (>40 years of age) and is usually in the 5–10% range. While the frequency of infection is lower in older women, it has been shown that they are more likely to have underlying disease.

HPV Infection and the Abnormal Cervix

The most common genital lesion caused by HPV infection is the genital wart (condylomata acuminata). HPV-6 and -11 are the predominant types associated with these lesions, which are benign and where the rare malignant conversion has only been documented in patients with an underlying immune deficiency. These warts are distributed throughout the female genital tract on the cervix, vaginal wall, vulva, perivulval and perianal region. In males the lesions are found on the penis, scrotum and perianal region.

The premalignant lesions associated with HPV can occur on the same sites as described above for warts, although the cervix is where malignant conversion is most often observed. The premalignant lesions of the cervix

are called intraepithelial neoplasia and are graded according to the Bethesda system (Kurman *et al.*, 1994) as low-grade squamous intraepithelial lesions (LSILs) or high-grade squamous intraepithelial lesions (HSIL). HPV-6 and -11 are found in LSIL, while the oncogenic types HPV-16 and -18 are found in all grades and in malignant disease. Table 33.4 gives a breakdown of the high and low risk of HPV types. The premalignant cervical lesions occur almost entirely on the transformation zone, the metaplastic zone between native squamous epithelium of the exocervix and the columnar epithelium of the endocervical canal, and are white in appearance after the addition of 5% acetic acid to the surface of the epithelium. Invasive cancer arises from these areas of HSIL and malignant cells migrate up into the uterus and out to local lymph nodes. HPV-16 is the most common virus found in intraepithelial and malignant disease, with a detection rate of 70% in cases of HSIL in Germany and the United Kingdom. Worldwide this type has been isolated in 50–60% of cases of invasive cancer of the cervix.

HPV-6 and -11 have not been found in malignant disease of the cervix, but have been isolated from locally invading lesions of the vulva such as verrucous carcinoma. However, when the genomes of the viruses were sequenced it was found that there were duplications in the long control region, which may be associated with the

change in pathogenesis. The HPV types and associated lesions are shown in Table 33.5.

There is a difference in the state of the HPV-16 DNA in premalignant and malignant lesions. In LSIL and HSIL the HPV-16 DNA is free and unintegrated, while in the majority of malignant cells the DNA is integrated. While integration is random within the chromosomes of cells, the HPV genome is usually integrated in the E1 or E2 regions of the DNA, resulting in the retention of the expression of the E6 and E7 proteins, which appear essential for the malignant phenotype. It is not clear how important integration is for the development of invasive cancer, since in a minority of cases the viral DNA is episomal in malignant cells, but continued expression of E6 and E7 appears necessary.

Malignant disease of the penis, while rare in developed countries, is much more common in developing parts of the world. HPV-16 and -18 were detected in over 50% of penile cancers in Brazil (McCance *et al.*, 1986) where in one area of the north-east of the country the incidence of penile cancer is 10 times that seen in Europe. Again in malignant disease of the penis the viral DNA is integrated into the host cell chromosomes in the majority of cases.

While HPV types have a role in the aetiology of cervical cancer, there are certainly other factors involved that act with the virus to produce invasive disease, since not everyone infected and exhibiting premalignant lesions will develop cancer. It is estimated that up to 25% of women with LSIL will progress to HSIL if not treated, while most will regress over a three-year period. However, in older women (>40 years of age) infection and persistence are associated with more serious underlying disease and so they are a group to be closely monitored (McCance, 1998). The co-factors involved have not been delineated, although smoking and use of oral contraceptives (>5 years) may be such components.

Persistence Infections

Epidemiological evidence suggests that HPVs can persist in squamous epithelium without producing clinically obvious lesions. Up to 50% of allograft recipients develop cutaneous warts within a year after transplant, this proportion being high when compared with the incidence in age-matched controls. This suggests that transplanted patients experience either new infections or reactivation of persistent virus, the latter being supported by the finding of HPV DNA sequences in biopsies of normal areas of larynx from individuals who have had episodes of laryngeal papillomas. As the recurrence rate of laryngeal warts is high, this suggests that the virus is capable of persisting somewhere in the larynx, respiratory tract or oral cavity without producing recognizable lesions—an inapparent infection.

Also, the viruses associated with the lesions in EV patients are not normally found in lesions from immunocompetent individuals, yet EV is such a rare disease that these patients cannot circulate the viruses amongst themselves. It would seem that these viruses are circulating in the normal population, causing inapparent infections. This is supported by the fact that viruses isolated from warts and SCC in immunosuppressed individuals are often the same types observed in EV patients.

In addition, during pregnancy, genital warts can appear on the vulvar epithelium and then disappear post partum. It is not known if this is an hormonal effect, or due to perturbations in the immune response that may accompany pregnancy, or the result of acquiring a recent infection from her partner. In none of the above situations is there any direct evidence as to which cells harbour the virus. The basal epithelial cells are the most likely site, although there is a considerable turnover of cells. However, not all cells in the basal epithelium have the same capacity to divide, so the viral DNA may be sequestered in quiescent basal cells, which when they subsequently divide may activate replication and produce lesions.

DIAGNOSIS

Apart from the familiar hand and verruca (plantar) warts, the clinical appearance of papillomavirus infections varies considerably, from the scaly flat lesions on cutaneous epithelium of individuals with EV to the aceto-white flat lesions on the cervix. The reader is referred to specific papers for details of the clinical presentation of genital

lesions (Walker *et al.*, 1983). This section will deal with the laboratory diagnosis of HPV, in particular the genital isolates.

Culture Methods

Although several efforts have been made, no easily amenable cell type has been capable of supporting replication with production of infectious papillomavirus particles. The nude mice kidney capsule model or the SCID mouse subcutaneous system has been used to propagate some HPV types, but they cannot be considered *in vitro* systems and are not amenable to most virus laboratories. Also, the raft system (McCance *et al.*, 1988) only produces low amounts of infectious virus and the technique itself is rather cumbersome. There is therefore no readily available simple culture system for HPV propagation.

Serological Methods

Recently, with the advent of yeast and baculo virus-produced virus-like particles, it has become possible to detect antibodies by an enzyme-linked immunosorbent assay (ELISA) technique in the serum of patients infected with HPV. At present there is a limited number of HPV types that have been used as antigens in these assays, but the initial results suggest that antibodies are detected in approximately 50% of infected individuals, which is less sensitive than DNA-based detection methods. The reasons for the low positivity rates in infected people is unclear, but it has to be remembered that the virus is confined to the stratified epithelium of the genital tract and few cells in a lesion support viral particle production.

In addition, the mature viral particles are only produced in the outer layers of the epithelium, where the immune response is at its least effective. Serological assays may not therefore be very sensitive for diagnostic or screening purposes.

Polymerase Chain Reaction (PCR)

The most sensitive method for the detection of HPV infection is by PCR. This is a powerful technique which amplifies a specific piece of DNA from a small amount of template. The advantages of this method are (i) the extreme sensitivity; (ii) the versatility, in that it can be used to detect more than one type of HPV when degenerate primers are used: it is, in fact possible to detect even unknown HPV types (i.e. ones that have not been cloned and sequenced); (iii) it is possible to test large populations. The major disadvantage stems from the false sensitivity of the method whereby it is possible to amplify contaminating sequences and so have false positives. This was a major problem in the beginning, but now that it is recognized investigators are more careful and include strict controls.

Several sets of partially or degenerative primers have been used to detect HPV types in the DNA extracted from lesions, and are directed to the L1 ORF. The first described, MY09/MY11 (Bauer *et al.*, 1991) has been improved (PGMY09/PGMY11) and used with a filter containing 27 HPV types (Gravitt *et al.*, 1998). This means that the PCR products can be directly hybridized to the filter, allowing for a rapid method to detect specific HPV types. Other sets such as GP5⁺/GP6⁺ (de Roda Husman *et al.*, 1995) and SPF-10 (Kleter *et al.*, 1998) have also been used successfully to detect multiple HPV types in clinical samples. The main difference between the sets of primers is that some detect certain HPV types better than others, but since these types are of low frequency in the populations studied, in reality there is little difference in the sensitivity of detection between the sets (van Doorn *et al.*, 2002). None of the PCR sets have been licensed for use as diagnostic tools, although the hybrid capture method described next has been approved for diagnostic use in the United States.

Hybrid Capture Method

This method is commercially available as a kit from Digene Diagnostics (Maryland, USA), and uses type-specific RNA probes to detect viral DNA in samples. The method is not as sensitive as PCR, but does not have the problems of false positives associated with PCR since it does not rely on the PCR-type amplification of the signal. In practice, although not as sensitive as PCR, the method is sufficiently sensitive to detect HPV DNA and has been

shown to be more sensitive than cytology in detecting HPV from lesions diagnosed as atypical squamous cells of unknown significance (ASCUS), LSIL and HSIL. Cytological smears diagnosed as ASCUS are difficult to interpret, since after biopsy more serious disease may be detected and HPV typing has been shown to be helpful in these situations. This test detects 16 mucosal types, whereas PCR can theoretically detect all HPV types.

TREATMENT

Although in most cases warts are a cosmetic nuisance and will eventually disappear spontaneously, they are notoriously difficult to treat. However, since premalignant lesions, especially on the cervix, may lead to malignant disease, treatment to eliminate disease is important. This section will concentrate on the treatment of genital areas as others (Bunney, 1982) have dealt with the treatment common hand and plantar warts.

Podophyllin

Podophyllin is a resin mixture obtained from the roots of the American mandrake (*Podophyllum* sp.) and is an irritant on cutaneous and mucous surfaces. It is an antimetabolic agent and should be used with care. It is painted carefully onto the surface of genital warts and should remain for no longer than 6 hours and then be washed off. It is poorly adsorbed by cutaneous surfaces and so has a limited effect. Several treatments are required and the continual inflammation produced can lead to fibrosis of the areas treated, without getting rid of the lesions. Podophyllin is even less effective in treatment of plantar warts and should never be used for treatment of hand warts.

Cryotherapy

Liquid nitrogen (-190°C) and dry ice (solid carbon dioxide, -50°C) can be applied to warts to produce local destruction of the lesion. Care should be taken to limit application to the lesion and not surrounding areas, as this will lead to pain and blistering of the healthy area. Cryoprobes are used to apply these cryogenics to the cervix.

Electrodiathermy

This is used in treating mucosal lesions such as those on the cervix to destroy the diseased tissue by heat.

Laser Evaporation

The carbon dioxide laser has been used to treat lesions on mucosal surfaces (cervix and vaginal wall) (Singer and

Walker, 1985) as well as cutaneous lesions. The success rate of laser treatment of the cervix is very good, with cure rates of 85–90%. However, its efficacy with cutaneous lesions has not as yet been adequately assessed. The difficulty with these lesions is in knowing how deep to vapourize to eliminate diseased tissue.

Loop Electrosurgical Excision Procedure (LEEP)

This is a relatively new procedure for the removal of cervical lesions and makes use of a heated loop, which very precisely removes the complete lesion. One advantage over laser evaporation is that the lesion is removed intact and the tissue can be used for pathological staging without having to biopsy the lesion first. In addition, the margins of the lesion are intact and so the extent of lesion removal can be assessed. Loop electrosurgical excision procedure (LEEP) also allows the lesion to be used for other studies, such as HPV typing.

Surgery

Curettage of common warts is not a common mode of treatment. In any case, not all warts are suitably sited for surgical removal. Furthermore, if all the abnormal tissue is not moved, small islands of warts can recur around the site of the initial lesion.

Interferon

Interferon has been used to treat recurrent laryngeal warts and cervical neoplasias. In the former cases, tumour load was first reduced by surgery or by CO₂ laser, interferon then being given parenterally. Although recurrences were rare within two years after starting the interferon course, it was necessary to maintain patients on interferon to prevent new lesions. The expense of this regime and possible side effects associated with interferon administration are drawbacks to this method of treatment. Cervical pre-malignant lesions have also been treated with interferon, but variable results have been reported.

Imiquimod

Imiquimod is an immune-response modulator that has shown some success in the treatment of external genital warts which are usually recalcitrant to treatment. The cure rate using a 5% cream is between 35 and 52% in females and the side effects are usually local skin reactions such as erythema, oedema and erosion. The drug is a synthetic imidazoquinoline that binds to the toll receptors TLR-7 and -8 and stimulates the innate immunity to produce a range of cytokines such as interferon- α (IFN- α), IFN- γ , tumour necrosis factor- α (TNF- α), interleukin 1 (IL-1), IL-8, IL-10 and IL-12. These in turn activate T-cell responses to the virus.

VACCINATION

Two vaccines, one from Merck & Co called Gardasil and the other from GlaxoSmithKline called Cervarix have been developed. Both vaccines are based on the same concept, but with different adjuvants and covering different combinations of HPV types (Wheeler, 2007).

Nature of the Vaccine

Both vaccines contain the major capsid protein L1, produced in either yeast (Gardasil) or insect cells (Cervarix). The L1 protein folds into an icosahedral structure called a virus-like particle in an identical fashion to the viral capsid and so produces a protective immune response to conformational epitopes on the virus particle. Gardasil contains the L1 protein from the high-risk types HPV-16 and -18 and also the low-risk types HPV-6 and -11, while Cervarix contains only the high-risk types HPV-16 and -18. The adjuvants used also differ, with Gardasil containing the conventional alum (aluminium hydroxyphosphate sulfate) while Cervarix contains a new adjuvant called ASO4 (aluminium hydroxide and 3-deacylated monophosphoryl lipid), which the manufacturers suggest may increase the cross-protective nature of the vaccine so that immune responses are raised to other closely related types not in the vaccine. Cross-protection remains to be proved in long-term vaccine trials.

Vaccine Trials

Both vaccines are given intramuscularly as three doses at zero, two and six months for Gardasil and zero, one and six months for Cervarix in a volume of 0.5 ml. To date the combined phase II and III for both vaccines show an efficacy of 100% for HPV-16 and -18 associated cervical intra-epithelial neoplasia (CIN)-2 or -3 and 100% efficacy for the Gardasil for protection against HPV-6- and -11-associated genital warts (Harper *et al.*, 2006; Villa *et al.*, 2005). The antibody titres to L1 are much higher in vaccinees than in people infected by the normal route of transmission. These results are impressive but the combined follow-up is a median of only 21 months, so longer term follow-up is required to confirm these statistics. Safety is good with no serious side effects and only some minor soreness at the site of inoculation. Also, initial impressions are that women who became pregnant during the vaccination period have similar side effects to the women receiving placebo, that is, they have no added risk.

Age to Vaccinate

Data from the trials suggest that the vaccine does not protect people who have already acquired the infection

and so it is important that vaccination is carried out in an age group that is unlikely to have become sexually active. In both the United States and United Kingdom approximately 25% of females are sexually active at 15 years of age and over 70% by 18 years (Wheeler, 2007). In addition, nearly half the women between the ages of 19 and 21, and 10% of 13- to 15-year-olds, report having had four or more sexual partners in their lifetime and HPV acquisition after the start of sexual activity is quite rapid. Therefore, it is important to vaccinate young prepubescent women before sexual activity is likely. At present the recommendation in the United States and United Kingdom is to vaccinate girls of 11 years of age. There are no plans to give the vaccine to males, although they are an important part of the natural history of HPV infections.

The cost of the vaccine course (three doses) will be in the range of £350 in the United Kingdom or \$350 in the United States. While it may have little effect on the incidence of malignant disease in the developed world it could have a major impact in third world countries where 80% of the cancer cases worldwide are found. However, at the price given above, the vaccine will have very limited exposure there and some arrangement with the manufacturers and these developing countries will need to be implemented to have the desired result.

Duration of Protection

While the median follow-up so far is 21 months, a small proportion of the vaccines have been followed for up to five years with no perceptible waning of their antibody titres (Villa *et al.*, 2005). Therefore, early indications are that repeat vaccinations may not be needed in the medium term and it may be that the HPV vaccine will have a similar schedule to the hepatitis B vaccine. One potential problem is that while HPV-16 and -18 make up 70% of the case of cervical cancer worldwide, the other 30% are caused by viruses not contained in the vaccine. There is a theoretical possibility that the other HPV types may become more prevalent once competition from HPV-16 and -18 wanes.

The Human Polyomaviruses

Kristina Dörries

Institute for Virology and Immunobiology, Julius-Maximilians University, Würzburg, Germany

CLASSIFICATION AND DETECTION

In the past, the human polyomaviruses were grouped with papillomaviruses, polyomaviruses and SV40, the so-called vacuolizing agent, in the family *Papovaviridae*. Molecular studies made clear that Simian virus 40 (SV40) is highly related to the other polyomaviruses, and with growing knowledge on the genomic structure and function of proteins the previous subfamily is now classified as independent family of *Polyomaviridae*. The classical human viruses are now grouped as polyomavirus hominis (huPyV) type 1 (BKV) and type 2 (JCV). Although mouse polyomavirus was detected almost 50 years ago, the existence of primate polyomaviruses was not realized until the 1960s, with the detection of SV40 in monkeys. Ten years later, JCV and BKV were described. JCV was isolated from brain tissue of a patient with progressive multifocal leukoencephalopathy (PML) in human fetal brain cultures, and BKV grew in cell cultures after inoculation with urine from a renal transplant recipient (Padgett and Walker, 1976; Zu Rhein, 1969).

VIRION STRUCTURE AND COMPOSITION

Polyomaviruses are non-enveloped viruses with icosahedral capsids about 40 nm in diameter containing three virus-encoded proteins—VP1, VP2 and VP3. The shell surrounds a DNA molecule that is stabilized by cellular histones in a chromatin structure. From studies on SV40 and murine polyomavirus it is known that 360 molecules of the major capsid protein VP1 are associated with approximately 30–60 molecules of each of the minor capsid proteins VP2 and VP3. The icosahedron is composed of

72 pentamers. Each consists of five VP1 molecules and one molecule VP2 or VP3. VP1 is the most related capsid protein among the three primate viruses. BKV can be propagated in tissue culture, whereas a cell line for the effective propagation of JCV has not yet been found. Virus preparations contain at least two kinds of particles. *In vitro* passage of polyomaviruses at high multiplicity is accompanied by the generation of considerable amounts of empty capsids. In addition, defective viral genomes containing deletions, duplications and rearrangements of viral genetic information can be encapsidated, if they are in the appropriate size limits. *In vivo* the amount of empty shells is considerably lower, pointing to a highly effective virus growth under natural conditions. Complete virus particles form a band at a density of 1.34 g ml^{-1} in CsCl_2 equilibrium density gradients, whereas empty capsids have a density of about 1.29 g ml^{-1} (Figure 34.1).

Recombinant JCV VP1 self-assembles into pentameric capsomers, and under appropriate conditions, these molecules will further assemble into virus-like empty capsids (VLPs) (Chang *et al.*, 1997). Calcium ions are required for capsid stability and disulfide bonds exist between capsid proteins, as reducing agents are required to disassemble virus particles. The human polyomaviruses are able to haemagglutinate erythrocytes at high virus concentrations. Each virus also has distinct antigenic epitopes and can be distinguished by neutralization and haemagglutination inhibition assays.

VIRUS LIFE CYCLE

One of the first steps in the viral life cycle is the adsorption of the virion to the cell surface. In view of the

Figure 34.1 JCV purification out of PML brain tissue. (a) Optical profile of the centrifugation with banding of virus particles in two bands; intact virus particles at a density of 1.345 g ml^{-1} of CsCl_2 . (b) Restriction endonuclease cleavage of DNA extracted from the major peak of the gradient followed by Southern blotting and JCV-specific radioactive hybridization. (1–4) Cleavage with single cut enzymes *EcoRI*, *BamHI*, *HpaI*, *PstI* generating linearized form III DNA at about 5 kb in length. (5,6) Cleavage with single and more cut enzymes in combination (*BamHI/PvuII*, *BamHI/HindIII*) generating DNA fragments A–D and A–E. (c) Electron micrograph of negatively stained JCV icosaedal virus particles of the small virus peak representing empty particles without encapsidated viral DNA.

stringent cell specificity of JCV for glial cells the initial experiments were based on the assumption that the high number of gangliosides in the central nervous system (CNS) made these types of molecules good candidates for a JCV receptor. It was demonstrated that JCV VLPs bind to glycolipids and glycoproteins containing sialic acids and require $\alpha(2,6)$ -linked sialic acid bound to a protein for successful infection. However, binding to the respective sialic acid alone was not sufficient to promote virus infection. Recently, the proteinacious part of the receptor molecule in glial cells was characterized as the serotonergic receptor 5HT_{2A} . The two components are present in the most prominent target cells *in vivo*, glial as well as kidney epithelial cells and are important for initial attachment. Interestingly, endothelial cells, which did not express 5HT_{2A} , were infected by JCV *in vitro*, and produced a virus yield comparable to that in glial cell cultures suggesting additional mechanisms of entry.

JCV binding to infected cells is followed by activation of the MAP kinase ERK1 and ERK2 pathway, signalling

events required for downstream steps of entry and infection. JCV requires proper assembly of clathrin-coated pits for rapid entry into the target cell. Following entry, the virus co-localizes with the clathrin marker transferrin in endosomes clarifying that JCV utilizes clathrin-mediated endocytosis for entry. This is in line with the fact that 5HT_{2A} is internalized in the same way. After entry, polyomaviruses are transported generally through the cytosol to the nucleus. For such directional intracellular transport viruses depend on the active cytoskeletal transport machinery. During early JCV infection intact microtubules are necessary as well as the intact intermediate filament network for productive infection. This is probably attributed to actin participation in assembly of the clathrin machinery rather than direct involvement of actin filaments in viral trafficking (Chapagain *et al.*, 2007; Elphick *et al.*, 2004).

Early studies on BKV receptors demonstrated a role for sialic acids, galactose and polysialylated gangliosides in BKV attachment. Recent experiments suggest that

$\alpha(2,3)$ -linked sialic acids attached to an *N*-linked glycoprotein are sufficient for viral infection. A coreceptor as described for JCV has not yet been identified for BKV, however, BKV apparently does not share protein receptor specificity with the other primate or the murine polyomaviruses. In addition, the gangliosides are also used as BKV receptors, but similar to the sialic acid components, the gangliosides used, GD1b and GT1b, differ from the molecule used by JCV (GT1b). The gangliosides and $\alpha(2,3)$ -linked sialic acids independently mediate BKV infection, suggesting that BKV might use alternate receptors or even entry pathways in different cell types. Because of the high structural similarity among the major capsid proteins, the BKV sialic acid receptor is believed to interact with the same BC loop domain of VP1 as utilized by JCV.

Following attachment, a relatively slow internalization phase requires 2–4 hours for completion. In contrast to JCV, BKV appears to use caveolae-mediated endocytosis as entry pathway. In biopsy material, BKV particles were located within invaginations of the cytoplasmic membrane morphologically consistent with caveolae. Although the steps are not yet clarified, it is clear that an acidification step as well as a tyrosine phosphorylation signal is needed/necessary for BKV infection. Microtubules are involved in the transporting process, probably allowing virus vesicles to shuttle along the microtubule track. The infection is microtubule-dependent for about 10 hours post infection. Although actin disruption does not interfere with BKV transport to perinuclear sites, the dynamic of microfibre reorganization is an important factor, possibly facilitating the transport process. Further trafficking to the nucleus is dependent on co-localization of BKV with CT-B between 4 and 6 hours post infection, suggesting that BKV passages through the Golgi by the endoplasmic reticulum (ER) after fusing BKV vesicles to stacked tubules continuous with the Golgi and the ER. Alternatively, BKV may bypass the Golgi and accumulate in the ER. Electron microscopic examination revealed that vesicles containing BKV fuse with ER-like structures and possibly Golgi organelles and then accumulate at perinuclear regions (Dugan *et al.*, 2007). Uncoating of polyomaviruses is believed to occur inside the nucleus.

Polyomavirus expression is essentially divided into three major stringently controlled phases. After expression of the regulatory early protein large T antigen (TAg), early post infection, TAg initiates replication of viral DNA. Shortly after onset of DNA replication, virus multiplication enters the late phase, which includes expression of late mRNAs. Translation of the late regulatory agnoprotein and the production of viral capsid proteins is followed by virion assembly. Regulated by complex

interactions of viral promoter elements with cellular factors and the viral regulatory proteins, late genes are expressed efficiently only after DNA replication. In contrast, early genes continue to be expressed at late stages of infection, than serving as viral transcription factors. The functions of TAg and agnoprotein are controlled by consecutive phosphorylation events. However, tropism of huPyV is predominantly to resting, differentiated cells. In order to produce enzymes necessary for virus growth, they have evolved mechanisms to overcome cell cycle growth arrest. A majority of the cell cycle-stimulating activities are induced by TAg. Consequently, expression of TAg can lead to transformation of a cell from a normal to a growth-deregulated state. The best-studied cellular growth-promoting and -inhibitory proteins interacting with TAg are the tumour suppressor proteins retinoblastoma binding protein (pRB), p53 and their downstream factors (White and Khalili, 2005).

In comparison to other polyomaviruses, JCV has a long lytic life cycle with an early transcription and DNA replication phase lasting about five days followed by continuing initiation of late RNAs for 15–20 days. In contrast is the high amount of virus produced and the fast progression of JCV infection *in vivo*. This discrepancy was solved recently by the discovery that JCV infection is able to interfere with programmed cell death (Pina-Oviedo *et al.*, 2007). JCV infection is able to induce the expression of a member of the inhibitor of apoptosis family of proteins, survivin. Survivin is normally expressed during embryonic development and is silenced in adult tissue. Dysregulation of suppression results in reduced cell death and abnormal cell viability. In glial cells high levels of survivin were expressed as early as day 5 post infection. Preliminary results suggest that this is an early event mediated by JCV TAg and replaced by proapoptotic measures late in infection, when production of late proteins increases and the late agnoprotein might be involved in the suppression of pro-survival signalling (Merabova *et al.*, 2008).

Viral auxiliary proteins have diverse effects on different stages of infection including transcription, viral assembly and the release of viral particles. The late leader regulatory protein agnogene plays an important role by modulating viral gene transcription and DNA replication. Agnoprotein may interact with the viral key regulatory protein TAg, which is expressed early during infection. However, in contrast to the other viral proteins it is not only found in the nucleus but is also localized in cytoplasmic compartment with high concentrations in the perinuclear area, particularly in the late stages of infection. Agnogene of BKV has intracellular localization similar to that of JCV. Since proteins smaller than 60 kDa cannot overcome passive diffusion within cytosol without interactions with associated

molecules, it was assumed that agnogene-binding proteins play a role in its cytoplasmic localization. JCV agnogene inhibition impairs the viral maturation pathway. The first JCV agnogene-binding protein characterized was the cytoskeleton microtubule protein tubulin. Then interaction with the fasciculation and elongation protein FEZ1 was described. FEZ1 is a protein that plays an essential role in kinesin-mediated transport pathways. Agnogene appears to block the association of FEZ1 with microtubules, thereby inducing the dissociation of FEZ1. Whether this is a potentially protective function by inhibiting the release of progeny virus from JCV-infected cells or promotes an effective intracellular translocation of progeny virus is not clear (Khalili *et al.*, 2005; Suzuki *et al.*, 2005).

The mechanism underlying JCV virion assembly include the synthesis of major and minor capsid proteins in a defined ratio from alternatively spliced mRNA molecules. Unlike the bipartite BKV nuclear localization signal (NLS), JCV has a weak monopartite NLS. JCV VP1 needs VP2/3 for proper import, suggesting that assembly of pentamers occurs in the cytoplasm. The capsid proteins are translocated to the nucleus in a cooperative manner and accumulate at the dot-shaped nuclear domain ND10. It is likely that capsid assembly at this site is associated with DNA replication followed by formation of intranuclear viral inclusions. The newly packaged virion progeny is thought to be released by lytic rupture, however, electron microscopical studies report secretion of virions from the plasma membrane of intact cells (Clayson *et al.*, 1989).

JCV has a stringent cell specificity and replicates efficiently *in vitro* only in human glial cells (Walker and Padgett, 1983), whereas BKV can be grown in a wide range of human cell types. With the upcoming knowledge on virus host interactions related to the viral life cycle, it becomes more and more likely that cell specificity of both human polyomaviruses is regulated by a large number of mechanisms that might additionally vary from cell type to cell type.

Molecular Structure of the Genome

The genomic structure is highly related among the primate polyomaviruses. The supercoiled, circular double-stranded DNA of the human viruses is about 5100 bp in length. The genome is divided into two regions encoding multiple overlapping genes. Each DNA strand carries about one half of the genetic information. Early and late mRNAs are synthesized bidirectionally from opposite strands of the genome. Protein-coding sequences consist of open reading frames for the early and late proteins. The noncoding region directs activity and specificity of virus multiplication. It is divided into two regulatory segments with a single origin of DNA

replication (ORI) and the transcriptional control elements within the promoter region (Dörries, 1997; Kim *et al.*, 2001) (Figure 34.2).

The coding sequences exhibit high DNA sequence homology. Homology between the human viruses is greater in all proteins than between JCV and SV40 (69%). JCV DNA shares between 83 and 59% amino acid homology with BKV in the cases of large TAG and agnogene respectively. The rates are even higher in functionally active regions of the virus genes. The early region codes for the tumour or TAGs. Both human polyomaviruses encode two major proteins, small t (tAg) and large TAG, so-called on the basis of size. The multifunctional TAG directly controls the virus life cycle and interacts with key cellular regulatory circuits. Functional activities include effects on nuclear localization, on viral DNA replication by direct DNA binding, helicase activities and binding to DNA polymerase alpha that initiates DNA replication. Interaction with cellular tumour suppressor proteins is associated with cellular transformation and TAG as a transcription factor is known to be crucial for the regulation of early and late gene transcription. Many of the activities depend on the TAG viral chaperone domain, which interacts with cellular chaperones to orchestrate functions that require the rearrangement of multiprotein complexes.

The tumour antigens are generated from a common pre-mRNA molecule by one alternative splicing event leading to identical N-termini and different C-terminal DNA sequences. Recently, three additional early virus proteins, T'135, T'136 and T'165, were characterized in JCV-infected cells. All T proteins use the first alternate splice donor site, leading to the same 132 N-terminal amino acids. For T' proteins a second splice donor site is combined with alternate acceptor sites. Whereas T'165 shares the C-terminus with TAG, T'135 and T'136 have unique ends encoded by an alternate reading frame. Expression of the proteins is modulated during the virus life cycle and appears to be related to TAG-mediated DNA replication and transcriptional control. T' proteins may utilize the shared tumour suppressor and chaperone-binding domains to enhance DNA replication by differential interaction with pRB and related proteins. Significant differences in splicing pattern in JCV-transformed cells and increased expression of the '17 kDa' species suggested correlation with transforming activity of JCV. Additionally, it has been proposed that the apoptotic function of TAG might be negatively influenced by T' proteins (Frisque *et al.*, 2006; Kim *et al.*, 2001).

The late region of the viral genome encodes two minor proteins, VP2 and VP3, and a major capsid protein, VP1. Late mRNAs are generated from a common precursor by alternative splicing. The sequences of the minor

Figure 34.2 Circular genomic map of the human polyomavirus JC subtype GS/B. Coding DNA segments are represented by shaded arrows. Numbers designate the first nucleotide of the start and stop codons for the proteins (Loeber, G. and Dörries, K. (1988) DNA rearrangements in organ specific variants of polyomavirus JC strain GS. *Journal of Virology*, **62**, 1730–1735). Position of splice donor and acceptor sites are indicated. The position of the unique *Bam*HI and *Eco*RI restriction sites are indicated on the inner circle.

proteins VP2 and VP3 are overlapping. VP2 contains the entire VP3 sequence at its C-terminus and an additional sequence of approximately 400 amino acids at its N-terminus. In contrast, the major protein VP1 is generated by an alternative reading frame. The three primate polyomaviruses all encode the nonstructural regulatory agnoprotein in an open reading frame in the late leader region. The protein is probably not essential for virus multiplication but takes part in the orchestration of efficient progeny virus production. It is produced late in the virus lytic cycle and physically and functionally interacts with the early key regulator TAg and the cellular transcription factor YB-1. Recently, it became obvious that agnoprotein plays an important role in the viral life cycle by modulating viral gene transcription and DNA replication. Likewise, it is involved in the morphogenesis of virus particles, the localization of capsid proteins to the nucleus, intracellular vesicular transport, and appears to deregulate cell proliferation by association with tumour suppressor p53 (Khalili *et al.*, 2005) (Table 34.1).

The non-coding part of the genome is framed by the start codons for early and late genes. The ORI is located between the TATA box and the initiation codon for the early genes. This segment includes the conserved binding sites for large TAg. Corresponding to similar DNA replication strategies, the polyomavirus ORI DNA segment is highly conserved in sequence and structure. In contrast, the promoter region to the late side of the control region reveals extensive differences. Heterogeneity of structure and sequence of individual transcription factor binding sites is reflected in the divergent cell type specificity and activity of transcription among the huPyV types (Dörries, 1997).

Control of Viral Gene Expression

DNA Replication

Regulatory mechanisms leading to DNA replication are closely related among the primate polyomaviruses. This is reflected in an ORI that is constructed by protein-binding

Table 34.1 Human polyomavirus early and late proteins

Protein	BKV		JCV	
	Size (amino acids)	Mol. wt (kDa)	Size (amino acids)	Mol. wt (kDa)
<i>Early</i>				
tAg	172	20	172	20.2
TA _g	695	90	688	79.3
T'135	NR	NR	135	17
T'136	NR	NR	136	22
T'165	NR	NR	165	23
<i>Late</i>				
Agno	66	8	71	8
VP1	362	46 ^a	354	39.6
VP2	351	40.5 ^a	344	37.4

^aMolecular weight varies considerably between laboratories. NR, not reported.

elements with comparable sequence and spacing requirements. Bidirectional replication takes place in the presence of the core ORI and TA_g, proceeding from the ORI elements with the TA_g-binding sites terminating at a site about 180° from the initiation site. The features shared by all ORI regions are an inverted repeat on the early side, a GC-rich palindrome in the centre and an AT sequence on the late side of ORI. All core ORIs contain these elements and replication studies on the human polyomaviruses confirmed that besides TA_g binding, site II and the inverted repeat are essential for DNA replication. Whereas the presence of flanking sequences stimulates DNA replication, the transcriptional control region (TCR) does not affect DNA replication activity directly. Interestingly, the efficiency of DNA replication directed from JCV ORI is substantially lower than that from BKV ORI. TA_g produced in each of the viruses varies considerably in its ability to support replication from homologous or heterogeneous origins. It is likely that differences of ORI sequences or spacing among the primate polyomaviruses are responsible for these observations (Kim *et al.*, 2001) (Figure 34.3).

Transcriptional Expression

The transcriptional control region (TCR) of the human polyomaviruses is composed of a great number of different regulatory protein-binding motifs. Promoter activity is mediated bidirectionally and often independently from the binding motifs by multiple interactions of transcription factors and associated cellular and viral proteins stimulating basal, cell type-specific, and, in response of external stimuli, induced functions of the viral promoter (Kim

et al., 2001; Manley *et al.*, 2006; Merabova *et al.*, 2008; Monaco *et al.*, 2001).

The JCV control region is artificially dissected in the ORI domain and following four TCR subdomains (A–D) in each of which a clustering of early and late interactive promoter sites is observed. Outside the TCR domain on the early site of ORI a binding sequence is located for the potent transcriptional enhancer nuclear factor-κB (NF-κB) and a potential binding site for a member of the nuclear factor of activated T cells (NFAT1) family. NF-κB is constitutively expressed in B lymphocytes and can be retained in the cytoplasm by an inhibitor κB protein. This binding can be released through stimulation by a number of agents acting as tumour promoters, such as phorbol-myristate-acetate (PMA) or inflammatory cytokines. It results in the transport of NF-κB to the nucleus, where the binding to the consensus DNA sites exerts activity. Upon PMA treatment both JCV promoters are responsive to NF-κB induction leading to increased JCV activity. In addition, tumour necrosis factor alpha (TNF-α) is able to enhance binding of NF-κB to the JCV κB site. Similarly NFAT1 is responsive to TNF-α and interleukin 2 (IL-2). This stimulated the idea that activation of the transcriptional control *in vivo* is dependent on the expression of inducible factors involved in immunologically regulated signalling pathways to modulate JCV expression (Figure 34.4).

It has been shown that interference with κB function in late gene expression decreased, but did not abolish, activity. This suggested that additional TCR elements may confer inducibility to the JCV late promoter coming into effect during the persistent state of infection. The GGA/C-rich sequence (GRS) motif within the ORI might also interact with the κB motif. The GRS is similarly inducible by PMA and inflammatory cytokines. The responsive region interacts with the novel GGA/C-binding protein GBP-i. GBP-i is induced in a wide range of cell types; thus it could play a role in mediating JCV activation at all suspected sites of persistence. Comparable to the NF-κB class of proteins, the GBP-i complexes probably represent a combinatorial assembly of various protein species, which is changed upon induction. Duality of function could involve the basal transcriptional machinery and other transcription proteins associated with late promoter activity. One potential factor is transforming growth factor-β (TGF-β) acting through the GRS and the NF-1 sites. In such a model the status of the viral promoter could be modulated through the GRS and variable interaction of cytokine induced proteins. Although these cytokines may use different signal transduction pathways for protein activation, in consequence, the nuclear milieu will contain the factors leading to expression by interaction with a promoter containing the respective contact sites.

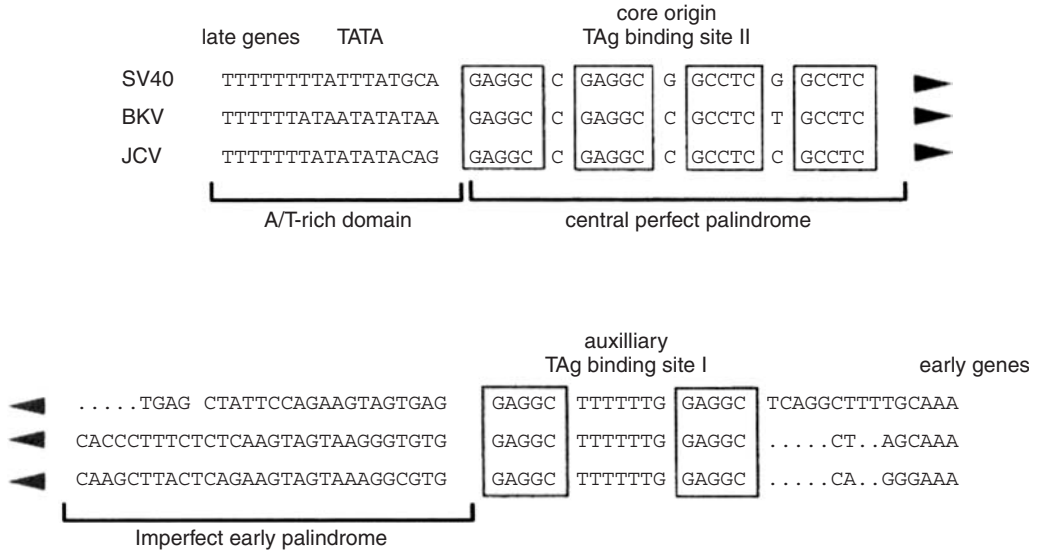

Figure 34.3 Alignment of the DNA sequence encompassing the origin of DNA replication in the noncoding genomic region of the primate polyomaviruses SV40, BKV and JCV. All sequences are given in the sense of the early coding strand. TAG consensus pentanucleotide recognition sites common to all virus strains are in boxes.

Figure 34.4 JCV TCR with protein-binding sites and interaction of cellular and viral transcription factors. The transcriptional control region (TCR) structure of prototype JCV Mad-1 is shown between the start codons (arrows) for early and late genes. ORI, origin of DNA replication; TA, TATA box; TR, tandem repeated promoter elements. Similar shading represent identical DNA sequences (see legend to Figure 34.5); A–D are dissected promoter domains. MCP, minimal core promoter; LCE, lytic control element. Binding sites and the respective proteins are indicated below the promoter domains. Filled circles indicate interaction of transcription factors. *TAT*, *TAR* are HIV-1-related transactivation domains. Arrows indicate interaction of inducing agents with the respective proteins. The position of the SP1-binding site in JCV TCR type II genomes is indicated at the top of the figure.

Most JCV TCR subtypes contain SP1-binding sites around the TATA box activating early promoter activity. The JCV early minimal core promoter (MCP) in domain C binds the glial-specific transcription factor Tst-1/SCIP/Oct-6, a member of the POU-domain protein family. It is an intrinsically weak transcriptional regulator and relies on viral or glial cell-specific coactivators. TAG has been identified as viral coactivator that stimulates the function of Tst-1 synergistically by direct interaction and activates the high mobility group proteins HMG-I/Y as cellular coactivators. Additional crosstalk was assumed with the glial cell-specific late transcriptional silencer OP-1 that contacts downstream of the Tst-1 binding. Another cellular nucleic acid-binding protein, Cnbps, negatively regulated the JCV early promoter, and the TAG-binding protein p53 is discussed as a transcriptional silencer. The OP-1 motif also interacts with the adjacent NF-1 site. OP-1 and NF-1 form a composite element that increases JCV early activity and reduces JCV late activity. In the same region the JCV lytic control element (LCE) interacted with $\text{pur } \alpha$ and YB-1. The YB-1 family are responsive to a wide variety of stimuli including stress signals, drug and IL-2 treatment in T cells and activate transcription from both the viral early and late promoter. It was proposed that $\text{pur } \alpha$, YB-1 and TAG are also involved in the transition of JCV early-to-late promoter activity.

The B-domain in the early orientation contributes positively to expression in glial cells and is also important for transcriptional activation of JCV late genes. The central motif responds to glial factor 1 (GF-1) and appears to be a part of the human Sp1/2 factor. GF-1 protein expression is most abundant in brain tissue. Interestingly, the amount of GF-1 is higher in kidney cells than in other cell types. Therefore it is thought that the level of GF-1 in kidney cells could be responsible for the ability of JCV to replicate in urogenital tissue. Pronounced high-affinity NF-1-binding sites (NF-1A/B) are closely associated with overlapping binding sites for nuclear factor Jun as well as cyclic AMP-responsive element (CRE) and a site resembling the sequence for the activator protein AP-1. NF-1 sites are involved in basal as well as in glial cell-specific modulation of JCV early and late promoters, they are affected by TAG transactivation and BAG-1, a novel factor, interacts with anti-apoptotic Bcl-2 protein (Devireddy *et al.*, 2000). Cell-specific activity in glial cells includes the CRE overlapping with the AP-1 site. The second messenger cAMP and forskolin substantially increase JCV early gene expression. Activity is mediated by a CRE-binding protein (CREB). Importantly, the mechanisms of induction for the factors are through different signal transduction pathways. This combination allows a highly flexible JCV transcriptional re-

sponse to a large number of environmental signals. In domain A a transactivator element associated with HIV-1 TAR homologous sequences and Tst-1-binding sites has been identified. The D domain is close to the start codon of the late proteins spanning binding sites for NF-1, c-jun, YB-1 and an NF- κ B-responsive region. YB-1 in this position is believed to be a transcriptional coactivator for regulation from the NF- κ B site. NF- κ B/re1 subunits modulate JCV late promoter activity at multiple levels. This provides an exquisite control mechanism over constitutive and induced NF- κ B activity (Sweet *et al.*, 2002).

The BKV promoter region has been less well characterized. However, similar to the JCV promoter region the so-called noncoding control region (NCCR) of BKV also consists of the conserved ORI region with a true palindrome, two inverted repeats and an AT-rich region and is dissected in subdomains designated by letters P, Q, R and S. They harbour a string of conserved promoter-binding sites for transcription factors NF-1 and Sp1, which are required for early transcription. There are AP-1-binding sites, believed to be important for basal BKV activity, and there are potential NF- κ B and C/EBP β -binding sites immediately upstream from the early initiation codon. The interaction of an NF- κ B and the C/EBP β transcription factors cooperatively stimulate BKV early expression. Exogenous agents activate BKV early transcription by the adenylate cyclase pathway. They signal through a cAMP-responsive element, CREB, and phorbolsters mediate activity probably through a putative responsive element in the early region. In the late region the oestrogen responsive element (ERE) and the nonconsensus glucocorticoid response element (GRE)/progesterone response element (PRE) overlap the NF1 and p53-binding sites immediately upstream. The major late promoter (MLP) sequences harbour multiple NF1 sites. Usually NF1 factors act as transcriptional activators, however, here they are also involved in repression of transcription, probably because NF1 binding is involved in early to late switch of promoter activity (Gorrill and Khalili, 2005; Kraus *et al.*, 2001; Moens and Rekvig, 2001).

Heterologous Transactivation of Virus Transcription

Additional to activating effects of cellular transcription factors, viruses are thought to influence human polyomavirus expression through the direct or indirect interaction of a heterogeneous gene product. In general, transactivation can occur at any step of protein synthesis, beginning with the initiation of transcription and ending with post-translational modifications. In the case of JCV and BKV, promoter activity and DNA replication were affected. The question whether HIV-1 may transactivate human polyomaviruses has been discussed since it

became clear that PML is one of the most prevalent opportunistic infections and new BKV-induced syndromes were described in patients with AIDS. The HIV-1-encoded transregulatory protein Tat has been found to be a potent activator of the JCV late promoter. Tat is a transcriptional activator and an essential component for the establishment of a productive HIV-1 infection. In the JCV promoter at least two responsive elements, the TAT element in the ORI domain and the TAR element, have been identified. Transactivation occurs *in vitro* at the level of transcription by HIV-Tat induction of the JCV promoter. Limited expression of HIV-1 proteins has been detected in astrocytes, indicating that astroglial cells might be a site of co-infection. Co-infection of astrocytes by JCV and HIV-1 *in vitro* altered HIV-1 gene expression and JCV gene expression was slightly increased in HIV-1 replicating cells. The effect was due to interaction of JCV agnogene and Tat protein. Changes in subcellular localization of both proteins as well as a negative impact on the interaction of Tat with its target DNA, TAR and critical upstream transcription factors suggested that agnogene may utilize different pathways to interfere with the transcriptional activation of the long terminal repeat (LTR) by Tat, thereby controlling the level of JCV as well as HIV-1 gene expression in astrocytes (Kaniowska *et al.*, 2006). In oligodendrocytes HIV-1 expression is regularly low, but biologically active Tat protein is secreted by the HIV-1-infected cell and could affect neighbouring cells by transcellular or receptor-mediated interaction. In polyomavirus-infected cells transcription from Tat responsive promoter elements was induced. Alternatively, after super-infection of already infected cells Tat could directly interact with the respective promoter elements. Recently, it became clear that the activation of BKV by HIV-1 transcriptional regulatory proteins is dependent on interaction with the NF- κ B-binding site and a pentanucleotide motif, the so-called BKVE-TAR site, at the early site of the promoter. In contrast, BKV TAg is able to transactivate the HIV-1 LTR (Gorrill *et al.*, 2006).

Transactivating effects of another retrovirus, human T-cell lymphotropic virus type I (HTLV-I), is modulated by interaction with the regulatory protein Tax. Transactivation is also postulated for herpes viruses. Cytomegalovirus (CMV) infection is often activated in immuno-impaired patients and common target tissues are kidney, lung, the CNS and lymphoid organs. Increased JCV DNA replication is mediated *in vitro* by the human CMV immediate-early transactivator 2 (IE2). Similarly, it was found that BKV TAg is able to induce the expression of CMV early gene expression (Dörries, 2001). Human herpes virus type 6 (HHV-6) infection was co-localized with JCV in PML lesions. HHV-6 establishes persistent

infection in brain, urogenital tract, lung, liver or peripheral blood cells and often occurs after transplantation. Obviously, huPyVs and HHV-6 have a wide range of target organs in common. Due to putative transactivation mechanisms of other herpes viruses, a comparable interaction of HHV-6 with the human polyomaviruses is possible.

Although the mechanisms of huPyV transactivation by heterogeneous viruses *in vivo* are at present not completely understood, the increasing number of HIV-1 patients with active polyomavirus infections argues for a potential role of concomitantly infecting viruses for the activation of polyomavirus infections and the pathogenesis of polyomavirus-associated disease.

Genomic Heterogeneity of Viral Subtypes

Analysis of JCV isolates from all over the world revealed that a large number of JCV subtypes (at present 14) exist. Comparable variations in the BKV and the SV40 genome pointed to a general role of genomic heterogeneity among the polyomaviruses (Dörries, 1997; Knowles, 2001). Throughout the JCV genomes numerous single-base changes were observed and the TCRs exhibit extensive structural differences. Single-base mutations in coding genes do not affect the reading frames and most are silent, having no effect on the amino acid composition of the proteins. In contrast to BKV, JCV DNA does not exhibit sufficient sequence variation to generate different serotypes. Therefore genotypes are exclusively defined by their DNA sequence. The biological significance of the changes remains uncertain. Although the role of the major capsid protein VP1 and its mutations at the receptor binding groove has been intensively studied, the possible involvement of protein alterations in viability or cell specificity of viral subtypes has not yet been clarified.

Of all the viral genes, VP1 shows the greatest degree of variation, whereas the agnogene is the most conserved. The clustering of mutations on the terminal end of VP1 and TAg proteins provides the tool for V-T subtyping of JCV genotypes from different regions of the world. It is used for virus transmission studies and is thought to be a marker for population migration. At present, major V-T genotypes are assigned to different geographic regions by creation of a phylogenetic tree from isolates all over the world. Three separate JCV genotypes 1 were found in individuals of European origin. Type 2, the so-called European/Asian type, was traced in a wide region extending from Europe to western and eastern Asia. Additional types (types 3 and 6) were dominantly found in African states and in Afro-Americans. Type 7 is located in South East Asia and southern China populations. In Asia most territories are dominated by type 2A, which is closely related

to the Japanese types Cy and My. Type 8 is a related clade in the South Pacific region. The relationships among genotypes is still under debate and it can be assumed that the number of true genotypes will increase as more populations are tested for their JCV strains (Agostini *et al.*, 2001).

Changes within the noncoding region of JCV are used for classification of three major TCR subtypes: class I, class II and the archetype. All major JCV variants isolated so far can be grouped into those basic types. The extensive heterogeneity of the JCV TCR gave rise to the hypothesis that the rearrangements might be involved as a virulence factor in the pathogenic process. It was assumed that JCV TCRs may change from a basic persisting subtype in peripheral organs to a virulent virus type growing efficiently in glial cell (Dörries, 1997). The variable TCR elements are constructed of segments with a high degree of sequence conservation that can be deleted or duplicated and rejoined to new units in individual subtypes. The junction between these domains are variable in length and preferentially used as breaking regions thus serving as a source of rearranged sequence pattern. Type I DNA

contains two TATA sequences by inclusion of the TATA box in the repeated element; type II DNA has only one TATA sequence and a 23-bp insertion, which includes a potential enhancer core sequence followed by extensively rearranged repeats. The archetype with a single promoter element and a 66-bp insertion does not exhibit any major repetitions (Figure 34.5).

Genomic comparison of JCV populations revealed that a peripheral archetype virus may invade affected tissue. Duplicated promoter elements may subsequently be generated at activated states of infection. More virulent subtypes may outgrow others in heterogeneous TCR populations, which could be disseminated from the periphery to the brain during persistent infection resulting in the homogeneous populations found in PML tissue. Immune impairment does not play a major role in the induction of rearrangements and it is not cell type dependent. At present, it is rather likely that a number of stable TCR subtypes may develop, which might than be less sensitive to rearrangements than others. Nevertheless, it also remains open whether TCR heterogeneity is a determining factor in virus growth rate or is related to pathogenicity. Along

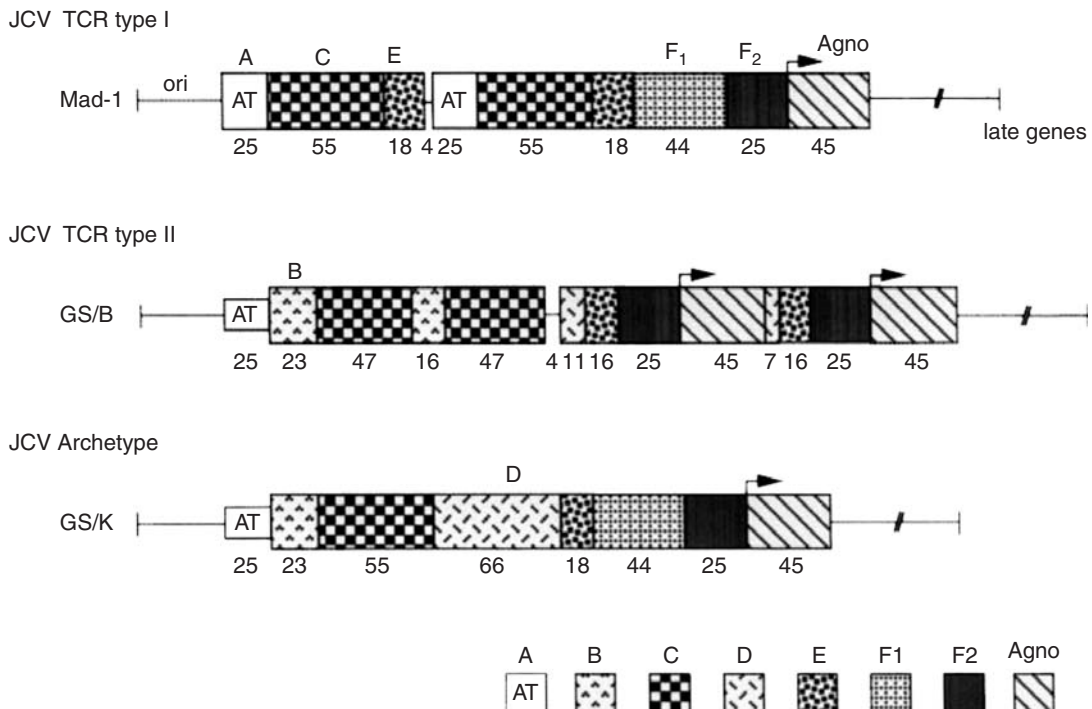

Figure 34.5 Structure of JCV transcriptional control region (TCR) subtypes. JCV TCR subtype I: American JCV prototype Mad-1; TCR subtype II: European JCV prototype GS/B. Archetype: European isolate JCV GS/K. The sequence is divided into seven boxed segments (A, B, C, D, E, F₁, F₂) differing in number and/or length. A represents the TATA box. The initiation codon for the putative agnogene is indicated by an arrow. Segment length is given in base pairs; AT, TATA box; Ori, origin of DNA replication.

these lines, in some PML patients the European/American genotype 2 was found in combination with PML type TCRs. In consequence, it was asked whether a specific genotype might constitute a pathogenic strain. However, genotype 1 and 2 can be linked to both archetypal and PML-type TCR elements in patients with PML and persistently infected individuals. Since geographic clustering of JCV TCR type II genomes cannot be excluded, it has to be further evaluated whether a specific type of JCV genotype/TCR subtype combination is dominantly associated with PML (Agostini et al., 2001; Elsner and Dörries, 1998).

Heterogeneity of BKV genomes with diverging sequences in coding regions and the TCR were regularly described. A number of different isolates and serological groups corresponding to BKV genotypes were detected. Nucleotide substitutions responsible for antigenic diversity are located in the N-terminal quarter with the BC1 and BC2 loops of the VP1 major capsid protein with changes in the amino acid sequence and potential implications for the secondary and tertiary structure of the protein. At present, BKV isolates are classified into four subtypes by genotyping and serological methods (Knowles, 2001). Subtype I is the most prevalent subtype. Based on DNA sequence mutations it has been further classified into four subgroups, assigned geographically to Africa, South East Asia, north-eastern Asia and Europe. It is thought that BKV prototype I probably emerged in Africa and might then have diverged into subgroups with population spread to other continents. Similarly, other BKV subtypes can be divided in a variable number of subgroups that can be associated with different geographic regions. Whether this is due to population isolation or to genetic drift is not yet clear. A number of attempts to associate BKV subtypes with clinical conditions or a particular group of patients remains debatable.

The TCR has been sequenced in a large number of BKV isolates. Comparable to the JCV promoter, the BKV archetype mediates the interaction with a large number of cellular transcription factors. TCR genetic variations among naturally occurring BKV isolates are due to point mutations, duplications, deletion and rearrangements of TCR regions. Changes in the biological activity of TCR variants from diseased and healthy individuals have been described, but an unquestionable association of certain TCR variants with BKV-associated diseases has not been found. The organ in which severe rearrangements may occur has not yet been defined, but a higher variability of genomic diversity appears to rise in the background of progressive disease, linking changes to higher activity of replication and its activating factors rather than to an organ-specific function. BKV and JCV have in common that the biological role of the genetic diversity of subtypes

as well as that of the heterogeneous TCRs is not yet fully understood (Cubitt, 2006).

STATE OF HUMAN POLYOMAVIRUS INFECTION

Primary Infection

Primary contact with the human polyomaviruses is generally asymptomatic. It usually occurs during childhood or early in adulthood, leading to lifelong infection in the immunocompetent host. Viruses normally undergo an initial replication cycle in cells proximal to the site of entry and prior to viraemia. The route of infection has not yet been defined, although BKV seroconversion has been associated with tonsillitis, upper respiratory tract disease, mild pyrexia and transient cystitis. Investigation of nasopharyngeal aspirates and saliva by polymerase chain reaction (PCR) occasionally demonstrates the presence of BKV DNA, but subsequent virus isolation is often unsuccessful. In contrast, urinary excretion is observed at high levels in young children early in infection. This was supported by studies on sewage in regions all over the world, revealing that human polyomaviruses are distributed to fresh waters. BKV and JCV DNA at high concentrations suggested not only urine but also human excrement as a source of viral excretion. The finding of BKV in stool and rectal swabs of young children confirmed that BKV in the gastrointestinal tract could also be a source of BKV exposure and the high frequency of transmission early in childhood.

BKV-specific IgM antibody in umbilical cord blood or in the sera of children less than two weeks of age suggests prenatal infection. This was supported by PCR detection of BKV DNA in maternal and fetal tissue. In addition, BKV DNA in male and female genital tissue on a background of a low prevalence of JCV DNA pointed to a possible sexual transmission. Family studies of BKV subtype distribution have revealed that BKV transmission is common outside the family. This is in contrast to JCV and suggests a higher transmission efficiency of BKV. In addition it almost excludes vertical transmission as a general mode of BKV transmission. Matching molecular fingerprints in both the donor and transplant recipient additionally confirmed the kidney as a source for post-transplant infection. At present the alimentary tract is proposed as the more likely port of entry (Figure 34.6).

Despite the knowledge that JCV infection is widespread in the population, almost nothing is known about how JCV is transmitted in humans. Urinary excretion is a common event, although direct infection of B lymphocytes and tonsillar stroma favours the respiratory tract. However, quantitative analysis of JCV

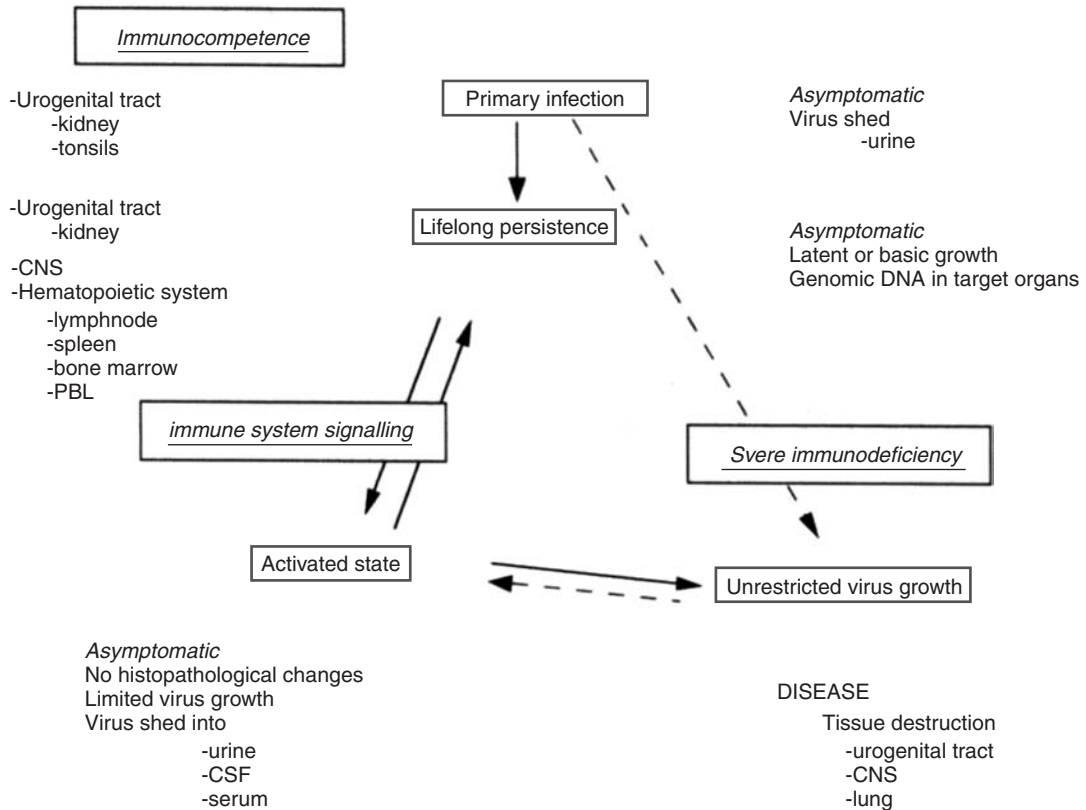

Figure 34.6 Course of human polyomavirus infection.

in saliva and oropharyngeal fluid showed that JCV DNA is only rarely present. This makes saliva and oropharyngeal fluid an unlikely source of transmission during latency. So far there is no evidence for JCV infection of the fetus. JCV-specific IgM antibodies were not detected in the cord blood of infants whose mothers had a rise of anti-JCV haemagglutination inhibition antibody titres during pregnancy. Detection of JCV in the colon suggested the lower gastrointestinal tract as a possible entry site. JCV is also distributed to fresh water by faecal contamination. Genomic typing of urinary strains in Japanese families revealed transmission within families and outside the family group. Since children have many opportunities to come into contact with urinary JCV infection, it is likely that urinary excretion is a prominent source of JCV in the human population (Berger *et al.*, 2006; Knowles, 2006).

Persistent Infection

The discovery of BKV came from the observation of cytological abnormalities in the urinary sediment of a kidney

transplant patient. Later studies revealed that BKV is an urotheliotropic virus affecting the epithelia of the renal calyces, renal pelvis, ureter and urinary bladder. It can be detected in about 20% of randomly selected autopsy samples. Analyses of prostate biopsies revealed virus infection of glandular epithelium in 60% of asymptomatic tissue, comparable to the rate of infection in the bladder. Sperm gave an incidence of 95% and cervix and vulvar tissue an incidence of 70%. In contrast, glandular tissue was free of JCV virus and in sperm 21% of the samples were positive for JCV DNA. Recently, BKV as well as JCV were detected in ocular tissue. The high rate of viral DNA in asymptomatic tissue and semen suggests that these sites might be involved in polyomavirus persistence (Berger *et al.*, 2006; Knowles, 2006).

JCV was first detected in the urinary tract of immunosuppressed individuals and pregnant women. PCR analysis suggested that the number of affected individuals closely parallels the percentage of people with serological evidence of contact with JCV. Thus the kidney is one

site of JCV infection. JCV DNA was detected more often in kidney tissue, renal pelvis and ureter than BKV, whereas BKV was predominantly located in urinary bladder samples. This characterized the renal tract as a site of persistence. The higher detection frequency in the renal medulla indicates that epithelial cells lining collective tubules are the major targets and more often subject to activation processes than other cells in the renal tract. JCV is also frequently present in the upper and lower intestinal tract, infecting the oesophageal and gastric mucosa at 76–100% normal biopsies. This demonstrates that the virus is highly prevalent in the human upper and lower gastrointestinal tract representing a new site of JCV persistence.

The dissemination of the human polyomaviruses to a wide range of organs led to the hypothesis of a possible haematogeneous spread in the host. This was supported by an early report on polyomavirus particles in lymphocytes of immunocompetent children and induced studies on a general role of lymphoid cells in the establishment of polyomavirus persistence. In tonsils BKV DNA was associated with the lymphoid tissue of Waldayer's ring, indicating involvement of lymphocytes in polyomavirus infection. Lymphoid interaction of BKV was further supported by a stimulatory effect of virus infection on human lymphocytes in cell culture, and the demonstration of specific BKV receptors on the surface of peripheral blood cells. Interestingly, only a small number of cells carried receptors for BKV. They were discussed as B lymphocytes. Nevertheless, virus protein expression was restricted to less than 1% of the cells, pointing to an attenuated replication in lymphocytes. Although the virus is able to attach and penetrate into monocytes, expression remained negative. However, the treatment of monocyte cultures with BKV antisera was followed by antibody-dependent enhancement of virus replication. Therefore it is conceivable that circulating monocytes or tissue resident macrophages in the normal individual might be permissive for polyomavirus infection.

The presence of full-length BKV DNA in leukocytes of persistently infected individuals confirmed the involvement of BKV in peripheral blood infection (Dörries, 1997). A large body of analyses has been performed, concentrating on the search for virus DNA in peripheral blood mononuclear cells (PBMCs) by PCR. The results have been highly variable, giving incidences of no presence of BKV DNA in 60% of bone marrow transplantation (BMT) patients, none in between 10% and 100% of HIV-1 patients and no virus in a group of systemic lupus erythematosus (SLE) patients. Similarly, presence of BKV DNA in 53–94% of healthy individuals contrasted a finding of no virus DNA, respectively. These discrepancies might be due to geographical localization, group selection and

technical differences, however, the amount of BKV DNA was estimated to be low, compared with that of JCV in PBMCs. Taken together, there is a body of evidence for a regular lymphotropism of BKV in the host.

Haematogeneous spread of JCV to the CNS in PML was suspected in early reports because of the multifocal distribution of JCV foci in PML. Occasional involvement of spleen and lymph node led to the assumption that lymphoid cells might also be involved in virus spread. This was confirmed by demonstrating JCV DNA and capsid protein in a small number of B lymphocytes in bone marrow and spleen of patients with HIV/PML. CD4/CD8⁺ T lymphocytes were not affected. The presence of JCV-infected PBMCs in perivascular parenchyma and in Virchow—Robin spaces further supported the haematogeneous route of entry into the brain for JCV. Although JCV DNA could not be detected in the spleen of patients with HIV-1 and controls, the detection rate of 40% in patients with PML suggests that virus DNA may accumulate in lymphoid organs. The thesis of lymphocytes as a reservoir and a vector for dissemination of JCV closed a gap in our understanding of viral pathogenesis. The role of JCV infection in lymphoid cells was further clarified by the detection of tonsillar B lymphocytes and tonsillar stroma cells as host cells for JCV infection. Cultivation of tonsillar cells followed by demonstration of JCV DNA established the susceptibility of tonsillar cells. These findings strongly not only suggest the involvement of the tonsils in primary infection but also argue for a persistent polyomavirus infection in tonsillar cell types.

The role of lymphoid cells in JCV persistence and pathogenesis was studied more intensively by asking whether JCV DNA is present in circulating peripheral blood cells in patients who are immunocompromised. The infection rates in peripheral lymphocytes of patients with PML were the highest at about 30–100%, irrespective of the underlying disease, the affected cell type, the number of infected cells or the virus load. This pointed to a regular involvement of lymphoid cells in the disease process. The rate of positive cells in risk group patients without evidence of PML was between 10 and 60%. Detection of JCV DNA in PBMCs of healthy people at similar rates demonstrated that replication leading to the detection of JCV DNA in PBMC is independent of the type of immune impairment. *In situ* hybridization added further support to the idea that the human polyomaviruses are regularly associated with PBMCs. In most PBMC samples the concentration of virus-specific DNA was estimated in the range of less than 1 genome equivalent in 20 cells (Dörries, 2006).

Further attempts to characterize virus—cell interaction addressed the question for the cellular target of JCV in

lymphoid tissue or peripheral blood. PCR analyses suggested that JCV was not associated with B cells and haematopoietic precursor cells alone. It became clear that unsorted blood cells from a normal individual might be negative for JCV, whereas sorted populations from the same patient amplified JCV DNA. This corresponds to a low virus load in PBMCs. JCV DNA could be detected by PCR in B and T lymphocyte populations, in granulocytes, in monocytes or in all cell types of a given blood sample. However, the most prominent cell population affected was the granulocyte. A cell type that may not only be specifically associated with JCV infection, but is also involved in phagocytosis. The susceptibility of haematopoietic precursor cells for virus infection was mediated by enhanced expression of the transcription protein nuclear binding factor NF-1. The expression of high levels of JCV receptor molecules on B cells and a low level replication of JCV in human B lymphocytes *in vitro* additionally suggested the involvement of those cell types in natural JCV infection. Investigations on JCV expression in haematopoietic cells suggests a preferential latent state of virus infection in PBMCs that might be activated by immune modulatory events in PML. Clearly, more experiments are necessary to understand the role of JCV DNA in PBMCs for viral persistence and possible consequences for the disease process. Although the suggestion that haematopoietic cells form a reservoir for the virion in the diseased brain might be questionable, it is conceivable that JCV-infected lymphoid cells may act as a vector for JCV CNS invasion and dissemination during persistent infection.

The pathogenic question, whether PML results from cytolytic invasion of the CNS under severe immunosuppression or as a consequence of a preceding persistent infection, remains controversial (Dörries *et al.*, 2003; Eash *et al.*, 2004). Although JCV can easily be demonstrated in disseminated areas of PML autopsy material, in non-PML adults JCV DNA sequences were rarely detected. JCV obviously has no topographical preference, because dissemination patterns are comparable to those in PML. JCV DNA molecules in brain tissue were exclusively episomal. The amount of virus-specific DNA in asymptomatic individuals was in an estimated range of 1–100 genome equivalents per 20 cells or lower, thus confirming that it is restricted to isolated cells and most likely represents chronic infection and not the early stages of disease.

BKV-associated CNS disease (Vallbracht *et al.*, 1993) demonstrates that BKV replicates occasionally in the CNS. Attempts to detect BKV in asymptomatic brain tissue in different groups of patients often were not successful. Although considerably less frequent than JCV, isolation of full-length BKV genomes from CNS tissue and sequencing of new genomic BKV DNA subtypes was

in line with a persistent type of BKV infection in the CNS (Elsner and Dörries, 1998; White *et al.*, 1992).

The findings prove that human peripheral polyomavirus infection is associated with subclinical virus entry into the CNS, probably long before the development of clinically overt PML. Although the cell type or types targeted by the virus are not yet characterized, productive *in vitro* JCV replication in microvascular endothelial cells indicates that JCV may also infect endothelial cells, thereby crossing the blood—brain barrier (Chapagain *et al.*, 2007). Irrespective of the route, virus activation during persistence may lead to an increased number of infected cells and a higher detection frequency in cases of severe immunosuppression. This being in line with the assumption that impairment of immune competence favours involvement of the CNS in polyomavirus infection.

Concomitant JCV and BKV Infection

Double infection of JCV and BKV was established after organ transplantation in HIV-1 infected patients, in pregnancy and in immunocompetent individuals by urinary excretion or antibody rise against both viruses. Molecular detection of JCV- and BKV-specific DNA confirmed that concomitant persistence frequently occurs in kidney tissue. Extensive homologies of the genomic structure, similarities of virus spread and state of infection very early started the discussion on possible other sites of dual JCV and BKV infection. After PBMCs were found to be a target of polyomavirus infection, the presence of JCV and BKV DNA in blood cells of the same individual was not surprising. Concomitant infection was evidenced molecularly in healthy and immunosuppressed individuals. Although BKV was not expected to invade the CNS at a high rate, the cell specificity of BKV is less stringent than that of JCV, therefore several laboratories investigated dual infection in the CNS. Cloning from CNS gene libraries and PCR revealed frequent BKV dissemination to the brain. Indirectly, BKV infection of the human CNS was confirmed by the report of a subacute BKV-associated meningoencephalitis in a patient with AIDS. The physical state and genetic complexity of BKV genomes was comparable with that of JCV DNA, however, the low concentration of brain-derived BKV-specific PCR products suggests a considerably lower activity of BKV in the CNS than that of JCV. This gives strong evidence for concomitant polyomavirus infection in the CNS and demonstrates that not only JCV but also BKV is neurotropic in the human host.

Asymptomatic Activation of Infection

Transient polyomavirus viraemia probably occurs at the time of primary infection; however, in most instances

the presence of virus in the urine is due to activation processes. JCV DNA was detected in the urine of about 30% of American and 60% of Japanese and European non-immunocompetent individuals. Incidence of excretion was dependent on age, with lower rates in the young, gradually increasing in older age. Although BKV shedding is frequently lower than that of JCV, BKV follows the early peak of primary infection in early childhood with a higher incidence of viruria. Viruria declines until the third decade of life and then increases gradually with age reaching 44% as the highest level in the ninth decade. In contrast, JCV reaches more than 70% in the same age group. Pregnancy is among the most common conditions that have been linked to viral activation. Incidence of viruria as detected by periodic cytological examination was about 3–7% in case of JCV, and up to 54% in case of BKV. The onset of viruria was late in the second trimester and during the third trimester of pregnancy. In excretors, once it was established virus shedding continued intermittently to term and then ceased in the post-partum period. The detection rates parallel high or rising antibody titres in a comparable study population, and therefore probably represent the true rate of activated persistent infections. Renal transplant recipients experienced viruria at a considerably higher rate. Duration periods may last over month to even years. In bone marrow transplant recipients most viruria was due to BKV with an incidence of up to 87% in the post-transplant period. Although these findings point to a significant role of the immune state for the level of polyomavirus expression in the kidney, an enhancement of urinary excretion by HIV-1-induced immunosuppression was not detectable. Similarly, PML patients do not necessarily have concomitant JCV viruria. Aggressive chemotherapy does not increase virus frequency, and in other immunosuppressive diseases viruria can be intermittent with sparsely distributed infected cells in cytological positive urine, similarly pointing to a rather low rate of virus production. Because of the high frequency of JCV and BKV excretion throughout adulthood, the authors suggest that JCV infection regularly may not be in a latent but in a productive persistent state. Since most data were accumulated by less sensitive methods, it is conceivable that virus expression is permanently maintained at a basic level (Dörries, 2006; Zhong *et al.*, 2007).

Activation at other sites of persistent infection is less intensively examined. This is due to reduced virus expression in asymptomatic transient activation states and the low virus load in persistently infected healthy individuals. In patients with HIV/PML mononuclear cells in PML tissue have been characterized expressing JCV-specific proteins. Thus it appears likely that a JCV infection in PBMCs is activated under as yet unknown circumstances. Besides the close association of viral DNA with PBCs,

circulating JCV DNA was detected in cell-free plasma. The rate of viraemia varied from no virus present to 4% in patients with SLE or control groups including healthy individuals. Virus load is in the range of 5×10^2 copies per μg DNA. In transplant patients between 0 and 28% of individuals had JCV viraemia alone. The virus load was in the range of $10^3 - 10^4$ genomes per ml serum. In HIV-1-infected patients rates from 4 to 23% were reported. Although no correlation with immunodeficiency could be calculated, the incidence of detection appeared to be slightly higher in patients with PML. Often the presence of JCV DNA in PBCs and free circulating virus was not correlated, suggesting that either JCV-carrying cells are quickly eliminated or there is source for JCV in plasma other than infected PBCs (Dörries, 2006).

Free circulating BKV is routinely detected in patients with BKV-associated diseases; in healthy individuals viraemia was reported in up to 27.6%. Viraemia does not normally exceed a virus load of about 10^2 viral genome copies per ml in individuals without BKV disease. In contrast, detection rates in prospective studies of renal transplant recipients were reported to be up to 75%, the viral load was considerably higher, ranging from 10^3 to 10^6 viral genome copies per ml and detection of BKV in plasma closely follows the detection in urine. In addition, BKV load decreased not only in urine but also in plasma after successful therapy. This indicates that activated BKV infection in the kidney is related to virus load in plasma and may therefore contribute to the circulating virus load (Hirsch *et al.*, 2005).

The increasing incidence of JCV DNA in brain tissue with age and in patients with malignancies point to viral activation in the CNS. The detection of virus-specific protein in a limited number of glial cells in non-PML brain and PCR amplification of JCV DNA in the cerebrospinal fluid (CSF) of the same patient group similarly points to asymptomatic JCV activation in persistently infected brain tissue. JCV DNA was detected in the CSF in immunocompetent individuals with different neurological symptoms and/or patients with HIV-1 infection with highly divergent results (0.22–100%). Nevertheless, in the high-risk groups active infection appears to be more frequent than in immunocompetent individuals. Although an influence of the immunosuppressive state as defined by the $\text{CD4}^+/\text{CD8}^+$ T lymphocyte ratio in AIDS patients was not found, the role of immune modulatory mechanisms for JCV activation became clear when JCV DNA was detected at varying rates in patients with multiple sclerosis or those receiving different immunomodulatory or anti-inflammatory therapies. Although the amount of virus-specific DNA is considerably lower in persistent

CNS infection, it is similarly distributed as typically described in PML tissue. This is in line with rare and transient activation events. In addition, replication is probably severely restricted and thus remains limited to few isolated cells. In cases of extensive immuno-impairment, however, it is likely that virus activation leads to an increasing number of infected cells. Whether a lifelong accumulation of JCV in the CNS might eventually contribute to uncontrolled cytolytic virus growth and PML can probably only be answered in an appropriate animal model (Dörries, 2006).

BKV DNA in the CSF was first detected in immunosuppressed patients with BKV-associated CNS disease (Vallbracht *et al.*, 1993). Consequently, the presence of BKV in CSF is similarly indicative for an active BKV infection as it is in case of JCV infections. Studies on patients with PML occasionally reveal the presence of BKV DNA in CSF, pointing to a possible persistence and asymptomatic activation of BKV in the CNS. Although co-infection of both polyomaviruses is widely accepted, it can be anticipated that BKV dissemination to the CNS and shedding to the CSF is generally a rare event.

If the current knowledge is summarized, it must be assumed that activation of BKV and JCV infection is species-specific and as a result of immune system alterations induced by pregnancy, older age, malignant tumour growth or AIDS. Some of those individuals may undergo sporadic activation as a consequence of their genotypes or of incidental transactivation events by other viruses. In general, however, virus growth appears to be dependent on the impairment of immunological control resulting in a differentially regulated activation pattern in target organs. Although related mechanisms are so far unknown, the higher frequency of deficiencies correlated with T-cell function in patients with PML confirms deficient cellular immunity as a major virulence factor.

Polyomavirus-associated Diseases

Activation of huPyV infection may either represent transient asymptomatic events or pathological processes. The induction of fatal disorders, however, is almost exclusively observed under long-lasting severe impairment of the immune system and immunomodulatory therapies increase the incidence of polyomavirus-associated disease, thereby confirming a close relationship of virus growth and immunomodulation. BKV is a urotheliotropic virus almost exclusively linked to urogenital tract diseases. Mild courses are reported in primary BKV infection, whereas BKV disease is associated with persistent BKV infection. Virus-associated pathogenic effects are observed in polyomavirus-associated nephropathy (PVAN)

and ureteral stenosis as complications of renal transplantation, as well as in haemorrhagic cystitis after BMT and human stem cell transplantation (HSCT) (Table 34.2).

Haemorrhagic cystitis is a late-onset complication and a common cause of prolonged hospitalization, morbidity and occasional mortality in patients undergoing bone marrow or HSCT. Recipients of autologous tissue are at a particular risk. Its incidence varies from 7 to 68% of BMT cases. The pathogenesis of post-engraftment haemorrhagic cystitis includes a large number of risk factors, with the activation of BKV infection being the most common and consistent risk factor. It is characterized by painful haematuria due to haemorrhagic inflammation of the urinary bladder mucosa resulting in damage to the bladder epithelium and blood vessels. The manifestations vary from microscopic haematuria to severe bladder haemorrhage. Haemorrhagic cystitis is divided into four categories according to severity of haematuria from grade 1 to grade 4. In most cases haemorrhagic cystitis resolves spontaneously, but in some cases BKV excretion may continue, followed by severe manifestation of haemorrhagic cystitis until death from extensive chronic graft-versus-host disease (GVHD).

The association of BKV with haemorrhagic cystitis is not only determined by the large amounts of virus ($>10^{12}$ copies per ml of urine) but also by the pattern of viruria. Two patterns of excretion can be observed. In about 50% of patients BK viruria occurred at about two to three weeks post transplantation. Interestingly, in this group all patients with haemorrhagic cystitis had a peaking of BKV viruria (more than 3-log increase over baseline level), which invariably preceded the onset of haematuria by a median of 29 days. Moreover at the time of haematuria, BKV viruria was already on the decline or had reached basic levels. In a second pattern, a persistent low level BK viruria without peaking occurred and in this group none developed haemorrhagic cystitis. Whether BK viraemia is associated with the risk of developing haemorrhagic cystitis and can be used as a second disease marker remains disputable. Recently, elevated pretransplant BKV-specific antibody titres of the recipient were reported as an additional discriminating factor for haemorrhagic cystitis (Wong *et al.*, 2007). The definition of risk factors in addition to serial quantification of BKV urinary load is an important aim for the development of early antiviral therapeutic strategies.

The emergence of PVAN during the last decade is well documented by the increase of prevalence rates from 1% in 1995 to about 8% in 2003. The majority of cases occur within the first year after renal transplantation, but approximately a quarter of cases are diagnosed later. Allograft loss due to PVAN ranges from 10% to >80% of cases, but may be lower in centres with active screening

Table 34.2 Human polyomavirus-associated diseases

Patients	JCV infection		BKV infection	
	Disease	Cell type involved	Disease	Cell type involved
Immunocompetent	None observed		Mild respiratory disease Mild pyrexia Transient cystitis	
Immunocompromised Urogenital system	Nephropathy	Tubular interstitial cells	Nephropathy (PVAN) Ureteral stenosis Haemorrhagic cystitis	Epithelial cells Fibrocytes Bladder epithelial cells
Lung	None observed		Interstitial pneumonitis	Epithelial cells Pneumocytes Endothelial cells Fibrocytes
CNS	Progressive multifocal leukoencephalopathy (PML)	Oligodendrocytes Astrocytes Rare inflammatory infiltrates	Subacute meningoencephalitis	Epithelial cells Fibrocytes Endothelial cells Astrocytes
	Immune reconstitution inflammatory syndrome (IRIS)	Same as in PML and pronounced inflammatory infiltrates		Ependymal cells Peripheral blood mononuclear cells
	Granule cell neuropathy (GCN)	Granule neurons		
	Meningitis	Cell type not defined		
	Meningoencephalitis	Cell type not defined		

and intervention programmes. Molecular studies indicate that most of the cases of PVAN are caused by BKV. Only in less than 3% of cases JCV has been detected. Clinical features may mimic graft rejection or drug toxicity, but histopathological examination almost always demonstrate BKV infection. BKV-associated pathologic lesions have a characteristic appearance with streaky fibrosis of the renal medulla and circumscribed cortical scars. Microscopically, sclerosed glomeruli, atrophic and necrotic tubules and interstitial fibrosis associated with mononuclear cell infiltration can be observed. Fibrocytes and tubule cells are often enlarged with intranuclear BKV inclusions extruding from the epithelial layer into tubular lumen causing marked denudation of basement membranes. Polyomavirus-induced tubular injury is viewed as a major morphological correlate for allograft dysfunction. The pathogenesis of PVAN involves the interaction of multiple risk factors. Intense immunosuppression is perceived as a major risk factor. With few exceptions, PVAN has been diagnosed in patients receiving a maintenance ther-

apy consisting of three of four drug classes (calcineurin inhibitors, antimetabolites, mTOR inhibitors and corticosteroids). The majority of patients received combinations containing tacrolimus or mycophenolate mofetil (MMF), which were used concurrently in >50% of the cases. An increased risk for BKV replication and PVAN has been reported for tacrolimus—MMF—corticosteroid combinations (Hirsch *et al.*, 2006; Roskopf *et al.*, 2006).

Strong evidence for BKV-induced systemic and CNS disease originally came from patients with AIDS. Histopathological evaluation revealed an association of BKV with affected lung, kidney, and CNS tissue. The major pathological findings were tubulointerstitial nephropathy, interstitial desquamative pneumonitis and subacute meningoencephalitis. In the kidney, alterations principally consisted of focally accentuated tubular necroses. Virus was detected in epithelial cells along the entire nephron. Alterations in the lung were characterized by intra-alveolar aggregates of desquamated pneumocytes with virus in exfoliated pneumocytes, in epithelial and

in smooth muscle cells of the bronchioli. Occasionally, isolated endothelial cells in the lung carried virus protein. A common feature in both organs was focal interstitial fibrosis with a mild inflammatory response. Whereas fibrocytes were infected, inflammatory cells were free of virus products (Vallbracht *et al.*, 1993).

In the CNS no pathological changes apart from mild inner atrophy were described. Mononuclear cells indicating chronic inflammation loosely infiltrated thickened fibrotic leptomeninges. In cortex and adjoining white matter oedematous tissue alterations were found. Reactive astrocytes were localized in the outer layers of the cerebral cortex. The ventricular system exhibited focal degeneration of its ependyma and spongiform destruction of subjacent brain tissue. The choroid plexus disclosed fibrosis of stroma and atypical epithelial cells. In some areas necrosis and exfoliation of the plexus epithelium occurred. Small infiltrates were seen in association with the lesions. The dominant target cells of BKV infection were fibroblasts of the loose reticular connective tissue, endothelial and smooth muscle cells of blood vessels, astrocytes and infiltrating macrophages in pons and medulla oblongata. Epithelial cells in the choroid plexus and astrocytes of the subependymal brain tissue were additionally infected. The only glial cell type involved in BKV-associated CNS disease was the astrocyte, whereas oligodendrocytes and nerve cells were not affected. The detection of a BKV-associated disease affecting kidney, lung and the CNS is in line with the involvement of those organs in BKV persistence.

In contrast to BKV, JCV was never observed as an aetiological agent in urogenital tract or lung disease. The only and most prominent disease associated with JCV is the CNS disorder PML (Berger and Major, 1999). Although SV40 was described as the cause of PML in three American and Japanese patients, it later became clear that most probably JCV was the only agent responsible for the disease. PML is a demyelinating disorder occurring as a late complication of pre-existing systemic diseases that impair immunological competence. Several years of treatment precede PML in diseases such as systemic rheumatic diseases, lupus erythematosus, chronic asthma, sarcoidosis and chronic polymyositis. The use of more potent immunomodulatory and immunosuppressive therapies adds to risk of increasing numbers of PML cases in as yet unrelated basic disorders. Before the AIDS era malignant proliferative diseases were the dominant basic disorders in PML in about half of the cases. In HIV-1-infected patients a steadily increasing number of cases was associated with AIDS prior to the introduction of highly active antiretroviral therapy (HAART). Although longer PML survival times can be observed under HAART, the rate of PML patients remains stable at about 5% of patients with AIDS.

Table 34.3 Causes of JCV activation and induction of PML prior to the AIDS epidemic and immunomodulatory therapies

Conditions associated with activation of persistent infection	PML (% of cases ^a except AIDS)
Age	None
Pregnancy	None
Inflammation	None
Transplantation	Rare
Diabetes	Rare
Lymphoproliferative disease	62.2
Myeloproliferative disease	6.5
Carcinomatous disease	2.2
Immune deficiency states	16.1
Granulomatous/inflammatory disease	7.4

In addition, a higher frequency of PML can be observed in correlation with immunomodulatory therapies and is probably due to higher JCV activation rates (Table 34.3).

The onset of classic PML is often insidious. In the earliest manifestation multiple pinhead-sized demyelinating lesions are described beneath the cortical ribbon. New small foci are continuously added in neighbouring tissue as the growth centres of new lesions. This concept of the histologic evolution of the disease is supported by the clinical evolution: the onset might be gradual, but each new functional impairment becomes progressively more severe. Once clinical signs appear, the disease usually progresses steadily. Early neurologic symptoms regularly indicate multiple disseminated lesions in the brain. Extent and topography of lesions correlate well with duration and symptomatology of the illness (Table 34.4).

The pathognomonic feature of the disease is the striking alteration of oligodendrocytes with eosinophilic inclusion bodies in the peripheral rim surrounding the zone of myelin loss. The central area is composed of reactive astrocytes including giant cells in mitosis and astrocytes resembling malignant cells of pleomorphic glioblastomas. The basic cause of tissue destruction is a cytolytic JCV infection of the oligodendrocyte resulting in loss of myelin, tissue breakdown and impairment of brain function. Studies on the mechanisms involved revealed the absence of apoptosis-related changes in the nuclei of oligodendrocytes in areas adjacent to virus particles. The lack of apoptotic markers in PML suggested non-apoptotic cell death and necrosis as the major mechanism of oligodendrocyte lytic destruction. Recently, it was detected that expression of the normally dormant anti-apoptotic protein survivin is induced by JCV infection, probably leading to

Table 34.4 Development of PML lesions

<i>I Early lesion</i>
Altered oligodendrocytes in areas of demyelination
Nuclei enlarged (2–3×)
Regular chromatin pattern is lost
Nuclei tint deeply with basophilic dyes
Irregular basophilic nucleic inclusions
Seldomly activated pleomorphic microglia
Pinhead size (mm) lined up the cortical ribbon
<i>II Aging lesion</i>
Reduced number of altered oligodendrocytes in the centre of demyelination
Shrinkage of nuclei at the rim of lesions
Widely distributed larger foci with coherent tissue
<i>III Late lesion</i>
Altered oligodendrocytes at the peripheral advancing zone surrounding the area of myelin loss
In the centre
Very sparse or absent oligodendrocytes
Singly scattered reactive hypertrophic astrocytes
Giant astrocytes in mitosis
Astrocytes resembling cells in pleomorphic glioblastomas
Forming irregular necrotic patches (cm)

inhibition of apoptosis during JCV infection. As a consequence, increased survival of JCV-infected glial cells would also increase the risk of rapid disease progress, whereas release could be through necrosis or lysis of cells (Seth *et al.*, 2004). Viral expression products and virions are found in nuclei and cytoplasm of the oligodendrocytes. Bizarre astrocytes may contain JCV; however, it appears likely that astrocytes represent a semi-permissive cell type mediating reduced JCV expression or, alternatively, being sensitive to virus transformation.

In contrast to classic PML, in patients with AIDS fronto-parietal and grey matter involvement increased. However, there are cases reported with only one lesion present. An inflammatory reaction with perivascular mononuclear cell infiltrates is often observed. Mononuclear cells in the Virchow—Robin spaces occasionally contain JCV-specific DNA and capsid antigen, and in the subcortical white matter adjacent to blood vessels the density of infected cells appears to be increased. JCV-infected cells have also been detected beneath the ependymal layer. This indicates a close topographical association between the infected cells and the ventricular system (Mazlo *et al.*, 2001).

The duration of disease after the onset of neurological symptoms is reported to be on average four to six months (Berger and Major, 1999). However, there have been cases of more than 12 months, with an intermit-

tently progressive or subclinical course over more than years. Those cases are more often found in combination with HIV-1 infection under HAART therapy. Since the introduction of HAART the definition of HIV/PML cases has had to be adapted to reflect changes in the disease pattern probably resulting from HAART-induced immune reconstitution in about one half of the patients. For these groups a new terminology is proposed for disease outcome. It is based on diagnostic criteria for definite, probable and possible PML with a definition of PML outcome based on disease activity. Disease progression can be classified as 'active' or 'inactive' based on clinical, radiological, virological and pathological criteria. Patients in 'active PML' have a high diagnostic evidence of disease activity throughout the course of the illness over a few months. Patients with 'inactive PML' lack evidence for disease activity. Stabilization may occur at any time of disease progression. Usually it occurs in a few months after first diagnosis and there is virtually no progression over years of follow-up even following withdrawal of HAART (Cinque *et al.*, 2003).

Although HAART influences the outcome of PML often positively, there are cases described of new onset or clinical worsening of PML shortly after initiation of HAART. This occurs in a setting of recovery of the immune control as described by increase of CD4⁺ T cells and decrease of HIV-1 viral load. It is usually associated with an inflammatory reaction in brain lesions and has been called immune reconstitution inflammatory syndrome (IRIS). Usually the resolution of the inflammatory phase results in clinically improvement. Another syndrome, JCV granule cell neuronopathy (GCN), is distinct from PML. In an HIV-1-infected patient JCV caused a lytic infection of cerebellar granule cell neurons associated with cerebellar symptoms. Furthermore, a case of JCV meningitis and a meningoencephalitis occurred in patients with systemic lupus erythematosus and an immunocompetent girl (Koralnik, 2006). These cases demonstrate that new courses of persistent and activated JCV infection can be expected and only the use of standardized terminology in the description of clinical and biological studies will allow us to understand the mechanisms of pathogenesis and therapeutic intervention.

Oncogenicity of the Human Polyomavirus

Cancer is thought to progress through multiple stages and with each step cells with increasing malignant phenotype may arise. Progression can be driven by mutations in tumour suppressor genes or oncogenes; it can also be dependent on newly acquired transforming proteins. These genes encode proteins regulating genome stability, cell cycle proliferation or apoptosis. The polyomaviruses with the large TAg provide a prototype of viral oncogenes.

The first 121 amino acids are the shortest fragment to induce transformation. Here TAg interferes with two key tumour suppressor proteins that regulate cell cycle progression, pRB and p53. Activation leads to elevated steady state levels of p53 ending in a block of the cell cycle, and inactivation of pRB family members promotes proliferation. In addition, p53 protection against DNA damage by inhibiting cell cycle progression and apoptosis activity is prevented. Binding to β -catenin and its translocation to the nucleus enhances expression of genes such as c-myc and cyclin D1 involved in promotion of the cell cycle. JCV TAg also binds to insulin receptor substrate 1 (IRS-1), inducing its translocation to the nucleus. This interferes with Rad51-dependent DNA repair and appears to be involved in the activation of the apoptosis inhibitor survivin. JCV attempts to prevent cells from apoptosis by activating the survivin pathway and this has been demonstrated not only in clinical samples from PML but also in glioma cell lines. Alternative splice variants of JCV TAg yielding truncated proteins have been shown to interact differentially with proteins of the retinoblastoma family, thereby possibly contributing to cell transformation. Small tAg is probably not essential for the viral life cycle, however, it is likely that tAg is an oncoprotein that stimulates multiple growth-promoting pathways. It binds to the negative regulator protein phosphatase 2A (PP2A), a key regulator with multiple functions in cellular signalling including cell cycle progression and transformation, and tAg is associated with the molecular chaperone CDC37 which functions in G₁/S cell cycle transition and activation of the Ras-MAPK pathway. The late leader protein agnogene may have profound effects on the virus—cell interaction in the absence of other viral proteins. This includes dysregulation of cell cycle progression, irregular response of the cells to DNA damage, increased chromosome damage and impaired DNA repair. Besides the role of the regulatory proteins in the tightly controlled replication cycle, it can be assumed that they are able to transform cells by disrupting cellular signalling pathways. They also have a mutagenic effect on cellular DNA and promote karyotype instability. Since elimination of mutated cells is impaired, it appears likely that these functions may contribute to the development of neoplasia in a nonpermissive setting (Frisque *et al.*, 2006; Khalili *et al.*, 2005; White and Khalili, 2006).

The discussion of a possible oncogenicity of a huPyV in humans had its origin not only in the oncogenic potential of the early proteins, but also in the bizarre pleomorphism of astrocytes within lesions of PML. This was described as a hallmark of PML in the initial description of the disease and later oligodendroglioma and multifocal glioblastoma were reported, corresponding topographically to the demyelinated lesions in PML. Thus onco-

genicity of JCV and BKV was examined almost from the beginning in experimental animal systems. Developing tumour types reflected the cell type specificity of the viruses. Corresponding to the specificity of JCV for glial cells predominantly CNS tumours were observed in cerebrum, cerebellum, in the brainstem and in the spinal cord. Mesenchymal tumours within cerebral meninges were classified as malignant meningiomas. Ependymomas are the dominant type of intraventricular tumours, and occasionally choroid plexus tumours developed. The most common neoplasms were medulloblastomas followed by malignant astrocytomas, glioblastoma multiforme, neuroectodermal tumours and pineocytomas. Regularly, the virus genome was integrated, JCV TAg was expressed and rescue of JCV from tumour tissue was occasionally successful.

The oncogenic potential of BKV appears to be less pronounced. The most prominent cell types affected by BKV infection in humans—epithelial cells, fibrocytes, ependymal cells, astrocytes and endothelial cells—are reflected by different tumour types in experimental animal models. Choroid plexus papillomas and papillary ependymomas were observed alone, whereas sarcomas and ependymomas were also associated with insulinomas, osteosarcomas and tumours of the intestine. In the tumours BKV DNA is either integrated in the cellular genome or in a free episomal state. Most cells express nuclear TAg and virus can often be rescued by cell fusion with permissive cells. The spectrum of BKV-induced tumour types is comparable in all sensitive animal species and it is thought that human polyomaviruses might also be responsible for the respective tumour types in their natural host. However, despite the oncogenicity of these viruses in animal systems, association with human tumours remains controversial.

TAg expression was analysed immunohistologically in medulloblastomas, oligodendrogliomas, astrocytomas, glioblastomas, ependymomas, choroid plexus and urinary tract tumours. The results were inconsistent. Antibody titres to TAg in sera from tumour-bearing patients exhibited no significant difference to sera from normal people. JCV DNA sequences have been detected so far in up to 57% of oligodendrogliomas, 75% of various astrocytomas, 60% of glioblastomas, 83% of ependymomas and 87% of medulloblastomas. Examination of the p53 level in tumours expressing TAg suggested close association of both proteins within the tumour cell. Recent analyses of individual tumour cells by laser capture microdissection revealed the presence of JCV DNA sequences from the early, late and control region in addition to TAg and agnogene expression. No capsid protein was observed, thereby excluding productive infection and enforcing the role of JCV in tumour development (Pina-Oviedo *et al.*, 2006; White and Khalili, 2005).

Human polyomavirus DNA and protein has also been detected in lung tumours. However, virus was also present in normal tissue and it remains unclear whether this represents a persistent type of infection. Search for viral DNA in B-cell lymphomas is similarly controversial and needs to be further clarified. In gastrointestinal tumours JCV DNA and proteins have been detected. Most colorectal cancers are characterized by chromosomal instability and it is hypothesized that JCV TAG might be responsible for this effect. Since JCV DNA was detected at similar rates in normal tissue, the colon is accepted as a new site of persistence. Although no evidence of an excess risk for colorectal cancer in JCV- and BKV-seropositive individuals was detected in a prospective study, the molecular findings are in line with a potential role of JCV in the development of gastrointestinal tumours (Shin *et al.*, 2006; Zheng *et al.*, 2007).

BKV DNA was only occasionally detected in a series of human tumour types. This included brain tumours, osteosarcomas, insulinomas and Kaposi's sarcoma, pancreas and various urinary tract neoplasms. Analyses of the state of BKV DNA revealed that mostly episomal virus DNA and virus could be rescued. This is indicative of a persistent state of infection, rather than an association with transforming activities, although BKV DNA could also be present in the integrated state. TAG expression in neuroblastomas and its interaction with p53 has also been described. Recently, a potential role of BKV in prostate and bladder cancer was discussed. Whereas a possible association of BKV with bladder cancer remains open, analyses of prostate cancer tissue and precursor lesions have demonstrated the presence of BKV DNA at higher frequency than in normal tissues. In addition TAG co-localizes with p53, thus underlining a potential role of BKV in prostate cancer (Das *et al.*, 2004; Moens and Rekvig, 2001). Detection of virus DNA in tumour tissue in organs also harbouring persistent virus makes a differentiation of persistent infection and transformation difficult. Furthermore, it cannot be ruled out that polyomaviruses interact synergistically with other factors to induce malignant growth in human cells. In that case, the presence of virus DNA in tumour tissue could be a consequence of an event occurring early in the history of tumour development, when the cell cycle might be deregulated by TAG and its interaction with cellular factors. After genetic alterations are established, the virus genome and transcription products might be dispensable. In such a setting the role of huPyV remains uncertain and a more detailed analyses will be required to answer the question whether or not JCV and BKV are involved in human tumorigenesis.

DIAGNOSTIC EVALUATION OF POLYOMAVIRUS-ASSOCIATED DISEASE

Diagnosis of PML by Biopsy

The only disease linked to JCV is PML. The classic method of PML diagnosis involves neurological evaluation and neuro-imaging of the brain followed by definitive laboratory diagnosis on biopsy material. Topographical selection of samples for stereotactic biopsy at the outer rim of lesions is followed by the identification of virus products and typical cellular changes in glial cells. The extraordinary multiplication rate of the virus in diseased tissue allows detection of viral nucleic acids and proteins by classical immunohistological methods. Molecular detection of JCV by PCR in biopsy samples is usually confirmed by histopathology. Essential pathological criteria for the term 'active PML' in AIDS are the presence of JCV-infected glial cells, bizarre astrocytes and lipid-laden macrophages in the context of demyelination. In contrast, 'inactive PML' is characterized by the presence of demyelinated areas without JCV proteins by immunohistochemistry. Regression of astrocytic and oligodendroglial changes, disappearance of macrophages and JCV proteins have already been described in biopsy-proven PML in the pre-AIDS era (Cinque *et al.*, 2003). In the asymptomatic state of infection virus DNA is regularly not detectable by diagnostic PCR analysis of single brain samples. If the infection is activated in immuno-impaired individuals, the virus load might increase and could then be detectable. However, compared with the thousands of genome equivalents present in PML tissue the amount of virus is considerably lower. Consequently, in cases with doubtful results quantitative PCR analysis of any type differentiates a persistently activated and a PML-associated JCV infection. At present, a combination of stereotactic biopsy and PCR techniques ensures a rapid diagnosis of PML with the highest sensitivity and specificity available.

Demonstration of Polyomavirus DNA in CSF

In view of the higher frequency of PML in AIDS patients and the future development of immunomodulatory therapies, less-invasive methods with a comparable detection rate in early diagnosis are frequently used. Although the concentration of JCV in affected tissue is extraordinary high, virus load in CSF is considerably lower and qualitative and quantitative PCR are the only reliable techniques available for virus detection. PCR on CSF often caused divergent diagnostic results. Reports on the test specificity vary from 10 to over 90%. In particular, the sensitivity of qualitative test systems reduced the prognostic significance of the technique. High-sensitivity PCR on the CSF of high-risk HIV-1 patients without PML resulted in JCV

amplification and an increasing number of false-positive PML diagnoses. This finding can be explained by asymptomatic activation of JCV CNS infection in states of immunocompromise. Whether this is indicative of an early state of disease or might represent a timely restricted activation is not yet known. In PML, CSF samples were tested negative in autopsy verified cases. Serial sampling revealed that early in disease the virus load can be low, often almost undetectable, and may increase in the late stages of disease. In these cases repeated CSF sampling at time intervals depending on the clinical and radiological progression of the disease is an essential factor for virus detection. Nevertheless, there are cases that remain negative even in the late stages of disease. Course of disease history is comparable to that of patients shedding JCV either continuously or intermittently into the CSF. However, the virus load appears to be dependent on the individual state of cellular immunity. This is further confirmed by long-term surviving PML patients, whose virus load was first diminished considerably and was eventually eliminated by improvement of the immune state by therapeutic intervention (Eggers *et al.*, 1999).

Modern quantitative PCR techniques allow specific detection ranges over a 7-log dynamic range (McNees *et al.*, 2005). This was the basis for therapeutic monitoring in cases where the immunological state could be improved. It became clear that in classical PML cases the virus load may vary between 1.5×10^2 and 324×10^6 . A correlation of virus load with the volume of CNS lesions could not be established, whereas survival time appears to be inversely related to virus load. In HIV/PML patients on HAART, analysis of sequential CSF samples is even more complicated, at present leading to an increased prevalence of undiagnosed PML cases even after analyses of multiple CSF samples. In patients with diagnoses other than PML, virus load is regularly very low in comparison with virus load early in disease. This argues for the analyses of sequential samples in cases of doubt (Alvarez-Lafuente *et al.*, 2007).

In view of the asymptomatic activation of JCV persistent infection under immunosuppression and the individual responses to immune modulatory therapy in risk group patients, PCR must be understood as a supporting diagnostic tool. The definition scheme for PML is based on criteria for 'definite PML' involving (i) progressive uni- or multifocal neurological disease, (ii) typical magnetic resonance imaging (MRI) lesions associated with (iii) typical brain biopsy features with confirmation of JCV-specific products. 'Probable PML' represents cases with typical clinical and imaging findings, with amplification of JCV DNA in CSF, but without bioptic diagnosis. Absence of histological confirmation and JCV demonstration in

CSF in a setting of PML typical clinical and radiological findings leads to a diagnosis of 'possible PML'. If either pathological diagnosis can be performed, or JCV can be detected in CSF in serial CSF samples this may later classify for a 'definite PML' diagnosis. Incidentally discovered white matter lesions or JCV amplification in CSF without active clinical or radiological findings should not be considered as representative of PML (Cinque *et al.*, 2003).

Diagnosis of BKV-associated diseases

Diagnosis of BKV-associated diseases is based predominantly on detection of viraemia, viruria or histopathological demonstration of BKV in tissue. In case of haemorrhagic cystitis first diagnosis is based on clinical symptoms. However, demonstration of BKV involvement in the disease process is complicated by asymptomatic activation of BKV infection in 50–100% of patients, whereas only 5–40% of them develop haemorrhagic cystitis. Qualitative detection of BKV in patients with haemorrhagic cystitis can be performed by PCR, immune histology or electron microscopy on urine or BKV-infected decoy cells. However, the presence of BKV alone is not indicative of haemorrhagic cystitis. This problem was resolved by the introduction of quantitative detection methods. In contrast to 10^4 and 10^5 DNA copies per ml of urine in asymptomatic patients, haemorrhagic cystitis-indicative virus loads were determined as 10^8 – 10^{12} BKV DNA copies per ml of urine. With a virus load of more than 10^7 DNA copies per ml the risk of developing haemorrhagic cystitis increases considerably. In viraemic patients the risk has been reported to increase with a virus load of $>10^4$ DNA copies per ml plasma. This is indicative of activated BKV infection preceding clinical manifestation. In addition, it was found that there is a predictive correlation of high virus load and acute GVHD before the onset of haemorrhagic cystitis. Since haemorrhagic cystitis is sometimes fatal, this provides the tool for early diagnosis and strongly argues for a monitoring scheme and early intervention for patients at risk (Bogdanovic *et al.*, 2004).

PVAN is most commonly recognized after allograft biopsy due to renal dysfunction in the advanced stages of PVAN. Therefore a screening scheme has been developed for patients at higher risk of developing PVAN allowing early detection and reduction of PVAN-induced renal complications. This includes viral quantification by PCR in serum and urine and urine decoy cell monitoring as a noninvasive method of PVAN diagnosis and monitoring (Hirsch *et al.*, 2005). Detection of mRNA in urine with a cut-off value of 6.5×10^5 BKV mRNA copy number per ng of total RNA was found to be predictive for PVAN. Similarly, persistent decoy cell shedding greater than 10 cells per cytospin has been found to be associated

with PVAN. This is recommended for monitoring at three-month intervals post transplant and every six months thereafter in addition to more intense monitoring during treatment of rejection episodes. In case of a positive screening assay and possible PVAN, quantitative assays are used to determine threshold values of $>10^7$ BKV DNA copies per ml of urine and a value of 10 000 copies per ml in serum. Persisting polyomavirus loads above these thresholds for >3 weeks is highly suggestive of PVAN and allograft biopsy is recommended.

The definitive diagnosis of PVAN requires a histological identification of intranuclear inclusion bodies in affected cells. Alterations seen by light microscopy are not pathognomonic for PVAN. BKV association can be determined by immunohistochemistry for viral proteins, by *in situ* hybridization to identify BKV DNA or by electron microscopy to demonstrate polyomavirus particles morphologically. However, because of the focal nature of PVAN and the possibility of sampling error there is consensus that negative results cannot rule out PVAN with certainty. In cases with significant BKV replication above threshold levels additional studies are recommended. The resolution of PVAN following successful intervention is diagnosed based on the disappearance of viral cytopathic changes in cortex and medulla and absence of polyomavirus in plasma or urine. On the basis of highly variable patient-related and organ-specific risk factors all patients at risk of PVAN have in common a highly active state of BKV replication. Therefore screening for polyomavirus replication may allow earlier intervention with reduced allograft loss.

POLYOMAVIRUS-SPECIFIC IMMUNE RESPONSE

Humoral Immune Response

Determination of the virus-specific humoral immune response concentrates primarily on analyses of virus-specific antibodies and their dynamic titre changes in acute disease. The predominant polyomavirus subgroup-specific antigenic sites on the major capsid protein VP1 are accessible only after disruption of virions, in virus-infected cells or on purified VP1 protein. Consequently, virus-specific antisera against intact virus particles are species-specific. Species-specific antibodies can be distinguished from one another by neutralization and haemagglutination inhibition (HAI) assays with good correlation between virus-specific HAI, neutralizing antibody titres and quantitative PCR. Cross-reactivity between recombinant JCV and BKV virus-like particles used as antigen in enzyme-linked immunoassays (EIAs)

is negligible (Viscidi and Clayman, 2006). With the use of this more sensitive technique it became clear that the majority of prediagnostic samples in a case—control study do not change polyomavirus antibody status over a period of 15 years, however, absolute levels of antibodies to JCV and BKV decreased over time for 70% and 80% of individuals respectively (Rollison *et al.*, 2006). An increase in antibody levels appears to be related to activation processes either linked to immune modulatory events or disease. This is confirmed by the detection of higher antibody levels in AIDS patients with JCV or BKV viraemia (Engels *et al.*, 2005).

The prevalence of BKV-specific antibodies in sera is about 50% by the age of three years, and nearly all individuals are seroconverted by the age of 10 years. The incidence of JCV antibodies is about 50% during adolescence and more than 50% by adulthood. The rates differ slightly according to demographic data, geographical distribution and economic status. In contrast to JCV antibody titres, the range of BKV-specific antibody titres is strongly associated with age, titres decreasing linearly at a rate of 8.7% per 10 years (Knowles, 2006). In pregnant women rising titres indicate an incidence of active infection in more than 25% mediated by immunomodulation during pregnancy. The first polyomavirus-specific IgM assays were performed with BKV antigen. The prevalence of BKV-specific immunoglobulin type IgM in children was consistent with age distribution of primary BKV infection. Occurrence of BKV IgM in the range of 5% in sera from healthy blood donors is consistent with the finding that BKV activation is uncommon in healthy adults. Thus it is possible that cross-reactive IgM antibodies might be in the minority.

In organ transplant patients a BKV-specific humoral immune response is regularly mounted despite the immunosuppressive therapy regimens. BKV-specific antibodies were analysed in sera of renal transplant patients and their donors. The titres of donors predicted frequency, magnitude and duration of post-transplant viraemia. In recipients a temporal correlation between development of antibodies against BKV and clearance of the virus was defined, suggesting that recipients with a higher antibody level may have a better prognosis. Besides the enhanced antibody levels in viruric and viraemic donors and recipients, IgM and IgA antibodies were detected as well. Whereas IgM was rarely found in normal donors, IgA antibodies were demonstrated in 23% of donors and recipients with enhanced titre levels in activated infection. Median levels were higher in viraemic patients, thereby confirming that viraemia follows viruria and represents higher activation status. Since serologic changes were not observed in patients with chronic renal failure on dialysis, the serologic status in BKV-associated diseases

might play a role in future diagnostic strategies (Randhawa *et al.*, 2006).

JCV-specific IgG antibodies in normal people and age-matched patients with various tumours exhibited similar geometric mean titres. Since antibody levels are not influenced by age and titres in patients with malignancies remain stable even under multidrug therapy or immunotherapy, it can be assumed that JCV infection is not markedly influenced by these diseases or associated therapies. However, recently it became clear that patients with non-Hodgkin lymphoma who were originally seropositive developed increased JCV antibody levels in the course of disease, suggesting that a low-level activation during tumour development might be accompanied by increasing antibody titres (Rollison, 2006). Equally, under PML, the range of JCV-specific serum and HAI titres can often not be distinguished from those in the general population. This is explained by the severe basic illnesses abrogating a normal antibody increase; however, because of the fast course of PML modest titre changes might not be measured even in the modern EIA systems (Viscidi and Clayman, 2006). JCV-specific IgM antibodies were detected in 15% of healthy blood donors. In the same group almost all sera contained HAI antibodies, suggesting that blood donors harbour the virus in a persistent state. The high prevalence of JCV infections in adults led to the assumption that presence of IgM is frequently associated with JCV activation in the healthy. In about half of the PML patients a rise of IgM antibodies with increasing levels was observed under progression of the neurological illness. At present, the high prevalence of IgM-positive sera in healthy people does not allow a correlation of IgM presence and acute disease (Knowles, 2006).

In early studies the CSF was usually found to be unremarkable in PML, and JCV HAI titres were only rarely detected. Thus the humoral immune response has been regarded as essentially unhelpful for diagnosis in the past. However, recently a slight increase in CSF protein was reported in about one-quarter of PML patients, an elevated IgG-albumin index in about one-fifth, and a slight pleocytosis in other patients, further analyses revealed moderate blood—brain barrier impairment in PML patients. JCV-specific intrathecally synthesized HAI antibodies and oligoclonal bands were detected in CSF of 67% confirmed PML cases and changes of HAI titre in the CSF were observed under PML treatment. Thus JCV intrathecally produced HAI antibodies appear to be suggestive of active JCV multiplication within the CNS. This was further confirmed by EIA analyses with recombinant JCV VP1 capsid protein as antigen. An intrathecal immune response was detected in 78% of PML patients versus 3% of controls. Detection of JCV-specific oligoclonal bands was slightly less sensitive. Interestingly, a JCV-specific

intrathecal immune response against JCV VP1 evolved in HIV-1 patients during therapy. At present, it appears likely that a response evolves over time in the majority of PML patients (Weber *et al.*, 2001).

The range of titres in individual PML patients appears to be highly dependent on the state of the disease and may additionally reflect the type of underlying disease with characteristics differently affecting parameters of the immune system. Analyses of virus-specific, intrathecally produced antibodies and oligoclonal bands are well matched in PML versus non-immunosuppressed cases. It can be assumed that a mild intrathecal immune response with the presence of oligoclonal JCV-specific antibodies indicates intrathecal growth of JCV. It remains to be determined whether the finding of intrathecally produced JCV-specific antibodies and oligoclonal bands is indicative of acute disease and PML only, or might also be characteristic for a persistent activated state under immune impairment of other diseases.

Cellular Immune Response

JCV activation occurs in the context of immune impairment, and humoral immunity obviously is not able to control JCV spread. Therefore from the early beginnings breakdown of cellular immunity was suspected to play a major role in the pathogenesis of polyomavirus diseases. However, studies on the immune response were limited and did not contribute to a general understanding of polyomavirus-associated mechanisms of immune control. Recently, it was found that the major histocompatibility complexes class II and I were expressed at high levels in PML lesions, indicating an intact antigen presentation. In HIV/PML patients immune reconstitution by HAART therapy is related to a rise in helper CD4⁺ T-lymphocyte counts as well as a drop in HIV-1 load and clinical improvement of JCV-related neurological symptoms. However, about 50% of HIV/PML patients do not respond to HAART despite reduction of HIV-1 load and rise in CD4⁺ counts. Therefore it appears likely that the CD4⁺ T-cell subset does not play an important role in PML development.

Studies on cytotoxic CD8⁺ T lymphocytes revealed the presence of JCV-specific circulating cells directed against JCV proteins in long-term survivors of PML. Compared with other persistent viral infections, JCV-specific cytotoxic T lymphocytes (CTLs) were found at considerably lower frequencies. Comparison of the CTL responses among PML patients demonstrated that the frequency of JCV-specific CD8⁺ T cells is related to the outcome of disease. A strong response was detected in most patients with a prolonged disease course, whereas the response in classic PML patients or HIV/PML fast progressors was almost not detectable. Most of these cells, which have

been shown to control virus replication and disease progression, were directed against epitopes on the JCV VP1 capsid protein. Analyses of the frequency of CTLs in the PBMC population of healthy individuals demonstrated a broad range from one in 100 000 to one in 2494 PBMCs. These values are comparable to those in HIV/PML patients with a favourable outcome. In addition, it could be demonstrated that JCV-specific CD8⁺ cells co-localize with lymphocytic infiltrates and JCV-infected glial cells in PML lesions, suggesting that an active ongoing recruitment of CD8⁺ T cells and viral antigen-specific retention could occur. These data confirm that the JCV-specific cellular immune response plays an important role in the control of disease progression. In addition, it is conceivable that JCV-specific CD8⁺ T cells are able to control the spread of JCV even in immunosuppressed individuals. Therefore this cell population may provide a useful diagnostic and prognostic tool in the therapeutic management of these patients (Koralnik, 2006).

TREATMENT OF POLYOMAVIRUS-ASSOCIATED DISEASES

Treatment of huPyV infections concentrated for years on PML. Different treatment regimens have been proposed on the basis of molecular findings and small series of patients. However, randomized therapeutic trials have been introduced only recently and the observation of stabilized PML or even remission highlights the inadequacies of early anecdotal reports suggesting the value of specific therapies. Nucleoside analogues have proven to interfere with viral DNA synthesis in virus infections, and several compounds have been tried in the treatment of PML. Cytosine arabinoside (ARA-C, cytarabine) has been used and various degrees of improvement reported. Recently acquired molecular data showed that cytosine- β -D-arabinofuranoside suppressed JCV replication in tissue culture, supporting the potential interference of ARA-C with PML. However, the study on the efficacy of ARA-Cy by the AIDS Clinical Trials Group, trial 243, showed no benefit. In contrast, in a small group of non-AIDS PML patients the treatment stabilized PML in 36% of the patients for one year. Other analogues such as adenosine arabinoside (ARA-A, Vidarabine), iodo-desoxyuridine or zidovudine similarly do not appear to have an effect in the treatment of PML. The use of HAART in patients with HIV-related PML is associated with disease stabilization. Prolonged survival in about 50% of the patients is associated with decrease in JCV load. The survival rate significantly increased in patients receiving a protease inhibitor-containing regimen.

The effect of HAART on PML is believed to be the result of improved immune defence. However, in half of the patients PML progressed despite virological and immunological response to HAART. Failure to respond to HAART as demonstrated by high plasma viral loads has been associated with poor PML prognosis and a course of disease similar to that in the absence of antiretroviral therapy. Nevertheless, the use of HAART significantly improved survival time, although the prognosis for HIV/PML patients is still severe.

Cidofovir diphosphate, a structural analogue of deoxycytidine triphosphate, is known to be a potent virus inhibitor. It demonstrated a significant inhibitory effect *in vitro* and was therefore introduced as a potential drug in PML treatment. Anecdotal reports pointed to clinical improvement and follow-up studies reported beneficial effects, either alone or in combination with HAART in AIDS-associated PML. However, the efficacy of the drug remains controversial. The use of immunomodulatory agents in PML therapy is based on the findings of extended survival in patients with improvement of immunological competence. Alpha-interferon has established efficacy in the treatment of other polyomavirus-associated diseases, and prolonged survival has been reported. In contrast, other studies reported no significant enhancement in survival time. Similar discrepancies were found with the combination of adenine arabinoside and β -interferon or transfer factor revealing no efficacy, whereas interferon alone was associated with modest improvement in the clinical picture and on MRI. Recently, an effect on survival after IL-2 treatment of a lymphoma patient after BMT was contradicted in another patient. In addition, treatment with low-dose heparin sulfate was suggested to prevent seeding of JCV to the CNS by activated lymphocytes. Other agents have been tried either alone or in combination. However, unequivocal effective therapy of PML as yet remains elusive, and further investigations are needed to decide which of the different approaches might be effective for the treatment of PML (Cinque *et al.*, 2003; Roskopf *et al.*, 2006).

There is currently no standardized treatment available for patients diagnosed with BKV-associated disease. The most common treatment strategy is to reduce or discontinue immunosuppressive drugs and treatments if possible. The management of haemorrhagic cystitis is generally symptomatic. This approach is designed to rescue viral replication, but may be associated with risks such as acute rejection and graft loss in renal transplant recipients, so patients must be monitored closely. Several case reports have described the successful use of antiviral agents such as vidarabine, ribavirin and cidofovir, however, they were used on a small number of patients

and are still not defined as a standard therapeutic option. Based on these reports, cidofovir may be effective for treatment of haemorrhagic cystitis in the setting of BKV and should be considered for patients who fail conventional methods for controlling haemorrhagic cystitis. With vidarabine therapy the viral inclusion bodies in urinary sediments disappeared. If viruria recurred it could be successfully cleared with another course of vidarabine, thus it appears to be a safe alternative for treatment of haemorrhagic cystitis (Gorczyńska *et al.*, 2005; Roskopf *et al.*, 2006).

Prophylactic and therapeutic interventions for PVAN are limited since antiviral drugs with specific activity directed against the viral life cycle are not available for prevention or treatment of PVAN. Antiviral agents used with anecdotal success include cidofovir, leflunomide, quinolone antibiotics and intravenous immunoglobulin. The efficacy of these strategies is unclear, because it was always accompanied by reduction of immunosuppression. This allows reconstitution of immune responsiveness to BKV and may lead to stabilization and prevention of graft loss. Different regimens have been developed for patients with progressive PVAN as potentially effective therapies, however, it was found that therapeutic regimens were most successful in the early stages of disease. Recently, this was verified by a prospective study on monitoring and the impact of reduction of maintenance immunosuppression on the BKV viral load kinetics and PVAN. In all viraemic patients the treatment resulted in clearance of viraemia and prevented development of PVAN without increasing the rate of acute rejection or causing graft dysfunction. It was also observed that reduction of viral load correlated with improved BKV-specific cellular immunity. Reduction of drug doses may result in improvement or stabilization of PVAN, however, uniformly accepted threshold values for drug levels have not yet been identified. The impact of antilymphocyte preparation may depend on the type of agent used and the specific clinical situation. Avoidance or early cessation of steroids in calcineurin inhibitor-based regimens may reduce the incidence of PVAN or positively influence the course of PVAN, where steroid treatment for acute rejection was followed by decreased maintenance immunosuppression. Recent studies suggest that a brief increase in immunosuppression followed by subsequent decrease may be the best way to manage rejection episodes occurring at or after PVAN diagnosis (Hirsch *et al.*, 2006; Vats *et al.*, 2006).

Although a number of drugs and therapeutic regimens for the treatment of polyomavirus diseases were associated with some beneficial effect, an established antiviral therapy is not available. The high prevalence of these viruses in humans and their pathogenic potential makes

intensive analyses of viral activation mechanisms and the development of specific drugs essential aims for the near future.

Human Parvoviruses

Kevin E. Brown

Virus Reference Department, Centre for Infections, Health Protection Agency, London, UK

INTRODUCTION

Parvoviruses are, as their name suggests, small viruses (from the Latin *parvum*, meaning 'small'), with a single-stranded DNA genome. The *Parvoviridae* family consists of two subfamilies, the *Densovirinae* and the *Parvovirinae*: the *Densovirinae* are all viruses of insects and the *Parvovirinae* are viruses of vertebrates (Tattersall *et al.*, 2005). The *Parvovirinae* is further subdivided into five genera based on the replication pattern, sequence homology and transcription map (Table 35.1). At least four different types of parvovirus are known to infect humans, of which human parvovirus B19 (B19V) is the best studied.

The genus *Parvovirus* contains a wide range of viruses of mammals and birds, some of which cause major diseases in their animal hosts, but some, first isolated as contaminants of cell cultures, have unknown primary hosts. No member of this family is known to infect humans.

B19V was initially discovered in the serum of an asymptomatic blood donor (coded 19 in panel B) as a cause of false-positive results in counter-immunoelectrophoresis tests for the detection of hepatitis B virus surface antigen (Cossart *et al.*, 1975). Originally the virus was classified with the autonomous parvoviruses, but is now the type member of the *Erythrovirus* genus. Subsequently, related parvoviruses have been identified in cynomolgus monkeys, pig-tailed macaques and rhesus macaques. These erythroviruses share with B19V up to 60% homology, similar genome organization and similar biological behaviour in natural hosts.

The dependoviruses have been described in a number of mammalian and avian species. To date, at least nine different primate dependoviruses have been described

(Gao *et al.*, 2004), and adeno-associated viruses (AAVs) 1, 2, 3, 8 and 9 are common human infections (Gao *et al.*, 2004). Although AAV DNA has been detected in a wide range of tissues, including some fetal abortion tissues, none of the dependoviruses have been definitively linked with disease in either humans or animals.

Bocaviruses are viruses that infect the respiratory and gastrointestinal tract of young animals. Recently sequences of a human bocavirus (HuBoV) have been identified in respiratory samples of Swedish children with lower respiratory tract infections (Allander *et al.*, 2005). Subsequent studies have identified HuBoV DNA sequences in children in many different parts of the world, but often associated with other pathogenic viruses. However, there is increasing evidence that the virus is pathogenic, and especially associated with wheezing and respiratory disease in young children (Allander *et al.*, 2007). The viral sequences have also been identified in faecal samples from children (Vicente *et al.*, 2007), and it is unclear if this is the virus responsible for the parvovirus-like particles that have been described in human faecal specimens.

Using similar methods to those used to identify HuBoV, a fourth group of parvoviruses, Parv4 (Jones *et al.*, 2005), has also recently been identified. The viral sequences are commonly found in pooled serum samples (Fryer *et al.*, 2007), and in bone marrow and lymphoid tissue of intravenous drug users and people with haemophilia (Manning *et al.*, 2007). However, whether the virus is pathogenic is unclear and, as with HuBoV, currently there have been no published studies of antibody seroprevalence. The virus has not been grown in culture, and preliminary studies of the transcription map suggest that Parv4 does not group with any of the other parvovirus genera.

Table 35.1 The *Parvovirinae*

Subfamily	Genus	Virus	Host
<i>Parvovirinae</i>	<i>Parvovirus</i>	Canine parvovirus—CPV	Dogs, foxes
		Mice minute virus—MVM	Mice
		Porcine parvovirus—PPV	Pigs
	<i>Dependovirus</i>	Feline parvovirus—FPV	Cats
		Adeno-associated virus 1–6—AAV	Humans, primate
		Avian adeno-associated virus—AAAV	Birds
		Canine adeno-associated virus—CAAV	Dogs
		Bovine adeno-associated virus—BAAV	Cattle
		<i>Erythrovirus</i>	Parvovirus B19—B19V
	Simian parvovirus—SPV		Primates
	Rhesus parvovirus—RhPV		
	Pigtailed macaque parvovirus—PtPV		
	<i>Bocavirus</i>	Bovine bocavirus	Cows
		Canine bocavirus	Dogs
		Human bocavirus—HBoV	Humans
	<i>Amdovirus</i>	Aleutian mink disease virus	Minks
	Unclassified	Parv4	Humans

HUMAN PARVOVIRUS B19 (B19V)

Structure

In electron micrographs of negatively stained preparations parvovirus B19V appears as non-enveloped, icoahedral particles with a diameter varying from 18 to 25 nm, and often both ‘full’ and ‘empty’ capsids are visible (Figure 35.1). The infectious particles have a buoyant density of $\sim 1.41 \text{ g ml}^{-1}$ in caesium chloride gradients, whereas the empty particles have a density of 1.31 g ml^{-1} .

Figure 35.1 The appearance of B19V particles by immune-electron microscopy.

The particles do not contain lipids or carbohydrates. As with all parvovirus particles, the infectious particle is stable over a wide range of pH and resistant to lipid solvents, although B19V is not quite as resistant to heat as other parvoviruses (Blumel *et al.*, 2002). B19V can also be inactivated by formalin, β -propiolactone, oxidizing agents and γ -irradiation.

Genome Organization

Parvovirus virions consists of a linear single strand of DNA with a molecular weight of approximately 1.8×10^6 . In contrast to the autonomous parvoviruses that preferentially encapsidate single-stranded DNA of negative polarity, parvovirus B19 encapsidates both positive and negative strands with equal frequency. The genome of B19V is one of the largest among the parvoviruses, comprising 5596 nucleotides (nt), and with long (365 nt) imperfect palindromic sequences at both the 5' and 3' termini. These segments of the DNA fold back on themselves to form hairpin loops which are stabilized by hydrogen bonding. There is some mismatching in the middle of the hairpin, leading to two slightly different sequence configurations (referred to as the flip and flop configurations).

In contrast to most other parvoviruses, there is a single strong promoter at the far left side of the genome (map point 6, or p6) which regulates the synthesis of all nine of the different viral transcripts (Figure 35.2 (Ozawa *et al.*, 1987)). The single nonspliced transcript encodes the nonstructural (NS) protein and, by a combination of different splicing events, the other eight encode the two capsid proteins (VP1 and VP2) and two smaller proteins

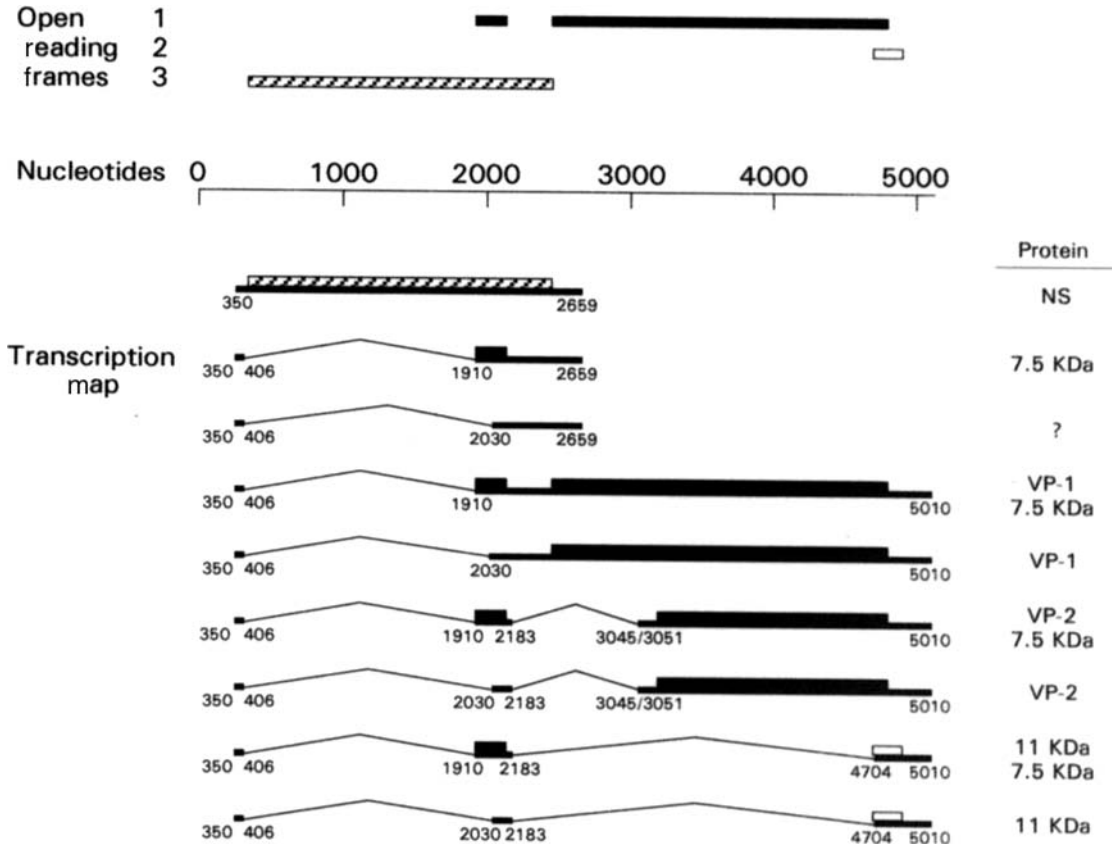

Figure 35.2 Transcription map of parvovirus B19V.

(7.5 and 11 kDa proteins). Until recently, the length and structure of the hairpin sequences thwarted attempts to produce a full-length clone of the virus. The virus has now been cloned, and knockout studies of different regions of the virus have allowed elucidation of the critical roles of the different proteins (Zhi *et al.*, 2006).

Viral Proteins

The only unspliced transcript encodes the NS protein, a 78 kDa phosphoprotein. The protein has DNA-binding properties, adenosine and guanosine triphosphatase activity, nuclear localization signals and is essential for B19V infectivity and DNA replication (Zhi *et al.*, 2006). In addition, expression of the NS protein causes host cell death through triggering caspases and induction of apoptosis.

There are two structural proteins in B19V, VP1 (84 kDa) and VP2 (58 kDa), which differ only in that VP1 has an additional 227 amino acids at the N-terminus (VP1u). The capsid of B19V is composed of 60 capsomers: VP2 is the major capsid protein, with only ~5% VP1 in the infectious particle. Expression

of VP2 capsomers alone will self-assemble to form recombinant empty capsids that resemble B19V particles morphologically and antigenically (Kajigaya *et al.*, 1991). The major cellular receptor for B19, globoside or P antigen (Brown *et al.*, 1993), binds to VP2. The VP1 unique region (VP1u) is known to be important in generating neutralizing antibodies (Saikawa *et al.*, 1993), has phospholipase activity (Zadori *et al.*, 2001), and is critical for the production of infectious virus. Structural studies of B19V have been undertaken for B19V using both crystal diffraction and cryo-electron microscopy studies. They indicate that as seen for other parvoviruses, B19V has a central structural core of eight anti-parallel β -sheets, but the large loops that give the prominent spikes on the threefold axis of canine and feline parvoviruses (FPVs) are absent from B19V capsids (Kaufmann *et al.*, 2004).

Virus Variation

Although generally there is <5% sequence difference between different isolates of B19V, sequences with ~10%

difference have been identified, and the sequences are divided into three different genotypes (Servant *et al.*, 2002). The predominant genotype identified is genotype 1, with only limited reports of the identification of genotypes 2 and 3. Most studies in blood and blood products have failed to identify genotypes 2 and 3 (Baylis, 2008). However genotype 2 and 3 have been identified in bone marrow and tissues, and one study from Finland suggested that genotype 2 may have been more prevalent in the 1960s (Norja *et al.*, 2006). Genotype 3 infection also appears to be much more common in parts of Africa (Candotti *et al.*, 2004).

Although there are three genotypes, there are only limited differences between the amino acid sequence of the different viruses. Antibody and cross-neutralization studies indicate that there is only a single B19V serotype.

PATHOGENESIS

B19V was first identified in a sample being tested for hepatitis B (Cossart *et al.*, 1975), and for a number of years following its discovery B19V appeared to be associated with, at most, a mild, nonspecific, febrile illness accompanied by self-limiting leukopenia. In the early 1980s the central role of B19V in the aetiology of aplastic crisis in chronic haemolytic anaemias was identified and then, in 1983, erythema infectiosum (fifth disease) began to emerge as the common manifestation of B19V infection. Subsequently the virus has been shown to be responsible for a significant percentage of cases of hydrops fetalis and to cause chronic infection in the immunocompromised. It is now clear that the pathogenesis of B19V-associated disease involves two components. The first is due to the lytic infection of susceptible dividing cells and the second is dependent upon interaction with the immune response.

Volunteer Studies

Studies of experimentally infected volunteers have allowed the kinetics of infection to be elucidated. In both cases volunteers (9 and 3 respectively) were infected by intranasal inoculation of a saline solution containing approximately 10^8 virus particles. The volunteers were followed daily and clinical, biochemical, haematological and viral studies undertaken (Figure 35.3).

Viraemia was first detected from day 6 and reached a peak at days 8–9 at about 10^{11} particles per ml, a level comparable to that seen in natural infections in blood donors and patients with aplastic crisis (Anderson *et al.*, 1985). Virus was also detected in throat swabs and gargles at the time of viraemia only. Virus was not found in urine or faecal samples. On days 6–8 the volunteers showed

the typical symptoms of a viraemia, with headache, myalgia, and chills, associated with pyrexia. These features are now known to be due to the production of inflammatory cytokines (Isa *et al.*, 2007). During the viraemia reticulocyte numbers fell to undetectable levels, recovering 7–10 days later, and there was a consequent temporary fall in haemoglobin of about 1 g dl^{-1} in a normal individual. Lymphopenia, neutropenia and thrombocytopenia also occurred though slightly later, with the lowest numbers being recorded 6–10 days after inoculation and not so consistently as the changes in reticulocyte numbers and haemoglobin concentration.

In the second study bone marrow morphology was also examined at intervals (Potter *et al.*, 1987). On day 6 post inoculation the marrow appeared normal. However at day 10 there was an almost total loss of erythroid precursors at all stages of development. The erythroid progenitor cells (BFU-E) from bone marrow and peripheral blood were reduced at this time. The myeloid compartment of the bone marrow appeared normal, but myeloid precursors from peripheral blood were reduced as soon as two days from the onset of the viraemia.

The viraemia resolved as the patients developed a detectable antibody response (Figure 35.3) and a second phase of the illness began in most of the volunteers at day 15–17 (Anderson *et al.*, 1985), as the IgM response peaked and IgG became detectable, characterized by pruritis followed by the development of a fine maculopapular cutaneous eruption. The rash extended over the limbs and was accompanied by arthralgia and a mild arthritis. The rash was present for two to four days and the joint symptoms for four to six days. In the second study none of the patients developed the second phase symptoms. It may be significant that in the second study all (3/3) the volunteers were male and that joint symptoms in natural B19V infection appear to be much less frequent in male patients.

All the volunteers who received $>10^6$ virus particles in the inoculum, and were B19V antibody negative (IgG <0.3 au (arbitrary unit); equivalent to <0.3 IU ml^{-1}) developed viraemia and an antibody response to the virus. Volunteers with a positive B19V IgG (IgG <2 IU ml^{-1}) did not become infected. One of the pilot volunteer patients had 'equivocal' levels of IgG and appeared to develop a modified infection, with minimal viraemia and a boosting of his immune response.

In both of the studies, viraemia was monitored by the relatively insensitive dot-blot hybridization technique. Studies with polymerase chain reaction (PCR) have now shown that B19V DNA can be detected for many weeks or months following acute infection (Lefrere *et al.*, 2005), and can probably be detected in tissue for the rest of life (Norja *et al.*, 2006).

Figure 35.3 Virological, haematological and clinical events during B19V infection of volunteers.

Cell Tropism

Parvovirus B19, like the other autonomous parvoviruses, depends on host cell factors or functions only present in cells transiting the late S- or early G₂-phase of mitosis for replication. However, B19V also has a very narrow target cell range and can only be propagated in human erythroid precursor cells. When bone marrow or peripheral blood cells are cultured to develop erythroid colonies in the presence of B19V, the formation of colonies is inhibited. For erythroid cells from bone marrow, susceptibility to parvovirus B19V increases with differentiation; the pluripotent stem cell appears to be spared and the main target cells are the CD36-positive BFU-E and CFU-E cells (cells capable of giving rise to erythroid colonies *in vitro*) and erythroblasts.

Erythroid progenitors from a variety of sources have been used to study *in vitro* viral replication,

including human bone marrow, fetal liver and peripheral blood. B19V will also replicate in a limited number of erythropoietin-dependent megakaryocytic cell lines including UT7/Epo and KU812Ep6. However the yield of virus from all these cell lines is poor, and they cannot be used as a source of antigen for diagnostic tests.

Erythroid specificity of parvovirus B19V is in part due to the tissue distribution of the primary virus' cellular receptor, globoside, also known as blood group P antigen (Brown *et al.*, 1993). P antigen is found on erythroid progenitors, erythroblasts and megakaryocytes. Purified P antigen (globoside) blocks the binding of virus to erythroid cells and these cells can be protected from infection by preincubation with monoclonal antibody to globoside. P antigen is also present on endothelial cells, which may be targets of viral infection involved in the pathogenesis of transplacental transmission, possibly

Figure 35.4 Giant pronormoblast, typically seen in the bone marrow and occasionally in the peripheral blood of patients with B19V infection.

vasculitis and the rash of fifth disease, and on fetal myocardial cells. Rare individuals who genetically lack P antigen on erythrocytes are resistant to B19V infection, and their bone marrow cannot be infected with B19V *in vitro* (Brown *et al.*, 1994b). However, erythroid specificity may also be modulated by specific erythroid cell transcription factors. At least two other antigens have been proposed as co-receptors for B19V, integrin and the KU80 autoantigen.

The virus is cytotoxic, producing a cytopathic effect with characteristic light and electron microscopic changes. Infected cultures are characterized by the presence of giant pro-normoblasts (Figure 35.4), 25–32 μm in diameter, with cytoplasmic vacuolization, immature chromatin and large eosinophilic nuclear inclusion bodies. By electron microscopy virus particles are seen in the nucleus and lining cytoplasmic membranes, and infected cells show marginated chromatin, pseudopod formation and cytoplasmic vacuolation, all typical of cells undergoing apoptosis. However, not all the giant pro-normoblasts contain virus particles, and part of the cytopathy probably reflects the expression of the cytotoxic NS protein. Megakaryocytopoiesis is also inhibited by B19V parvovirus *in vitro* but this is in the absence of virus replication and almost certainly due to the NS cytotoxicity.

Immune Response

The pattern of B19V disease is strongly influenced by the immune response. Bone marrow depression in parvovirus infection occurs during the early viraemic phase and under normal conditions is terminated by a neutralizing antibody response. The pathogenesis of the rash in erythema infectiosum and polyarthralgia is almost certainly immune-complex mediated. In volunteer studies,

the rash and joint symptoms appeared when the high titre of viraemia had dropped significantly and coincident with a detectable immune response (Anderson *et al.*, 1985).

Persistent B19V infection is the result of failure to produce effective neutralizing antibodies by the immunosuppressed host. Antibodies to parvovirus, as determined in immunoassays or enzyme-linked immunosorbent assay (ELISA), are not present in most patients, but a pattern of antibody response suggestive of early infection (weak IgM antibody and IgG antibody directed to VP2 only) may be found in patients with congenital immunodeficiency. Confirming the role of the humoral response appears to be dominant in controlling human parvovirus infection, administration of commercial immunoglobulins can cure or ameliorate persistent parvovirus infection in immunodeficient patients: fifth disease symptoms can be precipitated by treatment of persistent infection with immunoglobulin (Frickhofen *et al.*, 1990).

The infected fetus may suffer severe effects because red blood cell turnover is high and the immune response deficient. During the second trimester there is a great increase in red cell mass. Parvovirus particles can be detected by electron microscopy within the haematopoietic tissues of liver and thymus. B19V DNA and capsid antigen have been detected in the myocardium of infected fetuses (Porter *et al.*, 1990), and there is evidence that the fetus may develop myocarditis, compounding the severe anaemia and secondary cardiac failure. By the third trimester, a more effective fetal immune response to the virus may account for the decrease in fetal loss at this stage of pregnancy.

Role of the Cellular Immune Response

There have only been a limited number of studies on the role of the cellular immune response in controlling B19V infections. B19V infection induces both a CD4 and CD8 proliferative response, with a CD4 response primarily to capsid proteins and a CD8 response to the NS protein. The CD8 response is prolonged for many months even after an acute infection (Norbeck *et al.*, 2005), and suggests a previously unrecognized role for the control of B19V infection.

EPIDEMIOLOGY

Parvovirus B19 is a common infection in humans, and serological studies indicate that infection is worldwide (Kelly *et al.*, 2000), with infections occurring in all populations, apart from some isolated groups in Africa and Brazil. In temperate climates infection occurs throughout the year but outbreaks are more common in late winter, spring and the early summer months. These outbreaks

of infection are often centred on primary schools, where up to 40–60% of the school may be clinically affected by the rash illness of erythema infectiosum (EI). During these outbreaks, susceptible adults (parents and teachers of cases) frequently become infected.

In addition to seasonality, the virus exhibits longer term cycles: in Jamaica, peaks of incidence (monitored as cases of aplastic crisis) occur every three to four years. In the United Kingdom, the cycle seems somewhat longer, with peaks occurring every four to five years.

Clinical observations of the frequency of cases of EI among different age groups reflect the serological profile of the population; antibodies are most commonly acquired between the ages of 4 and 10 years, after which the frequency continues to rise, but more slowly. By age 15 years approximately 50% of children have detectable IgG. Infection also occurs in adult life, so that more than 75% of those over 45 have detectable antibody (Vyse *et al.*, 2007). Women of child-bearing age show an annual seroconversion rate of 1.5% (Koch and Adler, 1989). Studies in many different countries (United States, Scandinavia, France, Germany, Japan) all show similar patterns.

Case-to-case intervals, determined by the time elapsing between acquisition and excretion of the virus, are independent of the type of disease. Volunteer studies predict case-to-case intervals of 6–11 days, which accords well with case-to-case intervals observed both in outbreaks of EI and in aplastic crisis. Transmission between siblings is common, and in families where more than one child is affected by chronic haemolytic anaemia all susceptibles should be monitored for two weeks if one develops an aplastic crisis.

Transmission

Although spread from respiratory tract to respiratory tract is the common route of transmission of B19V, the high-titre viraemia that occurs during infection can lead to transmission by blood and blood products, and documented transmissions are reported in the literature. As noted earlier (and Figure 35.3), low levels of B19V DNA can be detected in blood for many months following acute infection, and the reported prevalence of B19V DNA in blood varies widely depending on the sensitivity of the assay being used, and on the presence of local epidemic of infection in the community, but with sensitive assays can be ~0.5% (Brown and Simmonds, 2007). The significance of low levels of B19V being transfused into immunocompromised seronegative individuals is not known.

B19V DNA can be detected in plasma pools and blood products. Although plasma pools invariably contain parvovirus B19V DNA for many years it was considered that the high titre of neutralizing antibodies present in

plasma pools would prevent transmission of infectious virus. It is now known that infusion of plasma pools containing high titre virus ($>10^7$ IU ml⁻¹) can transmit infection, and therefore in Europe and the United States, all human plasma has to be tested and shown to contain $<10^4$ IU ml⁻¹ B19V DNA.

CLINICAL FEATURES

The consequences of B19V infection range from the wholly asymptomatic to serious and potentially fatal conditions in a minority of the population that is particularly predisposed. The spectrum of clinical consequences of infection depends in part on the natural variation in symptomatology that occurs, and in part on recognizable host factors (Table 35.2).

Minor Illness

Combined clinical and laboratory studies of infection in children, in whom B19V infection is most common, have indicated that about half of all infections are asymptomatic. Nonspecific respiratory tract illness is the next most common consequence of infection. This can be mild or severe enough to mimic influenza and these respiratory tract illnesses coincide with the viraemic phase of the illness.

Rash Illness/Erythema Infectiosum

Erythema infectiosum is most common in children aged 4–11 years and was probably first described by Robert Willan in 1799. In 1905 Cheinisse classified it as the ‘fifth rash disease’ of the classical exanthema of childhood, and this name ‘fifth disease’ remains in use to this day. The

Table 35.2 Disease manifestations and persistence of parvovirus B19V infection in different host populations

Disease	Acute/ chronic	Host
Fifth disease	Acute	Normal children
Polyarthropathy syndrome	Acute/ chronic	Normal adults
Transient aplastic crisis	Acute	Patients with increased erythropoiesis
Persistent anaemia	Chronic	Immunodeficient/ immunocompromised patients
Hydrops fetalis/ congenital anaemia	Acute/ chronic	Fetus (<20 wk)

link between B19V infection and EI was made in 1983 (Anderson *et al.*, 1984), and human parvovirus B19 is now known to be the only aetiological agent for EI.

EI had been well described by clinical investigators prior to the discovery of B19V. Infection is characterized by a nonspecific prodromal illness which often goes unrecognized. Fifth disease may be associated with symptoms of fever, coryza, headache and mild gastrointestinal symptoms (nausea, diarrhoea). The exanthem occurs in three stages. Approximately 18 days after acquisition of the virus, and two to five days following the prodromal stage of the infection, the classic slapped cheek eruption appears, a fiery red rash on the cheek, accompanied by relative circumoral pallor (Figure 35.5). The edges of the involved areas may be slightly raised and there is relative circumoral pallor. At this stage the appearance may be suggestive of scarlet fever, drug sensitivity or other allergic reactions, or collagen vascular diseases. One to four days later the second stage appears, an erythematous maculopapular rash on the trunk and limbs. This rash is initially discrete but spreads to involve large areas. As this eruption fades it produces a typical lacy or reticular pattern. This third stage of the exanthem is highly variable in duration and maybe transient, or recurrent over one to three or more weeks with periodic evanescence and recrudescence. The rash can be exacerbated by exercise, emotion, hot baths or sunlight. In addition, there may be great variation in the eruption's appearance; from a very faint erythema that is easily missed to a florid exanthema,

and is often pruritic in adults, especially on the soles of the feet. While classic cases of EI are easy to recognize clinically, especially during outbreaks, the wide variation in the form of the rash may make individual cases hard to distinguish from other viral exanthema, including rubella.

Rarely the rash may be purpuric, or resemble Henoch–Shonlein purpura. In most B19V infections the platelet count is normal but thrombocytopenia has been recorded. Occasionally other dermatological presentations are seen, including vesicopustular rash, purpuric glove and stocking syndrome, and erythema multiforme.

Joint Involvement/Arthropathy

In children, B19V infection is usually mild and of short duration. However, in adults, and especially in women, there may be arthropathy in ~50% of patients (Woolf, 1990). It is now also clear with the widespread application of B19V diagnostic tests that the joint involvement may occur in the absence of any evidence of a rash.

In adults the most common presentation is with a sudden onset of symmetrical arthralgia and even frank arthritis affecting the small joints of the hand. Proximal interphalangeal and metacarpophalangeal joints are most often affected, followed by wrists, ankles, knees and elbows. Shoulders, cervical spine and lumbar spine as well as the hips may also be involved. There may be pain and stiffness in the joints, which may be accompanied by minor swelling or synovitis. Resolution usually occurs within a few weeks, but persistent or recurring symptoms

Figure 35.5 Child with characteristic slapped cheek appearance of fifth disease.

can continue for years (Reid *et al.*, 1985). In children the joint involvement may be asymmetrical and symptoms seem more severe than in adults and may be of longer duration.

In the absence of a history of rash, the symptoms may be mistaken for acute rheumatoid arthritis, especially as prolonged symptoms do not correlate with serologic studies, such as the duration of B19V IgM response, or persistent high-titre viraemia. In addition B19V infection can be associated with transient autoantibody production including transient rheumatoid factor. In one large study of patients attending an 'early synovitis' clinic in England, 12% had evidence of recent infection with B19 (White *et al.*, 1985). Three patients would have fulfilled the American Rheumatism Association's diagnostic criteria for definite rheumatoid arthritis. B19V infection should be considered as part of the differential diagnosis in any patient presenting with acute arthritis. In contrast to rheumatoid arthritis, B19V infection is not generally associated with joint destruction. However, differentiation between early rheumatoid arthritis and B19V arthropathy is important, as immunosuppressive therapy prescribed for rheumatoid is not indicated in parvovirus B19V infection.

The role of parvovirus B19V in the aetiology of chronic arthritis is unclear. Parvovirus B19V DNA can be found in synovial tissue of many patients, including children with arthritis. However B19V DNA can also be detected in synovial tissue in patients without arthropathy, and in one controlled study although B19V DNA was indeed detected in synovial tissue of 28% of children with chronic arthritis, but also found in 48% of non-arthropathy controls (Soderlund *et al.*, 1997), indicating that PCR-detectable DNA may persist in synovial tissues, as in other tissues for months/years/life.

It has been postulated that B19V is involved in the initiation and perpetuation of rheumatoid arthritis leading to joint lesions (Takahashi *et al.*, 1998), but these results have not been reproducible by other groups. In addition, in one study of long-term follow-up none of 54 patients with B19V-associated arthralgia reported persistence of joint swelling or restricted motion, and no evidence of inflammatory joint disease was found (Speyer *et al.*, 1998). Recent data suggest that rheumatoid arthritis may be triggered by a number of different pathogens in a susceptible individual. B19V infection may be one of the possible triggers, especially in children with juvenile rheumatoid arthritis (Lehmann *et al.*, 2003), and may also lead to a flare in disease activity.

Transient Aplastic Crisis

Transient aplastic crisis (TAC) is the abrupt cessation of erythropoiesis characterized by a fall from steady-state values of haemoglobin concentration, disappearance of

reticulocytes from peripheral blood and the absence of red blood cell precursors in the bone marrow. It is classically seen in patients with haemolytic anaemia, where the B19-induced cessation of erythropoiesis lasts five to seven days and patients present with symptoms of worsening anaemia, namely fatigue, shortness of breath, pallor, lassitude, confusion and sometimes congestive cardiac failure. The event is serious in most patients and occasionally it is fatal. Blood transfusion is required in the acute phase but after about one week the bone marrow recovers rapidly. There is a brisk reticulocytosis and the haemoglobin concentration returns to steady-state values.

TAC was the first clinical illness associated with B19V infection. When stored sera from 600 children admitted to a London hospital were examined six children had evidence of recent B19V infection (either antigenaemia or seroconversion). All were Jamaican immigrants with sickle cell disease presenting with aplastic crisis. There was a reduced haematocrit, and evidence of aplastic crises on their bone marrow (Pattison *et al.*, 1981). Studies since then have shown that more than 90% of all cases of aplastic crises in patients with chronic haemolytic anaemia are due to B19V infection. Most cases occur in children under the age of 20 but adults who remain susceptible to the virus infection may have B19-associated aplastic crises in later life.

B19V-associated aplastic crises are not confined to patients with sickle cell anaemia, but have been described in a wide range of patients with underlying haemolytic disorders, such as hereditary spherocytosis, thalassaemia, red cell enzymopathies such as pyruvate kinase deficiency and autoimmune haemolytic anaemia. Aplastic crisis can also occur under conditions of erythroid 'stress', such as haemorrhage, iron deficiency anaemia and following kidney or bone marrow transplantation. Acute anaemia has been described in normal patients and a drop in red cell count (and reticulocytes) was seen in healthy volunteers (Anderson *et al.*, 1985), but usually there is sufficient haematopoietic reserve, and this is not clinically apparent.

Although they have an ultimately self-limiting disease, patients with aplastic crisis can be severely ill. Symptoms include not only the dyspnoea and lassitude of worsening anaemia, but the patient may develop confusion, congestive heart failure, severe bone marrow necrosis cerebrovascular complications and the illness can be fatal. Aplastic crisis may be the first presentation of an underlying haemolytic disease in a well compensated patient.

Community-acquired aplastic crisis is almost always due to parvovirus B19V and should be the presumptive diagnosis in any patient with anaemia due to abrupt cessation of erythropoiesis as documented by reduced reticulocytes and bone marrow appearance. In contrast to patients

with EI, those with TAC are often viraemic at the time of presentation with concentrations of virus as high as 10^{14} IU (genome copies) ml^{-1} , and the diagnosis is readily made by detection of B19V DNA in the serum. As the B19V DNA is cleared from the serum, B19V-specific IgM becomes detectable. Typical TAC is readily treated by blood transfusion. It is a unique event in the patient's life, and following the acute infection immunity is lifelong.

TAC and B19V infection in haematologically normal patients is often associated with changes in the other blood lineages. There may be varying degrees of neutropenia, and thrombocytopenia. Transient pancytopenia is less common. Haemophagocytosis, which can occur after many different viral infections, has been noted in acute and persistent B19V infection.

B19V Infection in Pregnancy

Animal parvoviruses are known to cause congenital infections in a variety of animals, leading to fetal loss in rodents and pigs, and to congenital infections in cats and dogs, and B19V is no different, with B19V infection during pregnancy possibly resulting in either miscarriage or the development of hydrops fetalis. Following fetal loss, the clinical features of the fetuses are similar, with evidence of leukoerythroblastic reaction in the liver and large pale cells with eosinophilic inclusion bodies and peripheral condensation or marginatum of the nucleus. B19V DNA can be detected by dotblot, PCR or *in situ* hybridization, and parvovirus particles seen by electron microscopy (Field *et al.*, 1991).

However, an adverse fetal outcome is not typical following maternal B19V infection, and the timing of maternal infection is also crucial. In a prospective British study of over 400 women with serologically confirmed B19V during pregnancy, the excess rate of fetal loss was confined to the first 20 weeks of pregnancy and averaged only 9%, with a risk of hydrops fetalis of 2.9% following maternal infection between weeks 9 and 20 (Miller *et al.*, 1998). Transplacental transmission of B19V infection has been estimated at $\sim 33\%$, and discordant infections in twin pregnancies have been recorded. Transplacental transmission can occur even in the absence of maternal symptoms and there may be significant delay between maternal infection and development of hydrops, with intervals ranging from 2 to 17 weeks. No abnormalities were found at birth in the surviving infants, even when there was evidence of intrauterine infection by the presence of B19V IgM in the umbilical cord blood. There were also no long-term sequelae of B19V infection in the 129 children followed for over seven years, although three children were reported to have developmental delay.

B19V probably causes 10% of all cases of non-immune hydrops. Non-immune hydrops fetalis is rare (1:3000 births) and in approximately 50% of cases the aetiology is unknown. In a study of 55 cases of non-immune hydrops, the majority were due to cardiovascular or chromosomal abnormalities, but B19V infection was diagnosed in 14% of the cases (Ismail *et al.*, 2001).

Congenital Malformations

Although sporadic case reports have noticed an association between genitourinary abnormalities, cerebral abnormalities and ocular malformations, the abnormalities reported are all relatively common and without a control population it is difficult to interpret the abnormalities as being due to B19V. No systematic studies have shown evidence for congenital abnormalities following B19V infection. In the two British studies only one case with congenital malformation seen (a ventral septal defect) and it was concluded that the risk of congenital malformations due to B19V infection was less than 1%. In a similar study in the United States, again no increase in adverse long-term outcomes was observed. Thus there is no evidence to date that B19V causes birth defects, although it should be remembered that the sample sizes in the studies have been too small to detect a rare defect, that is, one with a rate of 1% or less. Nevertheless there is no reason to recommend termination of pregnancies complicated by laboratory-proven B19V virus infection.

Infants born with chronic anaemia following a history of maternal B19V exposure and intrauterine hydrops have been described. In three such cases two at birth were found to have hypogammaglobulinaemia, and viral DNA was present in the bone marrow, although absent from the serum (Brown *et al.*, 1994a). One child died but the other two remained persistently anaemic in spite of immunoglobulin therapy. In a related study of bone marrow from children with Diamond-Blackfan anaemia, B19V DNA was found in 3/11 marrow smears, all from children who underwent remission of their anaemia. Thus intrauterine B19V infection may be responsible for some cases of congenital anaemia, although the incidence is probably rare.

Pure Red Cell Aplasia

A chronic B19V infection resulting in pure red cell aplasia occurs in immunocompromised individuals who have failed to produce neutralizing antibody to the virus. Chronic infection has been reported in a wide variety of immunosuppressed patients, ranging from patients with congenital immunodeficiency, acquired immunodeficiency syndrome (AIDS), lymphoproliferative disorders and transplant patients. The stereotypical presentation

is with persistent anaemia rather than immune-mediated symptoms of rash or arthropathy. Patients have absent or low levels of B19V-specific antibody (Kurtzman *et al.*, 1989b) and persistent or recurrent parvoviraemia as detected by B19V DNA in the serum. Bone marrow examination generally reveals the presence of scattered giant pronormoblasts. Administration of neutralizing antibody in the form of human normal immunoglobulin often leads to a fall in virus titre, reticulocytosis and in some cases rash illness presumed to be due to immune complexes (Kurtzman *et al.*, 1988).

In less severely immunosuppressed patients (i.e. systemic lupus erythematosus on steroid therapy) prolonged anaemia following B19V infection has also been described. However in these patients there was a spontaneous, albeit delayed, development of antibodies, and viraemia resolved without therapy. Presumably such patients represent one end of the spectrum of disease manifestations of B19V in patients with a compromised immune system.

Atypical Presentations

A wide variety of symptoms and diseases have been associated with parvovirus disease (Table 35.3 and see Török, 1997), generally as case reports or limited small series of patients. Determining the role of B19V in these diseases is often difficult: the diseases are rare and B19V may not be the only cause. In addition, with sensitive PCR-based assays B19V DNA can be detected in bone marrow and other solid tissues from healthy individuals for years following acute infection. When the disease is rare, large multicentre trials may be required to substantiate or disprove the causal relationship. Many of these

Table 35.3 Atypical disease presentations of parvovirus B19V

Infection in the healthy host
Neurological disorders/encephalitis
Myocarditis
Hepatitis
Glomerulonephritis
Haematological
Thrombocytopenia
Neutropenia
Pancytopenia
Haemophagocytosis
Rheumatic diseases
Chronic fatigue syndrome
Fibromyalgia
Myositis
Vasculitis
Kawasaki disease
Polyarteritis nodosa

diseases have an autoimmune component associated with their pathogenesis (Lehmann *et al.*, 2003), and B19V is one of many of the putative causes or triggers.

LABORATORY DIAGNOSIS

Aplastic crisis is the only one of the clinical syndromes that can be assumed, with some accuracy, to be due to B19V infection. Even so, in patients with chronic haemolytic anaemia moderate to severe degrees of hypoplasia may be associated with systemic bacterial infection or marrow-suppressive drugs, and anaemia in the immunocompromised may have many other causes. Illnesses associated with maculopapular rashes with or without joint involvement also have a multiplicity of causes and only a minority of cases of hydrops fetalis will prove to be due to B19V infection. Thus accurate diagnosis of B19V infection depends upon specific laboratory tests.

Specimens

Serum is the principal specimen used for the laboratory diagnosis of B19V infection. This approach is suitable for virus detection in cases of aplastic crisis, persistent infection in immunosuppressed patients and persistent fetal infection. The detection of specific IgM antibody in serum is the cornerstone of the diagnosis of rash illness, and is often valuable in cases of aplastic crisis. Standard blood specimens are all that are required and no special arrangements are needed for transport to or storage in the laboratory. It should be remembered that viraemic samples may contain high titres of infectious virus, and care should be taken when handling samples, especially those taken early in the course of an aplastic crisis, to ensure that seronegative individuals in the laboratory are not infected (cases of laboratory-acquired infection have been described).

B19V studies can also be performed on tissue samples. DNA can be extracted from fresh, frozen or fixed samples for detection of parvoviral DNA. Detection of B19V by either immunohistochemistry or *in situ* hybridization can also be performed on formalin-fixed, paraffin-embedded tissue, so that standard pathology protocols can be used for dealing with bone marrow or fetal tissue.

Specific Antibody Detection

Standard solid-phase enzyme-labelled immunoassays (ELISAs) are the preferred method for the serological diagnosis of recent B19V infection, although immunofluorescent and Western blot assays are commercially available. Due to the inability to grow B19V in standard

cell culture systems, antigen used in these assays is recombinant proteins expressed in insect, yeast or bacterial cells, or linear peptide.

The best assays to detect recent infection with B19V are IgM capture or indirect assays, using recombinant viral-like particles as antigen. The commercial assays based on viral-like particles have excellent sensitivity and specificity. Sera containing high test : cut-off optical densities are associated with recent infection, but low positives can be seen in autoimmune diseases, and in patients with other rash-like illness. However, high concentrations of anti-B19 IgM usually appear within three to four days of the onset of symptoms and antibody can be detected in over 90% of cases by the third day of TAC or at the time of rash in EI. IgM antibody remains detectable for two to three months following infection (Figure 35.3). In patients presenting with symptoms of aplastic crisis, and occasionally in rash-like presentations specific IgM may not appear until 7–10 days after the onset. Therefore if a negative or equivocal result for anti-B19V IgM is obtained with a serum taken within 10 days of the onset of the illness, the serum should be tested for B19V DNA and/or a second specimen to be taken about 14 days after the onset of symptoms should be requested. Specific IgM is detectable for two to three months after acute infection. Interpretation of equivocal low concentrations of anti-B19V IgM in sera taken after this time can be difficult. However, B19V DNA generally remains detectable in serum for several months following infection, and low B19V IgM can be confirmed by the detection of B19V DNA. Alternatively tests to look for low-avidity antibody to the Vp1u, or the detection of antibody to linear epitopes to B19V VP2 proteins can be used to try and determine the time of infection. These assays are especially helpful in determining timing of possible infection in pregnancy (Enders *et al.*, 2005).

Evidence for previous infection is by detection of B19V IgG, preferably by indirect assay. For greatest sensitivity assays using recombinant viral-like particles should be used. B19V IgG is usually present by the seventh day of illness and probably is lifelong thereafter. As more than 50% of the population have IgG antibody to B19V infection, detection of B19V IgG in a single sample is not useful for the diagnosis of acute infection, but can be used to document seroconversion.

In 1995 the WHO Expert Committee on Biological Standardization recommended that an international standard (IU ml⁻¹) be set for anti-parvovirus B19V IgG testing. The international standard chosen correlates well with the original au scale in the earlier literature. In the 12 months following infection patients usually have relatively high (>50 IU ml⁻¹) concentrations of anti-B19V IgG and the finding of such concentrations supports the

diagnosis of infection during that time. However, there is marked individual variation in the maximum amounts of specific IgG that can be demonstrated in a patient, so that the finding of only low values (>20 IU ml⁻¹) does not exclude recent infection. Previous infection (and therefore immunity in most individuals) is indicated by the detection of >5 IU ml⁻¹ of anti-B19V IgG. However, a negative result cannot be taken to be synonymous with susceptibility.

There is a poor humoral immune response in immunocompromised patients with chronic parvovirus infection and only low concentrations of anti-B19V IgG (and IgM) can be detected in these patients. None of the detectable antibody neutralizes virus infectivity and this is taken to be an essential component of the pathogenesis of the chronic infection. The diagnosis of B19V infection in these patients is dependent on the detection of viral antigen or DNA.

Virus Detection

The culture of B19V in erythroid progenitor cells remains a research procedure and is not used in the routine diagnosis of B19V infections. Instead B19V detection relies on the detection of either viral antigen or viral DNA. Although ELISA- and haemagglutination-based assays have been developed to detect B19V antigen this is generally in the context of blood screening, and they are not used for B19V diagnosis. Instead, detection of viral DNA by quantitative PCR is the mainstay of detection of B19V. A variety of different primers and probes have been described, the most sensitive assays are capable of detecting 1–10 virus particles. Quantitation of the viral load is critical, as low levels of viral DNA (<10⁴ IU (genome copies) ml⁻¹) can be detected for months, or even years after acute infection.

The significance of low levels of B19V DNA in tissue or bone marrow can be confirmed by looking for evidence of viral antigen (by immunohistochemistry) or for evidence of replicating virus by detection of viral RNA.

The diagnosis of B19V infection in a fetus also depends upon the detection of viral DNA (or RNA). Maternal infection will have occurred some weeks previously and maternal serum may therefore be B19V-specific IgM negative. In most instances the fetus has also been found to be specific IgM negative but there is frequently a persistent viraemia. Therefore the diagnosis is best made by detection of B19V in fetal blood samples by the techniques described above. Equally virus can be detected in fetal tissues taken at autopsy from which DNA has been extracted or detected by immunohistochemistry or *in situ* hybridization on formalin-fixed, paraffin-embedded tissue sections. Fixed material can also be used for electron microscopy, but scattered B19V particles within cells

may be more difficult to recognize due to the large number of ribosomes of similar size, often necessitating immuno-gold techniques.

TREATMENT AND PREVENTION

There is no specific antiviral chemotherapy for B19V infection. Symptomatic relief of troublesome joint symptoms may be required for B19V-associated arthralgia, and blood transfusion may be necessary in the acute phase of aplastic crisis.

The only specific treatment for B19V infection is the intravenous administration of human immunoglobulin in cases of persistent infection in the immunocompromised patient. Human normal immunoglobulin preparations are a good source of neutralizing antibodies to B19V virus since at least half the adult population have been exposed to the virus. Controlled trials have not been done but on an empirical basis the administration of 0.4 g kg⁻¹ body weight per day for 5–10 days has proved effective in reducing viraemia and allowing the haemoglobin to return to near-normal values (Frickhofen *et al.*, 1990; Kurtzman *et al.*, 1989a). Patients sometimes relapse months later but they have been shown to respond to repeat courses.

Prevention of disease by isolating susceptible individuals is impractical because infections may be asymptomatic or subclinical, and even symptomatic individuals are most frequently infectious before any sign of illness. Theoretically, susceptible individuals with chronic haemolytic anaemia (or immunocompromised children) could be temporarily protected by the administration of human immunoglobulin but to date this has not been put into practice.

Many animal parvovirus infections are prevented in animals by vaccination, and the prospects for a B19V parvovirus vaccine are good. The immunogen will be recombinant capsid rather than attenuated or killed virus, due to the difficulty of cultivating B19V *in vitro* and the potential dangers of inadvertently modifying, for the worse, the host range of B19V by selection *in vitro*. Baculovirus-produced B19V capsids induce neutralizing antibodies in experimental animals (Kajigaya *et al.*, 1991), even without adjuvant. The presence of VP1 protein in the capsid immunogen appears critical for the production of antibodies that neutralize virus activity *in vitro*, and capsids with supranormal VP1 content are even more efficient in inducing neutralizing activity (Bansal *et al.*, 1993), and sera from human volunteers immunized with this type of candidate vaccine had neutralizing antibody titres equal to or higher than those observed after natural infection. Phase I trial results appear promising, and phase II trials are planned. However, the targets for such a vaccine remain to be

determined. Should only patients at high risk of severe or life-threatening disease, such as sickle cell patients be protected? Or, in view of the wide variety of disease manifestations affecting all strata of the population should a universal vaccine policy be pursued?

Human Retroviruses

Robin A. Weiss

University College London Medical School, London, UK

INTRODUCTION

Retroviruses are important human pathogens, which have also played several key roles in medical advances. It is thanks to the retroviral enzyme reverse transcriptase (RT) that complementary DNA (cDNA) is made, allowing the production of recombinant proteins as drugs; we also could not perform reverse transcription polymerase chain reaction (RT-PCR) assays to quantitate the load of many viruses of medical importance without the viral enzyme. If oncogenes had not been discovered and characterized in animal retroviruses, our understanding of the molecular basis of human cancer would have developed much more slowly. Finally, the use of retroviruses as vectors for gene transfer has had a significant impact on clinical gene therapy. This chapter introduces retroviruses both as pathogens and as medical tools, and briefly covers the retroviruses in humans other than the well-known pathogens human immunodeficiency virus (HIV) and human T-lymphotropic virus (HTLV). These retroviruses and their associated pathologies are discussed in detail in Chapters 37 and 38.

Retroviruses occur in numerous vertebrate species and are associated with a diversity of diseases: malignancy, autoimmune disease, immunodeficiency syndromes, aplastic and haemolytic anaemias, bone and joint disease (osteopetrosis and arthritis) and neuropathy (Table 36.1). Historically, veterinary diseases such as bovine leukosis and sheep pulmonary adenomatosis were recognized to be transmissible in the mid-nineteenth century. In the early years of the twentieth century, swamp fever in horses, and leukaemia and sarcomas in chickens were first identified as having a viral aetiology. Retroviruses were later found to be associated with malignant disease in mice, cats, ruminants, primates and other hosts,

including fish. A comprehensive text covers most aspects of the molecular biology of animal and human retroviruses (Coffin *et al.*, 1997). There is also a recent critical review of all the claims for association of retroviruses with human diseases (Voisset *et al.*, 2008).

The first genuine human retrovirus to be characterized was the human T-lymphotropic virus type 1 (HTLV-1) in 1980 (Poiesz *et al.*, 1980) while HIV-1 was first reported in 1983 (Barre Sinoussi *et al.*, 1983) just two years after the recognition of acquired immune deficiency syndrome (AIDS) as a new disease entity.

There are also numerous cases of zoonotic infections of humans by retroviruses maintained in animal reservoirs, for example, foamy viruses. HIV-1 and HIV-2 had zoonotic origins in the twentieth century, while HTLV-1 and HTLV-2 became human-to-human infections much earlier. However, new simian-to-human infections of HTLV-1-related viruses still occur.

RETROVIRUS REPLICATION AND GENOMES

Retroviruses are a single taxonomic group of RNA viruses that encode the RNA-directed DNA polymerase reverse transcriptase. Upon infection, this enzyme catalyses the synthesis of a double-stranded DNA genome. The provirus subsequently becomes integrated into host chromosomal DNA and serves as a template for viral genomic and messenger RNA transcription by the host cell's RNA synthetic and processing systems (Figure 36.1). Other special features of retroviruses include a diploid RNA genome, a high frequency of intermolecular recombination between related viruses and the ability to acquire host genes which encode functions responsible for neoplastic

Figure 36.1 Simplified replication cycle of a retrovirus. The virion containing two RNA genome copies enters the virus via a specific cell surface receptor complex. The single-stranded RNA genome is converted into a double-stranded DNA provirus by the virion enzyme reverse transcriptase (RT). The provirus inserts into host chromosomal DNA in the same orientation as the original virion RNA. Transcription of RNA from the integrated DNA provirus is mediated by cellular RNA polymerases, and this RNA serves both as messenger RNA for the synthesis of viral antigens and as genomic RNA, which becomes packaged into progeny virions budding from the cell surface. The straight arrows indicate steps in replication that can be blocked by antiretroviral drugs.

transformation (oncogenes). Moreover, there are numerous endogenous proviruses in the normal cellular DNA of all vertebrates examined (including humans), which represent 'fossil' infections by retroviruses of the germline of the hosts' ancestors and which are passed from generation to generation in a mendelian manner (Weiss, 2006).

All retroviruses carry at least three genes with the genome structure in the order 5' LTR-*gag-pol-env*-3' long terminal repeats (LTRs). *Gag* encodes a precursor protein which is cleaved to yield three or four structural core and matrix proteins; *pol* encodes the RT, protease and integrase, synthesized from a *gag-pol* precursor; while *env* encodes a precursor cleaved to form the two envelope proteins, surface (SU) and transmembrane (TM). The core proteins are often named by molecular weight (e.g. p24 and p17 of HIV). The outer SU protein is glycosylated and is known as gp120 (e.g. for HIV with an approximate molecular weight of 120 000) or gp70

(e.g. gamma-retroviruses such as murine leukaemia virus (MuLV)). The anchored TM protein, to which the SU protein is bound, is glycosylated in some retroviruses (e.g. gp41 of HIV) but not others (e.g. p15E of C-type oncoviruses). The DNA proviral genome is capped by LTRs at both ends and the RNA form has a polyadenylate tract at the 3' end, like mRNA. The LTRs are the sites for integration of the DNA provirus with cellular DNA, and contain important promoter and enhancer sequences that bind cellular and viral proteins regulating viral gene expression. Integration is an obligatory step in the retroviral life cycle. The main steps in replication that are targets for antiretroviral drugs are indicated in Figure 36.1.

TAXONOMY

The *Retroviridae* used to be divided into three subfamilies: the *Oncovirinae*, which include those with oncogenic potential; the *Lentivirinae* or slow viruses, including HIV and the prototype maeda-visna virus (MVV) of sheep which causes progressive wasting disease, pneumonia and degeneration of the central nervous system; and the *Spumavirinae* or foamy viruses, which have not been shown to be pathogenic in any species. Retroviruses are now reclassified into seven distinct genera by dividing oncoviruses into five, as they are only distantly related by genome sequence and morphology (Figure 36.2 and Table 36.2). More generally, retroviruses are divided into those with 'simple' genomes, having *gag*, *pol* and *env* genes and perhaps one other gene, and those with 'complex' genomes. Members of the latter group possess regulatory genes, such as *tat* and *rev* of HIV and *tax* of HTLV, and accessory genes, such as *nef*, *vif* and *vpr* of HIV.

HUMAN AND ZONOTIC RETROVIRUS INFECTIONS

At least five groups of retroviruses have been reported as human infections.

1. Human immunodeficiency virus types 1 and 2 are the lentiviruses that cause AIDS. Before the term HIV was coined in 1986, HIV was called lymphadenopathy virus (LAV), HTLV-3 or ARV. HIV and AIDS are covered in Chapter 38.
2. Human T-cell lymphotropic virus types 1 to 4 (HTLV-1, etc.) are deltaviruses (note the nomenclature HTLV-3 to avoid confusion with a previous name for HIV). Type 1 causes adult T-cell leukaemia and neurological disease, and is reviewed in

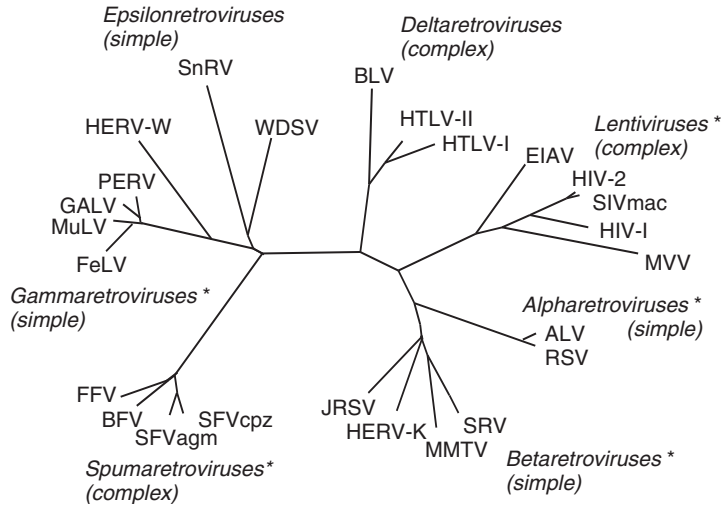

Figure 36.2 Phylogenetic tree of the seven main genera of retroviruses. Abbreviations beginning with H are human viruses. The * denotes genera that include endogenous viral genomes in addition to exogenous infectious viruses.

Table 36.1 Diseases caused by retroviruses in animals

Disease/disorder	Species affected
Leukaemia	Avian, mouse, cat, primates
Lymphoma	Avian, mouse, cat, primates, fish
Carcinoma	Avian, mouse, sheep
Sarcoma	Rat, chicken, fish
Anaemia, aplasia	Cat, horse
Autoimmune disorders	Cat, primates, sheep, mouse
Immune deficiency	Cat, primates
Nervous system	Sheep, goat, mouse
Osteopetrosis	Chicken
Arthritis	Goat

Chapter 37. Only a small proportion of people infected with HTLV-1 progress to disease. The Tax protein and the bZIP factor may play a role in initiating HTLV malignancies (Yasunaga and Matsuoka, 2007).

- Primate foamy virus (PFV) is a spumavirus originally detected in cultured nasopharyngeal carcinoma cells of a Kenyan patient. This finding marked the first report of human infection by a retrovirus (Achong *et al.*, 1971). Because the PFV genome is indistinguishable from that of the simian foamy virus type 6 of chimpanzees, it probably represents a zoonosis and several other examples of foamy virus infections transmitted to humans from various species of Old World monkeys and apes have been recorded (Heneine *et al.*, 2003). Zoonotic

PFV infection without clinical symptoms has been recorded in primate handlers who have suffered bites or puncture wounds and is frequently seen in people who worship at Hindu temples that are populated by macaques and langurs. However, there is no evidence of human-to-human transmission of PFV, not even from PFV-infected people who were blood donors (Heneine *et al.*, 2003; Murray and Linial, 2006).

- Murine retroviruses—Since the discovery of RT in 1970 there have been numerous reports of retrovirus infections in human cells in culture, which were thought to represent human retroviruses. However, several of these infections resulted from *in vitro* contamination by murine, feline or non-human primate retroviruses, whereas others could not be firmly substantiated. Other reports recorded PCR detection of retroviral genomes in noncultured human biopsy samples, for example, of murine mammary tumour virus sequences in human breast tumour tissue. Most of these claims have been difficult to confirm or substantiate and require cautious interpretation in case they originate from the extraordinary sensitivity of detecting retroviral sequences in animal material (such as sera) contaminating human specimens in the laboratory. A good rule of thumb is that the detection of unusual, low-level retroviral sequences in DNA from human biopsies should not be taken as evidence of genuine infection unless the retroviral genomes are clearly integrated into human DNA, which can be ascertained by analysis of host sequences flanking the integration sites (Voisset *et al.*, 2008).

Table 36.2 Classification of retroviruses of vertebrates

Genus	Example	Virion morphology ^a	Genome
Alpharetroviruses	Rous sarcoma virus Avian leukosis virus	Central spherical core; C-type —	Simple
Betaretroviruses	Murine mammary tumour virus Simian retrovirus type I	Eccentric spherical core; B-type Central spherical core; D-type	Simple
Gammaretroviruses	Murine leukaemia virus	Central spherical core; C-type	Simple
Deltaretroviruses	Human T-cell leukaemia virus	Central spherical core	Complex
Epsilonretroviruses	Fish dermal sarcoma virus	Central spherical core; C-type	Simple
Lentiviruses	Human immunodeficiency virus	Cone-shaped core	Complex
Spumaviruses	Primate foamy virus	Central spherical core; long envelope spikes	Complex

^aBetaretroviruses and spumaviruses have condensed cores visible in the cytoplasm of infected cells, whereas in the other retroviruses the cores condense as crescent-shaped bodies during maturation and budding at the cell membrane.

5. XMRV—Evidence of retroviral integration into human DNA has been provided for a gammaretrovirus, xenotropic MuLV-related virus (XMRV), which is closely related to xenotropic MuLV. Endogenous strains of MuLV are denoted ecotropic if their host range is restricted to rodents, xenotropic if they cannot reinfect murine cells but can infect ‘foreign’ species such as human cells, and amphotropic if they can infect both murine and human cells. XMRV has been found in stromal cells of prostate cancer biopsies in patients homozygous for a variant of the RNaseL enzyme that gives reduced activity (Dong *et al.*, 2007). RNaseL is a downstream effector of the interferon pathway to which XMRV is sensitive. The natural history of XMRV is not yet elucidated, and it might represent a zoonotic infection from mice that only infects people with defects in the interferon response pathway. There is also preliminary evidence of human infection by a virus related to murine mammary tumour virus, a betaretrovirus, in patients with primary biliary cirrhosis (Voisset *et al.*, 2008).
6. Human endogenous retroviruses (HERVs) are mendelian loci in human chromosomes representing ‘fossil’ infections of the germline (Weiss, 2006). Approximately 8% of human DNA sequences are derived from HERV insertions and some 42% of human DNA derives from retrotransposons (de Parseval and Heidmann, 2005). The best-characterized HERV genomes are related to mammalian gamma- and betaretroviruses (HERV-K; which uses tRNA for lysine as a primer) but others exist too. No deltaretroviruses are known to have become endogenous. HERV genomes are almost all defective, that is, human endogenous retroviral genomes have not been rescued in infectious form, in contrast to baboon endogenous virus (BaEV) and porcine endogenous virus (PERV) of pigs, which threaten the safety of human xenotransplantation from these

sources (Magre *et al.*, 2003). Many HERV genomes express envelope and other proteins. For example, HERV-W (which uses tRNA for tryptophan as a primer) in the human placenta may be necessary to effect cell fusion in the syncytiotrophoblasts (de Parseval and Heidmann, 2005). HERV-K is expressed in testicular tumours and in the pancreas of type 1 diabetes while HERV-W is expressed in multiple sclerosis brain lesions, yet none of these viral genomes have been shown to play a causal role in these diseases (Voisset *et al.*, 2008).

RETROVIRAL VECTORS

Retroviruses have been turned to clinical use as vectors in gene therapy and immunotherapy (Gaspar and Thrasher, 2005). Because retroviral genomes naturally integrate into host chromosomal DNA they provide an excellent means of delivering therapeutic genes or genes encoding antigens for vaccination. MuLV, a gammaretrovirus, was pioneered for gene therapy, using three plasmids in packaging cells: expressing MuLV *gag* and *pol* to provide core proteins and viral enzymes, vesicular stomatitis G protein as an envelope, and the therapeutic gene in a vector carrying packaging signals and the LTR of MuLV. However, in a successful, curative clinical trial of gene therapy of infants with severe combined immune deficiency due to adenine deaminase deficiency, some patients developed leukaemia as a result of the integration of the vector with an active LTR adjacent to a host oncogene. Safer vectors have been developed without promoters and enhancer sequences in the LTR, or omitting the need for integration altogether (Philpott and Thrasher, 2007).

Lentiviral vectors, usually based on the HIV-1 genome, or that of equine infectious anaemia virus, have an advantage over MuLV vectors in their capacity to infect

nondividing target cells (Philpott and Thrasher, 2007). Foamy virus vectors are under development because this type of retrovirus has not been associated with disease in animals or humans (Murray and Linial, 2006; Rethwilm, 2007).

The Human T-Lymphotropic Viruses

Graham P. Taylor

Department of Genito-Urinary Medicine and Communicable Diseases, Faculty of Medicine, Imperial College, London, UK

INTRODUCTION

The HTLV-BLV viruses are a subfamily of the family *Retroviridae*. They comprise the more well-known human T-cell lymphotropic virus types 1 and 2 (HTLV-1, HTLV-2); bovine leukaemia virus (BLV); and an increasing number of simian T-lymphotropic viruses/primate T-lymphotropic viruses (STLVs/PTLVs), which are closely related to HTLV-1 and -2, including the recently described HTLV-3 (Calattini *et al.*, 2005; Wolfe *et al.*, 2005) and HTLV-4 (Wolfe *et al.*, 2005). HTLV-1 infection is usually asymptomatic but is associated with malignant and inflammatory diseases and a mild or selective impairment of immune function in a minority. Disease associations with HTLV-2 are less well established. STLVs have been associated with malignant disease in non-human primates, but not necessarily in the primary host species. In a small proportion of naturally infected cattle, BLV is associated with a B-cell leukaemia. However, leukaemia or lymphoma is very common in sheep experimentally infected with BLV.

HISTORY

The discovery of HTLV-1 as an important human pathogen was the result of two distinct lines of research. One, the long search for cancer-causing retroviruses in humans, was dependent on the earlier discovery and refinement of tests for reverse transcriptase (RT), together with the identification and use in cell culture of T-cell growth factor, now known as interleukin 2 (IL-2). In 1980, Gallo's team

found that one of their many transformed T-cell lines derived from leukaemia/lymphoma patients contained a retrovirus (Poiesz *et al.*, 1980). This virus was HTLV-1, also sometimes referred to as the human T-cell leukaemia/lymphoma virus type I. The second was the recognition (1974) and description (1977) of a new disease entity, adult T-cell leukaemia-lymphoma (ATLL) by Takatsuki and colleagues (Uchiyama *et al.*, 1997). The clustering of this disease particularly in south-western Japan suggested an environmental or infectious aetiology. Gallo's cell line was derived from the lymphocytes of an Afro-American patient with an aggressive form of cutaneous T-cell lymphoma subsequently recognized to be cutaneous ATLL.

In 1981 Miyoshi and colleagues produced an immortalized T-cell line by the co-culture of peripheral blood lymphocytes from a woman with ATLL with cord blood cells from a male baby (Miyoshi *et al.*, 1981). This cell line (MT-2), which has an XY karyotype, was observed to produce numerous extracellular type C retroviral particles and was positive for adult T-cell leukaemia antigen by indirect immunofluorescence (Hinuma *et al.*, 1981). Using viral antigens from MT-2 cells to develop a serological test they demonstrated that nearly all ATLL patients and a high proportion of their relatives had antibodies to this virus (Yoshida *et al.*, 1982). Known initially in Japan as adult T-cell leukaemia virus (ATLV), sequence analysis showed that ATLV was almost identical with HTLV-1. Seroprevalence studies revealed that ATLV/HTLV-1 was endemic in south-western Japan with 15% of the population seropositive, rising to 30% in some villages. In central Japan only 1% of the population were seropositive, with higher rates again in the north. The inhabitants

of central Japan are believed to have come from mainland Asia about 300 BC, displacing the 'older' population to the north and south-west. This distribution suggests that the arrival of HTLV-1 in Japan preceded this migration.

A high seroprevalence of HTLV-1 in patients in Martinique with tropical spastic paraparesis (TSP) was first described by Gessain *et al.*, (1985) and the description of an identical condition, HTLV-1-associated myelopathy (HAM) in Japan was published the following year (Osame *et al.*, 1986). This disease is commonly referred to as HAM/TSP but here the acronym HAM will be used as the data presented refer only to HAM. HTLV-1 seronegative TSP occurs.

A related virus, HTLV-2 was isolated from the cells of a patient with an atypical hairy cell leukaemia (HCL) by Kalyanaraman *et al.*, (1982). HCLs are usually of B-cell origin but the infected cell line expressed T-cell markers. Although HTLV-2 was isolated from a second patient with HCL, subsequent extensive investigation has failed to confirm any association between HCL and HTLV-2 infection. HTLV-2 shares 60–70% sequence homology with HTLV-1 and anti-HTLV-2 antibodies are detected by HTLV-1 lysate or whole virus-based assays.

STLVs have been found in macaques and other Old World monkeys, and STLV-1 appears to be more closely related to HTLV-1 than to other STLV/PTLVs. HTLV-1/STLV-1 strains cluster geographically rather than by host species. During the last few years a number of STLVs closely related to, but discrete from, HTLV-1 have been characterized. These include relatives of HTLV-2 (Giri *et al.*, 1994) and viruses that cluster neither with HTLV/STLV-1 nor -2. The first of these, found in an Eritrean baboon (*Papio hamadryas*), was designated PTLV-L, after Leuven where the baboon was residing and the virus was isolated (Goubau *et al.*, 1994). STLVs isolated from wild-caught red-capped mangabeys (*Cercocebus torquatus*) from Cameroon are distinct from, but cluster with, PTLV-L in the newly designated PTLV-3 type (Meertens *et al.*, 2002). In 2005 an HTLV isolated from natives of Cameroon was found to demonstrate seroreactivity similar to HTLV-2 but genomic sequencing independent from HTLV-1 and HTLV-2 and distinct clustering with the PTLV-3s. HTLV-III having been used, along with lymphadenopathy virus (LAV) as an early name for HIV-1, this virus has been designated HTLV-3 (Calattini *et al.*, 2005). Thus far, HTLV-3 has been found only in subjects with a connection with the bush-meat trade and there is no evidence of disease association or nonzoonotic transmission. In addition to HTLV-3, an independent group also identified multiple human infections with STLV-1 viruses and a further distinct isolate, HTLV-4 (Wolfe *et al.*, 2005).

THE VIRUS

Morphologically HTLV-1 and -2 resemble C-type retroviruses (Figure 37.1). They can be grown *in vitro* in immortalized lines obtained by culturing patients' cells with phytohaemagglutinin (PHA) and IL-2. *De novo* infection of T cells and cell lines requires co-cultivation using irradiated or mitomycin-C-treated HTLV producer cell lines. The HTLVs are not readily transmissible in cell-free form and this is reflected in the observation that only whole fresh blood transfusion and not plasma or other cell-free fractions results in transmission (Okochi *et al.*, 1984).

Susceptible cell lines can be identified by the formation of syncytia (giant multinucleated cells) upon contact with virus-producing cells. This interaction requires the presence of the HTLV-1 envelope and specific cell membrane ligands (receptors). The syncytial assay has proved useful in studying HTLV-1, particularly for the detection of neutralizing antibodies and cellular receptors (Clapham *et al.*, 1984). *In vitro* many cell types from a broad range of species, including astrocytes, can be infected. *In vivo* HTLV-1 primarily infects CD4⁺ lymphocytes whilst HTLV-2 infects CD8⁺ lymphocytes. However HTLV-1 infection of CD8⁺ lymphocytes does occur and is more common among HTLV-1-specific cytotoxic CD8⁺ lymphocytes than other CD8⁺ cells (Hanon *et al.*, 2000). Infection of B cells, monocytes (Koyanagi *et al.*, 1993) and natural killer (NK) cells (Igakura *et al.*, 2003) has been reported, but Richardson found no evidence of such infection cells *in vivo* (Richardson *et al.*, 1990) Whether HTLV-1 infection of neural cells occurs *in vivo* remains controversial.

The glucose transport protein GLUT-1 (Manel *et al.*, 2003) has been identified as a receptor for HTLV-1 but since this is widely distributed while HTLV-1 tropism is narrow, an additional receptor seems probable. The

Figure 37.1 HTLV-1 electron micrograph. Electron micrograph of HTLV-1 particles produced by a T-cell line transformed *in vitro*. Note the variable size of the particles and the diffuse spherical core.

envelope proteins of HTLV-1 and HTLV-2 are the target for neutralizing antibodies. Sera from British or American patients and asymptomatic carriers of HTLV-1 neutralize equally viruses from other countries including Japan (Clapham *et al.*, 1984). This suggests that there is a single worldwide serotype for HTLV-1.

The 9 kb genome of HTLV-1 contains the three major open reading frames (ORFs), *gag*, *pol* and *env*, of all retroviruses flanked by two long terminal repeats (LTRs) with an additional regulatory region, pX (Figure 37.2). The names, product size and functions of the genes of HTLV-1 are summarized in Table 37.1. The HTLV-2 genome is very similar except that five ORFs have been identified in pX.

The LTR containing the viral promoter and other regulatory elements are divided into three regions, U3, R and U5. The U3 region contains elements that control proviral transcription, messenger RNA termination and polyadenylation.

The first major reading frame (*gag*) encodes a 429 amino acid precursor polyprotein Pr53^{Gag}. A second major reading frame within the *gag-pol* complex encodes a second precursor Pr76^{Gag-Pro} which gives rise to the viral protease. This frame slightly overlaps with *gag* and is generated by a frameshift suppression of the *gag* terminator codon. During viral assembly the *gag* precursors accumulate at the inner face of the plasma membrane and are anchored there by the matrix domain. In the absence of protease immature viral particles are released. During and early after viral budding cleavage of Pr53^{Gag} into the three major structural proteins of the core of the virus, 19 kDa (matrix protein), 24 kDa (capsid protein) and 15 kDa (nucleocapsid protein), results in the formation of the mature virion. The viral genome is transported to the cell envelope bound to the *gag* precursor. The matrix domain of the *gag* precursor is involved in targeting of the *gag* precursor-genome complex to the plasma membrane (this also requires myristylation of the polyprotein) and in

Figure 37.2 Schematic representation of the HTLV-1 genome. (Source: Modified from Franchini, G. (1995) *Blood*, **86**, 3619–39. Reproduced with permission.)

Table 37.1 Products of HTLV-1 genes

5' LTR		Contains regulatory elements essential for viral replication			
<i>gag</i>	Group <i>antigen</i>	Nucleocapsid proteins	p19 p24 p15	Matrix Capsid Nucleocapsid	
<i>pol</i>	<i>Polymerase</i>	Reverse transcriptase	RT	transcription of DNA from RNA	
		Proteinase		cleavage of protein precursors	
		RNaseH		digestion of RNA template	
		Integrase		integration of proviral DNA into host genome	
<i>Env</i>	<i>Envelope</i>	Surface glycoprotein	gp46	SU

efficient budding of the viral particle from the cell. The mature (cleaved) matrix protein also plays a role early in the replication cycle, in viral entry, as virions with defective matrix proteins have reduced infectivity even when properly released (Le Blanc *et al.*, 1999). The capsid proteins assemble during viral maturation to form the shell around the core of the nucleus. The N-terminal domain is essential for viral particle formation (Rayne *et al.*, 2001). In the viral particle the nucleocapsid protein is also a key component of the capsid and is in close contact with the genome. In the cell the nucleocapsid domain of the *gag* precursor polyprotein is important for recognition and packaging of the viral genome. Retroviral *gag* function is reviewed in (Wills and Craven, 1991).

The remaining products of *pol*, RT and integrase are encoded by a different ORF and are cleaved from a 99 kDa precursor protein. RT transcribes the single viral RNA strand, generating first the complementary DNA strand

and then, using that as a template, the viral DNA version of the original RNA; the latter is digested by RNase H. The double-stranded viral DNA is then integrated into a host cell chromosome. Having no proofreading mechanism, RT is error prone, and a high frequency of mutation would be expected to result in HTLV/STLV sequence diversity. However, as we will see later, this does not occur.

Env encodes a 481-amino-acid protein that after glycosylation has a molecular weight of 62 kDa and is processed into an outer surface protein of 46 kDa and a transmembrane protein of 21 kDa. The envelope precursor is translated from a 4.2 kb mRNA from which *gag* and *pol* have been spliced out.

The fifth genomic region, referred to as pX, is located between *env* and the 3' LTR. The region codes for *tax* and *rex* which are translated from a double spliced 2.1 kb mRNA as well as three additional proteins encoded by

ORFs I, II and III, whose functions are slowly being revealed. Tax, a 40 kDa protein that is expressed early, drives viral transcription from Tax responsive elements (21 bp repeats) in the LTR U3 and is an important upregulator of viral replication. In addition *tax* transactivates a range of host cellular genes through which it is thought to affect cell replication and play an important role in the pathogenesis of ATLL. The immunodominant peptides for the host cytotoxic T-lymphocyte response are also usually found in the Tax protein. This may be important both for the control of infection and in the pathogenesis of inflammatory disease associated with HTLV-1, of which the archetype is HAM.

Rex is a 27 kDa phosphoprotein which determines the export of unspliced *gag-pol* mRNA and singly spliced *env* mRNA from the nucleus, thereby controlling the production of viral proteins and infectious virus. Rex production results in increased export of *env* mRNA and unspliced viral RNA for the Gag/Pol proteins essential for the production of new virions and aids a shift from doubly spliced P_x RNA to *gag-pol* and *env* RNA. Thus the overall effect of Rex may be virion production soon after infection followed by downregulation of viral expression. This may protect the infected cell from death due to the cytolytic effect of virion production and protect both the infected cell and the virus from the host immune response (Hidaka *et al.*, 1998).

The Tax (p37) and Rex (p26) proteins of HTLV-2 are slightly smaller than those of HTLV-1. HTLV-2 Tax shares 72–74% amino acid homology with HTLV-1 Tax. However the C-termini of HTLV-2 Tax (both HTLV-2a and HTLV-2b) are different from HTLV-1 Tax. Tax IIa has a 22-amino-acid truncation at the C-terminus while the C-terminus of Tax IIb has 25 amino acids which are totally different from Tax I (Lewis *et al.*, 2000). *In vitro* HTLV-2 Tax proteins activate transcription of NF- κ B and the c-AMP response element-binding protein (CREB) pathways just as well as HTLV-1 Tax, although Tax from some HTLV-2a isolates had much less transcriptional activity possibly due to low levels of expression of Tax (Lewis *et al.*, 2002). However both Tax IIa and Tax IIb are less efficient at transforming rat fibroblast cell lines than Tax I (Endo *et al.*, 2002).

The additional proteins are p13 and p30 (ORF II) and p12 from ORF I. P30^H localizes to the nucleus and may modulate transcription of cellular genes. P13^H localizes to mitochondria and *in vitro* disrupts the mitochondrial inner membrane potential. Although not essential for viral replication these proteins are important for viral infectivity. P12^I exhibits weak oncogenic activity and is important in infectivity. (Reviewed by Ciminale *et al.*, 1996 and by Johnson *et al.*, 2001).

Encoded from the antisense strand of the P_x region is the HTLV-1 bZIP protein (HBZ) (Gaudray *et al.*, 2002). This

leucine zipper protein inhibits CREB binding to the viral promoter, thus countering the action of Tax (Lemasson *et al.*, 2007). Conversely, HBZ mRNA has been shown to contribute to T-cell proliferation (Satou *et al.*, 2006).

DIAGNOSIS

Detection of HTLV-1 and -2 infection is primarily by serology. A particle agglutination assay based on whole viral lysate is sensitive for both viruses and relatively inexpensive but limited by poor specificity. First-generation commercial enzyme immunoassays (EIAs) were more specific than the agglutination assays but less sensitive, particularly for HTLV-2. EIAs incorporating recombinant peptides are highly sensitive and specific for HTLV-1 and HTLV-2. Immunofluorescence assays using fixed infected cells with uninfected cells as controls can be used to confirm and type infections but are subjective. Peptide-based assays that discriminate between HTLV-1 and HTLV-2 have been developed but HTLV-1 infection is usually confirmed by the detection of antibodies to *gag* (p19 and p24) and *env* (gp21 and gp46) by Western blot (Figure 37.3), although radioimmune precipitation assays (RIPAs), radioimmune binding assays (RIBAs), line immunoprecipitation assays (LIAs) and competitive enzyme-linked immunosorbent assays (ELISAs) can also be used. p19 antibody is often absent in, and is not required to confirm, HTLV-2 infection. Recombinant *env* peptides have improved the sensitivity and specificity of Western blotting and type-specific antigens rgp46-I and rgp46-II enable the infections to be discriminated without resort to molecular methods. Minimal criteria for the diagnosis of HTLV infection are the detection of antibodies to one *gag* and one *env* protein. Western blots that reveal some virus-specific bands but which are not sufficient to make a positive diagnosis are termed 'indeterminate'. Further investigation is then warranted, including DNA amplification using generic or type-specific primers and repeat serology after a few weeks. Viral culture may be required to confirm an infection but is costly, time consuming and must be conducted in a category 3 laboratory (The HTLV European Research Network, 1996). Although HTLV-1 viral DNA load is frequently high in asymptomatic carriers, very low levels, <1 HTLV DNA copy per 100 000 peripheral blood mononuclear cells (PBMCs), can be found and a negative polymerase chain reaction (PCR) does not exclude the diagnosis of HTLV infection. In European studies HTLV-1/2 infection was not confirmed in the majority of low-risk subjects with Western blot indeterminate sera, whereas among HIV-infected injecting drug users HTLV-2 infection might be found by DNA amplification. Indeterminate Western blot patterns are common in the tropics and may be more common than confirmed

Figure 37.3 HTLV-1 and -2 Western blot with recombinant peptides which discriminate between HTLV-1 and HTLV-2 infection. (Genelabs HTLV 2.4, Singapore.)

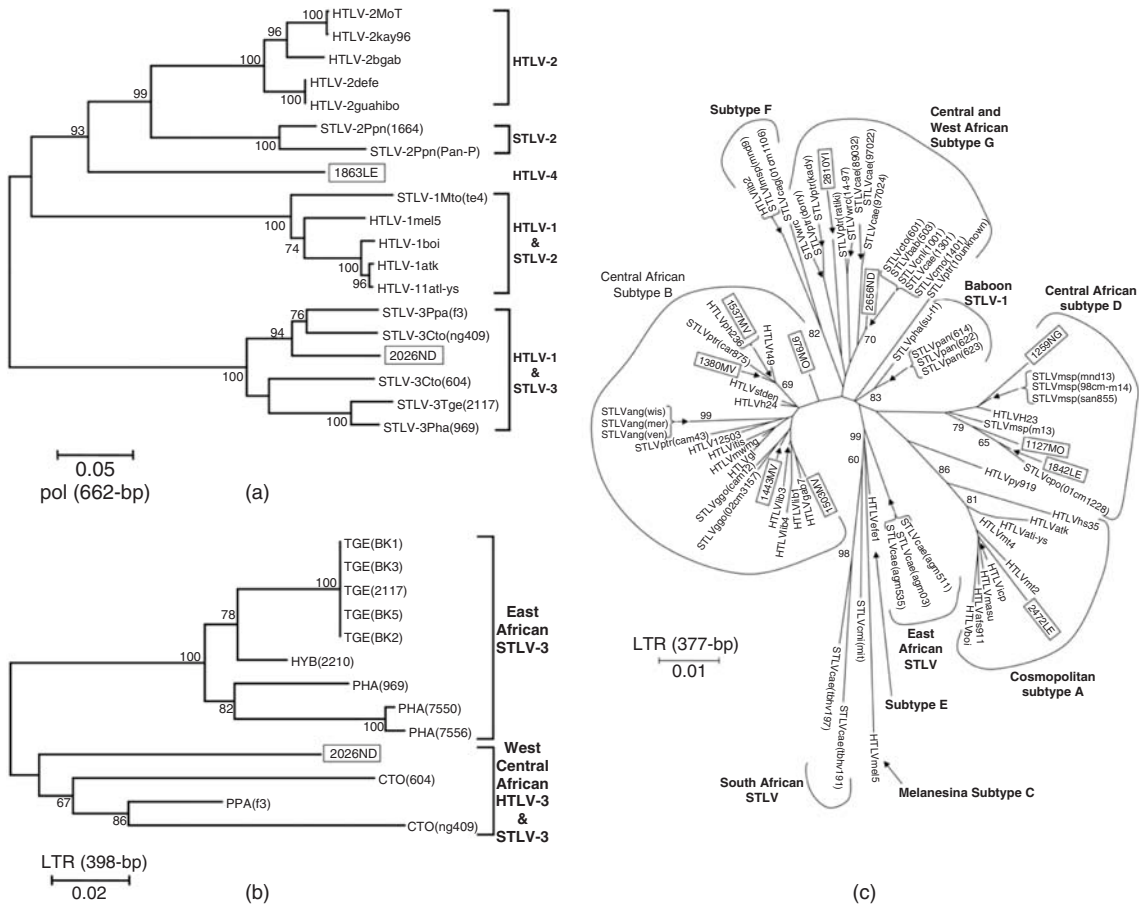

HTLV-1 infection, even in endemic areas. In this setting antibodies to Gag proteins only have been associated with a low risk of HTLV infection (Rouet *et al.*, 2001).

The presence of the recombinant surface membrane glycoprotein (RD21 in the HTLV 2.4 Western blot kit, Genelabs, Singapore) alone may reflect recent infection and a follow-up sample should be obtained. Antibodies to the Gag proteins p19 and p24 usually appear early following seroconversion whereas antibodies to the transmembrane glycoprotein gp46 appear later. Anti-Tax antibodies occur late or not at all (Manns *et al.*, 1991).

VIRAL VARIATION

Despite the high mutation rate seen with RT, HTLV-1 has a highly conserved genome with only about 4% sequence variation between isolates from around the world. The

only exceptions are isolates from Australian aborigines and Melanesians which form a distinct genotype or clade, HTLV-1_{MEL}, and which have up to 8% diversity in LTR and/or env. Most other isolates from Africa, Japan or the Caribbean belong to the Cosmopolitan clade, HTLV-1_{COS}. However, three other clades have been recognized, from Central Africa, from West Africa and from Japan (Ureta-Vidal *et al.*, 1994). In phylogenetic analyses, STLV-1, which is almost identical to HTLV-1, clusters with HTLV-1 by geography rather than by species (Figure 37.4). This suggests that there have been a number of simian-human transmissions (Koralnik *et al.*, 1994). HTLV-2 shares 60–70% sequence homology with HTLV-1. HTLV-2 isolates generally belong to genotype a or b. HTLV-2c (Eiraku *et al.*, 1996) has to date only been described in Brazil among Amazonian Indians

Figure 37.4 Phylogenetic analysis showing the relationship between HTLV-1/STLV-I subtypes.

(Ishak *et al.*, 2007) while HTLV-2d was described in Congolese pygmies (Vandamme *et al.*, 1998).

The highly conserved nature of HTLV-1, HTLV-2 and their simian counterparts is unexpected for a retrovirus and quite distinct from the rapid evolution of HIV and hepatitis C virus (HCV). RNA viruses usually evolve at 1/100 to 1/10 000 nucleotide substitutions/site/year whereas HTLV-2 is mutating at a rate of 1.7–7.31/10 000 nucleotide substitutions/site/year in the LTR. From family studies involving two to three generations it appears that HTLV-1 only undergoes a few replication cycles, perhaps early following infection, in each generation (Van Dooren *et al.*, 2001). It was suggested that HTLV-2 is evolving faster in injecting drug users than in endemic populations: 2.7 nucleotide substitutions per 10 000 sites per year in injecting drug users, which would be consistent

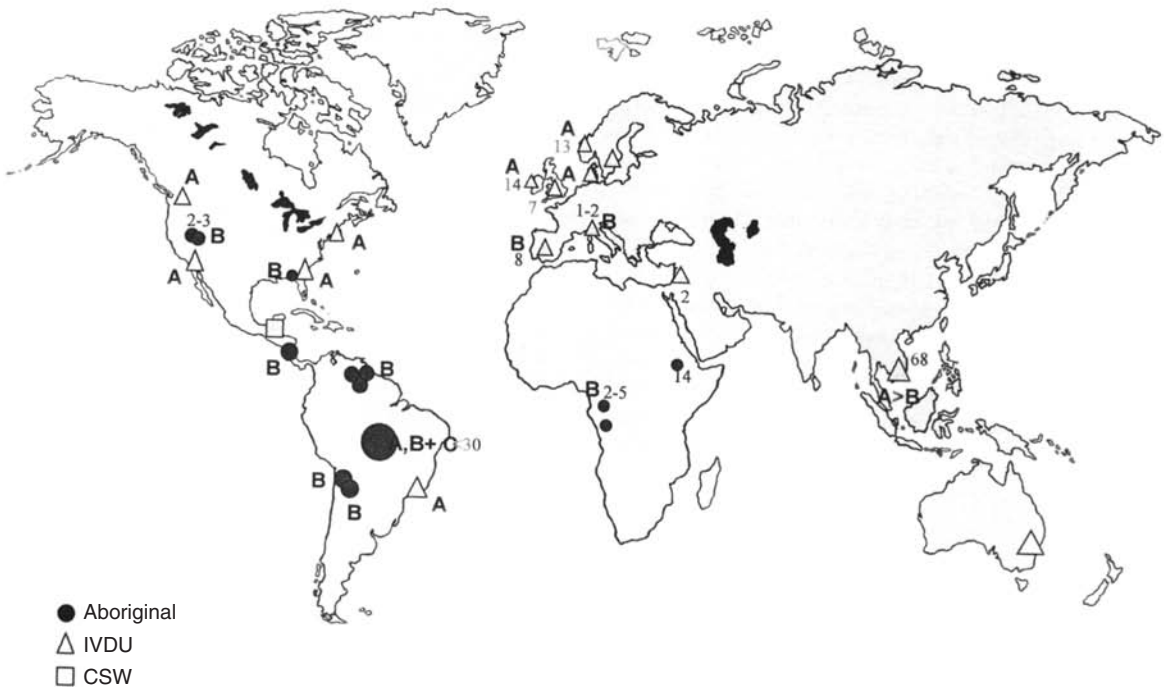

with the virus being transmitted from one host to another after a shorter period than in the endemic populations in whom mother-to-child transmission plays an important role in maintaining the virus in the population (Salemi *et al.*, 1999).

EPIDEMIOLOGY

It has been estimated that 20 million people worldwide are infected with HTLV-1, including 1.2 million in Japan. Other endemic areas are the Caribbean, parts of the south-eastern United States, Melanesia and parts of sub-Saharan Africa, especially West and Central Africa (Figure 37.5). Recently HTLV-1 infection has been found to be relatively common in southern Africa,

(a)

(b)

Figure 37.5 Global seroprevalence of (a) HTLV-1 and (b) HTLV-2.

particularly Natal. Up to 0.5% of blood donors in Brazil are HTLV-1 seropositive, with considerable regional variation. HTLV-1 infection is recognized among many native South American indigenous peoples as well as among black and Japanese immigrants. However, population mixing has been extensive and in Brazil the proportion of neurology patients with HAM/TSP is equal among the main racial groups. Iran is another recently described area of HTLV-1 infection, with cases described in neighbouring Middle East and Central Asian countries. The prevalence of HTLV-1 among European Union blood donors is low (2–7 per 100 000) but remarkably similar across the length and breadth of the European Union. Seroprevalence rates 50–100 times higher have been found among women attending antenatal clinics and among men and women attending sexually transmitted disease (STD) clinics. In Central and Eastern Europe very few studies have been conducted, but cases of HTLV-1-related pathology have been diagnosed in patients from Bulgaria, Romania and in a Georgian family. Despite the importance of injecting drug users in the spread of HIV-1 infection in member states of the former USSR, HTLV-2 has not yet been detected in these high-risk populations (reviewed in Taylor, 1996). The most important recent developments in European epidemiology of HTLV infection have been (i) the confirmation, in a large multicentre study, that HTLV-1/2 infection in the European Union is 10-fold more common among pregnant women than among blood donors (Taylor *et al.*, 2005.) and (ii) the emergence of data showing HTLV-1 infection and ATLL to be relatively common in Romania. Romania can be considered to be the most recently described endemic area for HTLV-1 infection and the first to be described in a white population. The occurrence of ATLL indicates that HTLV-1 is unlikely to have arrived in Romania recently.

HTLV-2 infection is found among native American Indians in North, Central and South America and was until recently considered a New World virus. It seems likely that HTLV-2 was introduced into the injecting drug user population of the United States during the 1970s and into Europe slightly later. In Europe HTLV-2 is common among injecting drug users in Eire, Spain, Italy and Scandinavia, uncommon in the United Kingdom, and rare in Germany and France. The first isolations of HTLV-2 in Africa were from pygmy tribes both from Ethiopia and from West Africa (Gessain *et al.*, 1995; Goubau *et al.*, 1992). HTLV-2 infection in West African prostitutes (which may not imply a local origin), and in the Gabon in a male with no history to suggest exposure to an imported virus have been described. This virus is genetically close both to the Cameroonian pygmy isolate and to a North American isolate, emphasizing the conserved nature of these viruses (Letournier *et al.*, 1998).

These findings, and the identification of an HTLV-2-like primate virus in Central Africa, suggest that HTLV-2, like HTLV-1, may have originated in Africa. However, a number of questions remain as HTLV-2 is widely spread throughout the Americas but has been found in few populations in Africa.

To date PTLVs have not been identified in New World primates and with the exception of a report of HTLV-2 in Mongolia, which may have been a recently imported infection, there is no population-based evidence of HTLV-2 migrating from the Old to the New World.

TRANSMISSION

For both viruses transmission may be by three routes: from mother to child; through sexual intercourse; and through blood–blood contact. Family studies in Japan suggested that HTLV-1 was mainly transmitted from mother to child (Kajiyama *et al.*, 1986). HTLV-1 was identified in lymphocytes in breast milk and transmission through breastfeeding was demonstrated in marmosets and rabbits. The mother-to-child transmission rate in Japan was 25% if babies were breastfed, but only 5% if babies were bottlefed. It may be that maternal anti-HTLV antibodies protect breastfeeding infants until their titre starts to decline, as in one study in Japan short-term breastfed babies were no more likely to be infected than bottlefed babies (Takahashi *et al.*, 1991). Breastfeeding for six months is associated with higher rates of transmission that continue to increase if weaning is further delayed. After weaning there is no further risk of transmission (Ando *et al.*, 2003) until children reach adolescence and start to engage in other risk activities. Although in one study HTLV-1 was detected in cord blood none of the cord-blood positive babies became infected. HTLV-1 has been detected but not quantified in cervico-vaginal secretions (Zunt *et al.*, 2002) and the contribution of *in utero* and perinatal infections to the total infection rate is uncertain.

In the Gabon the mother-to-child transmission rate was 9.7% with transmission associated with higher maternal viral load (Ureta-Vidal *et al.*, 1999). There are conflicting data on mother-to-child transmission of HTLV-2 but among the Kayapo Indians in Brazil the risk of transmission from an HTLV-2-infected mother to her child was 30–50% (Ishak *et al.*, 1995).

Family studies also indicated that infection was likely to pass from husband to wife. In a Japanese cohort of 100 discordant couples practising unprotected sexual intercourse there were seven seroconversions during five years of observation. Uninfected females were 3.9 times more likely to become infected than uninfected males (Stuver *et al.*, 1993). Higher rates of transmission have

been reported: 60% of wives of seropositive husbands over 10 years in one study, but only 0.4% of husbands of seropositive wives; 50% of wives during one to four years of marriage in another. In a study of HTLV-1 and HTLV-2-infected blood donors in the United States, those with higher HTLV-1 proviral loads were more likely to have an infected partner. A similar association of transmission with high proviral load was seen in HTLV-2, although the viral burden is generally much less than in HTLV-1 (Kaplan *et al.*, 1996). Both HTLV-1 and HTLV-2 are more common in females. It is reasonable to suggest that condoms will efficiently protect against transmission, but no data are available.

HTLV-1 is transmitted by cell-containing blood products but not by plasma or plasma-derived products. This has been demonstrated in the rabbit model and through clinical observation. Fresh blood is more infectious than older blood due to the short life of stored lymphocytes. Infection has occurred following transfusion of 41 ml blood. Following transfusion with HTLV-1-infected blood the median time to seroconversion was 51 days (Manns *et al.*, 1994). The mean incubation period of HAM following infection by transfusion is three years, shorter than by other routes. In a post-mortem study the average time to first symptoms was eight and a half months but the duration of symptoms was not different from that in other patients with HAM (Iwasaki, 1990). The risk of HAM was 7.7-fold higher than expected among transfusion recipients in Japan and following the introduction of blood donor screening in 1986 the incidence of HAM fell by 16%. HTLV-1 is also transmitted through injecting drug use but this route is more commonly associated with HTLV-2. Indeed outside of the endemic areas of the Americas HTLV-2 is primarily transmitted through re-use of injection paraphernalia.

HTLV-ASSOCIATED DISEASE

HTLV-1 is recognized as a carcinogen by the International Agency for Research on Cancer (1996). HTLV-1 is clearly associated with ATLL and serological documentation of HTLV-1 infection is an essential part of confirming this diagnosis, whereas the demonstration of clonality is only required in unusual cases. The search for sero-epidemiological evidence of an association between HTLV-1 and other malignancies has been complicated by the frequent history of previous blood transfusion in patients with malignant disease included in such studies. However, two studies have demonstrated an increased rate of cervical carcinoma in patients with HTLV-1 and in one of these studies patients with HTLV-1 were also found to have more advanced disease. An interaction between HTLV-1 and human papillomavirus (HPV) directly

or through an effect on HTLV-1 on cell-mediated immunity is biologically plausible. However, since both HPV and HTLV-1 are sexually transmitted the association may reflect sexual activity rather than a biological interaction between two oncogenic viruses (International Agency for Research on Cancer, 1996). HTLV-1 has been implicated as a co-factor in the development of hepatocellular carcinoma due to HCV in a number of epidemiological studies in Japan (Arisawa *et al.*, 2006; Boschi-Pinto *et al.*, 2000) with evidence that HTLV-1 can upregulate HCV replication (Zhang *et al.*, 2007).

Although the initial association with atypical HCL was disproved, HTLV-2 infection was also reported in two patients with large granular lymphocytosis and one with large granular lymphocytic leukaemia, but the virus was found in the T lymphocytes and not the abnormal cells. Rare cases of CD8⁺ lymphoproliferation in patients with HIV-1/HTLV-2 co-infection have been reported, including one in which clonal expansion of HTLV-2-infected CD8⁺ lymphocytes was demonstrated (Poiesz *et al.*, 2000). In summary, there are as yet inadequate data to afford HTLV-2 carcinogenic status although it immortalizes T cells *in vitro* (reviewed in Araujo *et al.*, 2002).

ATLL may present as acute, chronic or smouldering leukaemia or as a lymphoma including a cutaneous presentation. ATLL cells are usually CD3⁺, CD4⁺, CD25 (IL-2 receptor- α)⁺ and in the leukaemic form characteristic poly-lobed 'flower' cells (Figure 37.6) can be easily identified. Although the cells are morphologically mature, the malignancy is aggressive and survival, despite therapy, measured in months. The most common presentations are acute leukaemia and lymphoma. The infrequent chronic and smouldering forms are associated with longer survival. Hypercalcaemia, due to expression of parathyroid hormone-related protein (Nadella *et al.*, 2007), is a common and characteristic finding (Kiyokawa *et al.*, 1987). Patients may present with acute renal failure and lytic bone lesions. Atypical presentation with opportunistic infections should also be considered.

HTLV-1 is associated with a number of inflammatory conditions characterized by a lymphocytic infiltration of the target organ (Figure 37.7). The lifetime risk of HAM in HTLV-1-infected people is 2–7%, except in Japan where it has been estimated at 0.25%. HAM has been diagnosed in about 200 patients in the United Kingdom, mostly of Caribbean origin, but also in the white population. This includes more than one case following transfusion with HTLV-1-infected blood in the United Kingdom. The condition is a chronic progressive spastic paraparesis without the relapsing/remitting character of multiple sclerosis (although with similarity to primary progressive multiple sclerosis). Chronic backache, hyperactive bladder, constipation and impotence are common.

Figure 37.7 Perivascular lymphocytic infiltration in CNS. (Source: Courtesy of Dr Margaret Esiri.)

Sensory signs and upper limb disease are unusual but can be found in long-standing disease. Other causes of myelopathy including cord compression should be excluded (Table 37.2). The female-to-male ratio is 2 : 1 and the onset is most common in the third and fourth decades, resulting in decades of morbidity with more than 50% eventually becoming wheelchair dependent. The condition is occasionally rapidly progressive and fatal within two years of onset.

In endemic areas uveitis is more common in HTLV-1 patients than in the general population. HTLV-1-associated uveitis usually responds to treatment with topical steroids, less often systemic steroids are required. The condition is generally mild but recurs in 25% of cases (Mochizuki *et al.*, 1992). In a prospective study of 200 patients with HTLV-1 in Martinique 14.5% had uveitis, but 37% had keratoconjunctivitis sicca and interstitial keratitis was also common (Merle *et al.*, 2002).

Polymyositis, alveolitis, arthritis and thyroiditis have been reported in subjects with HTLV-1, often in patients

Table 37.2 Differential Diagnosis of HAM

Paraneoplastic syndrome

with HAM. While these associations have not been confirmed epidemiologically, the histology/cytology characterized by lymphocytic inflammatory infiltration is consistent with an HTLV-1 aetiology.

Infective dermatitis is an eczematous condition of children that only responds to long-term antibiotic treatment against streptococcal and staphylococcal species that are otherwise not usually considered pathogenic. Skin biopsies reveal an inflammatory infiltrate of CD8⁺ lymphocytes. HTLV-associated infective dermatitis is rare outside the tropics. Encrusted (Norwegian) scabies has been reported in patients with HTLV-1 and suggested as a marker for the development of ATLL.

Studies in Japan have repeatedly shown reduced delayed hypersensitivity to tuberculin in HTLV-1-infected people; conversely there was no abnormality in delayed hypersensitivity skin testing to mumps virus or *Candida albicans* antigens in a cohort of HTLV-1-infected blood donors (Murphy *et al.*, 1997; Murphy *et al.*, 2001). Murphy described an increased adjusted odds risk of previous tuberculosis (TB) in HTLV-2-positive blood donors in the United States (Murphy *et al.*, 1993), while in Lima, Peru TB is significantly more common among patients with HTLV-1 infection than the general population (Verdonck *et al.*, 2007). It is not clear whether bronchiectasis, which appears to be more common in patients with HAM (Okada *et al.*, 2006), represents part of the inflammatory or immunosuppressive spectrum of HTLV-associated diseases.

Failure to clear *Strongyloides stercoralis* despite appropriate treatment is also recognized with HTLV-1 infection (Terashima *et al.*, 2002) and investigation for HTLV-1 is

considered an essential part of the management of patients with proven strongyloidiasis and the literature is littered with case reports of HTLV-1 infection and disseminated strongyloidiasis (strongyloides hyperinfection syndrome). The endemic regions for strongyloidiasis and HTLV-1 infection overlap considerably. Prolonged and repeated courses of ivermectin and albendazole may be required. Increased rates of infection and treatment failure have also been reported for *Schistosoma mansoni* in Brazil (Porto *et al.*, 2002).

A myelopathy similar to that seen with HTLV-1 has been reported in several subjects with HTLV-2 infection in the absence of HIV infection (Murphy *et al.*, 1997; Black *et al.*, 1996; Jacobson *et al.*, 1993) although some patients also have ataxia (Harrington *et al.*, 1993). Although the frequency of this condition is unknown and the causative role of HTLV-2 unproven, many specialists accept that there is a growing body of evidence to suggest that HTLV-2-associated myelopathy is a real entity.

In a cohort study of US blood donors, respiratory and urinary infections were more common among the HTLV-2-infected donors than in matched controls (Murphy *et al.*, 1999)

An association between *Mycosis fungoides* and the presence of HTLV-1 tax DNA has now been refuted. There appears to be an association between HTLV-1 and Sjögren's syndrome in endemic areas but this has not yet been confirmed in properly aged-matched studies. HTLV-1-defective provirus has been amplified from the salivary glands of seronegative patients with Sjögren's syndrome. Rare cases of seronegative but PCR-positive HAM/TSP are reported with defective provirus. *Tax* sequences are present in all these conditions. The absence of both humoral and cellular immune responses in these exceptional cases makes an understanding of the pathogenesis of these inflammatory conditions even more elusive.

PATHOGENESIS

Our understanding of the pathogenesis of ATLL is incomplete, based to a large extent on *in vitro* studies of HTLV-1 infected cells and Tax constructs and has to take into account a number of apparent discrepancies. HTLV-1 can immortalize T lymphocytes *in vitro* and these cells express HTLV-1 proteins but there appears to be little expression of HTLV-1 by ATLL cells *in vivo*. Only a small proportion (2–4%) of those infected with HTLV-1 develop ATLL and then only after many decades of infection. Indeed the observation that only a proportion of the mothers of patients with HAM but all the mothers of ATLL patients are carriers of HTLV-1 suggests that infection during infancy is important for the development

of ATLL. In common with other malignancies it is likely that transformation is a multistep phenomenon with the infection of a lymphocyte by HTLV-1 only one of several events leading to ATLL. Since HTLV-1 does not contain an oncogene and malignant transformation is not related to the integration-disturbing cellular genes important in oncogenesis, the transactivating characteristics of Tax assume importance. Although adult T-cell leukaemic cells contain integrated HTLV-1 that may be defective, *tax* is generally preserved.

In vitro, HTLV-1 induces T-cell activation and proliferation and immortalizes primary human lymphocytes that can become IL-2 independent. In these cells, as in other tumour virus models, Jak/Stat proteins are constitutively activated (Johnson *et al.*, 2001). Tax has been shown to stabilize and inactivate the tumour suppressor p53. Tax also interacts with cell cycle genes inducing phosphorylation of cyclin D1-cdk4/6 and cyclin D3 which may contribute to the shift from G₁- to S-phase in the cycle. Tax inactivates a cdk inhibitor and the human mitotic arrest deficiency 1 (MAD-1) protein.

Other examples of cellular genes transactivated by Tax are listed in Table 37.3. Tax has an inhibitory effect on β -polymerase, a DNA-repair gene. This may increase the likelihood of mutagenesis. Tax does not act directly on the cellular genes, or on the promoter sequences in the viral LTR, but binds to a number of specific transcription factors with resulting enhancement of their interaction with the target genes: nuclear factor- κ B (NF- κ B); activator protein 1 (AP1); CREBs/activating transcription factors (ATFs); serum-response factor (SRF) and nuclear factor of activated T-cells (NFATs).

The interaction between the IL-2R α gene and Tax has been of particular interest because of the high expression of IL-2R α (CD25) by T lymphocytes in ATLL. IL-2R α expression normally only occurs after antigenic stimulation by the T-cell receptor. However it appears that Tax is able to induce constitutive expression of the IL-2R α gene. There is a 12 bp sequence in the 5' IL-2R α gene promoter required for *tax* transactivation that shows homology with the NF- κ B-binding site. The NF- κ B precursor, a p105 heterodimer, is usually found in the cytoplasm because its nuclear localization signal is masked. Tax causes NF- κ B to dissociate from its inhibitor, I κ B, which results in increased transport of NF- κ B to the nucleus where the NF- κ B p50 is able to activate transcription of IL-2R α . A secondary effect of Tax is that the dissociation of p50 from the heterodimer releases the p65 protein which is then free to dimerize with the product of the c-Rel oncogene. This p65-Rel heterodimer is also able to activate the NF- κ B motif. Thus Tax may further enhance the activation of the many genes under the influence of NF- κ B.

Table 37.3 Cellular genes transactivated by Tax

Regulated through AP-1	NFAT	NF- κ B	CREB
<i>AP-1 proteins</i>	IL2	IL-2R α (CD25)	ETR101
FOS	IL13	IL-15R	
FOSL1(FRA-1)	TNFSF6 (Fas ligand)	IL-8	
JUN		TERT (telomerase)	
JUND	IRF4 (Interferon regulatory factor 4)	MYC	
TGFB1 (TGF- β)		TNF (TNF- α)	
NR4A1 (TR3/nur77)		LTA (TNF- β)	
TIMP-1		PTHR1 (PTHr-P)	
IL-8		TNFRSF4 (OX40/OX40L)	
		GM-CSF	

Based on Taylor (2007).

One theory of T-cell transformation by HTLV-1 has been that by promoting activity of both IL-2R and IL-2 genes Tax gives rise to continuous proliferation of the cells by positive feedback, the autocrine loop theory. However, stimulation of Tax-transduced T cells can occur in an IL-2-independent manner, tax-transfected cells continue to grow after anti-CD3 stimulation in the absence of IL-2 and not all tax-transformed T cells express IL-2, although they all express IL-2R.

Other mechanisms potentially important in HTLV-1-associated leukemogenesis include: the promotion of S-phase in the cell cycle; interactions with tumour suppressor genes for example, p53 and Rb; and effects on genomic stability.

While the oncogenic potential of HTLV-1 has been recognized from the time of its discovery a similar role has not been proven for HTLV-2. This could merely be a function of their different epidemiology; the HTLV-2 endemic populations are small and often remote and therefore rare malignancies might be missed while in industrialized states HTLV-2 is mostly spread among adults who may not incubate the infection for long enough. With the exception of a few isolates of HTLV-2a in which Tax protein expression is low, the transactivating function of HTLV-2 Tax via NF- κ B does not differ significantly from HTLV-1 *in vitro* (Lewis *et al.*, 2002).

The pathogenesis of HAM is also incompletely understood. It is rare to obtain histopathology at the time of the initial symptoms but a perivascular lymphocytic infiltration of the spinal cord, which is at first CD4⁺ and later predominantly CD8⁺ is found, followed by demyelination and atrophy. HTLV-1 is rarely found in the lesions and when detected is probably in circulating CD4⁺ (and to a lesser extent CD8⁺) lymphocytes. The peripheral lymphocyte proviral load is approximately 10-fold higher in HAM than in asymptomatic carriers although there is considerable overlap between the ranges. There appears to be a threshold of about 1 HTLV DNA copy per 100

PBMCs above which the risk of HAM increases exponentially (Nagai *et al.*, 1998). Higher viral load in the CSF than in the peripheral blood has been associated with HAM (Lezin *et al.*, 2005) and these viral load measures may be useful to discriminate HTLV-1 infection from other causes of neurological disease in HTLV-seropositive patients (Puccioni-Sohler *et al.*, 2007), especially if the presentation is atypical. Finally, at a given viral load, *ex vivo* PBMC Tax expression (in short-course unstimulated culture) is independently associated with HAM (cf. asymptomatic carriage) (Asquith *et al.*, 2005a).

HTLV-1 Tax-specific cytotoxic T lymphocytes (CTLs) while found in the majority of patients with HAM (Jacobson *et al.*, 1990) are also detected in asymptomatic carriers (Parker *et al.*, 1992). Limiting dilution chromium release assays have shown a high frequency of such CTLs (Daenke *et al.*, 1996) and using MHC-peptide tetramers as many as 10% of circulating CD8 lymphocytes have been found to recognize a single HTLV-1 epitope (Bieganowska *et al.*, 1999). Chromium release assays are laborious and estimate much lower frequencies of virus-CTL than tetramers but the latter do not measure lytic activity. ELISpots can be used to identify the number of cells releasing specific cytokines, for example, interferon gamma (IFN- γ) or IL-2, when incubated with peptides and again high frequencies are found (Goon *et al.*, 2004). A lytic efficiency assay has been described. This is dependent on the observation that infected PBMCs spontaneously express viral proteins during unstimulated *ex vivo* culture, peaking at 12–18 hours. Removal and measured addition of autologous CD8 cells alters the absolute number of CD4 Tax-positive cells and the killing rate of each CD8 cell can be determined. In these assays it becomes clear that at a set viral load the lytic efficacy of CTL from patients with HAM is less than that from asymptomatic carriers (Asquith *et al.*, 2005b).

T-helper responses to HTLV-1 have been difficult to study but using a short-incubation ELISpot assay higher

frequencies of CD4 cells secreting IFN- γ in response to HTLV-1 Env and Tax peptides have been found in patients with HAM (median 2/1000 CD4 cells) compared with asymptomatic carriers (Goon *et al.*, 2002).

Polyclonal expansion of HTLV-1-infected lymphocytes has been reported in patients (without malignancy) with high proviral load, particularly patients with HAM. As with the oligo/monoclonal proliferation of T lymphocytes in ATLL, viral replication in these cells occurs through cell division, without the need for reverse transcription

and integration. Thus, HTLV-1 appears to be able to replicate through two quite distinct mechanisms –cell division and virion production. The relative contribution of ‘cellular’ and ‘viral’ replication to HTLV-1 proviral load in patients with HAM and in asymptomatic carriers is uncertain. The continuous presence of a strong anti-Tax CTL response suggests continuing expression of Tax by some cells. It is possible that this may drive the proliferation of the clonally expanding cell populations. Despite the low rate of detection of HTLV-1 proteins *in vivo* there

Figure 37.8 Cell-to-cell transfer of HTLV-1 gag protein. In an isolated HTLV-1-infected CD4 lymphocyte HTLV-1 gag p15 (red) is unpolarized (a), while HTLV-1 env gp46 (red) accumulates at the cell surface (b). Forty minutes after contact with an uninfected CD4 lymphocyte, HTLV-1 p15 (c), p19 (d) and gp46 (e) polarize at the cell–cell junction. (f) HTLV-1 gag p19 (red) from the infected (CFSE stained –green) CD4 lymphocyte is transferred to the uninfected CD4 lymphocyte. (g) The transfer of HTLV-1 genome (red) from the CFSE stained infected CD4 lymphocyte to the uninfected control CD4 cell can be demonstrated by peptide nucleic acid fluorescence *in situ* hybridization (PNA-FISH) after 120 minutes. (Source: Courtesy of Professor C.R.M. Bangham.)

is now good evidence that HTLV-1-infected CD4 and CD8 cells are capable of expressing viral proteins and that such cells are lysed by HTLV-1-specific CTLs. It has been proposed that the efficiency of these CTLs *in vivo* at identifying and lysing virus protein-expressing cells contributes significantly to the apparent absence of viral expression described. Recently 'direct' cell-to-cell spread of HTLV-1 following the development of a virus-induced synapse has been demonstrated in primary cells *ex vivo* (Figure 37.8) (Igakura *et al.*, 2003). It is now clear that contact with an uninfected cell realigns the cell structure, resulting in localization of viral proteins (and genome) at the site of contact (Nejmeddine *et al.*, 2005). Electron microscopy shows the expression of viral particles at the synapse with a very narrow space between the cells (Figure 37.9). This, if it occurs to any degree *in vivo*, may help explain the absence of free virions in plasma.

There are three main theories concerning HAM pathogenesis: (i) the inflammatory response is directed against virus in the CNS, (ii) the inflammatory response against HTLV-1 targets similar host CNS peptides, and (iii) CNS tissue is an innocent by-stander damaged when CTLs recognize migrating HTLV-1-expressing CD4⁺ cells. The latter has been considered most probable, although the potential role of HTLV-specific CD4 cells and NK cells might also be considered. Molecular mimicry between HTLV-1 and the human neural ribosomal nucleoprotein A1 has, however, been reported (Levin *et al.*, 2002). The effect of Tax on matrix metalloproteinases and on tissue inhibitors of metalloproteinases disturbing the neuronal

milieu which has been reported *in vitro* could be implicated in the degeneration of neurons.

Although HAM is associated with high proviral load, differences in the rates of HAM per HTLV-1 infected subjects in different populations suggest that other, possibly host factors, are important. Of the candidate factors, human leukocyte antigen (HLA) types have attracted considerable interest. HLA types are known to be associated with other inflammatory diseases but could also influence outcome by controlling viral replication. In Japanese ATLL patients HLA-A26, B61 and DR9 were found at an increased frequency while HLA0A24 and HLA-Cw1 were less frequently found than in controls. Conversely, in patients with HAM HLA-Cw7, B7 and DR1 were found more commonly than in controls and patients with ATLL. It has been suggested that in Japan the A26Cw3B61DR9DQ3 haplotype is representative of ATLL and is associated with a low immune response, while A24Cw7B7DR1DQ1 is the representative haplotype of HAM and is associated with a high immune response. Among different ethnic groups HLA class I haplotypes were variable but examination of class II suggested that some haplotypes associated with disease are panethnic while others are ethnospesific (Sonoda *et al.*, 1996). In a study of Japanese blood donors and patients with HAM, possession of HLA-A*02 and HLA-Cw*08 were found to protect against HAM through an association with lower HTLV-1 viral burden, whereas HLA-B*5401 was associated with an increased risk of disease (Jeffery *et al.*, 1999, 2000). Further studies, of single nucleotide polymorphisms in the same population, have revealed that TNF-963A predisposes to HAM (odds ratio = 9.7), SDF-1+801A 3' UTR reduced the risk of HAM by half, while the IL-15 191C allele also conferred protection against HAM by being associated with lower proviral loads (Vine *et al.*, 2002).

TREATMENT

Few instances of curative treatment of ATLL have been reported and there have been no randomized controlled clinical trials. Until recently the overall management has been to treat the disease as per other malignancies and the regimens for non-Hodgkin's lymphoma such as cyclophosphamide, adriamycin, vincristine and prednisolone (CHOP) are favoured. Although successive improvements in chemotherapy have increased remission rates to 42%, ATLL is essentially a highly drug-resistant malignancy and survival remains less than 12 months for the acute leukaemia and lymphoma presentations. Enhanced transcription of the multidrug resistance gene (MDR1) with significant P-glycoprotein-mediated drug efflux in

the T cells of HTLV-1-infected individuals, with and without malignancy, has been demonstrated, as has the ability of the HTLV-1 tax protein to activate the MDR1 promoter. Other treatments such as deoxycoformycin, interferons β and γ , and topoisomerase II have been tried with limited success. Since CD25 is expressed by all ATLL cells, anti-Tac (CD25) antibodies have been tried although with limited success. Improved remission rates (56%) were obtained with ^{90}Y -trium-labelled anti-Tac antibodies (Waldmann *et al.*, 1995). There are also minimal data on anti-CD52 (Campath-1h).

Successful eradication, not only of ATLL cells but also of HTLV-1 infection, has been reported following stem cell transplantation and this approach is increasingly used for selected patients. Reduced intensity conditioning may be appropriate for older patients but early deaths from complications remain a significant problem and at present only a minority of patients with ATLL are suitable for SCT either through lack of a matched donor or clinical considerations. Grafting of patients not in remission has not proved successful.

Improved remission rates and survival have been reported in uncontrolled studies, with the combination of IFN- α and zidovudine (Gill *et al.*, 1995; Hermine *et al.*, 1995; Matutes *et al.*, 2001). The mechanism of activity of these compounds in ATLL is not clear; they are not effective when given independently and do not appear to have a cytotoxic effect. Interest in this treatment followed anecdotal improvement in a patient with ATLL and HIV. At present, this approach carries the best outcome but the timing (whether to start early, during chemotherapy) and dosing of therapy needs further refinement. The use of molecular markers such as p53 to predict response to therapy holds promise.

Novel approaches under investigation include the combination of arsenic with interferon, proteasome inhibitors and blocking the transferrin receptor. The immune suppression seen in patients with ATLL is more severe than in other malignancies, and prophylaxis against *Pneumocystis* pneumonia, *Cryptococcus* and herpes viruses is recommended. Where appropriate, infection with *Strongyloides stercoralis* should be sought and treated.

The treatment of HAM is also difficult and there have been, to date, only two randomized controlled studies. Early reports of the use of pulsed high-dose steroids, steroid-sparing cytotoxics and plasmapheresis, all targeting the immune response, were encouraging (Osame *et al.*, 1990) but the improvements have not been long term (Matsuo *et al.*, 1989). High-dose vitamin C (Kataoka *et al.*, 1993) and oxpentifylline have also been promoted (Shirabe *et al.*, 1997). Extensive research into the treatment of HIV-1 has resulted in the licensing of five

classes of antiretroviral therapy. Unfortunately the current protease inhibitors and non-nucleoside RT inhibitors have no activity against HTLV-1. The nucleoside analogue reverse transcription inhibitors (NRTIs) zidovudine and zalcitabine have been shown to be active against HTLV-1 *in vitro* and in animal models. Unfortunately zalcitabine and two other NRTIs, didanosine and stavudine, are neurotoxic. Zidovudine was reported to improve mobility in ambulant patients in one study (Sheremata *et al.*, 1993) but not in another (Gout *et al.*, 1991). Neither reported proviral load measurements. In the management of HAM it is important to consider that in long-standing disease demyelination and atrophy may prevent improvement even if viral replication or the production of damaging cytokines has been reduced. Clinical improvement with a reduction in HTLV-1 proviral load was reported with lamivudine (Taylor *et al.*, 1999) but in a randomized placebo-controlled study zidovudine plus lamivudine was not effective (Taylor *et al.*, 2006).

The earliest studies of IFN- α were of short duration but temporary benefit was observed (Shibayama *et al.*, 1991; Kuroda *et al.*, 1992). In a randomized study of IFN- α given for four weeks with two months follow-up, a dose related effect was observed. Thus the 16 patients prescribed 0.3×10^6 IU did not benefit but a clinical response was reported in 3/17 and 6/16 patients randomized to 1×10^6 and 3×10^6 IU daily respectively (Izumo *et al.*, 1996). IFN- β 1A for six months did not alter the clinical status of 12 patients in an observational study and although a reduction in CTL activity was documented in three patients this was not specific to HTLV-1 (Oh *et al.*, 2005).

Symptomatic management remains the mainstay of therapy. Bladder spasticity with urgency, frequency, nocturia and incontinence is often distressing. Some patients respond well to oxybutinin. The anabolic steroid danazol has been reported to improve these symptoms. Intravesical instillation of capsaicin has been shown to reduce the bladder spasticity in these patients, with symptomatic improvement lasting months (Dasgupta *et al.*, 1996) but this approach is no longer favoured. Intranasal antidiuretic hormone cautiously used may reduce nocturia in refractory cases. In a minority of patients the bladder is hypotonic and catheterization, intermittent or permanent, is necessary both to relieve symptoms and to protect renal function. A titrated dose of baclofen may reduce limb spasticity –tizanidine may be tried if baclofen is not tolerated. The combination of urinary frequency with impaired mobility is particularly frustrating for patients with HAM. Lumbar pain, which has a radicular pattern, is common. Management can be complex and long-acting local anaesthesia can be useful in more severe cases. Some

patients respond to specific analgesia such as amitriptyline, carbamazepine, gabapentin or pregabalin. Although less commonly used as an analgesic sodium valproate has additional potential as a histone deacetylase inhibitor both in ATLL and HAM (Achachi *et al.*, 2005; Lezin *et al.*, 2007; Mosley *et al.*, 2006).

With the exception of HTLV-1-associated uveitis, which usually responds to topical corticosteroids, very little is known about the management of other HTLV-1-associated inflammatory diseases. Where possible, patients with HTLV infection and disease should be referred to specialized centres and offered access to clinical trials.

PREVENTION OF DISEASE

There is no vaccine for HTLV-1 or HTLV-2 infection. Although the association of HAM with high proviral load and viral expression suggests that load-reducing therapy may in the future be part of the treatment or prevention of this disease, current strategies must be directed at preventing infection. Two transmission routes can be targeted relatively easily. Many blood transfusion services now include HTLV-1/2 antibody screening of all or of new donors. This was first introduced in Japan in 1986 where blood transfusion accounted for up to 60% of seroconversions in the Kyushu region of south-western Japan (Kamihira *et al.*, 1987). Blood donor screening has been standard practice in the United States and Australia for many years and more recently introduced in South American countries. With the commercial production of suitably sensitive and specific screening assays HTLV-1/2 blood donor testing has been introduced in the majority of EU countries. In France more than 300 HTLV-1 positive blood donors have been detected since screening began in 1991. In the United Kingdom, donor screening was introduced in August 2002. Prior to that the risk of transmission was almost certainly reduced by leukodepletion introduced in 1999 to protect recipients from the transmission of prions. Screening of blood donors undoubtedly prevents infection in recipients, but cost effectiveness in terms of preventing HTLV-1-associated disease in them has been questioned (Tynell *et al.*, 1998). In such analyses more weight has been given to the 'cost' of developing ATLL following transfusion rather than HAM although the latter causes more morbidity and is a much more common consequence.

HTLV-1, and probably HTLV-2, can also be transmitted through organ donation. In endemic areas it has been suggested that donors and recipients should be matched for HTLV-1 antibody status. Elsewhere the arguments that apply to blood donor screening should apply to donated organs.

Eighty per cent of mother-to-child transmission can be prevented by avoidance of breastfeeding. In Japan carrier mothers are identified through antenatal screening programmes and during the next few years the impact of these programmes should become apparent as the first generation of screened babies are now reaching child-bearing age. In the United Kingdom the prevalence of HTLV-1/2 infection in women attending metropolitan antenatal clinics is approximately 1 : 200 (cf. HIV-1) but HTLV-1 antibody testing has never been offered as a routine part of antenatal care. Although breastfeeding is less common in the United Kingdom there is now increasing concern to prevent the transmission of other viral infections by this route and recognition that when offered there is a high uptake, by the mothers, of interventions to reduce transmission. Reduction of HTLV-1 transmission from mothers to their infants is likely to prevent most cases of HTLV-associated disease in the United Kingdom –ATLL by preventing infection of the infant and HAM by preventing both early infection and by reducing the pool of infected people who will transmit HTLV-1 sexually in adult life. Any effect on the incidence of disease would not be seen for several decades.

HIV AND HTLV CO-INFECTION

Co-infections of HTLV-1 or HTLV-2 with HIV-1 occur where risk factors are shared. Thus HTLV-1 and HIV-1 co-infections are likely to be most common in Latin America, the Caribbean and in West/Central Africa whereas HTLV-2 co-infection with HIV-1 is common among injecting drug users in Europe and North America.

HTLV-1 and HIV-1 share tropism for CD4⁺ lymphocytes but CD4⁺ lymphocyte counts and CD4/CD8 ratios are normal in HTLV-1 infection alone. Studies in Brazil and French Guiana have reported decreased survival in patients co-infected with HTLV-1 and HIV-1 and more advanced HIV disease than anticipated from the CD4 counts. Thus the initiation of prophylaxis against *Pneumocystis* pneumonia and/or antiretroviral therapy at CD4 levels higher than currently recommended should be considered. No effect of HTLV-2 on HIV-1 outcome was found in a study of North American and Italian injecting drug users whereas increased risk of sensory motor polyneuropathy has been observed with this co-infection. HAM is more common in HIV-1 co-infection. HTLV-2 viral load seems to be inversely related to HIV-1 viral load, though whether this association is causal is uncertain. HTLV-2 infection may be more difficult to detect serologically and indeterminate Western blot results warrant further, molecular, investigation.

Human Immunodeficiency Viruses

Deenan Pillay, Anna Maria Geretti and Robin A. Weiss

University College London Medical School, London, UK

INTRODUCTION AND CLASSIFICATION

Acquired immune deficiency syndrome (AIDS) first came to the notice of physicians and epidemiologists in 1981 in the United States when a handful of homosexual men presented with *Pneumocystis carinii* pneumonia (PCP) and Kaposi's sarcoma (KS). These diseases were previously extraordinarily rare in young adults and indicated an underlying immune deficiency. The patients showed a selective depletion of CD4⁺ T-helper lymphocytes in the peripheral blood. It was noted that a larger proportion of gay men suffered from generalized lymphadenopathy. In 1982, investigators at the Centers for Disease Control and Prevention (CDC) in Atlanta, USA, detected similar cases of what soon became known as AIDS among injecting drug users, sex workers and recipients of blood transfusions and blood products, especially of pooled clotting factors administered for haemophilia. These epidemiological observations led to the conclusion that AIDS was not simply a consequence of gay lifestyle, but was caused by an infectious agent, probably a virus that was sexually and parenterally transmitted (Weiss, 2008).

Human immunodeficiency virus type 1 (HIV-1) was first isolated in 1983 (Barré-Sinoussi *et al.*, 1983). Several further HIV-1 isolates were reported in 1984 from the United States which, together with serological studies of prevalence, made a convincing case for HIV being the cause of AIDS. HIV-2 was first isolated in 1986 (Clavel *et al.*, 1986). Retrospective serological surveys indicated that HIV-1 had begun to spread among American gay men from 1977 onwards, showing a considerable incubation period before the manifestation of AIDS. The earliest known positive blood sample was collected in 1959 in Congo. However, molecular clock analyses of diversity suggest a common origin for HIV-1 (Group M) dating

from around 1931 (Korber *et al.*, 2000) and for HIV-2 from around 1940 (Lemey *et al.*, 2003).

HIV-1 and HIV-2 represent two separate viruses with distinct origins. Both viruses belong to the *Lentivirus* genus of retroviruses (see Chapter 36) and have a similar genome organization, but some of their accessory genes differ (Figure 38.1).

The origin of HIV-1 was almost certainly a zoonotic infection from chimpanzees, which harbour a related lentivirus, SIVcpz, whereas HIV-2 came from sooty mangabey monkeys in West Africa (Heeney *et al.*, 2006). HIV-1 is divided into three groups: the main group (M), the new group (N) and the outlier group (O). These groups represent three separate transfers from the chimpanzee or, in the case of group O, possibly from a gorilla (Van Heuverswyn *et al.*, 2006). Groups N and O remain largely confined to a part of West Central Africa (Gabon and Cameroon), although sporadic infection through contact with people from that region occurs. Only group M has radiated to cause the AIDS pandemic. The HIV-1 subtypes or clades lettered A to K all belong to group M. There also exist a number of so-called circulating recombinant forms (CRFs) of HIV-1 because genetic recombination is a feature of retrovirus replication (see Chapter 36). The most prevalent are CRF_01AE in South East Asia and CRF_02AG in West Africa. The genomic and antigenic variation manifest by HIV-1 groups and subtypes is important for diagnostic virology based on genomic and serological assays (Figure 38.2).

HIV-1 and HIV-2 strains can also be classified according to cell tropism phenotype, which does not relate directly to their major genotypic classification. Thus within each HIV-1 subtype there are virus isolates that are syncytium inducing (SI) or nonsyncytium inducing (NSI) for CD4 cells *in vitro*. Most primary, transmitting HIV-1

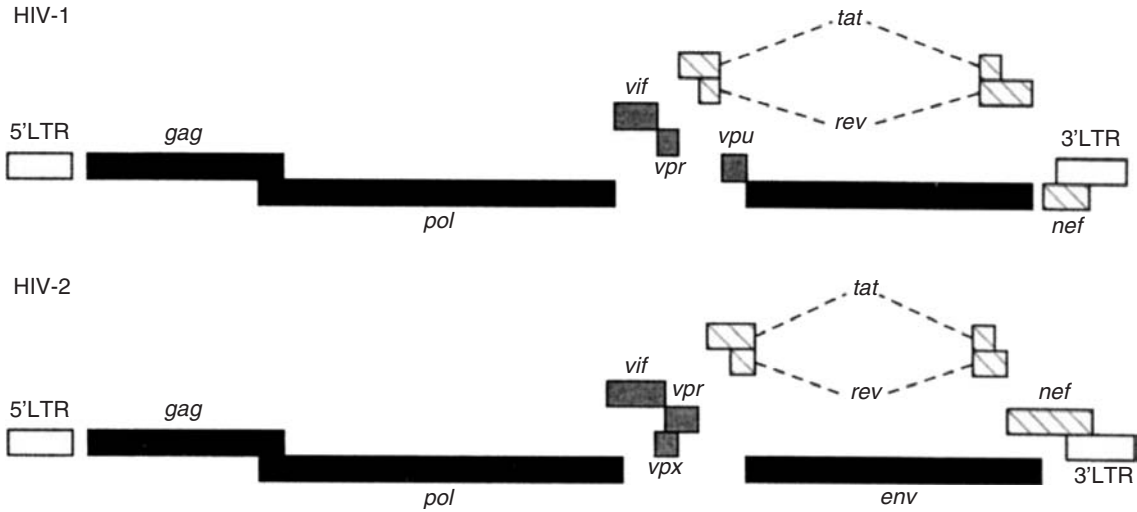

Figure 38.1 HIV-1 and HIV-2 genome maps.

Figure 38.2 Strain level classification of HIV group M diversity, using *gag* or *pol* gene sequences. (Source: From Gifford *et al.*, 2007.)

strains have an NSI phenotype, while SI substrains tend to appear in infected individuals later as they progress to AIDS. This phenotypic classification is related to cellular tropism for macrophages or T-cell lines reflecting which kind of chemokine co-receptor the virus uses to gain entry

into cells. Most NSI strains utilize the CCR5 co-receptor and are known as R5 viruses, whereas most SI strains utilize the CXCR4 co-receptor and are known as X4 viruses (Berger *et al.*, 1998). Some viruses are dual-tropic, known as R5X4 viruses.

EPIDEMIOLOGY

Risk Factors

The AIDS epidemic was first identified in the United States within the men having sex with men (MSM) risk group, in men and boys with haemophilia who were exposed to contaminated clotting factors, in recipients of blood transfusion and in intravenous injecting drug users. However, in Africa (where it was originally recognized as 'slim' disease (Serwadda *et al.*, 1985)) and when it spread to Asia, HIV has from the beginning been heterosexually transmitted, affecting men and women alike. With the rapid introduction of screening following the development of commercial antibody tests in 1985, HIV transmission through blood and blood products virtually disappeared, although this remains a problem in countries where screening is not stringent. As is described below, the epidemic has grown enormously since the early 1980s, with the major risks of transmission continuing to include heterosexual and homosexual intercourse, vertical transmission and intravenous drug use. With the improved understanding of the pathogenesis of HIV disease, it is now well established that the concentration of virus in the plasma of an infected individual is a good surrogate of infectivity to others. Thus, maternal plasma viral load is a predictor of perinatal transmission (Jourdain *et al.*, 2007). Similarly, the period of primary infection, when plasma viraemia is very high, is a particular risk for transmission, with some studies suggesting that 30% of new onward infections occur during this phase (Wawer *et al.*, 2005). These observations are important, since HIV is rarely diagnosed during early infection, and this period

therefore remains refractory to many standard intervention approaches, such as education or antiviral therapy. Another specific co-factor for sexually transmitted infection is coexisting genital ulceration, which may lead to enhanced local replication of HIV, and thus transmission.

Geography and Prevalance

UNAIDS (the Joint United Nations Programme on HIV/AIDS) estimates that 32.7 million people are living with HIV infection in 2006. Half of these are women, and 2.5 million are children. Each day around 7000 individuals are infected, and over 5700 people die from AIDS. Although recent models of the epidemic have revised these estimated figures downward, it is clear that the epidemic remains one of the world's leading health crises. Sub-Saharan Africa is most affected (22 million), with South Africa hosting the largest number of infections in the world. There are large differences in HIV prevalence in different cities in Africa for reasons that are still not clear, although sexually transmitted diseases associated with genital ulceration like herpes simplex type 2 infection, and lack of male circumcision are risk factors; women become infected at younger ages than men (Avert *et al.*, 2001). India is estimated to have 2.2 million infections, and the epidemic is also growing in Eastern Europe (Figure 38.3).

Within the United Kingdom, new diagnoses continue to rise, reaching over 7000 in 2006. These comprise two epidemics: that amongst heterosexuals, who are mainly infected in sub-Saharan Africa, and that within MSM. The latter group of transmissions occurs within the United Kingdom, which suggests that we are witnessing a failure in safe sex public health messages.

Molecular Epidemiology

The M group of HIV-1 can be separated into a number of subtypes, or clades, based on genetic differences. These subtypes are characteristically associated with geographical regions and/or risk groups of infected individuals (Figure 38.2). It is currently thought that these viruses all emerged from the epicentre of the epidemic, in what is now the Democratic Republic of Congo, a theory supported by the finding of all major viral clades circulating there (Vidal *et al.*, 2000). Thus, the presence of different subtypes around the world is likely to represent founder effects.

Recent advances in evolutionary methodologies have allowed insights into the likely progression of different lineages of HIV-1. These techniques include estimation of the timing and growth of epidemics based on sampling of contemporaneous, as well as historical, gene sequences, and include the concept of phylodynamics (Grenfell *et al.*, 2004). This refers to the detailed study of how pathogens evolve in the context of selective pressures and transmission bottlenecks, allowing the identification of the key determinants of epidemic history. Such approaches are most appropriately applied to highly variable pathogens such as RNA viruses. One example is the elucidation of the history of subtype B HIV-1. Using viral sequences of viruses isolated from the early Haitian epidemic in the 1980s, Gilbert *et al.* (2007) confirmed that spread of subtype B virus from Africa occurred during the 1960s, and that this virus subsequently was transferred to the United States, leading, at least in part, to the widespread subtype B epidemic. It is suggested that this represented one of the earlier transfers of the virus from Africa, and thus explains the broad diversity of subtype B viruses. Although only representing around 5–10% of the world's HIV, subtype B is the most intensely studied since it reflects the MSM and intravenous drug user epidemics in North America and western Europe, which is where most clinical HIV research has been undertaken.

At least three lineages of HIV-1 subtype C have now been identified, circulating in southern Africa, India and Brazil (together representing around 50% of worldwide infections). Similarly, subtype A can be differentiated between Kenyan, West African, Central Asian and South-West Asian epidemics (Gifford *et al.*, 2007)

In view of the large proportion of imported infections within the United Kingdom, the epidemic here is one of the most genetically diverse worldwide. Although the MSM epidemic remains overwhelmingly subtype B, recent data suggest that an increasing number of new MSM infections are with non-subtype B viruses, illustrating how the future molecular epidemiology may evolve. Indeed, the large number of sequences now generated through HIV drug resistance testing (although representing the

pol gene alone, only 10% of the HIV genome) provides a unique opportunity within infectious diseases to incorporate real-time phylogeny into existing surveillance schemes to monitor the epidemic.

There is increasing interest in biological and clinical differences between subtypes, particularly related to potential vaccine efficacy and antiviral efficacy. For instance, of the two coexisting subtypes in Uganda, subtype A infections appear to progress more quickly than subtype D (Kiwanuka *et al.*, 2008). *In vitro* studies on subtype C virus suggest that it remains less pathogenic than subtype B virus but the significance of these findings remains unclear (Arien *et al.*, 2005).

REPLICATION

HIV Culture and Isolation

HIV can be propagated in short-term cultures of CD4⁺ peripheral blood mononuclear cells (PBMCs) stimulated by phytohaemagglutinin and interleukin 2 (IL-2). The SI strains can adapt to growth in immortal CD4⁺ T-cell lines, which become chronic virus producers. R5 strains, however, need to be propagated in PBMCs, where they may be cytopathic, and in noncytopathic macrophage culture. Virus isolation is useful for determining the phenotype of HIV strains, and whether they have developed drug resistance, though genotyping is more rapid and is now more generally used. Figure 38.4 shows HIV particles produced by the CEM T-cell line in culture.

Isolation of HIV in cell culture can be detected by several means: (i) a cytopathic effect (CPE), including syncytia for X4 strains; (ii) detection of viral antigens in infected cells by antibodies, for example immunofluorescence, enzyme-linked immunocytology of infected cells, enzyme-linked immunosorbent assay (ELISA) for p24 antigen in cells or in supernatant medium from infected cultures; (iii) reverse transcriptase (RT) assay, either by enzyme activity or by ELISA, and (iv) genome detection, using polymerase chain reaction (PCR).

Genes and Proteins

Figure 38.1 shows the proviral genomes of HIV-1 and HIV-2. The gene maps are similar except that HIV-2 lacks *vpu* but carries *vpx*. The core and matrix proteins are encoded by *gag*. The Gag proteins of the mature virus are p17, p24, p7 and p6, and are processed by cleavage of the p55 precursor protein by the viral protease. The matrix antigen p17 is localized to the inner layer of the viral envelope and requires myristylation, which allows it to be tightly bonded to the inner envelope; matrix antigen is indispensable for budding. The core shell is made of

Figure 38.4 HIV-1 particles produced by CEM cells. Note the crescent-shaped core in budding particles and the condensed cone-like core in mature particles of approximately 100 nm diameter. The black spots are indirect immunogold labelling of antibody from an AIDS patient absorbed to the virus-producing cells.

p24 capsid antigen. This is the viral protein most usually detected clinically as a measure of antigenaemia. The *pol* gene encodes the enzymes protease, RT and integrase. The *env* gene encodes the gp41 and gp120 envelope glycoproteins, cleaved by cellular enzymes (furins) from the gp160 precursor.

In addition to *gag*, *pol* and *env*, HIV-1 and HIV-2 carry seven regulatory and accessory genes (Emerman and Malim, 1998). The *tat* gene encodes a protein that binds to TAR RNA sequences in the 5' long terminal repeat (LTR) to upregulate viral RNA transcription through complexes of cellular transcription factors and cyclin T. Rev serves to aid export of long HIV transcripts from nucleus to cytoplasm through recognition of Rev-response elements (RREs) in unspliced or singly spliced viral mRNA. Nef has multiple functions in signal transduction and downmodulation of CD4 cell surface expression. Vpr allows transport of newly infected pre-integration complexes (PICs) of the HIV proviral DNA into the nucleus for integration (by integrase) into host chromosomal DNA. Vpr also arrests cells in the G₂-phase of the mitotic cycle, enhancing virus production. Vpu has two known functions: degradation of cellular CD4 and enhancement of viral particle release, the latter by antagonizing tetherin function (Neil *et al.*, 2008). Tetherin is a host cell protein thought to represent an innate antiviral mechanism by inhibiting the release of enveloped viral particles from the cell. Vif is incorporated into virus particles and helps infection in new target cells by abrogating restriction to replication exerted by ABOBEC 3C (Sheehy *et al.*, 2002).

Although SI strains of HIV-1 can be propagated in T-cell lines with deletions or nonfunctional mutations in *nef*, *vpu* or *vif*, such mutations adversely affect HIV replication in PBMCs and macrophages so that attenuated infection or no replication occurs. Thus all the viral genes are required for efficient infection and pathogenesis *in vivo* (Stevenson, 2003).

HIV Replication and Antiviral Targets

HIV infects mainly CD4⁺ cells by binding to CD4 as a receptor (Dalgleish *et al.*, 1984). However, many of these cells are not lymphocytes. For example, monocytes, macrophages, dendritic cells (DCs), Langerhans cells and some brain cells, such as the microglia, express the CD4 receptor, and many are susceptible to infection by HIV. It is likely that infection of these cell types plays a major role in the pathogenesis of disease (Stevenson, 2003; Weiss, 2003). Importantly, HIV binds to the DC-SIGN receptor on DCs without infecting them, and hence can be delivered to CD4 lymphocytes in the lymph node (Geijtenbeek *et al.*, 2000; Pope and Haase, 2003).

The CD4 cell surface antigen is necessary but not sufficient for HIV-1 infection (Dalgleish *et al.*, 1984; Maddon *et al.*, 1986). While CD4 is required for high-affinity binding of gp120, co-receptors are required for subsequent steps leading to fusion between the viral envelope and cell membrane. The co-receptors were identified in 1996 to be chemokine receptors and help to explain the differential tropism for lymphocytes and macrophages (Berger *et al.*,

1999). Primary NSI strains of HIV mainly utilize CCR5 (R5 strains), which is the receptor for the chemokines MIP-1 α , MIP-1 β and RANTES, whereas SI strains utilize CXCR4 (X4 strains), the receptor for stromal derived factor 1 (SDF-1). Following gp120 binding to CD4, the co-receptor-binding site becomes exposed, allowing further attachment to CCR5 or CXCR4 receptor. The discovery that chemokine receptors act as co-receptors to CD4 (Feng *et al.*, 1996) helped to explain why these chemokines can inhibit HIV-1 infection *in vitro*. The tolerance of heterozygous and homozygous gene deletions of the CCR5 gene ($\Delta 32$) in the human population (see section on Host genetic determinants for HIV/AIDS below) with no apparent ill-effects has stimulated the development of CCR5 antagonists, which compete with HIV for binding to the co-receptor, and therefore inhibit viral replication.

The binding of gp120 to the cellular receptor CD4 and a chemokine co-receptor triggers a series of complex conformational changes in gp41 that lead to the fusion of viral and cellular membranes. There are three functional regions in the ectodomain of gp41: the fusion peptide, heptad repeat 1 (HR1) and HR2, and the transmembrane region. Crystallographic studies have demonstrated that the fusion-active (fusogenic) conformation of gp41 is a six-helix bundle structure in which three N-terminal helices (HR1) form a central trimeric coiled coil and three C-terminal helices (HR2) pack in an anti-parallel manner into hydrophobic grooves of the coiled core. The hairpin interactions between the HR1 and HR2 domains of gp41 bring the viral and host cell membranes together for fusion. One fusion inhibitor, enfuvirtide (ENF), is approved for clinical use. This is a synthetic 36-amino-acid molecule that corresponds to the HR2 peptide, and thus inhibits the normal fusogenic bundle formation.

Recent work has started to unravel the early stages of replication after cell entry and uncoating. The TRIM5 family of proteins is thought to confer species specificity on HIV-1 infection. Thus, monkey TRIM5 α restricts infection with HIV-1, through binding to the viral gag, and this restriction is conferred on human cells by expression of the same monkey TRIM species. Human TRIM5 α binds HIV-1 capsid poorly, explaining the lack of protection in humans.

Reverse transcription is initiated by the viral RNA-dependent DNA polymerase within the incoming virion. The viral genome comprises two identical strands of RNA, and the enzyme jumps strands during transcription. This provides the basis for recombination in a cell infected with more than one virus, since strands from each virus can be utilized within the jump. The other major mechanism of HIV variation lies in the error-prone nature of the RT process, since the

enzyme lacks proofreading mechanisms. The error rate is estimated at 10^{-4} , approximating to one mutation for every daughter virus produced. One further potential cause of viral genetic variation, particularly G-to-A hypermutation (a characteristic of HIV-1), is the activity of the host cell enzyme APOBEC3, which is a cytidine deaminase. It is thought that this family of proteins represents a long-standing innate antiviral defence mechanism. In response, the HIV vif protein acts to increase APOBEC destruction by cell proteasomes, thus maintaining the viability of proviral DNA species. Despite this, the detrimental impact of G-to-A mutations can be observed within proviral DNA, compared to plasma RNA (representing productive infections) (Gifford *et al.*, 2008). The viral RT remains the major target of antiviral drugs.

The synthesis of full-length proviral DNA within the reverse transcription complex produces the PIC. This comprises a number of viral proteins, including integrase, and host proteins such as the cellular transcription co-activator lens-epithelium-derived growth factor (LEDGF/p75). This PIC crosses the nuclear envelope into the nucleus. A key feature of HIV-1 is its ability to infect nondividing as well as dividing cells, such as macrophages and microglia cells, and thus nuclear entry is independent of mitosis.

Following nuclear entry, tethering of the viral integrase to host chromatin is thought to require LEDGF/p75 (Ciuffi *et al.*, 2005; Llano *et al.*, 2006). Subsequently, integrase catalyses integration via a number of linked steps. In the first step, the enzyme binds to the reverse transcribed double-stranded viral DNA in the cytoplasm and cleaves a GT dinucleotide from each 3' end of the viral DNA, in a reaction termed 3'-processing, to produce 3'-hydroxyl ends (CAOH-3'). In the second step, the PIC formed by the proviral DNA, the integrase and cellular and viral proteins, enters the nucleus, where the proviral DNA is inserted into the host genome in a process known as strand transfer. This involves cleavage of 4–6 bp in the host DNA and the joining of the CAOH-3' viral DNA ends to the 5'-phosphate ends of the host DNA. It is this stage which is inhibited by currently available integrase inhibitors. It is thought that integration is targeted at transcriptionally active areas of the host cell chromosome. Proviral DNA can also exist in an episomal, non-integrated form, as one or two LTR circles. The implications of this viral state for pathogenesis remains unclear.

Over 40 species of mRNA are produced by alternate splicing, but around half are estimated to be full-length RNA, which function as mRNA and genomic RNA for subsequent packaging into secreted virions.

The production of new HIV-1 virions is driven by the production of the gag precursor, incorporating the matrix

(MA), capsid (CA), spacer peptide 1 (SP1), nucleocapsid (NC), SP2 and p6 proteins. A frameshift also leads to expression of gag-pol polyproteins, incorporating the RT, protease and integrase enzymes. Production of viable virions occurs through a complex assembly process at the plasma membrane. The MA targets the gag to the assembly site, and the CA domain is involved in multimerization of gag polyproteins. The NC is responsible for packaging the genomic RNA for export. Simultaneously with budding, the protease acts to cleave the gag polyprotein into its constituent proteins. Cleavage of gag is a highly ordered process, initially at the SP2/NC site, followed by MA/CA and then p1/p6 sites. A new maturation inhibitor, named Berivimat, acts to inhibit the SP1-CA cleavage. By contrast, the protease inhibitor (PI) class of drugs act to inhibit all cleavage steps, leading to the production of immature virions which are non-infectious. The late stage of budding involves the binding of the PTAP motif in the viral p6 to the Tsg101 component of the host endosomal sorting complex ESCRT-1. A further host protein, the apoptosis-linked gene 2 interacting protein (Alix), appears to play an important role in this p6-Tsg101 interaction.

HOST GENETIC DETERMINANTS FOR HIV/AIDS

A number of host genetic factors affect either the risk of acquiring infection when exposed to HIV, or the rate of progression to AIDS following infection (O'Brien and Nelson, 2004). Different major histocompatibility complex (MHC) class I, class II and natural killer (NK) killer inhibitory receptor (Kir) alleles can be categorized as 'good' or 'bad' genes for AIDS progression. Since the frequency of MHC alleles varies in different populations, these may influence disease progression and also responses to immunotherapy.

Another set of polymorphic genes that impacts HIV/AIDS are those encoding chemokines that bind to CCR5, the co-receptor for R5 strains of HIV, and the CCR5 gene itself. The major ligands for CCR5 are CCL5 (RANTES) and CCL3L1 (MIP-1 α P). The higher the chemokine concentration in the plasma, the lower the risk of infection, and the slower the progression to AIDS when untreated, because CCL5 and CCL3L1 compete with HIV gp120 for binding to CCR5. CCL3L1 genes vary in copy number, and individuals with relatively high copy numbers express higher plasma concentrations of the chemokine (Gonzalez *et al.*, 2005).

The CCR5 gene is polymorphic (O'Brien and Nelson, 2004). A common mutation in the noncoding promoter region of CCR5 influences the degree of gene expression,

and consequently the density of CCR5 on the surface of target cells for HIV infection. In fact, it is the combination of high CCL3L1 expression coupled with lower CCR5 expression that is protective for HIV infection and for progression to AIDS. In Europeans, but not Africans, there is a relatively frequent mutation in the CCR5 gene in which 32 base pairs are deleted from the coding region, known as CCR5 Δ 32, so this allele does not express a functional CCR5 molecule. Indeed, CCR5 Δ 32 homozygotes (approximately 1% of the white population) are resistant to infection by R5 strains of HIV, although they remain susceptible to the generally less transmissible X4 strains. The CCR5 Δ 32 mutation first came to light through the study of exposed uninfected individuals. CCR5 Δ 32 heterozygotes express lower levels of CCR5 receptor than normals and hence exhibit a slower progression to AIDS.

The reason for the high frequency of CCR5 Δ 32 alleles in the white population remains unresolved. Its frequency increases with latitude, being highest in Scandinavian countries. Some have speculated that CCR5 Δ 32 may have given protection against a highly pathogenic agent in the past, such as smallpox or the plague. Another polymorphism is a mutation in CCR2, but it is not clear whether this mutation acts through CCR2 itself, or by affecting CCR5 expression, because CCR5 is an adjacent gene on the chromosome.

There are also human polymorphisms in the intracellular HIV restriction factors TRIM5 α and APOBEC3 (Holmes *et al.*, 2007; Towers, 2007). Whether different alleles affect susceptibility to HIV/AIDS remains to be definitively shown. However, interspecies polymorphisms in TRIM5 α (differences between humans and simians) does affect HIV and SIV susceptibility and may help to restrict cross-species lentivirus infection in situations of human exposure to infected non-human primates.

With the advent of whole-genome scanning for single nucleotide polymorphisms, new genetic loci are coming to light that affect susceptibility to HIV/AIDS, including those involved in interferon responses (Fellay *et al.*, 2007; Loeuillet *et al.*, 2008). This is a rapidly developing area of AIDS research and it is likely that polymorphisms in human genes that affect the metabolism of antiretroviral drugs will also be increasingly frequently defined (Telenti and Zanger, 2008).

VIRAL DYNAMICS AND PATHOGENESIS

Viral Dynamics

In untreated individuals, HIV infection is characterized by high levels of virus replication, generation of genetically diverging virus variants through the emergence of

mutations and recombination events, and reciprocal interactions with the immune system. Approximately 10^{10} new virus particles are produced daily and rapidly cleared, with a free plasma virus clearance rate of only a few hours. The half-life of virus-producing cells is less than one day, leading to an infected cell loss rate of 10^8 – 10^9 per day (Ho *et al.*, 1995; Ramratnam *et al.*, 1999; Markowitz *et al.*, 2003; Wei *et al.*, 1995). The high virus turnover ensures rapid adaptation to changing selective pressures and provides an opportunity for drug resistance, immune escape and cell tropism to evolve, while the resulting chronic immune activation leads to the dysfunction and gradual collapse of the immune system. Within the diverse virus variants circulating in plasma ('the quasispecies'), dominant populations represent the expression of a dynamic equilibrium between escape from selective pressures and preserved ability to replicate and infect ('viral fitness').

HIV replicates preferentially in activated CD4 T cells. Although most infected cells have a short lifespan, a fraction of cells survive long enough to revert to a resting memory state. The exclusion of host transcription factors (e.g. NF- κ B) from the nucleus virtually silences HIV gene expression in resting cells, and HIV persists as a stable, integrated and transcriptionally silent provirus, which is unaffected by antiretroviral therapy (Han *et al.*, 2007; Wong *et al.*, 1997). A proportion of latently infected cells can resume full virus production following activation. Thus, the latently infected CD4 T cells act as a reservoir, which is established early during primary infection and shows a slow subsequent rate of decay. Although the frequency of latently infected cells is only 1 in 10^6 resting CD4 T cells, the reservoir can rapidly repopulate the plasma quasispecies when antiviral therapy is interrupted, and represents the main barrier to eradicating the infection (Chun *et al.*, 1997, 1998; Siliciano *et al.*, 2003; Strain *et al.*, 2003). In viraemic individuals, the reservoir is continuously replenished, creating an archive for all quasispecies that have replicated at a high level, including drug-resistant mutants, with long-term implications for treatment (Monie *et al.*, 2005).

Cell Tropism and HIV Receptors

The expression of CCR5 or CXCR4 on different CD4 cells defines their susceptibility to infection by the corresponding R5 or X4 strains, thus determining virus tropism. The sequence of the V3 loop is the major determinant of co-receptor use, as a result of the structural homology between the crown of the V3 loop and the β 2– β 3 loop in the natural chemokine ligands. Additional determinants are found in V1 and V2.

R5 viruses appear to be more efficiently transmitted than X4 viruses and predominate in the initial and asymptomatic phases of the infection regardless of the route

of exposure (Pope and Haase, 2003). The mechanisms of the preferential selection are unclear. X4 viruses tend to emerge as the CD4 count declines, and are eventually detected in 40–60% of patients, coinciding with expanded cell tropism, increased virus replication rate, faster disease progression, and the onset of AIDS (Connor *et al.*, 1997). It is still debated whether the emergence of X4 viruses is the cause or consequence of disease progression. One proposed mechanism of enhanced pathogenicity is the ability of X4 viruses to infect immature thymocytes, the precursors of mature CD4 T cells (Correa and Muñoz-Fernández, 2001). R5 viruses detected in advanced disease can also differ from those detected in early infection by showing reduced dependence on high CD4/CCR5 levels for entry, decreased susceptibility to RANTES, and enhanced pathogenicity (Kwa *et al.*, 2003).

Dendritic Cells

Dendritic cells are professional antigen-presenting cells and important mediators of the adaptive immune response against HIV, but are also responsible for uptake, trafficking and dissemination of the virus (Pope and Haase, 2003). DCs express CD4, chemokines co-receptors, Fc receptors, DC-SIGN and other C-type lectin receptors that can mediate HIV uptake. DCs can capture HIV without becoming productively infected, transmit the captured virions by forming synapses with T cells and transport the virus to the lymphoid organs. They are also susceptible to infection. Although virus replication is generally less efficient than in T cells, progeny virus can be released to propagate the infection (Hladik *et al.*, 2007; Wu and KewalRamani, 2006). It remains to be determined whether DCs can provide a cellular reservoir for latent infection. Langerhans cells are a subset of DCs found in tissues, including the genital mucosal epithelium. Alongside intraepithelial CD4 T cells and subepithelial DCs, CD4 T cells and macrophages, Langerhans cells encounter HIV early after sexual exposure. It has been proposed that the virus ability to establish a systemic infection depends on its early interaction with Langerhans cells (Boggiano and Littman, 2007). Follicular DCs are found in the B-cell follicles and germinal centres of peripheral lymphoid tissues. They do not become productively infected with HIV, but in lymphoid tissues trap and retain large quantities of infectious virus particles on their surface, proximal to highly susceptible CD4 T cells.

CD4 T-cell Depletion

Approximately 3×10^7 CD4 T cells are lost every day, but the mechanisms of HIV-induced CD4 depletion

are not entirely known. The highest rate of CD4 T-cell destruction occurs during primary infection before the emergence of the adaptive immune response. HIV transmission is followed rapidly by dissemination to the lymphoid organs, particularly gut-associated lymphoid tissues (GALT), where around 60% of total CD4 T cells reside (Li *et al.*, 2005). Within days of the infection there is massive depletion of memory CD4 T cells in the GALT, independently of the route of transmission (Brenchley *et al.*, 2004; Li *et al.*, 2005). CD4 depletion in GALT persists after the acute phase of the infection and is only partially restored by antiretroviral therapy (Guadalupe *et al.*, 2006). Conversely, the depletion is not observed in HIV-infected long-term nonprogressors who remain clinically and immunologically well over many years of infection. These findings suggest that GALT plays a central role in HIV pathogenesis (Centlivre *et al.*, 2007).

Several explanations for HIV-induced CD4 T-cell loss have been proposed: impaired T-cell production by the thymus, decreased proliferative capacity of CD4 T cells, and increased death due to direct and indirect mechanisms. HIV can cause death of CD4 T cells in several ways (Letvin and Walker 2003; Pope and Haase, 2003): (i) by a direct CPE, including cell fusion by SI strains; (ii) by cytotoxic T lymphocytes and other immune responses that target infected cells and (iii) by apoptosis of infected and uninfected cells, due to lymphocyte activation and a changed cytokine and chemokine milieu. For patients with a CD4 count ≥ 500 cells μl^{-1} , the median time to a CD4 cell decline < 350 cells μl^{-1} is 2.5 years, ranging from 0.7 years in those with a plasma HIV RNA load ≥ 500 000 copies ml^{-1} to 4.7 years in those with a viral load < 1000 copies ml^{-1} (UK Collaborative HIV Cohort (CHIC) Study Steering Committee, 2007). These data clearly indicate that viral replication is a major driver of CD4 T-cell loss. However, the chronic immune activation characteristic of HIV infection seems to drive CD4 T-cell loss more than direct virus-mediated destruction. There exists a strong association between activation of the immune system, T-cell apoptosis, immunological exhaustion, uncontrolled HIV replication, plasma viral load and disease progression (Choudhary *et al.*, 2007; Day *et al.*, 2006; Deeks *et al.*, 2004; D'Souza *et al.*, 2007; Hazenberg *et al.*, 2003; Kaufmann *et al.*, 2007; Oxenius *et al.*, 2004). The mechanisms by which immune activation induces CD4 T-cell depletion are still incompletely understood. In HIV-infected people both CD4 and CD8 T cells show a significant upregulation of the inhibitory receptor programmed death 1 (PD-1). The observation that *in vitro* exposure of CD4 T cells to high concentrations of HIV gp120 induces Fas ligand expression at the cell surface provides one pathway by which Fas–Fas ligand-mediated T-cell apoptosis may occur. There are

also clear but not absolute correlates between the rate of disease progression and the immunogenetic background of the host (Carrington and O'Brien 2003). Several human leukocyte antigen (HLA) markers have been found to be associated with either faster (e.g. HLA-B*35 and C ω 4) or slower (e.g. HLA-B*27 and HLA-B*57) HIV disease progression among untreated individuals.

IMMUNE RESPONSES

As with other virus infections, systemic infection by HIV typically elicits both cellular and humoral immune responses. These help to control virus replication, but do not clear the infection entirely from the body. Hence there is no recovered, immune state for HIV, or for most other lentivirus infections of animals.

After primary infection, seroconversion occurs when antibodies first become detectable, and specific CD4⁺ and CD8⁺ T cells appear around the same time. Because virus-neutralizing antibodies do not appear until several months later, it was assumed that cell-mediated immunity was chiefly responsible for clearance of peak primary viraemia before the establishment of the viral load 'set point'. Indeed strong cellular immune responses aid survival, particularly a powerful T-helper cell response in so-called 'elite' controllers (Walker, 2007). However, recent studies indicate that non-neutralizing antibodies may play a role in virus clearance, mediated through complement (C'). Antibody plus C' can inactivate virus infection through lysis of the HIV envelope and other inhibitory mechanisms; C' may also reduce the number of virus-producing cells through antibody-dependent cellular cytotoxicity. But the action of C' may be a two-edged sword, because it can also enhance HIV infection of cells bearing C' receptors, such as macrophages and DCs. Thus innate immune components may exert contradictory protective and virulent effects during the course of HIV infection (Willey and Aasa-Chapman, 2008).

The immune response undoubtedly shapes HIV, just as HIV eventually takes its toll on the immune system. Early in the course of infection, HIV genetic variation is minimal, but a quasispecies of genomes representing a high degree of genetic variation follows soon after seroconversion. HIV is adept at throwing up immune escape mutants out of this quasispecies. This immune evolution is evident both for escape from recognition of Gag and Tat peptides recognized by cytotoxic T cells, and for escape from neutralization by antibodies. By the time that neutralizing antibodies appear, new variants of HIV also appear so that HIV keeps ahead of this host—virus interplay.

HIV particles also cover the most vulnerable neutralization epitopes on gp120 and gp41 under a carapace of

carbohydrate groups. The CD4-binding site on gp120 remains available as a relatively constant feature (though in a cleft) but other epitopes such as the co-receptor site on gp120 and the fusion site on gp41 are only revealed during induced-fit interactions with the receptors, so that antibodies have little time to act. X4-tropic viruses, however, have more exposed sites, and may be more readily controlled by humoral immunity. This may explain why X4 viruses tend to appear late in infection because they are opportunist HIV variants that only thrive in an already immunocompromised host (Weiss *et al.*, 2008; Willey and Aasa-Chapman, 2008).

THE LABORATORY DIAGNOSIS OF HIV INFECTION

Screening and Confirmatory Tests

The laboratory diagnosis of HIV infection is based on methods that detect antibodies and methods that detect the virus or virus components in blood. The chronological order of detection after primary infection is on average 9–11 days for viral RNA and 21–25 days for anti-HIV antibodies. Serology remains the cornerstone of the diagnosis of HIV infection in adults. Although early studies suggested that a small percentage of people may require up to six months for antibody to appear, the vast majority of infected individuals develop detectable antibodies within three to eight weeks of the infection when tested with current assays. Serological assays can be divided into screening tests and confirmatory (supplemental) tests. Screening tests are generally designed to detect infection with high sensitivity (low false-negative rate), whereas confirmatory tests detect the infection with high specificity (low false-positive rate). In practice, a combination of tests is used to allow diagnosis with high sensitivity and specificity, and to differentiate between HIV-1 and HIV-2.

Enzyme-linked immunoassay (EIA) and EIA-like formats for HIV antibody detection have undergone refinement through the years to increase sensitivity (>98%), specificity (>99%), and automation. Third-generation assays employ a mixture of recombinant viral proteins and synthetic peptides to detect antibodies against both HIV-1 and HIV-2, including all subtypes of HIV-1 group M and the outlier group O. The antigen-sandwich format is considered the most sensitive screening method, given its ability to detect all isotypes of antibody (including IgM). The test detects antibodies within three to four weeks, but does not usually differentiate between HIV types. Fourth-generation assays allow the combined detection of anti-HIV antibodies and p24 antigen, thereby increasing diagnostic sensitivity in recent infection by approximately one week.

The interpretation of screening assay results is as follows:

- *Negative screening test.* Unless a recent infection is suspected, a negative screening test result is considered sufficient to exclude infection.
- *Reactive screening test.* A reactive result requires confirmation and differentiation between HIV-1 and HIV-2. A positive report is released if consensus results are obtained from all assays, and a second blood is requested to confirm patient identity. Non-consensus in the confirmatory tests may be due to early infection, non-specific reactivity, or, rarely, a new non-reactive HIV subtype.
- *Recent infection.* In people with recent infection, anti-HIV antibodies may be initially low or undetectable. Follow-up testing demonstrates rising antibody responses confirming the diagnosis. The Western Blot will demonstrate the evolution of the serological response to specific HIV antigens. If a clinical diagnosis of primary infection is suspected, the diagnosis can be achieved by detection of viral RNA or proviral DNA. Viral load assays are widely used for this purpose. Approximately 50% of cases will also show detectable p24, but p24 antigen detection has been largely replaced by the more sensitive molecular methods.
- *Non-specific reactivity.* For patients with non-specific reactivity, the clinical follow-up involves establishing that they are viral RNA and proviral DNA negative and that they have non-evolving serology. They are followed over time for reassurance, and in the majority the reactivity will eventually wane.

Confirmatory tests traditionally include Western blot, line immunoassay (LIA), indirect fluorescent assay (IFA) and radioimmunoprecipitation assay (RIPA). The tests are highly specific, but labour-intensive and expensive. Western blot is considered the gold standard for validation of HIV test results. The assay uses antigens prepared from whole cultured virions, separated by electrophoresis and blotted onto a nitrocellulose membrane which is then cut into strips. The HIV-1 viral antigens are separated as follows (from top to bottom): gp160, gp120, p66, p55, p51, gp41, p31, p24, p17 and p15. Antibodies to the Gag proteins (p17, p24 and p55) appear first in the course of infection, decreasing in titre during disease progression. Antibodies to the Env glycoproteins (gp160, gp120 and gp41) appear later and persist in advanced disease. Although the interpretation criteria vary, reactivity to at least two of gp160/120, gp41 or p24 is required for a positive result. It is generally accepted that a negative result is the absence of all bands, although it has been proposed that results can be reported as negative if there is only a very

weak p17 band. Indeterminate classifications occur when there is reactivity to one or more antigens, but not fulfilling the criteria for positivity. LIA uses a similar principle to Western blot, but employs recombinant antigens and synthetic peptides applied on nitrocellulose strips, improving standardization and reducing background reactivity. A positive result for HIV-1 is usually defined by reactivity to p24 and gp41.

Simple and rapid confirmatory assays have been developed and alternative confirmatory strategies have been proposed. One example is the combination of two screening tests that use either antigens derived from different sources or different assay configurations, or a combination of screening test and virus detection test, to be followed by a confirmatory test only in case of discrepancies. Traditional confirmatory tests still have a place for sera yielding indeterminate results.

In general, plasma HIV RNA quantitative detection for primary diagnostic purposes is not recommended because the assay has been explicitly developed for use in known infected individuals, and may give a low false positive result in an uninfected individual.

Rapid Anti-HIV Antibody Assays for Point-of-Care Testing

The availability of antiretroviral therapy makes the early diagnosis of HIV infection imperative. In western countries, despite the success of voluntary testing services and the adoption of routine, opt-out testing in antenatal and genito-urinary clinics, a significant proportion of infected people remain unaware of their infection. These patients are known to repeatedly seek medical care for a series of minor and major ailments, but are not identified as HIV-infected until late in the disease course. A call has been made internationally to increase uptake of HIV testing and improve recognition of undiagnosed infection.

Two strategies have been proposed: wider adoption of routine opt-out HIV testing (Table 38.1) in a variety of health-care setting where HIV-infected patients may present (e.g. accident and emergency, general medical wards, TB clinics), and use of rapid point-of-care HIV antibody tests.

Rapid HIV tests use capillary blood collected by finger-prick or oral fluids, require no sophisticated equipment, can be performed by trained staff with limited technical expertise, provide a result in less than 30 minutes, and can be read visually. These features make them suitable for point-of-care (near-patient) testing. 'Salivary' antibody tests (e.g. the OraQuick Advance) use the crevicular fluid from capillaries beneath the tooth-gum margin, which is a transudate of blood. The concentration of antibodies in oral fluids is about 1/400 of that in plasma, requiring a high sensitivity of detection for acceptable assay performance.

The common assay formats are flow-through, lateral-flow and agglutination assays. They usually incorporate an internal control based on the detection of human IgG. Approved tests perform well when compared with laboratory screening assays (Branson 2007) and can detect group M and group O HIV-1 and HIV-2. In a voluntary testing service with a HIV-1 seroprevalence of 3.3%, the specificity of the Abbott Determine test with capillary blood is 99.6% (99.3–99.8%) and the positive predictive value 90.5% (82.8–95.6%). This translates into a false-positive rate of 1 : 11. In addition, relative to third-generation serological assays, the Determine and other rapid tests show an average delay of five to seven days in the detection of anti-HIV antibodies. Thus, point-of-care tests are best suited for specific settings where the advantages clearly outweigh the risk of false positivity and possible delays in recognizing early infection. They are most useful in situations when immediate results are required to guide management, such as testing pregnant women who present during labour, or the assessment of source people in exposure incidents to inform the use of post-exposure

Table 38.1 Centers for Disease Control and Prevention (CDC) definitions of HIV testing

Diagnostic testing: Performing an HIV test for people with clinical signs or symptoms consistent with HIV infection.

Screening: Performing an HIV test for all people in a defined population.

Targeted testing: Performing an HIV test for subpopulations of people at higher risk, typically defined on the basis of behaviour, clinical or demographic characteristics.

Informed consent: A process of communication between patient and provider through which an informed patient can choose whether to undergo HIV testing or decline to do so. Elements of informed consent typically include providing oral or written information regarding HIV, the risks and benefits of testing, the implications of HIV test results, how test results will be communicated, and the opportunity to ask questions.

Opt-out screening: Performing HIV screening after notifying the patient that (i) the test will be performed and (ii) the patient may elect to decline or defer testing. Assent is inferred unless the patient declines testing.

HIV-prevention counselling: An interactive process of assessing risk, recognizing specific behaviours that increase the risk for acquiring or transmitting HIV, and developing a plan to take specific steps to reduce risks.

prophylaxis (PEP). The tests are also valuable in clinical settings where a significant proportion of people tested by conventional methods fail to return for their results. The availability of rapid results allows appropriate counselling and management of the infected people, while avoiding the need for follow-up visits for those who test negative. Furthermore, the avoidance of venupuncture and the rapid availability of results can be an incentive for people to present for testing. Because the assay format is simple and most tests are stable within a wide temperature range, rapid HIV tests can also be used outside of traditional clinical settings to improve uptake among at-risk populations that may be otherwise difficult to reach.

The main advantages and disadvantages of rapid HIV tests are summarized in Table 38.2. The tests should be performed under conditions that satisfy accreditation requirements, including the establishment of rigorous training, quality assurance and audit programmes. Arrangements should also be in place for rapid confirmation of reactive results, to avoid unnecessary anxiety in patients who test falsely reactive. The World Health Organization recommends that prior to their implementation, point-of-care HIV tests first be evaluated at a reference laboratory and then at points-of-service, and that measures to ensure quality of testing should be in place.

Methods to Identify Recently Acquired HIV-1 Infection

Following seroconversion, several laboratory methods have been developed to allow differentiation of early versus established (greater than four to six months) HIV infection. The assays are used to study the dynamics of the epidemic and transmission networks, inform public health intervention programmes, and identify candidates for clinical trials and vaccine strategies targeting early infection (Table 38.3) (Gupta *et al.*, 2007).

The detuned assay has been widely applied but currently has limited availability. The test is based on the principle that in early infection a sample reactive in the

Table 38.2 Advantages and disadvantages of rapid point-of-care HIV tests

Advantages	Disadvantages
Easy to perform and interpret	Expensive
Require simple equipment	Reduced sensitivity in early infection
Avoid venupuncture	Prone to operator errors
Include a positive control	Subjective interpretation of results

Table 38.3 Assays for differentiating early (less than four to six months) from established infection

Assay	Principle
Detuned assay with Vironostika-LS EIA	High-sensitivity/low-sensitivity dual EIA
Barin 'Peptide' assay	High-sensitivity/low-sensitivity dual EIA
Calypte® BED Incidence HIV EIA	Proportion of HIV-1-specific IgG in a serum or plasma relative to the total IgG
AxSYM and Vitros avidity assays	Employ guanidine to elute low-avidity and low-affinity antibodies

sensitive EIA becomes nonreactive in a less-sensitive assay. The 'peptide' assay follows the same principles but offers the advantage of being independent of commercial platforms (Barin *et al.*, 2005). The Calypte® BED Incidence HIV EIA is a quantitative assay that detects gradually increasing levels of anti-HIV IgG after seroconversion. Avidity assays employ guanidine to disrupt low-avidity binding between IgG antibodies and corresponding antigen, using as platform the Abbott AxSYM HIV 1/2gO MEIA assay or the Ortho Anti-HIV 1 and 2 VITROS ECi assay (Chawla *et al.*, 2007; Suligo *et al.*, 2002). Although there is individual variability in avidity maturation, validated breakpoints can identify seroconversion within the previous four to six months. The choice of the breakpoint ultimately depends on the intended application of the assay. Adopting a lower cut-off value increases specificity, but may result in some loss of sensitivity.

HIV Diagnosis in Children

The diagnosis of HIV infection in infants is confounded by the transfer of maternal antibodies from approximately 32 weeks of gestation. It takes up to 18 months for the passive antibody to disappear. Early diagnosis may be obtained by virus detection and recommended methods include proviral DNA detection by PCR (gold standard). With DNA PCR, which predominantly uses in-house methodologies, strict quality control is required to minimize the risk of contamination. In view of the genomic diversity of HIV, a maternal sample should always be amplified with the first infant sample to confirm that the primers detect the maternal virus. If a maternal virus cannot be detected, a different primer set or a different test (e.g. HIV RNA detection or virus culture) should be used. A positive DNA PCR at any time requires a repeat test on a second blood sample for confirmation. Infected infants are usually DNA-positive by week 4 and HIV can

be reasonably excluded with two negative tests, one at six weeks of age and the other at age three months or older. Testing is usually done at zero to two days, six weeks and three months of age. If all these tests are negative and the baby is not being breastfed, then parents can be informed that the child is not HIV infected. An HIV antibody test should be done at 18 months of age to confirm loss of maternal antibodies. Detection of viral RNA by viral load tests is practical, but data on assay performance in this setting are limited. For an untreated infant, RNA tests may be more sensitive than either DNA PCR or culture

(Lambert *et al.*, 2003). A low copy number result, however, should not be assumed to indicate infection as it may represent false positivity.

THE NATURAL HISTORY OF HIV INFECTION AND ITS CLINICAL MANIFESTATIONS

The natural course of HIV infection can be divided into three phases (Figure 38.5). In the acute phase, the plasma viral load increases exponentially and then

Figure 38.5 The clinical, virological and immunological phases of HIV infection. The natural course of HIV infection can be divided into three phases: primary infection, asymptomatic stage and symptomatic stage. In the top panel, CD4 T-cell counts (O) show a rapid decline immediately after infection coinciding with the burst of virus replication, followed by recovery to near-normal levels, subsequent gradual loss over several years of asymptomatic infection, and accelerated loss in late disease. The reciprocal of these changes is shown by the β_2 -microglobulin level (●), a plasma measure of immune activation. In the bottom panel, the plasma viral load (●) achieves a peak during primary infection, which is mirrored by the p24 antigen (■), declines to a relatively stable set-point in the early asymptomatic infection and raises gradually over time, with an accelerate increase in late disease. Anti-HIV antibodies (Δ) become detectable within three to eight weeks of the infection and persist throughout the infection. However certain antibody subsets (i.e. anti-p24 antibodies, \diamond) may decline in advanced disease.

declines sharply in line with the emerging immune response and/or exhaustion of cellular targets (Perelson, 2002). After approximately six months, the viral load reaches a relatively constant level known as the set-point. The asymptomatic phase, lasting for 6–15 years, is characterized by gradual CD4 T-cell depletion which precedes and predicts the clinical manifestations of advanced disease. The viral load set-point ranges generally between 10^3 and 10^5 copies ml^{-1} and is highly correlated with the rate of CD4 T-cell loss and disease progression (Mellors *et al.*, 1996). The viral load increases over time by 0.1–0.2 \log_{10} copies ml^{-1} per year, and ultimately the immune destruction and the direct pathogenic effects of the virus result in the range of opportunistic infections, malignancies and neurological and gastrointestinal disorders characteristic of AIDS. The depletion of CD4 T cells accounts for the profound immune deficiency. Other manifestations of disease (e.g. CNS infection) probably reflect infection of other cell types, including macrophages, microglial cells, astrocytes and neural progenitor populations (Schwartz and Major, 2006). The rates of progression vary among infected individuals. A small proportion (5–8%) remain clinically free of disease with high CD4 cell numbers (CD4 counts) for more than 15 years following infection. The majority (70–80%) show a progressive deterioration in the course of seven to eight years, and a further subset (10–15%) experience rapid progression within five years. Table 38.4 outlines the classification most widely used to stage HIV infection. AIDS-defining conditions are summarized in Table 38.5.

Primary Infection

In 50–90% of cases, primary HIV infection is accompanied by the acute onset of a constellation of symptoms referred to as the acute retroviral syndrome or acute seroconversion illness (Figure 38.6). Symptoms develop rapidly one to six weeks after infection and in over 50% of cases include fever $>38^\circ\text{C}$, fatigue, pharyngitis, body aches and cervical lymphadenopathy (Vanhems and Beaulieu, 1997). The rash is erythematous, maculopapular and nonpruritic, and affects the face, trunk

Table 38.5 AIDS-defining conditions

Candidiasis of bronchi, trachea or lungs
Candidiasis, oesophageal
Cervical cancer, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 mo duration)
Cytomegalovirus disease (other than liver, spleen or nodes)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV related
Herpes simplex: chronic ulcer(s) (>1 mo duration) or bronchitis, pneumonitis, or oesophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 mo duration)
Kaposi's sarcoma
Lymphoma, Burkitt's (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
<i>Mycobacterium avium</i> complex or <i>M. kansasii</i> , disseminated or extrapulmonary
<i>Mycobacterium tuberculosis</i> , any site (pulmonary or extrapulmonary)
<i>Mycobacterium</i> , other species or unidentified species, disseminated or extrapulmonary
<i>Pneumocystis carinii</i> pneumonia
Pneumonia, recurrent
Progressive multifocal leukoencephalopathy
Salmonella septicaemia, recurrent
Toxoplasmosis of brain
Wasting syndrome due to HIV

and occasionally the extremities including the palms and soles. Neurological manifestations are observed in 12% of cases, most commonly in the form of meningitis or meningo-encephalitis. Acute opportunistic infections may occur, including PCP and oral and oesophageal candidiasis.

The GALT, rich in activated memory CD4 T cells, is the main site of early HIV replication. HIV has also been detected in cerebrospinal fluid (CSF) soon after infection.

Table 38.4 Centers for Disease Control and Prevention (CDC) staging of HIV infection

CD4 counts (cells mm^{-3})	Clinical group		
	A: asymptomatic, PHI or PGL ^a	B: symptomatic, non-C ^b	C: AIDS-defining conditions
>500	A1	B1	C1
200–500	A2	B2	C2
<200	A3	B3	C3

^aPHI, primary HIV infection; PGL, persistent generalized lymphadenopathy.

^bSymptomatic but not included in C are those conditions associated with defective immunity.

Figure 38.6 Symptoms that accompany primary HIV infection (acute retroviral syndrome or acute seroconversion illness).

Marked changes in the peripheral lymphocyte count are seen; the CD4 : CD8 ratio is reversed, CD8 cells increase and CD4 cells decrease. CD4 lymphopenia occurs early and is generally short lived, beginning to improve after day 9. The symptomatic phase of primary HIV infection lasts less than 14 days on average and is self-limiting. Complete clinical recovery is the norm. Multiple, severe and protracted symptoms, candidiasis, neurological involvement, and persistently high plasma viral load predict a rapid subsequent rate of disease progression. Whether antiretroviral treatment should be started in patients with primary HIV infection remains controversial. Early therapy may preserve immune responses but the long-term clinical benefit has not as yet been clearly demonstrated. In clinical practice, therapy is often used to limit symptoms in a severe seroconversion illness.

Asymptomatic Phase

Primary HIV infection is followed by an asymptomatic phase lasting 6–15 years. Clinically, patients are relatively free of symptoms, although lymphadenopathy may be a complaint in some cases. Virologically this does not represent a period of latency but rather the lymphoid tissue is actively infected by HIV (Stevenson, 2003) and there is a high turnover of HIV production and of infected lymphocytes with equally active replenishment (Ho *et al.*, 1995; Markowitz *et al.*, 2003; Ramratnam *et al.*, 1999; Wei *et al.*, 1995). The duration of the asymptomatic phase is variable and related to the severity of primary HIV infection, the phenotypic characteristics of the infecting viruses, the status of the host immunity, the lifestyle of the host and the use of antiretroviral therapies. This phase of clinical care is generally supportive, involving

surveillance for features of early progression and is the optimum time to commence antiretroviral therapy.

Symptomatic Phase

In untreated patients, early features of symptomatic disease are often nonspecific and associated with dermatological manifestations, such as eczema and human papillomavirus (HPV) lesions, as well as oral and vaginal candidiasis, recurrent chest infections, night sweats, weight loss and lymphadenopathy. Oral lesions become common, with gingivitis, candidiasis, herpes simplex lesions and aphthous ulcers. Oral hairy leukoplakia presents as white, ribbed lesions on the lateral margins of the tongue; it may be asymptomatic or produce soreness within the mouth. It is associated with Epstein—Barr virus (EBV) infection and responds to high-dose acyclovir or valaciclovir. As disease progresses and the CD4 count declines to <200 cells μl^{-1} , the risk of AIDS-defining conditions increases. HIV-induced disease affects multiple systems and organs through viral-mediated pathogenicity and immunodeficiency, leading to opportunistic infections and malignancies (Table 38.6).

Opportunistic Infections

Opportunistic infections seen in symptomatic HIV-1 disease may be categorized into: (i) those that do not cause disease in the immunocompetent host (e.g. *P. carinii*); (ii) those that cause mild disease in the normal host (e.g. herpes simplex virus (HSV), *Toxoplasma gondii*) and (iii) those that are conventional pathogens (e.g. *Mycobacterium tuberculosis*) but can produce widespread debilitating disease in the immunocompromised host.

Pneumocystis carinii

PCP is nearly always seen at CD4 counts <200 cells μl^{-1} . It is characterized by the subacute onset of fever, fatigue, dry cough and progressive shortness of breath. Diffuse, bilateral infiltrations with a batwing appearance are characteristic, but occasionally the chest radiograph may be normal at presentation. Diagnosis is made by detection of the organism in induced sputum or bronchoalveolar lavage. Treatment is usually with co-trimoxazole. Routine prophylaxis with co-trimoxazole in patients with CD4 cell counts <200 cells μl^{-1} markedly reduces the incidence of the infection.

Mycobacteria

The risk of active tuberculosis (TB) is high among HIV-infected people, and TB is the leading cause of death among HIV-infected people worldwide. *M. tuberculosis* causes disease in all stages of HIV infection. In

patients with CD4 counts <300 cells μl^{-1} the features of TB are similar to those of TB in immunocompetent hosts, with pulmonary disease the most common manifestation. At CD4 counts <200 cells μl^{-1} presentation can be atypical and nonpulmonary and disseminated disease may occur. Almost every tissue and organ can be affected. *M. avium* and *M. intracellulare* (together known as the *M. avium-intracellulare* complex (MAI)) are two closely related species of ubiquitous environmental organisms which can cause disseminated disease in patients with advanced disease, almost exclusively when the CD4 count is <50 cells μl^{-1} . Symptoms are nonspecific and include fatigue, fever, night sweats, weight loss, anaemia, abdominal pain and diarrhoea.

Cytomegalovirus

Cytomegalovirus (CMV) disease is common in untreated patients with advanced disease, especially at CD4 counts <50 cells μl^{-1} . Its manifestations primarily include progressive chorioretinitis, oesophagitis, colitis and neurological disease (e.g. encephalitis, polyradiculopathy, myelitis and mononeuritis multiplex). CMV retinitis occurred in 30–40% of AIDS patients prior to the introduction of highly active antiretroviral therapy (HAART). The lesions are initially asymptomatic but, as the perivascular exudates and haemorrhages involve the macula, vision becomes impaired. Replacement of retinal cells with fibroblasts may facilitate retinal detachment. Bilateral involvement is common. CMV pneumonitis is rare in AIDS patients because it requires active recruitment of the immune system to cause disease. Progression of CMV infection can be restricted by antiviral therapy with ganciclovir (or valganciclovir), foscarnet and cidofovir. The incidence of CMV retinitis is reduced by 80% in the era of HAART. Detection of CMV viraemia by PCR correlates with increased mortality (Deayton, 2004) and one non-randomized clinical trial reports reduced mortality when CMV retinitis was treated with systemic, rather than local, ganciclovir (Kempen, 2003).

Herpes Simplex Virus

In the early 1980s, chronic persistent ano-genital ulceration due to HSV was one of the first recognized manifestations of AIDS. Over the subsequent decades, a strong epidemiological association emerged between HSV-2 and HIV, reflecting common risk factors for infection as well as reciprocal promoting effects. Bidirectional interactions have been demonstrated between the two infections. Both HSV disease and subclinical HSV shedding recur frequently in HIV-infected people. Disease may be prolonged and respond poorly to therapy in patients with low CD4 counts. Frequent HSV reactivations enhance

Table 38.6 Major systems and organs affected by HIV infection

System or organ	Examples
Chest	Bacteria (e.g. <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Staphylococcus aureus</i> , <i>Pseudomonas aeruginosa</i>) <i>Pneumocystis carinii</i> pneumonia Mycobacterial infections Fungi (e.g. <i>Histoplasma</i> , <i>Cryptococcus</i> , <i>Aspergillus</i>) KS, lymphoma, bronchogenic carcinoma Lymphocytic and nonspecific interstitial pneumonitis
Mouth	Candidiasis Gingivitis and periodontitis Viral infections causing ulcerations (HSV, VZV, CMV) Oral hairy leukoplakia (EBV) Warts (HPV) KS, lymphoma, carcinoma Idiopathic parotid enlargement
Eye	Keratoconjunctivitis sicca Infectious keratitis (e.g. VZV) Retinal microvasculopathy Infectious retinitis (e.g. CMV, VZV, HSV, toxoplasma, syphilis)
Skin	Staphylococcal folliculitis Eosinophilic and other pruriginous folliculitis Bacillary angiomatosis Viral eruptions (e.g. HSV, VZV, molluscum contagiosum, HPV) Insect bite reactions, photosensitivity, drug reactions Seborrheic dermatitis, psoriasis, Reiter's syndrome KS
Gastrointestinal and hepatic	Oesophagitis (e.g. HSV, CMV, <i>Candida</i> , idiopathic) Diarrhoea Colonic disease (e.g. CMV) Proctitis (e.g. HSV) Enhanced progression of viral hepatitis B and C Biliary tract disease (e.g. CMV, <i>Cryptosporidium</i>) Pancreatitis
Nervous system	Infections (e.g. <i>Toxoplasma</i> , <i>Cryptococcus</i> , PML, CMV) Malignancies (e.g. primary central nervous system lymphoma) HIV-encephalopathy Distal sensory polyneuropathy Functional disorders (e.g. anxiety, depression, psychosis)
Haematological	Anaemia, granulocytopenia, thrombocytopenia Coagulopathy
Endocrine and metabolic	Dislipidaemia, lipodistrophy Hypogonadism
Cardiovascular	Pericarditis, pulmonary hypertension, atherosclerosis
Renal	HIVAN and immune-mediated renal disease

KS, Kaposi's sarcoma; PML, progressive multifocal leukoencephalopathy; HIVAN, HIV-associated nephropathy.

HIV replication, increasing HIV viral load in both plasma and genital tract, with implications for HIV transmission and disease progression. Conversely, HSV suppression with acyclovir or valaciclovir reproducibly reduces HIV RNA load in plasma and the genital tract by 0.3–0.4 log₁₀ copies ml⁻¹. Consistent with these findings, HSV-2 infection has been shown to increase the risk of HIV

transmission and acquisition by approximately two- to threefold (Ramaswamy and Geretti, 2007; Wald and Link, 2002), although HSV interventions have not been shown to reduce incidence to date. There is also evidence for a small but significant positive impact of anti-HSV therapy on HIV disease progression. Whether widespread use of suppressive anti-HSV therapy can lower HIV incidence

in at-risk populations is currently being evaluated in clinical trials. HIV infection is associated with a significant impairment of HSV-specific T-cell immunity, which is restored gradually by HAART. However, immunological recovery may remain partial (Ramaswamy *et al.*, 2007) and treated patients continue to experience more frequent HSV reactivations and shedding than HIV-negative people.

Varicella-zoster Virus

Patients with HIV infection can develop severe illness with either varicella or zoster. Progressive primary varicella, a syndrome with persistent new lesion formation and visceral dissemination may be life-threatening. In the pre-HAART era, approximately 25% of patients hospitalized with varicella developed severe complications, including haemorrhagic rash, pneumonitis and fulminant infection with disseminated intravascular coagulation. HIV-infected people have a higher frequency of zoster than the general population and zoster continues to be common in the HAART era. Varicella-zoster virus (VZV) reactivation is often seen at CD4 counts >200 cells μl^{-1} as one of the early manifestations of declining immune function. Although most have an uncomplicated clinical course, multi-dermatomal, disseminated and chronic atypical skin rashes can occur. Acute retinal necrosis and neurological syndromes including encephalitis, myelitis and meningitis can develop in the absence of rash.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a subacute, slowly progressing condition associated with JC virus producing oligodendritic lysis and selective white matter destruction. JC virus may be detected by PCR in the CSF (70–85% sensitivity) or brain biopsy. HAART has proven efficacy in prolonging the survival of patients with PML, but the combined use of HAART and cidofovir has failed to demonstrate a benefit compared with HAART alone.

HIV-associated Encephalopathy

HIV-associated encephalopathy (HIVE) is a syndrome complex of progressive cognitive, motor and behavioural dysfunction also known as AIDS dementia complex (ADC), HIV/AIDS dementia or HIV-associated cognitive motor complex. The syndrome occurs commonly in patients with advanced disease (CD4 count <200 cells μl^{-1}). Its hallmark is encephalitis affecting the white and subcortical grey matter. HIV RNA is frequently detected in CSF. Multiple pathogenic mechanisms are thought to be involved, including HIV replication in

brain macrophages and microglial cells, neurotoxic effects of HIV proteins, and inflammatory responses (Ellis *et al.*, 2007; Schwartz and Major, 2006). With the advent of HAART, a syndrome of minor cognitive motor disorder has become more common than ADC. HAART also leads to improvements of cognitive function in patients who already have ADC. Nonetheless, HIVE continues to occur in treated patients despite suppressed viraemia and CD4 count recovery, perhaps reflecting ongoing viral replication in the CNS as a 'sanctuary site', or immunopathogenic mechanisms independent of viral replication. Some antiretroviral drugs (e.g. zidovudine, lamivudine, nevirapine) show better penetration in the CSF than others, but is not known if they are more effective at treating HIVE.

Hepatitis B and Hepatitis C Co-infection

In the last two decades co-infection with hepatitis C virus (HCV) has emerged as a leading cause of liver morbidity and a frequent cause of death in people with HIV. It is estimated that approximately 30% of HIV-infected individuals worldwide are also infected with HCV, and HCV should be regarded currently as one of the most important opportunistic infections in HIV-infected patients (Vallet-Pichard and Pol, 2006). HIV/HCV co-infected patients show more aggressive liver disease than people infected with HCV alone, with accelerated progression of fibrosis. Development of cirrhosis and hepatocellular carcinoma occur within an average of 7 and 18 years of HCV infection respectively, compared with 23 and 28 years respectively in patients with HCV alone. Furthermore, proportionately fewer co-infected patients achieve a sustained virological response with pegylated interferon α and ribavirin compared with those infected with HCV alone. Co-infected patients also have an increased risk of HAART-related hepatotoxicity, although HAART is beneficial in these patients because it slows the progression of liver fibrosis.

Around 10% of HIV-infected individuals have chronic hepatitis B virus (HBV) infection and co-infection promotes fast progression to cirrhosis and increases the risk of liver-related morbidity and mortality (Thio *et al.*, 2002). Several nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) have activity against both HIV and HBV, including lamivudine, emtricitabine (FTC), adefovir (lower doses required to treat HBV than HIV), tenofovir (TDF) and entecavir (Bottecchia *et al.*, 2007). The effectiveness of lamivudine in the treatment of chronic hepatitis B is well documented, but the benefit is limited by the emergence of drug resistance, leading to increases in serum HBV DNA load and liver enzymes, and a risk of fulminant liver failure. HBV resistance mutations can be recognized in 94% of viraemic patients who have received

lamivudine for over four years. Currently, the combination of TDF with FTC (or lamivudine) is recommended for treating HBV in HIV co-infected patients, and this should be given in the context of a triple drug regimen against HIV. Options for treating HBV in patients who do not require HIV treatment due to high CD4 counts are limited. They may include pegylated interferon α , adefovir (at low dose, but poor efficacy as monotherapy) and/or telbivudine. Earlier initiation of HAART should be considered.

Malignancies

Historically, three types of malignancies have been regarded as AIDS-defining cancers: Kaposi's sarcoma, non-Hodgkin's lymphoma (NHL), and invasive cervical cancer. However, non-AIDS-defining cancers represent an increasing proportion of the malignancies observed in HIV-infected people. Compared with the general population, HIV-infected people have an increased risk of anal and other HPV-related genital cancers, lung cancer, liver cancer, cancers of the head and neck, and Hodgkin's lymphoma (HL), and show poor overall survival (Boshoff and Weiss, 2002; Grulich *et al.*, 2007; Long *et al.*, 2008). In addition, cancers of oesophagus, stomach, kidney, and brain, melanoma and non-melanoma skin cancers, myeloma, leukaemia, and possibly testicular seminoma have been observed at rates greater than expected in the general population. In contrast, rates of prostate, breast, ovarian and colorectal cancer appear to be comparable to those in the general population. Many of the cancers that occur at increased rates in HIV infection are those with a known or suspected infectious cause, including EBV, HBV, HCV, human herpes virus 8 (HHV-8) and HPV. The increased incidence of specific non-AIDS-defining cancers in HIV-infected populations has also been attributed to high rates of smoking and alcohol use. The incidence of KS, HL, NHL, liver cancer and anal cancer is also greater in HIV-infected people than in immunocompromised transplant recipients (Grulich *et al.*, 2007).

Kaposi's Sarcoma

Together with PCP, KS was one of the sentinel diseases that in 1981 alerted epidemiologists and physicians to the incipient AIDS epidemic. The incidence of KS in HIV-infected people started to decrease before 1996 and declined sharply after the introduction of HAART. However KS remains common in HIV-infected people. The incidence is related to human HHV-8 prevalence in a population and historically KS was seen more frequently in homosexual males than injecting drug users or haemophiliacs. Histopathologically KS is a multicentric angioproliferative disorder characterized by spindle cell proliferation,

neo-angiogenesis, inflammation and oedema, with the proposed involvement of a multipotential mesenchymal cell expressing markers of lymphatic endothelium (Dupin *et al.*, 1999). The pathogenesis is complex. It involves interaction between HHV-8 and HIV, leading to increased cell proliferation and survival, dysregulated angiogenesis, evasion of immunity and malignant progression. Infection with HHV-8 precedes the development of KS and is found in every case of the disease (Greene *et al.*, 2007; Hansen, Boshoff and Lagos, 2007). The genome of HHV-8 contains a number of potential oncogenes and the virus seems able to transform human endothelial cells. In addition the HIV Tat protein may also contribute to the disease process. It has been proposed that HHV-8 DNA load in plasma is associated with disease progression, but the findings have not been consistent.

KS often runs an aggressive course in patients with AIDS, with cutaneous as well as visceral involvement. Typically single or multiple purple lesions appear on the skin; these may range from benign and indolent to aggressive and invasive forms. Lesions may occlude the lymphatics, producing lymphoedema. Gastrointestinal KS can produce dysphagia or gastrointestinal bleeding. Pulmonary KS causes space-occupying bronchial lesions, producing wheeze, cough, dyspnoea and life-threatening haemoptysis.

The prognosis of KS is dependent upon the disease stage, the severity of HIV-associated immunosuppression and other systemic illnesses (Boshoff and Weiss, 2002). Usually, immune reconstitution with HAART leads to resolution of KS, but chemotherapy may be necessary. Pegylated liposomal doxorubicin has been established as the treatment of choice for patients with AIDS-associated KS in western countries.

Lymphomas

The incidence of lymphoma in patients with HIV infection greatly exceeds that of the general population. Histologically three groups are recognized (Grogg *et al.*, 2007): (i) Hodgkin's and non-Hodgkin's lymphomas also occurring in immunocompetent hosts (e.g. Burkitt's and Burkitt-like lymphomas, diffuse large-cell lymphomas); (ii) lymphomas occurring more specifically in HIV-infected patients (e.g. primary effusion lymphoma (PEL)) and (iii) lymphomas and lymphoproliferative disorders also seen in patients with other forms of immunosuppression. Aggressive B-cell NHL that also occurs in immunocompetent patients accounts for the vast majority of cases, but the relative risk of NHL is increased 60- to 200-fold in HIV-infected patients when compared with the general population. The lymphomas are usually widespread at presentation and frequently involve extranodal sites, as in primary CNS lymphoma.

The pathogenesis is thought to be multifactorial, including chronic immune activation and dysfunction and the oncogenic roles of EBV and HHV-8. EBV is detected in approximately 50% of lymphomas arising in the setting of HIV, ranging from nearly 100% of primary CNS lymphomas and HL, to 60–80% of immunoblastic diffuse large B-cell lymphomas and PEL, and 30–50% of Burkitt's lymphomas. HHV-8 is also linked to PEL.

Changes in the relative frequency of specific lymphoma subtypes have been seen following the introduction of HAART. Burkitt's lymphoma and centroblastic diffuse large B-cell lymphomas continue to occur in patients with normal or slightly diminished CD4 counts; PEL and immunoblastic diffuse large B-cell lymphomas (including primary CNS lymphoma) are generally seen in people with marked immunodeficiency and have become less common in the HAART era. Primary CNS lymphoma occurs most frequently as multiple lesions in the cerebrum. A few studies have proposed that detection of EBV DNA by PCR in the CSF of HIV-infected patients with a CNS lesion infers a diagnosis of lymphoma. However, EBV detection in the CSF *per se* has a low positive predictive value for primary CNS lymphoma (Ivers *et al.*, 2004), making interpretation problematic in the absence of other diagnostic signs.

Ano-genital Squamous Carcinoma

Rapidly progressive, squamous intraepithelial carcinomas can develop in the cervical canals of women and anorectal junction of men infected with HIV. Each site has a squamous-columnar border and there is evidence of viral causation (Palefsky, 2007). These regions are commonly infected with HPV in these patient groups and, especially as immunosuppression increases, the HPV-encoded oncoproteins (E6 and E7) known to promote genetic instability in cells may lead to tumour formation. Studies confirm an increased risk particularly of *in situ* cervical cancer but also of invasive disease in HIV-infected women and the disease course can be aggressive (Boshoff and Weiss, 2002). The incidence of cervical cancer has not changed since 1996, and rigorous gynaecological screening among HIV-infected populations is paramount. The role of routine anal cytology in men has not been clearly established.

The Effects of Antiretroviral Therapy on Morbidity and Mortality

The introduction of HAART has changed the natural history of HIV infection, with a decline in overall mortality and morbidity, and a change in the pattern of HIV-related illnesses. The incidence and mortality of AIDS-defining infectious diseases such as PCP, MAI and CMV and

for the AIDS-defining cancers KS and NHL have decreased (Hooshyar *et al.*, 2007). At the same time, there is increased incidence and mortality for non-infectious diseases such as liver disease, hypertension and other cardiovascular disease, non-AIDS malignancies, pulmonary disease and alcohol abuse. Although the incidence of most AIDS events declines after initiation of HAART, the decline is more rapid for some conditions than others, and greatest for events with a viral aetiology (d'Arminio Monforte *et al.*, 2005).

There is evidence to indicate that a CD4 cell nadir <200 cells μl^{-1} prior to restoration with HAART is not predictive of increased risk of opportunistic infections, leading to safe discontinuation of both primary and secondary prophylaxis. At the same time, it has now become apparent that unique presentations of many HIV-related conditions can occur upon the introduction of antiretroviral therapy, especially in people with low CD4 counts. The immune reconstitution inflammatory syndrome (IRIS) is characterized by worsening clinical, laboratory or radiological findings after initiation of HAART, coinciding with viral load suppression and CD4 count increase, and reflecting restoration of immune responses. IRIS may manifest as the apparent worsening of a recognized illness, but may also unmask previously unrecognized disease. For instance, cystoid macula oedema and vitritis due to CMV may be observed. In addition to infectious diseases, IRIS can also occur with autoimmune or malignancy-related conditions such as KS. The prognosis is generally favourable (Lipman and Breen, 2006).

ANTIRETROVIRAL THERAPY—A HISTORICAL PERSPECTIVE

Antiretroviral therapy, where available, has transformed HIV-1 infection into a treatable chronic condition rather than a death sentence (Pomerantz and Horn, 2003). With hindsight, many now recognize the suboptimal policies made during the early period of antiretroviral therapy. Zidovudine (ZDV) was the first licensed drug against HIV-1 in the late 1980s following demonstration of clinical benefit in a placebo-controlled trial, and there was widespread demand for monotherapy at this time. Controversy was fuelled by results of the French—UK Concorde study, which showed little benefit of initiating zidovudine therapy early, compared to later in disease. In the early 1990s dual therapy with ZDV and didanosine (ddI) or zalcitabine (ddC) (or other nucleoside analogues) proved beneficial over single therapy, which provided the underpinning for later combination treatments using three or more drugs. Monitoring of therapy response was undertaken by CD4

cell count changes during this period, as well as the time to clinical endpoints, such as AIDS and death.

The mid 1990s marked a paradigm shift in HIV therapy, driven by two independent advances. First, assays for accurate and sensitive quantitation of plasma viraemia became commercialized and therefore widely available. Second, results of the first clinical studies of protease inhibitor (PIs) demonstrated the profound potency of this class of drugs when combined with two nucleoside analogues, defined by reductions in viral load. Since the application of plasma virus quantitation to natural history cohorts showed viral load to be predictive of disease progression (Mellors *et al.*, 1996), a leap of logic was taken to postulate that a therapy-induced fall in viral load would lead to improved prognosis, and this was demonstrated subsequently. Since viral replication (as measured by plasma viral load) became central to theories of pathogenesis, the pendulum swung back to early initiation of therapy. This approach was exemplified by the statement at the time ‘it’s the virus, stupid’, and various estimates were made of the duration of therapy required to eradicate the virus from infected individuals.

Unfortunately, this optimism was tempered by two practical manifestations of therapy—adherence problems and toxicity, as well as the recognition of long-lasting reservoirs of infection within the body. Long-term PI therapy generated severe lipid abnormalities leading to body shape changes and cardiac problems (although some of these are now also known to be associated with long-term nucleoside analogue treatment) (Carr, 2003). The large pill burden of early triple therapy regimens also caused difficulty in drug compliance, and rates of therapy failure were significant. By the late 1990s, non-nucleoside reverse transcriptase inhibitors (NNRTIs), such as nevirapine (NVP) and efavirenz (EFV), had started to replace PIs within first-line regimens following encouraging clinical trial data.

In the early 2000s, the emerging toxicities associated with PIs and, with hindsight, nucleoside analogues, led to a reassessment of the ‘start early’ principle, and risk—benefit arguments were used to suggest initiation of therapy at a CD4 cell count of 200–350 cells μl^{-1} . With improvements in drug formulations, and management of these toxicities, the timing of starting therapy is currently being readdressed.

MONITORING OF ANTIRETROVIRAL THERAPY AND RESISTANCE

CD4 Count

The CD4 count is the major clinical indicator of immunocompromise and guides the initiation of antiretroviral

therapy and the use of chemoprophylaxis for opportunistic infections. Guidelines generally recommend starting HAART at a CD4 count <350 and well above 200 cells μl^{-1} , a threshold associated with a significant risk of AIDS-defining events. Earlier initiation of therapy at CD4 counts >350 cells μl^{-1} is currently being evaluated with the aim of further reducing morbidity and mortality, improving tolerability, and reducing the risk of onward HIV transmission. The potential benefits of starting therapy at higher CD4 cells counts must be balanced against the long-term risk of drug toxicity and declining levels of compliance over time, leading to treatment failure and emergence of drug resistance. Most patients commencing HAART with CD4 counts <350 cells μl^{-1} experience good virological responses and significant immunologic recovery. The immunological success of therapy is defined as a CD4 count increase of 100–150 cells μl^{-1} per year during the first few years of therapy, with most patients showing a plateau after seven years.

Plasma Viral Load

Molecular techniques for quantifying the viral load have become a pivotal component of clinical management. In untreated people, the viral load is a strong predictor of CD4 count decline, rate of disease progression and risk of mortality (Mellors *et al.*, 1996). In the HAART era, a viral load $>100\,000$ copies ml^{-1} serves as an indicator that therapy should be considered at a CD4 count closer to 350 than 200 cells μl^{-1} . Viral load reduction with HAART translates into immunological and clinical benefit, establishing viral load as a key surrogate marker of therapeutic success. Treatment guidelines recommend that the main goal of antiretroviral therapy is to achieve and maintain an ‘undetectable’ viral load, initially <400 copies ml^{-1} and more recently <50 copies ml^{-1} . Although it seems intuitive that viral load reduction to below the lowest measurable threshold is preferable, the target level of suppression is mainly defined by the technical properties of the viral load assay. While evidence indicates that viral replication continues in people with undetectable viral load, achieving and maintaining a viral load <50 copies ml^{-1} is clearly associated with long-term virological suppression, lack of evidence of viral escape, and sustained immunological and clinical benefit.

Viral load assays have evolved over the years to improve the sensitivity and range of quantification, ensure optimal performance with prevalent HIV-1 group M subtypes, and increase automation. First-generation viral load assays were based either on amplification of the signal in the branched chain DNA assay (Bayer VERSANT HIV-1 RNA assay) or on amplification of the target, including reverse transcriptase PCR (Roche RT-PCR), ligase chain reaction (Abbott LCX

assay) and nucleic acid sequence-based amplification or NASBA (BioMérieux Nuclisens HIV-1 QT assay). Second-generation assays are based on real-time PCR methods (Roche COBAS® TaqMan® HIV-1 Test and Abbott RealTime HIV-1 assay) or combined NASBA and real-time molecular beacon detection (BioMérieux NucliSens EasyQ assay). Commercial assays show good overall correlation and are reported to reliably detect and quantify all major HIV-1 group M subtypes (Schutten *et al.*, 2007). It is nonetheless important to remain vigilant about performance. The Abbott assay also detects group O viruses. A range of in-house real-time PCR-based assays for HIV-2 have been published.

The expanded access to antiretroviral therapy in developing countries requires the availability of simple, accurate and inexpensive methodologies for viral load monitoring. Methods evaluated include the PerkinElmerUltra p24 antigen assay, the Cavid ExaVir Load RT enzyme activity test and home-brew real-time PCR techniques. In the Cavid assay, the RT enzyme is extracted from the virus particle, followed by RT-mediated synthesis of BrdU-DNA from a poly(A) template bound to a 96-well plate. Synthesized DNA is then quantified using anti-BrdU conjugated to alkaline phosphatase. The assay is easy to perform and requires simple and inexpensive equipment, although throughput is low.

Drug Resistance

A key moment in the HIV replication cycle is the production of double-stranded DNA from the viral RNA template by RT. The enzyme has low fidelity, with no proofreading activity and an estimated error rate of 10^{-4} nucleotides. Misincorporations become fixed in the newly produced genome, mostly as point mutations, although duplications and insertions also occur. The high rate of virus replication further contributes to generating a high degree of viral diversity, and all mutations, including those responsible for drug resistance, can occur daily in an infected patient. Some of the mutants will not be functional, whereas others will persist within the quasispecies and will be archived in proviral DNA. It has been estimated that the prevalence of single drug-resistant mutants is relatively high within the quasispecies, whereas double and especially triple mutants are considerably less frequent. Resistant mutants generally have a reduced fitness relative to drug-susceptible wild-type virus, which will therefore dominate in the absence of drug pressure. Once therapy is introduced, if viral replication continues, the pre-existing mutants acquire a selective advantage and outgrow the wild-type virus. With ongoing virus replication, single mutants evolve to acquire further mutations, some increasing the level of drug resistance and others compensating for reduced fitness. Recombination events involving different virus strains

Table 38.7 Main principles of antiretroviral drug resistance

Drug-resistant mutants:

- pre-exist the introduction of therapy and are selected rather than created by drug pressure under incomplete virological suppression
 - carry mutations within proteins that play an important role in virus replication and as a result are generally less fit than wild-type virus and in the absence of drug pressure exist as minority, low-frequency species
 - continue to evolve under drug pressure to increase the level of resistance and over time acquire compensatory changes that restore viral fitness
 - lose the replication advantage if drug pressure is discontinued, with outgrowth of the wild-type virus which becomes again dominant
 - persist as low-frequency species and archived resistance once therapy is discontinued, ready to re-emerge upon reintroduction of drug pressure
-

co-infecting the same cell are a further source of genetic evolution. Thus, ongoing replication leads towards the emergence of virus which is simultaneously highly resistant and fit to replicate and infect (Table 38.7).

Antiretroviral drug resistance testing provides a valuable guide to the management of HIV-infected patients. Sequencing the viral genomic region of interest—also known as genotyping—is typically performed by automated population sequencing, which produces a consensus sequence of the dominant plasma quasispecies, allowing the identification of mutations that are known to be associated with drug resistance. The results are described by the codon position preceded by the wild-type amino acid and followed by the mutated amino acid. For example, the mutation associated with lamivudine (3TC) resistance M184V involves the substitution of a methionine for valine at codon 184 in RT. The International AIDS Society-USA (IAS-USA) regularly updates a list of significant resistance-associated mutations (Johnson *et al.*, 2007). Established assays target RT and protease, and new assays are becoming available to sequence other genomic regions of interest, including gp41 (fusion inhibitors), gp120 (CCR5 inhibitors), gag (PIs) and integrase (integrase inhibitors).

Phenotypic assays use the viral genes of interest derived from plasma RNA and transfected into a laboratory vector to generate a recombinant virus that can be grown *in vitro* in the presence of escalating concentrations of individual antiretroviral agents. Replication is measured as the expression of a reporter gene. Results are reported as fold changes in the drug concentration required to inhibit virus growth by 50 or 90% relative to a control

wild-type virus (inhibitory concentration, IC_{50} and IC_{90}). The virtual phenotype is a genotype interpretation method that matches the patient's derived viral sequence to genotype—phenotype pairs within a large dataset to predict the phenotype. The relative advantages and disadvantages of these approaches are summarized in Table 38.8.

A meta-analysis (Torre and Tambini, 2002) concluded there was benefit for using genotyping but not phenotyping to support clinical care, and that expert opinion added significantly to the effect. Both resistance testing systems can provide useful information however (Table 38.9), and both require appropriate interpretation of results. The interpretation of genotypic resistance test result is done through software-based algorithms that assign scores to individual mutations or apply specific rules to certain mutation patterns. The effects of mutations are not simply

additive and analysis of all but the simplest mutation patterns must take into account reciprocal synergistic and antagonistic interactions. Furthermore, the phenotypic and clinical effects of rarer mutations are often unknown. Over 20 rules-based genotypic interpretation systems have been proposed and several noncommercial software programmes are publically available (e.g. ANRS, DMC, REGA and Stanford). All systems require updating as new drugs enter clinical use and evidence for both new and old drugs grows. Differences between interpretation systems exist and the levels of agreement are highest for common mutation patterns. There are ongoing efforts to refine the systems and improve discrimination and concordance. However, although each of the major interpretation systems may consider slightly different mutations to be relevant for each antiretroviral drug, they can predict virological response to an overall similar extent (Fox *et al.*, 2007).

Table 38.8 Genotypic and phenotypic antiretroviral drug resistance assays

	Genotypic	Phenotypic
Availability	Wide	Limited
Turn-around time	1–2 wk	3–4 wk
Cost	++	++++
Commercial assays	Yes	Yes
Quality assurance	Available through national and local schemes	Not available
Sensitivity for low-frequency species	~20%	~20%
Output	Provides a consensus sequence of the viral population in the individual patient	Provides an average of susceptibility of the viral population in the individual patient
Recommended viral load (copies ml^{-1})	> 1000	> 1000
Interpretation	Specialist advice recommended	Specialist advice recommended

Table 38.9 Use of resistance testing in clinical practice

Clinical scenario	Resistance test	Comment
Primary infection	Recommended	Genotypic testing offers the highest sensitivity for the detection of transmitted resistance
New diagnosis of established infection	Recommended	Testing demonstrated to be cost-effective if prevalence of transmitted resistance is 4% or higher. Genotypic testing offers the highest sensitivity for the detection of transmitted resistance
Treatment failure	Recommended	Genotypic testing is generally cost-effective. Phenotypic testing should be considered in the presence of complex resistance patterns in multidrug experienced patients. Testing should be performed while on therapy as results are unreliable if therapy was discontinued more than 2–4 wk prior to testing
Pregnancy	Recommended	Recommended before starting therapy in drug-naive women Recommended in all women with a detectable viral load while on therapy

In phenotyping, cut-offs are employed to interpret the measured fold-changes. The cut-offs are either biologically defined as the spread of phenotypic susceptibilities measured in drug-naïve people, or clinically defined as the level of resistance that translates into reduced (lower cut-off) or abolished (upper cut-off) responses to treatment. Although a more intuitive indicator of drug resistance, clinical cut-offs represent an oversimplification. With most available antiretrovirals, increasing resistance and loss of activity should be seen as a continuum. Furthermore, clinical cut-offs are defined for individual drugs within a combination regimen, thus requiring complex statistical analyses to extrapolate the contribution of the drug of interest. Validation in treated populations other than those from which the cut-off was originally derived may not be readily available. The cut-offs must be regarded as drug-specific. For example, the 3TC resistance mutation M184V confers >100-fold phenotypic resistance to the drug and this is highly significant. In contrast, the TDF resistance mutation K65R confers only small shifts (less than twofold) in phenotypic susceptibility to the drug. Yet, TDF activity is virtually abolished in the presence of K65R. As with genotypic testing, information on biological and clinical cut-offs may not be available for newer drugs. With all systems, guidelines recommend that clinicians should consult a specialist to assist with the interpretation of results and selection of an optimized combination regimen.

One important limitation of both genotypic and phenotypic tests is their inability to detect resistance present at low frequency within the quasispecies (Flys *et al.*, 2005; Johnson *et al.*, 2005; Kassaye *et al.*, 2007; Palmer *et al.*, 2006). Emerging evidence indicates that low-frequency resistant mutants can have a negative impact on responses to antiretroviral therapy, at least in the context of regimens based on two NRTIs with NNRTIs. Methodologies have been developed to detect mutants with a frequency as low as 0.1%, including mutation-specific real-time PCR assays, single genome sequencing, parallel allele-specific sequencing (PASS), pyrosequencing and ultra-deep sequencing. The methodologies are currently either too laborious or too expensive for routine clinical practice.

Table 38.10 Methods for determining HIV tropism

Assay	Method
MT2	Culture of virus isolate on MT2 cells to assess ability to form syncytia, allowing detection of X4 virus
Culture on indicator cells line	Culture of virus isolate on cell lines engineered to express CD4 with CCR5 or CXCR4 (e.g. glioma human malignant glioma cell line U87)
Recombinant phenotypic assay	Recombinant virus containing the envelope gene sequence from the patient's plasma is used to infect engineered cell lines expressing CD4 with CCR5 or CXCR4
Genotypic	Prediction of tropism based on the sequence of the V3 loop and other parameters

Tropism

The introduction of small molecule (sm) CCR5 inhibitors in clinical practice requires the determination of the viral tropism prior to their use. In addition, assays may be needed in the near future for assessing patients who experience treatment failure on these new compounds (Table 38.10). Tropism assays commonly involve generation of recombinant viruses containing the *env* gene from plasma virus, and infectivity is tested within cells expressing relevant co-receptors (Coakley *et al.*, 2005). HIV tropism may also be predicted from the sequence of the V3 loop (Low *et al.*, 2007; Soulié *et al.*, 2008). Key genotypic determinants include V3 amino acids 11 and 25, but some of the models also use clinical determinants such as the CD4 count to improve prediction. Currently, the correlation of genotypic results with the virus phenotype remains imperfect, but several interpretation algorithms are undergoing optimization.

Fitness

Viral fitness can be described as the capacity of a virus to infect, replicate and produce mature infectious progeny in a defined host environment (Geretti, 2005; Nijhuis *et al.*, 2001). To escape from drug pressure, resistant mutants require changes in viral proteins that play a key role in virus replication and infectivity. Drug resistance carries therefore a fitness cost to the virus and the virus replication capacity is inversely correlated to the number and type of resistance mutations. It should be noted, however, that both drug-resistant and drug-susceptible viruses exhibit a wide range of replication capacities, reflecting variations in the many determinants of viral fitness.

Growth competition experiments assess viral fitness *in vitro* by mixing different strains in cell culture and determining the 'prevailing' virus. For instance, virus variants containing the protease mutations D30N or L90M are consistently out-competed by wild-type virus *in vitro*, while the D30N mutant is overtaken by the L90M mutant. Thus, both D30N and L90M have reduced fitness relative to wild-type virus, but the fitness cost is higher for the D30N mutant.

The fitness cost associated with a resistance mutation can to some extent be extrapolated from the kinetics of its disappearance from the dominant quasispecies once drug pressure is removed. The 3TC mutation M184V, for instance, disappears as early as two weeks after discontinuation of therapy, suggesting a significant impact on viral fitness. Conversely, when patients with drug resistance discontinue antiretroviral therapy, outgrowth of wild-type dominant quasispecies can be accompanied by an increase in plasma viral load and a drop in CD4 counts. The magnitude of the effect provides an indirect estimate of the fitness cost of the mutations, but can also reflect residual antiviral activity despite detectable resistance. The effect is not consistently seen. It is most often demonstrated with the NRTIs and variably with the PIs, but generally not with the NNRTIs (Deeks *et al.*, 2005).

Although the fitness cost of antiretroviral resistance can translate into a virological and immunological benefit, the optimal strategies for exploiting the effect remain to be determined. Evidence to date suggests that there is little rationale for continuing failing NNRTI therapy, whereas there is evidence for a beneficial effect associated with continuing NRTI or PI-based therapy. However, whether it is preferable to continue the NRTIs, the PIs or both remains controversial.

ANTIRETROVIRAL DRUG CLASSES

Five classes of antiretrovirals are currently available in clinical practice (Table 38.11), targeting virus entry, reverse transcription, integration and protein cleavage during maturation (Figure 38.7). Since the introduction of

HAART in the mid 1990s there has been a remarkable evolution towards effective, simple and convenient regimens. In the early days of triple therapy a patient on stavudine (d4T), 3TC and indinavir (IDV) received 10 pills and the dosing schedule was three times daily. Just over 10 years later, the first triple co-formulation has become available, containing TDF, FTC and EFV in one pill to be taken once daily. Despite increased convenience of dosing and improved efficacy and tolerability, successful antiretroviral therapy continues to demand high levels (>95%) of adherence to maintain virological suppression. The most common drug resistance detected in treated patients worldwide is directed against NRTIs and NNRTIs. This reflects the extensive use of these drugs in current therapy, but also the use of mono and dual NRTI therapy in the pre-HAART era and of suboptimal triple therapy regimens in early HAART era. In addition, first-generation NNRTIs such as NVP and EFV offer a low barrier against the emergence of resistance, due to the fact that a single mutation is sufficient to confer high-level resistance to the drugs.

Cross-resistance between drugs of the same class is extensive to complete for the NRTIs, complete for first-generation NNRTIs, and generally partial for the PIs, although accumulation of multiple protease mutations can lead to substantial to complete cross-resistance. New drugs within existing drug classes have been designed to be effective against drug-resistant strains. At the same time new drug classes offer additional treatment options for patients with drug resistance. Nonetheless, new drugs and drug classes remain susceptible to loss of activity. There is no cross-resistance between the fusion inhibitor ENF and smCCR5 inhibitors, but

Table 38.11 Current classes of antiretrovirals

Class	Examples
Nucleoside/nucleotide RT inhibitors (NRTIs)	Zidovudine, didanosine, stavudine, lamivudine, abacavir, tenofovir, emtricitabine Co-formulations: zidovudine/lamivudine, zidovudine/lamivudine/abacavir, abacavir/lamivudine, tenofovir/emtricitabine, tenofovir/emtricitabine/efavirenz
Non-nucleoside RT inhibitors (NNRTIs)	Nevirapine, efavirenz Etravirine, rilpivirine
Protease inhibitors (PIs) ^a	Saquinavir, indinavir, nelfinavir, fosamprenavir, atazanavir, tipranavir, darunavir Co-formulations: lopinavir/ritonavir
Entry inhibitors	Fusion inhibitors: enfuvirtide Small-molecule CCR5 inhibitors: maraviroc, <u>vicriviroc</u>
Integrase inhibitors	Raltegravir, <u>elvitegravir</u>

Underlining indicates unlicensed drugs in advanced development.

^aRitonavir is only used at low doses for boosting of other PIs.

cross-resistance can occur between maraviroc (MCV) and candidate smCCR5 inhibitors, and there seems to be complete cross-resistance between the integrase inhibitors raltegravir (RAL) and elvitegravir (ELV). Furthermore, clinical trials in treatment-experienced patients have clearly demonstrated that the use of any new drug requires support from other active drugs in the combination regimen, to prevent functional monotherapy and loss of activity. Thus, preventing resistance and cross-resistance remains an important goal of antiretroviral therapy.

Nucleoside/Nucleotide RT Inhibitors

Nucleoside and nucleotide analogues act to inhibit the viral RT. They are analogues of one of the four natural nucleosides (thymidine, cytidine, adenosine and guanosine) and, following triphosphorylation within the cell by

host cell enzymes, they compete with natural nucleotides as substrates for the viral RT. The nucleotide analogue TDF is a phosphonate, structurally similar to a nucleoside monophosphate, and requires two phosphorylations for activation. Incorporation of the NRTI triphosphate prevents the addition of further nucleotides to the DNA chain and terminates viral replication.

The NRTIs share the ability to inhibit the cellular DNA polymerase γ responsible for synthesis of mitochondrial DNA. The inhibition, alongside other proposed mechanisms, leads to a risk of mitochondrial toxicity. A wide range of adverse events have been attributed to mitochondrial toxicity, including lactic acidosis, hepatic steatosis, neuropathy, myopathy, pancreatitis, probably lipodystrophy and possibly polyneuropathy, pancytopenia, proximal

tubular dysfunction and osteopaenia. As a result of unfavourable toxicity profiles, d4T and the combination of d4T and ddI are no longer recommended for initial therapy, and TDF or abacavir (ABC) are preferred to ZDV for first-line therapy to reduce the risk of bone marrow suppression and lipoatrophy over prolonged ZDV use. Many studies implicate d4T and ZDV in the development of lipoatrophy, and switch studies with both ABC and TDF demonstrated a significant improvement in loss of fat. Zalcitabine (ddC) has modest potency and causes peripheral neuropathy and is now rarely used in clinical practice.

ZDV was the first licensed drug against HIV-1 (Pomerantz and Horn, 2003). Together with d4T, it is a thymidine analogue, and the two drugs are antagonistic, presumably due to competition for the same intracellular phosphorylation pathways. The acquisition of high-level ZDV resistance requires the sequential accumulation of several changes in the RT, involving amino acid positions 41, 67, 70, 215 and 219. Accumulation of three or more mutations confers significant resistance to ZDV and cross-resistance to d4T, ABC, ddI and TDF (Geretti, 2006). The mutations, known as thymidine analogue mutations (TAMs), tend to cluster according to two groups, namely that including M41L, L210W and T215Y (TAM I) and that including D67N, K70R, T215F and L219Q/E (TAM II). The determinants of one or other route remain unclear, but the first pathway is associated with greater levels of ZDV resistance and NRTI cross-resistance than the second pathway. For many years, d4T resistance was thought to be associated only with changes at RT position 75, which are rarely observed *in vivo*. Subsequently, it became evident that d4T can select TAMs and shares a significant degree of cross-resistance with ZDV. There is also evidence that the RT mutation K65R confers a degree of resistance to d4T and emergence of K65R has been observed in a small proportion of patients receiving first-line therapy with d4T/3TC/EFV.

Didanosine is an adenosine analogue which requires deamination prior to phosphorylation. Resistance is associated with mutations at codons 65, 69 and 74 in RT. In addition, the presence of multiple TAMs reduces ddI activity. ABC is a guanosine analogue, which is converted to carbovir triphosphate as the active component. A severe hypersensitivity reaction (HSR) occurs in approximately 5% of patients as a result of an immune-mediated reaction typically seen within the first six weeks of therapy. Rechallenge with ABC is contraindicated due to the risk of precipitating a life-threatening reaction. Identification of patients at risk of developing HSR can be achieved through genetic screening for the human leukocyte antigen HLA-B*5701. A large cohort study has demonstrated that ddI and ABC use is associated with a higher risk of

cardiovascular events, although this observation requires confirmation (D:A:D Study Group, 2008).

Resistance to ABC is mediated by the emergence of mutations at RT codons 65, 74, 115 and 184. In addition, the presence of multiple TAMs reduces susceptibility to the drug, and the effect is augmented by the presence of M184V. Clinical data, however, indicate that M184V in isolation does not significantly compromise responses to ABC.

TDF is a nucleotide analogue structurally related to adefovir. The drug undergoes renal excretion by glomerular filtration and active tubular secretion. Renal toxicity halted the development of adefovir for the treatment of HIV infection. With TDF, clinical cohorts have detected a low risk of generally mild renal functional abnormalities, although cases of acute proximal toxicity have been reported. The RT mutations selected by TDF are K65R and less commonly K70E/G. The presence of multiple TAMs is also associated with reduced drug activity. TDF is also a potent HBV inhibitor.

3TC and FTC are both cytidine analogues and structurally similar. Both also have activity against HBV. High-level resistance is generated by the M184V mutation in RT. The mutation emerges within weeks of 3TC monotherapy and is also the first mutation to emerge with triple therapy regimens containing 3TC or FTC. One interesting observation from the NUCA 3001 study was that people receiving monotherapy with 3TC experienced an initial suppression of viral load followed by rebound after two weeks, presumably coinciding with the emergence of M184V. However, the viral load remained suppressed by approximately 0.5 log₁₀ copies ml⁻¹ relative to the level measured pre-therapy (Eron *et al.*, 1995). More recently, a randomized clinical trial demonstrated that patients with M184V continuing 3TC monotherapy maintained a lower viral load (by 0.5 log₁₀ copies ml⁻¹) and showed a slower decline in CD4 counts over 48 weeks than did patients who discontinued all therapy, thus confirming the earlier observations (Castagna *et al.*, 2006). A number of explanations for these findings have been put forward. First, the fitness of the M184V mutant may be reduced. Second, residual antiviral activity may occur despite high-level resistance.

The main resistance mutations that confer resistance to the NRTIs are summarized in Figure 38.8. TAMs and T69 insertions (which usually occur with TAMs) reduce susceptibility by promoting excision of the incorporated NRTI, using pyrophosphate or ATP as acceptor and allowing the elongation of the DNA chain to resume. The mechanism is known as primer unblocking or pyrophosphorolysis. Other mutations such as M184V, K65R and L74V are discriminatory, as they prevent NRTI triphosphate incorporation. The M184V mutation shows several

interesting effects in *in vitro* systems, including enhanced RT fidelity, which in turn would reduce the rate at which new mutants (including drug-resistant mutants) are generated. In addition, the presence of M184V antagonizes pyrophosphorolysis, thus enhancing the chain termination effect of the nucleoside analogues. In clinical practice, the combination of ZDV with 3TC has been shown to delay the emergence of ZDV resistance whereas emergence of TAMs occurs more rapidly with combinations such as ZDV and ddI. In addition, M184V partially restores susceptibility to ZDV, d4T and TDF in the presence of TAMs and clinical evidence is available of improved virological responses to TDF in the presence of the mutation. Other mutations associated with hypersusceptibility effects include K65R, which increases susceptibility to ZDV, and L74V/I and the NNRTI mutations L100I and Y181C which increase susceptibility to ZDV and TDF.

The classic multi-nucleoside resistance pathways include a diverse cluster of amino acid insertions and deletions between positions 67 and 70, commonly 69S-(S-S) or 69S-(S-G), which usually occur with TAMs, and the Q151M complex. The first pattern confers resistance to all available NRTI. The Q151M mutation confers low-level resistance to TDF, 3TC, and FTC, and high-level resistance the other NRTIs. In combination with mutations at positions 75, 77, and 116, Q151M confers intermediate resistance to 3TC, FTC and TDF and high-level resistance to other NRTIs. Both patterns have become rather uncommon in treated patients. More commonly, multi-nucleoside resistance is associated with the presence of multiple TAMs or K65R with M184V, the latter

seen in patients failing therapy with TDF plus 3TC or FTC.

Non-nucleoside RT Inhibitors

The NNRTIs are a structurally diverse group of compounds, of which NVP and EFV are approved for use; etravirine (ETV) is a second-generation NNRTI. Delavirdine is licensed in the United States but rarely used. The drugs bind within a hydrophobic pocket near the active site of RT causing its allosteric inhibition. The pocket has a different structure in HIV-2 and group O HIV-1, so the NNRTIs are ineffective against these viruses.

NVP and EFV have proven efficacy in first-line therapy in combination with two NRTIs. With EFV, the major side effects are insomnia and vivid dreams, especially in the first weeks after starting treatment. With NVP, up to 13% of patients develop a mild to moderate rash, usually within the first six weeks of therapy. However, there is a risk of life-threatening reactions, including severe hypersensitivity, Stevens—Johnson syndrome, toxic epidermal necrolysis, and fulminant hepatitis. The risk appears to be gender- and CD4 count-dependent at least in some populations. As a result, NVP is currently contraindicated in women with CD4 counts >250 cells μl^{-1} and in men with CD4 counts >400 cells μl^{-1} . Whereas use of the drug has declined in recent years in western countries, NVP remains an important component of triple therapy in developing countries. Both drugs are metabolized primarily by cytochrome P450 (CYP) 2B6, leading to a potential for significant drug—drug interactions. There is also considerable inter-individual variability in the metabolism of

NVP and EFV, and this is at least in part related to host genetics. For example, a CYP2B6 G to T polymorphism at position 516 is associated with reduced clearance and higher drug levels, with implications for drug toxicity and prolonged drug persistence after discontinuation of therapy (Rotger *et al.*, 2007).

Failure of EFV- or NVP-containing regimens is usually accompanied by the presence of detectable mutations that cause high-level resistance to the drugs. Figure 38.9 summarizes the main RT mutations involved in resistance to the NNRTIs. NVP may select K103N or Y181C in RT. The genetic pathway to resistance is dependent on co-therapies. Thus, resistance to NVP monotherapy is usually caused by the Y181C mutation. By contrast, in the presence of ZDV, other mutations, such as the K103N are the preferred route, possibly because Y181C suppresses the emergence of ZDV resistance. The K103N mutation confers high-level phenotypic cross-resistance to EFV. Although the Y181C mutation confers only modest phenotypic resistance to EFV, complete cross-resistance is observed *in vivo*. This is attributed to the concomitant selection of low-frequency K103N in people with dominant Y181C. Failure of EFV-containing regimens is associated with the K103N mutation in up to 90% of cases, producing phenotypic cross-resistance to NVP.

Structural studies have contributed to the design of second-generation NNRTIs. Two new compounds, ETV (or TMC125) and TMC278 have improved activity against resistant viruses, both *in vitro* and *in vivo*. The introduction of ETV in routine clinical care demands a shift in our current understanding of antiretroviral treatment strategies. The raised genetic barrier relative to first-generation compounds indicates that it is now possible to sequence drugs within the NNRTI class, with an approach similar to that used for the NRTIs and PIs. Although cross-resistance does occur, multiple mutations are required to confer resistance to the drug, probably reflecting a high degree of molecular flexibility (Vingerhoets *et al.*, 2005). However, progressive loss of

susceptibility is seen as resistance mutations accumulate and activity is rapidly lost in patients with one or more NNRTI resistance mutations in the absence of other fully active drugs in the regimen. Within better structured regimens, a gradual loss of response to ETV occurs with increasing numbers of NNRTI resistance mutations (Lazzarin *et al.*, 2007; Madruga *et al.*, 2007; Nadler *et al.*, 2007). More precise predictors of ETV response will emerge through ongoing analyses.

Protease Inhibitors

In the mid 1990s, the combination of the first PIs with two NRTIs established the efficacy of triple therapy and marked a major step forward in HIV management. Over time, new drugs and drug formulations have become available that improve efficacy and dosing schedule and PIs are currently a key component of the treatment of drug-experienced patients. In addition, clinical trials have clearly established long-term efficacy in first-line therapy. During HIV replication, *gag* and *gag-pol* gene products are produced as precursor polyproteins which are subsequently cleaved by the protease enzyme at nine distinct sites to yield the structural proteins p17, p24 p9 and p7 and the viral enzymes protease, RT and integrase. PIs are competitive inhibitors of the protease enzyme thereby preventing maturation into a fully functional and infectious viral particle. All PIs are metabolized, at least partially, through the CYP3A4 iso-enzyme of the CYP system. This leads to significant interactions with other drugs, and also inter-individual differences in plasma drug levels. CYP3A4 is found primarily in the intestine and liver and is important in first-pass drug metabolism. A further major step forward in HIV treatment was the recognition that inhibition of CYP3A4 with a low dose of ritonavir (100–200mg) reduces hepatic and intestinal metabolism of concurrently administered PIs, thereby boosting drug levels, improving pharmacokinetic profiles, and improving treatment responses in both

treatment-naïve and treatment-experienced patients. The boosting effect of ritonavir may be mediated by additional mechanisms, including interference with efflux channels that actively transport PIs out of cells, and reducing protein binding of the PI.

Ritonavir boosting is required for PIs such as saquinavir (SQV), lopinavir (LPV), tipranavir (TPV) and darunavir (DRV) to achieve adequate plasma concentrations. Although optional for fosamprenavir (FPV) and atazanavir (ATV), co-administration of ritonavir improves the efficacy of these PIs relative to their unboosted counterparts. Increased drug levels also improve the barrier to the emergence of drug resistance in treatment-naïve patients and can overcome low to intermediate levels of PI resistance in treatment-experienced patients. The downside is that ritonavir boosting may lead to an increased frequency of side effects such as diarrhoea and raised blood lipids, and promote other metabolic abnormalities such as reduce glucose tolerance and abnormal fat distribution. The enhanced efficacy of ritonavir-boosted PIs (PI/r) has led to recent clinical trials of monotherapy with LPV/r, ATV/r and DRV/r and initial data indicate that a substantial number of patients may be able to maintain virological suppression. The strategy is subject to ongoing clinical trials.

The protease enzyme is a homodimer, each monomer comprising 99 amino acids. Three main domains are recognized: the active site, the dimerization domain and the flaps. The protease is highly polymorphic in PI-naïve patients. Although it has been proposed that certain polymorphisms may facilitate the emergence of resistance,

there is no evidence for a significant effect on drug susceptibility. The main PI resistance mutations are shown in Figure 38.10. Major mutations are generally selected first and have clear effects on drug susceptibility (e.g. D30N, G48V, V82A/F/T, I84V and L90M). Minor mutations accumulate in viral genomes already containing one or more primary mutations, have a less discernible effect on resistance, but may be selected because they improve viral fitness. In general terms, the total number of major PI mutations predicts response to the PIs. Mutations at codons 82, 84 and 90 in particular have wide resistance effects. First-generation PIs such as SQV, IDV and nelfinavir (NFV) are structurally poorly adaptable to mutations in the protease enzyme and the presence of only a few resistance mutations can cause significant loss of affinity and activity (Martinez-Cajas and Wainberg, 2007). Newer PIs including FPV, ATV, LPV, TPV and DRV have high to very high binding affinities and can tolerate higher numbers of mutations than can older PIs. Protease mutations however have a different impact on individual PIs and resistance testing should guide the selection of the most appropriate PI in patients with resistance (Figure 38.10).

Clinical trials in drug-naïve patients have repeatedly shown that the combination of a PI/r with two NRTIs as first-line therapy rarely results in the emergence of protease resistance at the time of virological failure. The determinants of viral load rebound in the absence of detectable resistance remain unclear. Overall high drug levels and rapid pharmacokinetics suggest that there may be limited opportunity for the optimal selection of resistance

in patients with incomplete adherence. The proposed hypothesis is that drug levels are either too high to allow significant viral replication to occur or, in the case of missed doses, become rapidly too low to exert significant selective pressure. Other important determinants of the high barrier to resistance are related to the structural interactions of the PI with the protease and the number of mutations required to confer significant phenotypic resistance. Protease resistance mutations can be associated with a significant fitness cost for the virus. However, compensatory mutations can emerge rapidly that restore virus fitness. In addition, changes may occur in the gag cleavage sites that serve as the natural substrate for the enzyme, which improve processing and increase resistance and fitness (Nijhuis *et al.*, 2007).

Indinavir (IDV)

The use of IDV/r in clinical practice has declined in recent years as a result of the significant risk of nephrolithiasis. Mutations selected by IDV occur at codons 46, 47 (V), 48, 54, 76, 82, 84, 88 and 90.

Saquinavir

The first PI to be developed and approved, SQV has undergone several re-formulations to improve bioavailability and tolerability. The hard gel capsule dosed with ritonavir remains an important option for PI-naïve patients. SQV/r may also retain activity against certain viruses with limited PI resistance. Key resistance mutations include G48V and L90M; the latter may be accompanied by mutations at codon 84.

Nelfinavir

NFV levels are relatively unaffected by co-administration of ritonavir, although improved drug exposure is achieved by administration with high fat meals. The drug is rarely used currently due to the frequent occurrence of diarrhoea and the availability of more potent PIs. Predominant use has been in PEP and pregnancy. Possible contamination of NFV stock with ethyl methanesulfonate has recently led to the withdrawal of NFV pending further toxicology studies. NFV resistance develops along one of three pathways, involving the mutations D30N (with or without N88D), L90M, or N88S, all with or without M46I/L.

Fosamprenavir

FPV is the pro-drug of amprenavir. It can be used unboosted in drug-naïve patients, but it is usually used in combination with ritonavir. FPV/r can be used once daily in treatment-naïve patients, but twice daily administration

is recommended in treatment-experienced patients. Mutations selected by FPV involve codons 32, 46, 47 (V), 50 (V), 54, 76 and 84. Due to structural similarities with DRV, there is a degree of cross-resistance between the two drugs.

Lopinavir

LPV is the only available PI co-formulated with ritonavir, initially in a capsule formulation and more recently as a tablet. Mutations selected by LPV follow one of two pathways: an IDV-like pathway associated with mutations at positions 46, 54 and 82, and a FPV-like pathway associated with mutations at positions 32, 47, 50 (V) and 76. In treatment-naïve patients the combination of LPV/r with two NRTIs has only rarely resulted in the emergence of PI resistance at the time of virological failure. Pre-existing protease resistance mutations reduce the genetic barrier and accelerate the selection of further resistance, although LPV/r generally retains good activity in PI-experienced patients with low to intermediate levels of PI resistance. The major toxicities of LPV/r are diarrhoea and raised lipids, especially triglycerides. LPV/r can be used once daily in treatment-naïve patients, but twice daily administration is generally preferred in patients with resistance.

Atazanavir

ATV is approved for use once daily either with or without ritonavir, although current guidelines recommend ritonavir boosting due to improved virological efficacy. Mutations selected by ATV include I50L and N88S. The signature mutation I50L does not confer cross-resistance to other PIs. Rather, I50L has been linked to hypersusceptibility effects for several PIs, although the clinical significance of the finding is currently unclear. A key benefit of ATV is the limited effect on lipid levels. ATV/r maintains activity in PI-experienced patients with a limited number of PI mutations, but is generally less effective than LPV/r in this setting.

Tipranavir

TPV is a nonpeptidic PI used with 200 mg of ritonavir twice daily, a higher dose of ritonavir than used to boost other PIs. TPV/r is effective in patients with extensive PI resistance, but its use is limited by problematic drug—drug interactions, poor gastrointestinal tolerability and concerns over hepatic and lipid-related adverse events and a possible risk of intracranial haemorrhage. Nonetheless, given the limited cross-resistance with DRV/r, TPV/r provides a valuable treatment option for patients with certain protease resistance patterns. Key mutations selected by TPV include V32I, I47V, I54V/A/M, V82L/T

and I84V. Resistance mutations predictive of virological responses in highly treatment-experienced patients have been identified and assigned a 'weight'. These include T74P and I47V (each +6), Q58E and V82L/T (+5), N83D (+4), I54A/M/V (+3), M36I, K43T and I84V (+2), and L10V and M46L (+1). Some mutations have hypersusceptibility effects and have been assigned a negative score: L24I and L76V (-2), I50L/V (-4) and I54L (-7). Responses decline with a score between 3 and 10 and are essentially lost with a score >10.

Darunavir

DRV is a nonpeptidic analogue of amprenavir with enhanced activity against resistant virus (McCoy, 2007). It is dosed twice daily with 100 mg of ritonavir in treatment-experienced patients and has shown excellent activity in the presence of extensive drug resistance. A once daily dose is currently under evaluation for PI-naïve people. Gastrointestinal symptoms and headache are the most commonly reported events. A genotypic score has been derived from studies in highly treatment-experienced patients, including the mutations V11I, V32I, L33F, I47V, I50V, I54L/M, G73S, L76V, I84V and L89V. Responses have been shown to decline in these highly experienced populations in the presence of three or more mutations. In phenotypic studies, I50V, I54M, L76V and I84V reduce susceptibility to the greatest extent. V32I, L33F, I47V, I54ML, G73CS and I89V have been the most common mutations to emerge with DRV/r treatment failure.

Entry Inhibitors

Current entry inhibitors target either gp41-mediated fusion of the viral envelope with the cell membrane (ENF, T20 or ENF) or the interaction between the viral gp120 and the CCR5 co-receptor (Esté, 2007). MCV is the first smCCR5 inhibitor to enter clinical practice and vicriviroc is in advanced development. In addition, the monoclonal antibody PRO140 is a new CCR5 inhibitor undergoing fast track development.

Enfuvirtide

ENF, the first fusion inhibitor to enter clinic practice (Lalezari *et al.*, 2003), is a synthetic peptide that mimics amino acids 127–162 of HIV-1 gp41. By binding the first HR1 region of gp41, ENF prevents the hairpin formation necessary for fusion. ENF must be administered twice daily by subcutaneous injection, and injection site reactions are frequent. Due to the complexity of the molecule, production costs are high. Use in clinical practice is limited to patients with extensive drug resistance, although the best activity of ENF is seen in the presence of other active drugs in the combination regimen.

Unless well supported, ENF is vulnerable to loss of activity through the rapid emergence of resistance. The best characterized resistance mutations occur in the highly conserved region of HR1 spanning amino acids 36–45 (e.g. G36D/E, V38A/E, Q40H, and N43D), and to a lesser extent, in other *env* regions. Continued therapy in the presence of resistance provides little or no virological benefit and is not generally recommended. Some interesting data however suggest that patients with resistance mutations at codon 38 may experience improvements in CD4 counts despite ongoing viraemia, possibly reflecting fitness or immunological effects of the mutant.

Maraviroc

MCV is a functional antagonist of the CCR5 receptor, which inhibits CCR5-mediated signalling without triggering internalization of the co-receptor. After binding, MCV shows prolonged co-receptor occupancy which is thought to explain the delayed viral load rebound observed after treatment discontinuation. Approximately 20% of drug-naïve and 60% of drug-experienced people harbour X4 or dual tropic strains as dominant quasiespecies and MCV has no significant antiviral activity in these patients. In addition, HIV-infected people may carry low frequencies of X4 and dual tropic viruses and these may be selected by MCV if virological suppression is incomplete. Two main mechanisms of HIV resistance to smCCR5 inhibitors have been described. A first mechanism is characterized by a switch in viral tropism from R5 to X4 or dual use. In most cases the switch is thought to occur within the viral population when selective suppression of R5 virus allows outgrowth of the pre-existing X4 and dual tropic strains. In the second mechanism, changes in the envelope allow the virus to bind to the co-receptor despite the alteration in shape caused by the presence of the inhibitor (Kuhmann *et al.*, 2004). The effect is mediated by mutations in the stems of the V3 loop and allows resistant virus to bind with higher affinity to the drug-bound co-receptor than wild-type virus. To date the mutation pattern remains to be clearly defined, making the genotypic identification of resistance problematic. The phenotypic effect is shown by a plateau in the maximal percentage inhibition (MPI) observed with increasing drug concentrations.

MCV has shown excellent tolerability in short-term clinical trials. There remain concerns about the long-term safety of CCR5 inhibition and on the possible pathogenic effects of causing an expansion of X4 viruses as a result of CCR5 inhibition. The chemokines that bind to CCR5 orchestrate leukocyte trafficking in tissues and play an important role in regulation of immunological processes. Although individuals homozygous for the CCR5 Δ 32 have normal life expectancy, it is not known whether they carry additional genetic changes that compensate for the

lack of CCR5 function. Furthermore, there is evidence that CCR5 Δ 32 is associated with an increased risk of symptomatic West Nile virus infection, and with improved recovery from HBV infection, suggesting significant immunological effects. Limited data indicate that after MCV discontinuation resistant virus reverts to minority species and in cases of tropism switch, R5 virus again becomes the dominant quasispecies. These observations suggest that the viral population selected during MCV therapy has no inherent advantage over the pre-treatment population in the absence of drug pressure. The long-term impact of the possible enrichment of resistant variants or X4 and dual tropic virus remains unknown at present.

Integrase Inhibitors

Several candidate integrase inhibitors have been developed. Current integrase inhibitors inhibit strand transfer (Nair and Chi, 2007). RAL is a pyrimidinone carboxamide and the first integrase inhibitor to enter clinical practice. In clinical trials, RAL showed high potency, good tolerability and no significant drug—drug interactions. A randomized clinical trial in treatment-naïve people compared the activity of RAL to that of EFV in combination with two NRTIs. Although the percentage of patients who achieved virological suppression was similar overall in the two treatment arms, patients receiving RAL showed a more rapid viral load response. The significance of this finding is currently under investigation (Murray *et al.*, 2007). RAL however has a low barrier to the emergence of resistance and patients with virological failure show mutations in the integrase gene. Several pathways of resistance have been identified, the most common involving mutations at codons 148, 155 or less commonly 143. Additional key resistance mutations occur at codons 74, 92, 138, 140, 157 and 163. Virtually complete cross-resistance has been observed with ELV, another integrase inhibitor undergoing clinical trials and work has started on the development of second-generation integrase inhibitors with enhanced barrier to the emergence of resistance.

TRANSMISSION OF DRUG RESISTANCE

Transmission of drug-resistant species of HIV-1 is well recognized, and in some populations has reached up to 10–15% of new infections. Following transmission, resistance can persist over months and years, unlike the situation of stopping therapy after emergence of resistance which leads to rapid outgrowth of wild-type virus that is archived from prior to treatment (Pao *et al.*, 2004 Little *et al.* 2008). One explanation for this difference is that transmission events involve a single or small number

of infectious virions. These are likely to be homogeneous. Therefore, in the face of transmission of resistant viruses, nonresistant virus is not also present to allow subsequent outgrowth. Nevertheless, some transmitted mutants can revert back to wild type, and minority species assays demonstrate that this is likely the case for M184V (Metzner *et al.*, 2005).

Transmitted resistance can compromise the response to first-line therapy. This is particularly the case for transmitted NNRTI resistance, which leads to more complete class resistance, than viruses carrying one or two nucleoside analogue or PI resistance mutations (Kuritzkes *et al.*, 2008). Many national and international guidelines on antiretroviral therapy now recommend routine resistance testing at time of diagnosis, in order to guide appropriate first-line therapy.

Despite case reports to the contrary, there is no evidence that disease progression following transmission of resistance *per se* is any different to cases of transmission of nonresistant viruses.

PREVENTION

The vast majority of HIV transmissions worldwide are due to sexual transmission. Therefore, safe sex messages remain the cornerstone of any prevention campaign. Nevertheless, the continuing epidemic, more than 20 years after the modes of transmissions were understood, suggests that such simple messages are far more complicated to implement. Indeed, there is some evidence that the impact of antiretroviral therapy in shifting HIV infection from a life-threatening condition to a chronic disease state has led to a relaxation in concern amongst some risk groups.

Short-term antiretroviral therapy has been utilized to prevent vertical transmission, and also as post-exposure prophylaxis for many years. More recently, this concept has been extended to pre-exposure settings, and this is discussed below. However, amongst infected individuals, antiretroviral use remains focused on providing benefit for that individual. There is increasing discussion about starting treatment at earlier stages of disease than current guidelines specify, particularly with improvements in the management of drug-related toxicities, and easier to take drug formulations. This will also have public health benefits, since earlier treatment will decrease the duration of high, infectious viraemia.

Vertical Transmission

Mother-to-Child Transmission

Historically, the rates of vertical mother-to-child transmission of HIV varied between African (30–50%), North

American (20–30%) and European (14%) studies, probably due to the inclusion of populations at different stages of disease. HIV may be transmitted throughout pregnancy, during delivery and as a consequence of breastfeeding (Lehman and Farquhar, 2007). Evidence indicates that the majority of transmission events occur perinatally and during breastfeeding. There is a linear correlation between maternal viral load and risk of transmission, but there is no evidence for a safe threshold and transmission has occurred in women with a viral load <400 copies ml^{-1} . HIV suppression in plasma is generally associated with undetectable HIV RNA in the genital tract, but dissociation can occur, leading to HIV shedding in cervico-vaginal secretions. Mode of delivery, duration of membrane rupture and delivery before 32 weeks of gestation are important predictors of transmission.

Strategies for interruption of vertical transmission have had a dramatic impact on the numbers of children infected with HIV in the developed world. In the pivotal study, treatment of the mother with zidovudine during the last trimester of pregnancy and the infant for the first six weeks of life produced a 60–70% reduction in vertical transmission (Connor *et al.*, 1994). In developed countries, some authorities still regard ZDV monotherapy as an option for selected women with a low viral load willing to deliver by planned caesarean section (PLCS). The risk of developing ZDV resistance during monotherapy appears to be low in this selected group. HAART is recommended in pregnant women who require treatment for their own health, have a high viral load ($>10\ 000$ copies ml^{-1}) or have evidence of drug resistance. In addition, PLCS is recommended for all women taking ZDV monotherapy and for those on HAART with detectable viraemia, whereas elective vaginal delivery is an option for women with no detectable viraemia on HAART. For PEP, most infants can be treated with ZDV monotherapy for four weeks, but HAART should be given to infants born to untreated mothers or mothers with detectable viraemia despite HAART. Exclusive formula-feeding is also recommended to all HIV-positive mothers. With these combined strategies, vertical transmission of HIV can be reduced to negligible levels (Fowler *et al.*, 2007). Approximately 30% of vertically infected children develop severe disease within the first year of life, but most develop disease over several years. Infections and failure to thrive are common features of paediatric HIV infection. Prognosis has been improved substantially with the use of HAART, but untreated children progress rapidly to disease, especially in resource-poor settings where mortality is greater than 50% by two years of age (Prendergast *et al.*, 2007).

The availability of HAART is limited in many developing countries. Trials of a single dose of NVP given to women in labour and to the infant have shown good

results, reducing transmission by almost 50%. However, one concern is related to the emergence of NVP resistance (and EFV cross-resistance) in a large proportion of treated women and their infants, which may compromise the activity of first-line NNRTI-based regimens (Flys *et al.*, 2005; Johnson *et al.*, 2005; Kassaye *et al.*, 2007; Palmer *et al.*, 2006). Avoiding breastfeeding in the developing world is also problematic. Lack of conferred immunity through breast milk and poor hygiene in preparation of bottle feeds lead to significant infant morbidity and mortality from gastrointestinal infections. In addition, formula-feeding is often stigmatized as indicating that the mother is HIV-positive.

Sexually Transmitted Infections

Sexually transmitted infections are a risk factor for acquisition of HIV. In addition local genital tract inflammation increases HIV shedding. It follows that control of sexually transmitted infections may be an important, and cost-effective, method for reducing transmission of HIV. The most compelling evidence relates to herpes simplex 2 infections. Thus, a randomized study of valaciclovir in HSV-seropositive, antiretroviral-naïve HIV-infected women demonstrated a significant reduction in plasma and genital tract HIV RNA (Nagot *et al.*, 2007), although the evidence to date is for a lack of impact of HSV treatment on HIV acquisition (Watson-Jones *et al.*, 2008).

Circumcision

Observational studies have demonstrated that circumcision has a protective effect on acquisition of HIV. A number of mechanisms have been proposed; foreskin contains high concentrations of cells permissive for HIV infection, such as DCs, macrophages and CD4 lymphocytes; reduced genital ulceration; foreskin may contain more disrupted epithelium compared with the more keratinized shaft of the penis.

More recently, three randomized clinical trials, all based in sub-Saharan Africa, have shown benefit of circumcision in reducing incidence of infection in men by 50–70%, and there is growing opinion that this may provide an important arm of HIV-prevention programmes worldwide (Weiss *et al.*, 2008).

However, there are a number of limitations of this strategy. First, benefit is conferred on the circumcised man, rather than women. This is of concern, since the risk of infection per coital act is higher for women than men, although any reduction of infections at the population level would be expected to lead indirectly to reductions in female infections. Second, the protection against transmission through anal sex (whether heterosexual or homosexual) remains unknown. Third, the degree to which the

benefit observed in the resource-poor world can be extrapolated to Northern countries is unclear. Finally, there will be a number of cultural and educational hurdles to overcome prior to widespread implementation of circumcision.

Microbicides

Topical administration of microbicides to vagina and/or rectum has been proposed as appropriate for women in particular, who otherwise may not be able to convince sexual partners to adopt safer sex practices. Compounds in development include polyanions, such as cellulose sulfate and PRO-2000, and non-ionic surfactants such as nonoxynol-9. These are thought to act by disrupting the virus—cell interaction. Progress in the field was slowed by the unexpected finding from two randomized trials of cellulose sulfate of enhanced rates of infection in recipients of the active compound. Possible reasons for these findings include an inflammatory effect of the compounds on genital epithelium, alterations to epithelial permeability and/or alterations to natural genital microbial flora. Nevertheless, further work is being undertaken, including the topical use of antiretroviral drugs, within the microbicides programme (van der Wigjert and Shattock, 2007).

Post-exposure Prophylaxis

Post-exposure prophylaxis (PEP) was initially addressed in the context of occupational exposure to HIV-1, such as needlestick injuries. Epidemiological studies have indicated that the average risk for HIV transmission after percutaneous exposure to HIV-infected blood in health-care settings is about 3 per 1000 injuries. After a mucocutaneous exposure, the average risk is estimated at less than 1 in 1000. It has been considered that there is no risk of HIV transmission where intact skin is exposed to HIV-infected blood.

More recently, attention has turned to post-exposure prophylaxis following sexual exposure (PEPSE), where the risk of acquisition is increased in the passive partner in anal intercourse.

A case—control study conducted by the CDC concluded that the administration of ZDV prophylaxis to healthcare workers occupationally exposed to HIV was associated with an 81% reduction in the risk for occupationally acquired HIV infection (Cardo *et al.*, 1997). Four factors were associated with increased risk of occupationally acquired HIV infection: (i) deep injury, (ii) visible blood on the needle, (iii) injury with a needle which had been placed in a source patient's artery or vein and (iv) terminal HIV-related illness in the source patient (now explained through a high viral load).

In the absence of randomized studies addressing the interval between a risk incident and initiation of PEP,

three lines of evidence provide guidance: (i) animal studies; (ii) human perinatal transmission studies and (iii) consideration of virological/immunological studies on the natural history of primary infection.

First, SIV/maaque animal models demonstrated a protective effect of TDF when administered within 72 hours of inoculation, and such protection was enhanced by treatment for more than 10 days. By contrast, in one study, PEP with intravenous ZDV, 3TC and IDV as early as 4 hours post infection in a SIV/HIV chimera (SHIV) infection of macaques did not prevent infection. One human perinatal transmission intervention study is also informative. In a subset of participants in the ACTG 076 protocol, where antenatal treatment of the pregnant woman with ZDV was omitted (through choice or limited clinical care), neonatal ZDV started within 48 hours of birth was associated with an HIV transmission rate of 9.3%, compared with a rate of 18.4% when ZDV was started at a later time (Connor *et al.*, 1994). Recent studies of the SIV—maaque model, as well as natural history studies following HIV-1 transmission in humans, demonstrate extensive infection of gut-associated CD4 lymphocytes, and their preferential depletion is evident at the time of primary infection. This suggests there is only a brief window of opportunity to prevent or abort infection (through administering PEP) before irreversible systemic infection and HIV seroconversion occur (Centlivre *et al.*, 2007).

Together, these studies provide some evidence that PEP is most likely to be effective when initiated as soon as possible (within hours, and certainly within 48–72 hours of infection), and continued for at least 28 days. It should be noted that the evidence base on which these conclusions are based is limited.

In HIV-infected patients, triple therapy has proved more effective than mono or dual therapy in suppressing HIV replication and avoiding the emergence of viral resistance. The US guidelines recommend two-drug PEP regimens following lower risk incidents and three-drug regimens only for higher risks (www.cdc.gov/mmwr/preview/mmwrhtml/rr5409a1.htm3). This two-tier approach adds to the complexity of the risk assessment process, at the expense of greater potency and protection for the exposed worker. The main arguments in favour of two-drug PEP (fewer side effects, better adherence and course completion rates) are being addressed through switching to better-tolerated agents with lower pill burdens. At the same time, a potent three-drug PEP regimen is preferred because resistance to antiretroviral drugs is found at significant levels in both treated and untreated infected individuals in the United Kingdom. Current guidance suggests truvada (TDF and FTC) and kaletra (LPV/r) as the PEP of choice, to be taken over four weeks. Data on the optimal duration of follow-up

are limited. However, based on expert opinion, UK guidelines now recommend, as a minimum standard, that follow-up should be for at least 12 weeks after the HIV-exposure event or, if PEP was taken, for at least 12 weeks from when PEP was stopped.

Pre-exposure Prophylaxis (PREP)

A number of animal model SIV experiments demonstrate the efficacy of pre-exposure prophylaxis (PREP) (García—Lerma *et al.*, 2008). There is increasing interest in the use of antiretrovirals with low toxicity prior to possible exposure. Such an approach is relevant for, for example, sex workers. Trials of TDF, with or without FTC, are ongoing. Concerns with this approach include the risk of resistance in cases where the recipient is already HIV infected, or indeed, rapid development of resistance in cases of transmission, and also the potential increase in risky behaviour consequent on the reassurance given by use of this approach.

VACCINES

A safe, efficacious vaccine that prevented HIV infection would provide the single most important means of curtailing the AIDS pandemic. Sadly, there is no imminent prospect of developing a prophylactic vaccine. Large phase III trials of vaccines based on envelope glycoproteins designed to elicit neutralizing antibodies did not show efficacy (Graham and Mascola, 2005). Similarly, recent vaccine trials of non-enveloped components designed to elicit cell-mediated immunity were curtailed early, owing to more cases of HIV infection in the vaccine arm than in the placebo arm (Sekaly, 2008).

The lack of a vaccine is not for want of effort. Part of the explanation is the sheer degree of variability of HIV. It is some 10 times greater even than influenza A virus, for which the WHO must annually decide what substrain to use. Moreover, unlike influenza virus, chronic infection by HIV means that there is no 'prevalent strain' in circulation, but rather thousands of strains distributed among a dozen major antigen subtypes and recombinant forms.

Many approaches to developing vaccines have been attempted: whole inactivated virus particles, subunit recombinant proteins, viral proteins expressed through DNA-based vaccines and delivery of genes in expression vectors such as vaccinia and adenoviruses. The one approach that has led to cross-protection against different SIV strains in macaques is a live-attenuated vaccine in which *nef* and other accessory genes are attenuated. However, it is doubtful that a live vaccine, however

'disabled', could be licensed for human use given the propensity for HIV to repair its fitness, and to recombine with incoming virus. Besides, the mechanism of protection by live-attenuated SIV strains remains a mystery, because it does not appear to be related to either humoral or cell-mediated immune responses. Therefore we do not even have a scientific principle to aid us in developing a safer vaccine.

In the absence of a prophylactic vaccine, effort has been turned towards a therapeutic vaccine or immunotherapy. It was hoped that HAART might sufficiently reduce virus load so that an immunogenic boost would lead to long-term suppression of virus by immunological means. However, there is little promise that this approach will be useful.

Nonetheless, experimental protection of macaques against challenge by the same virus strain as the immunogen has been achieved. For example, passive transfer of neutralizing antibody in sufficient concentration can block infection if administered at the time of challenge. SHIV may be useful in testing future envelope-based vaccine candidates. Much effort will continue to be placed on vaccine discovery and development. However, for the time-being HIV has humbled the vaccinologists.

Human Prion Diseases

John Collinge

MRC Prion Unit and Department of Neurodegenerative Disease, UCL Institute of Neurology, London, UK

INTRODUCTION TO PRIONS AND HISTORICAL PERSPECTIVE

The prion diseases, or transmissible spongiform encephalopathies, are a closely related group of neurodegenerative conditions that affect both humans and animals. They have been called previously the subacute spongiform encephalopathies, slow virus diseases and transmissible dementias. The prototypic disease is scrapie, a naturally occurring disease of sheep and goats, which has been recognized in Europe for over 200 years and is present in many countries worldwide. Other animal prion diseases described over the last few decades include transmissible mink encephalopathy (TME) and chronic wasting disease of mule deer and elk, both principally in the United States, and since the 1980s bovine spongiform encephalopathy (BSE)—first described in the United Kingdom and now seen in most European Union (EU) and some other countries. The more recently described feline spongiform encephalopathy of domestic cats and spongiform encephalopathies of an increasing number of species of zoo animals (Kirkwood *et al.*, 1990) are also now also recognized as animal prion diseases.

The human prion diseases have been classified traditionally into Creutzfeldt—Jakob disease (CJD), Gerstmann—Sträussler syndrome (GSS) (also known as Gerstmann—Sträussler—Scheinker disease) and kuru. Although these are rare neurodegenerative disorders, affecting about 1–2 per million worldwide per annum, remarkable attention has been focused on these diseases in recent years. This is because of the unique biology of the transmissible agent or prion, and also because of the fears that the epizootic of BSE could pose a threat to public health through dietary exposure to infected tissues.

Scrapie was demonstrated to be transmissible by inoculation between sheep (and goats) following prolonged incubation periods in 1936. It was assumed that some type of virus must be the causative agent and Sigurdsson coined the term ‘slow virus infection’ in 1954. There was considerable interest in the 1950s in an epidemic of a neurodegenerative disease, kuru, characterized principally by a progressive ataxia, amongst the Fore linguistic group of the Eastern Highlands of Papua New Guinea. Subsequent fieldwork, by a number of investigators, suggested that kuru was transmitted during cannibalistic feasts. Hadlow (1959) drew attention to the similarities between kuru and scrapie at the neuropathological, clinical and epidemiological levels, leading to the suggestion that these diseases may also be transmissible. A landmark in the field was the transmission by intracerebral inoculation with brain homogenates into chimpanzees of first kuru and then CJD by Gajdusek and colleagues in 1966 and 1968, respectively (Gajdusek *et al.*, 1966; Gibbs *et al.*, 1968). Transmission of GSS followed in 1981. This work led to the concept of the ‘transmissible dementias’. The term ‘Creutzfeldt—Jakob disease (CJD)’ was introduced by Spielmeyer in 1922, drawing from the case reports of Creutzfeldt (1920) and Jakob (1921) and was used in subsequent years to describe a range of neurodegenerative conditions, many of which would not meet modern diagnostic criteria for CJD. The criterion of transmissibility allowed diagnostic criteria for CJD to be assessed and refined; atypical cases could be classified as CJD on the basis of their transmissibility. All the animal and human conditions share common histopathological features. The classical diagnostic triad of spongiform vacuolation (affecting any part of the cerebral grey matter), neuronal loss and astrocytic proliferation may be accompanied by amyloid plaques.

The nature of the transmissible agent in these diseases has been a subject of intense and often heated debate for many years. The understandable initial assumption that the agent must be some form of virus was challenged, however, both by the failure to directly demonstrate such a virus (or any immunological response to it) and by evidence indicating that the transmissible agent showed remarkable resistance to treatment expected to inactivate nucleic acids (such as ultraviolet radiation or treatment with nucleases). Such findings had led to suggestions as early as 1966 by Alper and others that the transmissible agent may be devoid of nucleic acid (Alper *et al.*, 1966, 1967). Such findings led Griffith to suggest in 1967 that the transmissible agent might be a protein, and to propose several hypothetical mechanisms for replication (Griffith, 1967). Progressive enrichment of brain homogenates for infectivity resulted in the isolation of a protease-resistant sialoglycoprotein, designated the prion protein (PrP), by Prusiner and co-workers in 1982. This protein was the major constituent of infective fractions and was found to accumulate in affected brains and sometimes to form amyloid deposits. The term prion (from proteinaceous infectious particle) was proposed by Prusiner (1982) to distinguish the infectious pathogen from viruses or viroids. Prions were defined as 'small proteinaceous infectious particles that resist inactivation by procedures which modify nucleic acids'.

The protease-resistant PrP extracted from affected brains was of 27–30 kDa and became known as PrP^{27–30}. N-terminal sequencing of PrP^{27–30} enabled production of isocoding mixtures of oligonucleotides that were used to screen cDNA libraries prepared from scrapie-infected hamsters. These studies led to recovery of cognate cDNA clones by Weissmann and colleagues in 1985. Remarkably, PrP^{27–30} was encoded by a single-copy host chromosomal gene rather than by a putative nucleic acid in fractions enriched for scrapie infectivity. PrP^{27–30} was found to be derived from a larger molecule of 33–35 kDa designated PrP^{Sc} (denoting the scrapie isoform of the protein) (Oesch *et al.*, 1985). The normal product of the PrP gene, however, is protease sensitive and was designated PrP^C (denoting the cellular isoform of the protein). No differences in amino acid sequence between PrP^{Sc} and PrP^C have been identified. PrP^{Sc} is known to be derived from PrP^C by a post-translational process (Borchelt *et al.*, 1990; Caughey and Raymond, 1991).

Many of the key advances in understanding the pathogenesis of the prion diseases have come from study of the various forms of human prion disease. In particular, the recognition that the familial forms of the human diseases are autosomal dominant inherited conditions, associated with *PRNP* coding mutations (Hsiao *et al.*, 1989; Owen *et al.*, 1989), as well as being transmissible to laboratory

animals by inoculation, strongly supported the contention that the transmissible agent, or prion, was composed principally of an abnormal isoform of prion protein.

STRUCTURAL BIOLOGY OF PRIONS

A wide body of data now supports the idea that prions consist principally or entirely of an abnormal isoform of a host-encoded protein, the PrP, designated PrP^{Sc} (for review see Prusiner, 1991). PrP^{Sc} is derived from PrP^C by a post-translational mechanism (Borchelt *et al.*, 1990) and no covalent differences (Caughey and Raymond, 1991) between PrP^C and PrP^{Sc} have been demonstrated. It is proposed that PrP^{Sc} acts as a template which promotes the conversion of PrP^C to PrP^{Sc} and that this conversion involves only conformational change.

The conformation of the cellular isoform was first established by nuclear magnetic resonance (NMR) measurements of recombinant mouse PrP (Riek *et al.*, 1996). Since then NMR measurements on recombinant hamster, human and other mammalian PrPs show that they have essentially the same conformation.

Following cleavage of an N-terminal signal peptide, and removal of a C-terminal peptide on addition of a glycosylphosphatidylinositol (GPI) anchor, the mature PrP^C species consists of an N-terminal region of about 100 amino acids, which is unstructured in the isolated molecule in solution, and a C-terminal segment, also around 100 amino acids in length. The C-terminal domain is folded into a largely α -helical conformation (three α -helices and a short anti-parallel β -sheet) and is stabilized by a single disulfide bond linking helices 2 and 3. There are two asparagine-linked glycosylation sites (see Figure 39.1).

The N-terminal region contains a segment of five repeats of an eight-amino-acid sequence (the octapeptide repeat region), expansion of which by insertional mutation leads to inherited prion disease. While unstructured in the isolated molecule, this highly conserved region contains a tight binding site for a single Cu²⁺ ion with a dissociation constant (K_d) of 10^{-14} M. A second tight copper site ($K_d = 10^{-13}$ M) is present upstream of the octa-repeat region but before the structured C-domain (Hornshaw *et al.*, 1995; Jackson *et al.*, 2001). Clearly, it is possible that the unstructured N-terminal region may acquire structure following copper binding. A role for PrP in copper metabolism or transport is possible and disturbance of this function by the conformational transitions between isoforms of PrP could be involved in prion-related neurotoxicity.

The structured C-domain folds and unfolds reversibly in response to chaotropic denaturants and recent work

on the folding kinetics of mouse PrP^C (Wildegger *et al.*, 1999) demonstrates that there are no populated intermediates in the folding reaction and that the protein displays unusually rapid rates of folding and unfolding. These findings have been reinforced by hydrogen/deuterium exchange measurements on the human protein which show that the overall equilibrium constant describing the distribution of folded and unfolded states is the same as the protection factor (Hosszu *et al.*, 1999). This shows that there are no partially unfolded forms or intermediates that have a population greater than the unfolded state. The data suggest that PrP^{Sc} is unlikely to be formed from a kinetic folding intermediate, as has been hypothesized in the case of amyloid formation in other systems. In fact, on the basis of population it would be more likely that PrP^{Sc} were formed from the unfolded state of the molecule.

Inherited prion diseases may produce disease by destabilizing PrP^C, which would predispose the molecule to aggregate. Alternatively a mutation could facilitate the interaction between PrP^C and PrP^{Sc} or affect the binding of a ligand or co-protein. In order to relate the folding stability of PrP^C to its propensity for forming PrP^{Sc}, several of the human mutations have been copied into the recombinant mouse protein (Liemann and Glockshuber, 1999). Although this work concluded broadly that there is no absolute correlation between stability and disease, all of the fully penetrant pathogenic mutations show

significant destabilization, while non-pathogenic polymorphisms have little effect.

PrP^{Sc} is extracted from affected brains as highly aggregated, detergent-insoluble material that is not amenable to high-resolution structural techniques. However, Fourier transform infrared (FTIR) spectroscopic methods show that PrP^{Sc}, in sharp contrast to PrP^C, has a high β -sheet content (Pan *et al.*, 1993). PrP^{Sc} is covalently indistinguishable from PrP^C (Pan *et al.*, 1993; Stahl *et al.*, 1993).

The underlying molecular events during infection which lead to the conversion of PrP^C to the scrapie agent remain ill-defined. The most coherent and general model thus far proposed is that the protein, PrP, fluctuates between a dominant native state, PrP^C, and a series of minor conformations, one or a set of which can self-associate in an ordered manner to produce a stable supramolecular structure, PrP^{Sc}, composed of misfolded PrP monomers. Once a stable 'seed' structure is formed, PrP can then be recruited leading to an explosive, autocatalytic formation of PrP^{Sc}. Such a system would be extremely sensitive to three factors: (i) overall PrP^C concentration; (ii) the equilibrium distribution between the native conformation and the self-associating conformation and (iii) complementarity between surfaces which come together in the aggregation step. All three of these predictions from this minimal model are manifest in the aetiology of prion disease: an inversely proportional relationship between PrP^C expression and prion incubation period in transgenic mice (Bueler *et al.*, 1993; Collinge *et al.*, 1995b; Prusiner *et al.*, 1990; Telling *et al.*, 1995); predisposition by relatively subtle mutations in the protein sequence (Collinge, 1997); and a requirement for molecular homogeneity for efficient prion propagation (Palmer *et al.*, 1991; Prusiner *et al.*, 1990).

Little is known for certain about the molecular state of the protein that constitutes the self-propagating, infectious particle itself. It is hypothesized that prions are self-propagating fibrillar or amyloid forms of PrP in which the ends of the propagating fibrils constitute the infectious entity and the exponential rise in prion titre is a consequence of fibre fragmentation. While this concept of prion propagation as nucleation-dependent polymerization has been around for a long time (Come *et al.*, 1993; Gajdusek, 1988; Jarrett and Lansbury, 1993), there is now direct experimental evidence that PrP fibrillized *in vitro* may be infectious (Legname *et al.*, 2004).

Direct *in vitro* mixing experiments (Bessen *et al.*, 1995; Kocisko *et al.*, 1994, 1995) have been performed in an attempt to produce PrP^{Sc}. In such experiments an excess of PrP^{Sc} is used as a seed to convert recombinant PrP^C to a protease-resistant form (designated PrP^{RES}). However, the relative inefficiency of these reactions has precluded determining whether new infectivity has been generated. An

artificial species barrier has, however, been exploited to address this issue, and such conversion products, expected to have a different host specificity (and so which can be bioassayed in the presence of an excess of starting material), have not shown any detectable infectivity (Hill *et al.*, 1999a). These results argue that acquisition of protease resistance by PrP^C is not sufficient for the propagation of infectivity. However, more recently methods that have demonstrated *in vitro* amplification of prions have been reported which involve sequential cycles of sonication and incubation with brain homogenate as a source of PrP^C and presumably important co-factors (Castilla *et al.*, 2005).

The difficulty in performing structural studies on native PrP^{Sc} has led to attempts to produce soluble β -sheet-rich forms of PrP, which may be amenable to NMR or crystallographic structure determination. It is now recognized that the adage 'one sequence, one conformation' is not strictly true. Depending on solvent conditions, probably any protein chain can adopt a variety of conformations in which there is a degree of periodic order (that is extensive regions of secondary structure). However such alternative states do not have precisely and tightly packed side chains which are the hallmark of the native state of orthodox globular proteins.

Studies on a large fragment of the human PrP⁹¹⁻²³¹ have shown that at acidic pH PrP can fold to a soluble monomer comprised almost entirely of β -sheet in the absence of denaturants (Jackson *et al.*, 1999). Reduction of the native disulfide bond was a prerequisite for β -sheet formation and these observations of alternative folding pathways dependent upon solvent pH and redox potential could have important implications for the mechanism of conversion to PrP^{Sc}. Indeed this monomeric β -sheet state was prone to aggregation into fibrils with partial resistance to proteinase K digestion, characteristic markers of PrP^{Sc}. Unusually for a protein with a predominantly helical fold, the majority of residues in PrP⁹¹⁻²³¹ have a preference for β -conformation (55% of non-glycine/proline residues). In view of this property, it is possible that the PrP molecule is delicately balanced between radically different folds with a high-energy barrier between them; one dictated by local structural propensity (the β -conformation) and one requiring the precise docking of side chains (the native α -conformation). Such a balance would be influenced by mutations causing inherited human prion diseases. It is also worthy of note that individuals homozygous for valine at polymorphic residue 129 of human PrP (where either methionine or valine can be encoded) are more susceptible to iatrogenic CJD (Collinge *et al.*, 1991a), and valine has a much higher β -propensity than does methionine.

The precise subcellular localization of PrP^{Sc} propagation remains controversial. However, there is considerable

Figure 39.2 Possible mechanism for prion propagation. Largely α -helical PrP^C proceeds via an unfolded state (a) to re-fold into a largely β -sheet form, β -PrP (b). β -PrP is prone to aggregation in physiological salt concentrations. Prion replication may require a critical 'seed' size. Further recruitment of β -PrP monomers (c) or unfolded PrP (d) then occurs as an essentially irreversible process.

evidence implicating either late endosome-like organelles or lysosomes (Arnold *et al.*, 1995; Laszlo *et al.*, 1992; Mayer *et al.*, 1992; Taraboulos *et al.*, 1992). The environments of these organelles are evolved to facilitate protein unfolding at low pH prior to degradation by acid-activated proteases. It is possible that the α -PrP to β -PrP conversion, caused by reduction and mild acidification, is relevant to the conditions that PrP^C would encounter within the cell, following its internalization during recycling. Such a mechanism could underlie prion propagation, and account for the transmitted, sporadic and inherited aetiologies of prion disease (see Figure 39.2). Initiation of a pathogenic self-propagating conversion reaction, with accumulation of aggregated β -PrP, may be induced by exposure to a 'seed' of aggregated β -PrP following prion inoculation, or as a rare stochastic conformational change, or as an inevitable consequence of expression of a pathogenic PrP^C mutant that is predisposed to form β -PrP. It remains to be demonstrated whether such alternative conformational states of the protein are sufficient to cause prion disease in an experimental host or whether other cellular co-factors are also required.

A critical test of the protein-only hypothesis, both with respect to infectivity and 'strain-ness' would be to produce discrete prion strains synthetically from defined components.

Important steps in this endeavour have been reported. Purified, bacterially expressed recombinant N-terminally truncated mouse PrP has been aggregated into fibrillar material and bioassayed in transgenic mice (designated Tg9949) expressing very high levels of the same truncated mouse PrP (Legname *et al.*, 2004). Following prolonged

incubation periods, these Tg9949 mice developed a prion disease transmissible to wild-type as well as to further Tg9949 mice. The transmission characteristics at both primary and second passage of infectivity were consistent with production of a novel prion strain type, distinct from commonly used mouse-adapted laboratory strains. However, there remain major problems in interpretation of these data and the synthetic production of high-titre infectivity directly transmissible to wild-type animals has not yet been confirmed (Collinge and Clarke, 2007).

NORMAL CELLULAR FUNCTION OF PrP

While PrP plays a central role in pathogenesis of prion diseases, and mice devoid of PrP^C are resistant to scrapie and do not accumulate PrP^{Sc} or propagate infectivity (Bueler *et al.*, 1992), its normal biological function remains unclear. PrP is highly conserved among mammals, has been identified in marsupials, amphibians and birds, and may be present in all vertebrates. It is expressed during early embryogenesis and is found in most tissues in the adult (Manson *et al.*, 1992). However, highest levels of expression are seen in the central nervous system (CNS). The protein is found predominantly in neurons, particularly at synapses in cholesterol-rich microdomains or caveolae, known to play a central role in neuronal signalling events (for review see Anderson, 1993). PrP is also expressed widely in cells of the immune system (Dodelet and Cashman, 1998). Mice lacking PrP as a result of gene knockout (*Prnp*^{0/0}) showed no gross phenotype (Bueler *et al.*, 1992), although they were completely resistant to prion disease following inoculation and did not replicate prions (Bueler *et al.*, 1993). However, these mice were then shown to have abnormalities in synaptic physiology (Collinge *et al.*, 1994) and in circadian rhythms and sleep (Tobler *et al.*, 1996). While none of these observations define a molecular role for PrP^C, it has been argued that PrP may act as a receptor for an, as yet, unidentified extracellular ligand. Newly synthesized PrP^C is transported to the cell surface and then cycles rapidly via a clathrin-mediated mechanism, with a transit time of around an hour, between the surface and early endosomes (Shyng *et al.*, 1994).

It is possible that *Prnp*^{0/0} mice may be viable and healthy due to secondary compensatory mechanisms during neurodevelopment as has been documented in other models of targeted gene knockout. The most direct approach to answering this question was by knocking out neuronal PrP expression in a developed nervous system, avoiding potential compensatory mechanisms activated during neurodevelopment, and thus to observe directly the effects of acute depletion of PrP, revealing any critical function. This has now been achieved and excludes

PrP loss of function as a sufficient cause of prion neurodegeneration (Mallucci *et al.*, 2002).

PRION STRAINS

A major problem for the 'protein-only' hypothesis of prion propagation has been how to explain the existence of multiple isolates, or strains, of prions. Dickinson, Fraser and colleagues isolated multiple distinct strains of naturally occurring sheep scrapie in mice. Such strains are distinguished by their biological properties: they produce distinct incubation periods and patterns of neuropathological targeting (so-called lesion profiles) in defined inbred mouse lines (for review see Bruce *et al.*, 1992). As they can be propagated serially in inbred mice with the same *Prnp* genotype they cannot be encoded by differences in PrP primary structure. Furthermore, strains can be re-isolated in mice after passage in intermediate species with different PrP primary structures (Bruce *et al.*, 1994). Conventionally, distinct strains of conventional pathogen are explained by differences in their nucleic acid genome. However, in the absence of such a scrapie genome, alternative possibilities must be considered. Weissmann (1991) proposed an 'unified hypothesis' where, although the protein alone was argued to be sufficient to account for infectivity, it was proposed that strain characteristics could be encoded by a small cellular nucleic acid, or 'co-prion'. Although this hypothesis leads to the testable prediction that strain characteristics, unlike infectivity, would be sensitive to UV irradiation, no such test has been reported. At the other extreme, the protein-only hypothesis (Griffith, 1967) would have to explain how a single polypeptide chain could encode multiple disease phenotypes. Clearly, understanding how a protein-only infectious agent could encode such phenotypic information is of considerable biological interest.

Support for the idea that strain specificity may be encoded by PrP itself was provided by study of two distinct strains of TME prions which can be serially propagated in hamsters, designated hyper (HY) and drowsy (DY). These strains can be distinguished by differing physicochemical properties of the accumulated PrP^{Sc} in the brains of affected hamsters (Bessen and Marsh, 1992). Following limited proteolysis, strain-specific migration patterns of PrP^{Sc} on polyacrylamide gels were seen which related to different N-terminal ends of HY and DY PrP^{Sc} following protease treatment and implying differing conformations of HY and DY PrP^{Sc} (Bessen and Marsh, 1994).

Distinct human PrP^{Sc} types have been identified which are associated with different phenotypes of CJD (Collinge *et al.*, 1996b; Parchi *et al.*, 1996). The different fragment sizes seen on Western blots following treatment

with proteinase K suggests that there are several different human PrP^{Sc} conformations. However, while such biochemical modifications of PrP are clearly candidates for the molecular substrate of prion strain diversity, it is necessary to be able to demonstrate that these properties fulfil the biological properties of strains. In particular, that they are transmissible to the PrP in a host of both the same and different species. This has been demonstrated in studies with CJD isolates, with both PrP^{Sc} fragment sizes and the ratios of the three PrP glycoforms (diglycosylated, monoglycosylated and unglycosylated PrP) maintained on passage in transgenic mice expressing human PrP (Collinge *et al.*, 1996b). Furthermore, transmission of human prions and bovine prions to wild-type mice results in murine PrP^{Sc} with fragment sizes and glycoform ratios which correspond to the original inoculum (Collinge *et al.*, 1996b). Variant Creutzfeldt—Jakob disease (vCJD) is associated with PrP^{Sc} glycoform ratios which are distinct from those seen in classical CJD. Similar ratios are seen in BSE and BSE when transmitted to several other species (Collinge *et al.*, 1996b). These data strongly support the ‘protein-only’ hypothesis of infectivity and suggest that strain variation could be encoded by a combination of PrP conformation and glycosylation. Furthermore, polymorphism in PrP sequence can influence the generation of particular PrP^{Sc} conformers (Collinge *et al.*, 1996b). Transmission of PrP^{Sc} fragment sizes from two different sub-types of inherited prion disease to transgenic mice expressing a chimaeric human mouse PrP has also been reported (Telling *et al.*, 1996). As PrP glycosylation occurs before conversion to PrP^{Sc}, the different glycoform ratios may represent selection of particular PrP^C glycoforms by PrP^{Sc} of different conformations. According to such a hypothesis, PrP conformation would be the primary determinant of strain type with glycosylation being involved as a secondary process. However, since it is known that different cell types may glycosylate proteins differently, PrP^{Sc} glycosylation patterns may provide a substrate for the neuropathological targeting that distinguishes different prion strains (Collinge *et al.*, 1996b). Particular PrP^{Sc} glycoforms may replicate most favourably in neuronal populations with a similar PrP glycoform expressed on the cell surface. Such targeting could also explain the different incubation periods which also discriminate strains, targeting of more critical brain regions, or regions with higher levels of PrP expression, producing shorter incubation periods.

Recent work has shown strain-specific protein conformation to be influenced by metal binding to PrP^{Sc} (Wadsworth *et al.*, 1999). Two different human PrP^{Sc} types, seen in clinically distinct subtypes of classical CJD, can be interconverted *in vitro* by altering the metal-ion occupancy. The dependence of PrP^{Sc} conformation on the

Figure 39.3 Molecular strain typing of human prions.

binding of copper and zinc represents a novel mechanism for post-translational modification of PrP, and for the generation of multiple prion strains.

Molecular strain typing of prion isolates can now be applied to molecular diagnosis of vCJD (Collinge *et al.*, 1996b; Hill *et al.*, 1997a) and to produce a new classification of human prion diseases with implications for epidemiological studies investigating the aetiology of sporadic CJD (Figure 39.3) (Hill *et al.*, 2003; Parchi *et al.*, 1996, 1999). Such methods allow strain typing to be performed in days rather than the one to two years required for classical biological strain typing. However, an internationally agreed classification of human prion strains has yet to emerge.

This technique may also be applicable to determining whether BSE has transmitted to other species (Collinge *et al.*, 1996b), and thereby pose a threat to human health, for instance to sheep (Hill *et al.*, 1998; Hope *et al.*, 1999; Kuczius *et al.*, 1998).

Such ability of a single polypeptide chain to encode information specifying distinct phenotypes of disease raises intriguing evolutionary questions. Do other proteins behave in this way? The novel pathogenic mechanisms involved in prion propagation may be of far wider significance and relevant to other neurological and non-neurological illnesses. Other prion-like mechanisms have now been described and the recognition that certain heritable traits in yeast could be explained by conformational switching and aggregation in two yeast proteins, Ure2p and Sup35p, led to the emergence of the field of ‘yeast prions’ (Wickner *et al.*, 2004). These proteins have no sequence similarity to PrP. While there are differences to mammalian prions, which are naturally infectious lethal pathogens, the study of these analogous phenomena has led to rapid advances in investigating the processes of seeded fibril formation and the molecular basis of strain diversity and transmission barriers. Indeed a series of elegant studies have clearly established that yeast prions are

composed of protein fibrils, propagating by seeding, and that strain diversity is explained by distinct conformers (Brachmann *et al.*, 2005; Diaz-Avalos *et al.*, 2005; King and Diaz-Avalos, 2004; Krishnan and Lindquist, 2005; Tanaka *et al.*, 2004, 2005).

NEURONAL CELL DEATH IN PRION DISEASE

The precise molecular nature of the infectious agent and the cause of neuronal cell death remains unclear. The current working hypothesis is that an abnormal isoform of PrP is the infectious agent and, to date, the most highly enriched preparations contain one infectious unit per 10^5 PrP monomers (Bolton *et al.*, 1982). Various hypotheses have been proposed to explain the mechanism of spongiform change and neuronal cell loss. These have included direct neurotoxic effects from a region of the PrP encompassing residues 106–126 (Brown *et al.*, 1994; Forloni *et al.*, 1993; Tagliavini *et al.*, 1993) to increased oxidative stress in neurons as a result of PrP^C depletion which has been proposed to function as an antioxidant molecule (Brown *et al.*, 1997). Neurotoxicity of PrP 106–126 is, however, controversial (Kunz *et al.*, 1999). It has also been suggested that PrP^C plays a role in regulating apoptosis with disturbance of normal cellular levels of PrP during infection leading to cell death (Kurschner and Morgan, 1995, 1996). Certainly there have been numerous recent reports of apoptotic cells being identified in the neuronal tissue of prion disease brains (Williams *et al.*, 1997). Although PrP^C expression is required for susceptibility to the disease, a number of observations argue that PrP^{Sc} and indeed prions (whether or not they are identical) may not themselves be highly neurotoxic. Prion diseases in which PrP^{Sc} is barely or not detectable have been described (Collinge *et al.*, 1995a; Hsiao and Prusiner, 1990; Lasmézas *et al.*, 1997; Medori *et al.*, 1992c). Mice with reduced levels of PrP^C expression have extremely high levels of PrP^{Sc} and prions in the brain and yet remain well for several months after their wild-type counterparts succumb (Bueler *et al.*, 1993). Conversely, Tg20 mice, with high levels of PrP^C, have short incubation periods and yet produce low levels of PrP^{Sc} after inoculation with mouse prions (Fischer *et al.*, 1996). In addition, brain grafts producing high levels of PrP^{Sc} do not damage adjacent tissue in PrP knockout (*Prnp*^{0/0}) mice (Brandner *et al.*, 1996). The cause of neurodegeneration in prion diseases remains unclear. It remains possible that prion neurodegeneration is related, at least in part, to loss of function of PrP^C. That *Prnp*^{0/0} mice (other than those associated with overexpression of the *Prnp*-like gene *Dpl* (Moore *et al.*, 1999) do not develop neurodegeneration could be due to compensatory adaptations during

neurodevelopment. Complete or near complete ablation of PrP expression in an adult mouse using conditional gene expression methods has not yet been achieved. A recent study has demonstrated that mice inoculated with Sc237 hamster prions replicate prions to high levels in their brains, but do not develop clinical signs of prion disease during their normal lifespan, arguing that PrP^{Sc} and indeed prions (whether or not they are identical) may not themselves be highly neurotoxic (Hill *et al.*, 2000). An alternative hypothesis for prion-related neurodegeneration is that a toxic intermediate (PrP^L) is produced in the process of conversion of PrP^C to PrP^{Sc}, with PrP^{Sc}, present as highly aggregated material, being a relatively inert end-product (Hill *et al.*, 2000). The steady state level of such a toxic monomeric or oligomeric PrP intermediate could then determine rate of neurodegeneration. One possibility is that Sc237-inoculated mice propagate prions very slowly and that such a toxic intermediate is generated at extremely low levels that are tolerated by the mouse. A general protein-only model of prion propagation, encompassing both infectious and toxic species has been proposed (Collinge and Clarke, 2007).

THE 'SPECIES BARRIER'

Transmission of prion diseases between different mammalian species is restricted by a 'species barrier' (Pattison, 1965). On primary passage of prions from species A to species B usually not all inoculated animals of species B develop disease and those that do have much longer and more variable incubation periods than those that are seen with transmission of prions within the same species, where typically all inoculated animals would succumb with a relatively short, and remarkably consistent, incubation period. On second passage of infectivity to further animals of the species B, transmission parameters resemble within-species transmissions with most if not all animals developing the disease with short and consistent incubation periods. Species barriers can therefore be quantitated by measuring the fall in mean incubation period on primary and second passage, or, perhaps more rigorously, by a comparative titration study. The latter involves inoculating serial dilutions of an inoculum in both the donor and host species and comparing the LD_{50s} obtained. The effect of a very substantial species barrier (for instance that between hamsters and mice) is that few, if any, animals succumb to disease at all on primary passage, and then at incubation periods approaching the natural lifespan of the species concerned.

Early studies of the molecular basis of the species barrier argued that it principally resided in differences in PrP primary structure between the species from which the

inoculum was derived and the inoculated host. Transgenic mice expressing hamster PrP were, unlike wild-type mice, highly susceptible to infection with Sc237 hamster prions (Prusiner *et al.*, 1990). That most sporadic and acquired CJD occurred in individuals homozygous at *PRNP* polymorphic codon 129 supported the view that prion propagation proceeded most efficiently when the interacting PrP^{Sc} and PrP^C were of identical primary structure (Collinge, 1991). However, it has been long recognized that prion strain type affects ease of transmission to another species. Interestingly, with BSE prions the strain component to the barrier seems to predominate, with BSE not only transmitting efficiently to a range of species, but maintaining its transmission characteristics even when passaged through an intermediate species with a distinct PrP gene (Bruce *et al.*, 1994). For instance, transmission of CJD prions to conventional mice is difficult, with few if any inoculated mice succumbing after prolonged incubation periods, consistent with a substantial species barrier (Collinge *et al.*, 1995b; Hill *et al.*, 1997a). In sharp contrast, transgenic mice expressing only human PrP are highly susceptible to CJD prions, with 100% attack rate and consistent short incubation periods which are unaltered by second passage, consistent with a complete lack of species barrier (Collinge *et al.*, 1995b). However, vCJD prions (again comprising human PrP of identical primary structure) transmit much more readily to wild-type mice than do classical CJD prions, while transmission to transgenic mice is relatively less efficient than with classical CJD (Hill *et al.*, 1997a). The term 'species barrier' does not seem appropriate to describe such effects and 'species-strain barrier' or simply 'transmission barrier' may be preferable (Collinge, 1999). Both PrP amino acid sequence and strain type affect the three-dimensional structure of glycosylated PrP which will presumably, in turn, affect the efficiency of the protein—protein interactions thought to determine prion propagation.

Mammalian PrP genes are highly conserved. Presumably only a restricted number of different PrP^{Sc} conformations (that are highly stable and can therefore be serially propagated) will be permissible thermodynamically and will constitute the range of prion strains seen. PrP glycosylation may be important in stabilizing particular PrP^{Sc} conformations. While a significant number of different such PrP^{Sc} conformations may be possible amongst the range of mammalian PrPs, only a subset of these would be allowable for a given single mammalian PrP. Substantial overlap between the favoured conformations for PrP^{Sc} derived from species A and species B might therefore result in relatively easy transmission of prion diseases between these two species, while two species with no preferred PrP^{Sc} conformations in common would have a large barrier to transmission (and indeed transmission would

necessitate a change of strain type). According to such a conformational selection model (Collinge, 1999) of a prion transmission barrier, BSE may represent a thermodynamically highly favoured PrP^{Sc} conformation that is permissive for PrP expressed in a wide range of different species, accounting for the remarkable promiscuity of this strain in mammals. The contribution of other components to the species barrier is possible and may involve interacting co-factors which mediate the efficiency of prion propagation, although no such factors have yet been identified.

Recent data have further challenged our understanding of transmission barriers (Hill *et al.*, 2000). The assessment of species barriers has relied on the development of a clinical disease in inoculated animals. On this basis there is a highly efficient barrier limiting transmission of hamster Sc237 prions to mice. Indeed, the hamster scrapie strain Sc237, which is similar to the strain classified as 263K (Kimberlin and Walker, 1978), is regarded as non-pathogenic for mice (with no clinical disease in mice observed for up to 735 days post inoculation; Kimberlin and Walker, 1978) and was used in studies of species barriers in transgenic mice (Kimberlin and Walker, 1979; Prusiner *et al.*, 1990; Scott *et al.*, 1989). It was demonstrated that transgenic mice expressing hamster PrP (in addition to endogenous mouse PrP), in sharp contrast to conventional mice, were highly susceptible to Sc237 hamster prions with consistent short incubation periods which were inversely correlated to hamster PrP expression levels (Prusiner *et al.*, 1990; Scott and Fraser, 1989). Importantly, however, these studies defined transmission using clinical criteria and did not report PrP^{Sc} levels and types, or prion titres in the brains of clinically unaffected animals. However, while not developing a clinical disease, and indeed living as long as mock-inoculated mice, Sc237-inoculated mice may accumulate high levels of prions in their brains (Hill *et al.*, 2000). Previous studies on the species barrier between hamsters and mice (using the Sc237 or 263K strain) did not report if PrP^{Sc} and/or infectivity were present in clinically unaffected animals (Prusiner *et al.*, 1990; Scott *et al.*, 1989) or have attempted passage from mice only up to 280 days post inoculation (Kimberlin and Walker 1978). The barrier to primary passage appears in this case to be to the development of rapid neurodegeneration and the resulting clinical syndrome rather than a barrier to prion propagation itself.

PATHOGENESIS

In some experimental rodent scrapie models when prions are inoculated outside the CNS, and in natural sheep scrapie, infectivity is first detectable in the spleen and other lymphoreticular tissues (for review see Fraser *et al.*,

1992). Spleen titres rise to a plateau early in the incubation period, a considerable period before neuro-invasion is detectable. CNS prion replication then rises to high levels and the clinical phase occurs.

The route of entry of prions following oral exposure may follow invasion of Peyer's patches and other gut lymphoid tissues, the relative protease resistance of prions presumably allows a significant proportion of infectivity to survive the digestive tract. It is unclear how prions transit the intestinal mucosa although M cells may be involved (Heppner *et al.*, 2001). It has been suggested that myeloid dendritic cells mediate transport within the lymphoreticular system (LRS) (Aucouturier *et al.*, 2001). While mature B cells are required for peripheral prion propagation, this appears to be because they are required for maturation of follicular dendritic cells (FDCs). PrP^{Sc} accumulates in FDCs which are a long-lived cell type and it is thought that they are the site of prion propagation in the spleen (Mabbott *et al.*, 2000, 2003; Montasio *et al.*, 2000). However, neuro-invasion is possible without FDCs, indicating that other peripheral cell types can replicate prions (Oldstone *et al.*, 2002; Prinz *et al.*, 2002). Neuro-invasion involves the autonomic nervous system innervating lymphoid tissue with retrograde spread to the spinal cord or via the vagus to the brain stem (Beekes *et al.*, 1998; Bencsik *et al.*, 2001). Prions have been detected in the blood at low levels in some rodent models and experimental BSE-infected primates (Bons *et al.*, 2002; Brown *et al.*, 1999; Holada *et al.*, 2002) and transmission of BSE prions between sheep by transfusion has been reported (Hunter *et al.*, 2002). It is now clear that vCJD is transmissible by blood transfusion (see secondary vCJD section) (Wroe *et al.*, 2006).

While prominent lymphoreticular involvement is seen in some experimental models or natural prion diseases, it is undetectable in others (see Fraser *et al.*, 1992, for review). Both host and prion strain effects are relevant. For example infection of sheep with BSE prions results in a wide tissue distribution of infectivity but infection of cattle with this strain does not, infectivity being largely confined to the CNS. In humans infected with sporadic CJD prions, infectivity is largely confined to the CNS, while in vCJD there is prominent involvement of lymphoreticular tissues (Hill *et al.*, 1997b, 1999b; Wadsworth *et al.*, 2001). It is possible that species barrier effects are also relevant, and it has been suggested that on passage of prions in a new species, there is an obligate lymphoreticular phase.

ANIMAL PRION DISEASES

An increasing number of animal prion diseases are recognized. Scrapie, a naturally occurring disease of sheep

and goats, has been recognized in Europe for over 200 years and is present endemically in many countries. Accurate epidemiology is lacking, although scrapie appears to be relatively common in some countries. Remarkably little is known about its natural routes of transmission. TME and chronic wasting disease of mule deer and elk were described from the 1940s onwards, principally in the United States. It has more recently become apparent that chronic wasting disease is a common condition in wild deer and elk in Colorado. Again the routes of transmission are unclear. TME has occurred as infrequent epidemics amongst ranched mink and may result from food-borne prion exposure.

The appearance of BSE in UK cattle from 1986 onwards, which rapidly evolved to a major epidemic (Anderson *et al.*, 1996; Wilesmith *et al.*, 1988), was widely attributed to transmission of sheep scrapie, endemic in the United Kingdom and many other countries, to cattle via contaminated feed prepared from rendered carcasses (Wilesmith *et al.*, 1988). However, an alternative hypothesis is that epidemic BSE resulted from recycling of rare sporadic BSE cases, as cattle were also rendered to produce cattle feed. Whether or not BSE originated from sheep scrapie, it was however clear from 1990 onwards, with the occurrence of novel spongiform encephalopathies amongst domestic and captive wild cats, that its host range was different to scrapie. Many new species have developed spongiform encephalopathies coincident with or following the arrival of BSE, including greater kudu, nyala, Arabian oryx, scimitar horned oryx, eland, gemsbok, bison, ankole, tiger, cheetah, ocelot, puma and domestic cats. Several of these have been confirmed to be caused by a BSE-like prion strain (Bruce *et al.*, 1994; Collinge *et al.*, 1996b), and it is likely that most or all of these are BSE-related. More than 180 000 BSE cases have been confirmed in cattle in the United Kingdom, although the total number of infected animals has been estimated to be around 2 million. BSE has since been reported in many European countries, with significant epidemics reported in Switzerland and Portugal, and a number of other countries including Canada and Japan.

More recently, additional types of bovine prion disease have been reported in individual animals which appear to be caused by prion strains distinct from that causing epizootic BSE (Baron *et al.*, 2006). The pathogenicity of such 'atypical BSE' to humans is unknown. Also a type of sheep scrapie with a distinctive PrP^{Sc} type, known as 'atypical scrapie' has been increasingly recognized in several EU countries (Buschmann *et al.*, 2004). While this may be caused by a pre-existing sheep scrapie strain, perhaps selected by selective breeding programmes that have been used to try to eliminate endemic sheep scrapie, it will be important to investigate its potential to infect humans.

AETIOLOGY AND EPIDEMIOLOGY OF HUMAN PRION DISEASE

The human prion diseases have been traditionally classified into CJD, Gerstmann—Sträussler—Scheinker disease and kuru, and they can be further divided into three aetiological categories: sporadic, acquired and inherited.

Sporadic CJD makes up around 85% of all recognized human prion disease. It occurs in all countries with a random case distribution and an annual incidence of 1–2 per million. Hypothesized causes of sporadic CJD include spontaneous production of PrP^{Sc} via rare stochastic events, somatic mutation of *PRNP* or unidentified environmental prion exposure. An association with sheep scrapie is not supported by epidemiological studies which have found a fairly uniform worldwide incidence of sporadic CJD irrespective of scrapie prevalence (Brown *et al.*, 1987). Although spatiotemporal groupings of sporadic CJD have been previously reported (Adikari and Farmer, 2001; Farmer *et al.*, 1978), no direct evidence for exposure to a common source of infectious prions has been provided. Indeed, such apparent clustering of cases, while appearing to reach levels of significance when viewed in isolation, can be deemed to be expected by chance alone when analysed within the population as a whole (Collins *et al.*, 2002). However, the lack of such evidence does not exclude the possibility that a fraction of sporadic CJD is caused by environmental exposure to animal or human prions. There is marked genetic susceptibility in sporadic CJD in that most cases occur in homozygotes at codon 129 of *PRNP*, where either methionine or valine may be encoded. Heterozygotes appear significantly protected against developing sporadic CJD (Collinge *et al.*, 1991a; Palmer *et al.*, 1991; Windl *et al.*, 1996). Additionally, a *PRNP* susceptibility haplotype has been identified indicating additional genetic susceptibility to sporadic CJD at or near to the *PRNP* locus (Mead *et al.*, 2001).

The acquired prion diseases include iatrogenic CJD, kuru and vCJD and arise from accidental exposure to human prions through medical or surgical procedures, participation in cannibalistic feasts or dietary or other exposure to BSE prions. The two most frequent causes of iatrogenic CJD occurring through medical procedures have arisen as a result of implantation of dura mater grafts and treatment with human growth hormone derived from the pituitary glands of human cadavers (Brown *et al.*, 1992a, 2000). Less frequent incidences of human prion disease have resulted from iatrogenic transmission of CJD during corneal transplantation and surgical operations using contaminated instruments or apparatus (Brown *et al.*, 1992a, 2000). Primary and secondary vCJD are discussed

below. *PRNP* codon 129 genotype is also relevant to susceptibility and incubation period (see below).

Around 15% of human prion disease is inherited and all cases to date have been associated with coding mutations in the PrP gene (*PRNP*) of which over 30 distinct types are recognized (Figure 39.3). The inherited prion diseases can be diagnosed by *PRNP* analysis and the use of these definitive genetic diagnostic markers has allowed the recognition of a wider phenotypic spectrum of human prion disease to include a range of atypical dementias and fatal familial insomnia (FFI) (Collinge *et al.*, 1990, 1992; Medori *et al.*, 1992b). The protective effect of *PRNP* codon 129 heterozygosity is also seen in some of the inherited prion diseases, with a later age at disease onset in heterozygotes (Hsiao *et al.*, 1992).

The occurrence of cases of apparently sporadic CJD in unusually young people in 1995 (Bateman *et al.*, 1995; Britton *et al.*, 1995; Tabrizi *et al.*, 1996) led to concerns that BSE transmission to humans may have occurred. Arrival of further cases in 1996 led to the recognition of a novel clinicopathological type of human prion disease, new vCJD (Will *et al.*, 1996), indicating the arrival of a new risk factor for CJD in the United Kingdom (Collinge and Rossor, 1996). A link with BSE seemed highly likely on epidemiological grounds and this was strongly supported by experimental data, first from molecular strain typing studies (Collinge *et al.*, 1996b) and later by transmission studies into both transgenic and conventional mice (Hill *et al.*, 1997a; Bruce *et al.*, 1997). *PRNP* mutations are absent in vCJD, and all cases studied to date have been methionine homozygotes at codon 129.

The observation that vCJD is caused by the same prion strain as that causing BSE in cattle raised the possibility that a major epidemic of vCJD will occur in the United Kingdom and other countries as a result of dietary or other exposure to BSE prions and also (Collinge, 1999) concerns of potential iatrogenic transmission of pre-clinical vCJD via medical and surgical procedures. Transmission of vCJD by blood transfusion has now been documented. That only *PRNP* 129MM individuals are susceptible to BSE infection is questionable, since the other acquired human prion diseases, iatrogenic CJD and kuru, occur in all codon 129 genotypes as the epidemic evolves, with codon 129 heterozygotes having the longest mean incubation periods (Collinge, 1999; Lloyd *et al.*, 2002; Poulter *et al.*, 1992). Human BSE infection of other *PRNP* genotypes may simply have a longer latency (Collinge, 1999) and may also have a different phenotype due to propagation of different prion strains (Hill *et al.*, 1997a; Wadsworth *et al.*, 2004).

Estimates of the mean incubation period of human-to-human prion transmission come from study of growth hormone-related iatrogenic CJD and kuru.

The mean incubation period has been estimated in both examples to be around 12 years; in kuru, incubation periods can exceed 50 years (Collinge *et al.*, 2006). The effect of a species barrier is to considerably increase mean incubation periods and the range of incubation periods, which may approach the usual lifespan of the species concerned. The cattle-to-mouse barrier for the BSE strain results typically in a three- to fourfold increase in mean incubation period. Mean incubation periods of human BSE infection of 30 years or more should be considered (Collinge, 1999). Furthermore, prion disease in mice follows a well-defined course with a highly distinctive and repeatable incubation time for a given prion strain in a defined inbred mouse line. In addition to the PrP gene, a small number of additional genetic loci with a major effect on incubation period have been mapped. It can be anticipated that the human homologues of such loci may play a key role in human susceptibility to prion disease, both following accidental human prion exposure and exposure to the BSE agent. By definition, the patients identified to date with vCJD are those with the shortest incubation periods for BSE. These in turn, given that no unusual history of dietary, occupational or other exposure to BSE has been identified, would be expected to be predominantly those individuals with short incubation time alleles at these multiple genetic loci in addition to having the codon 129 methionine homozygous *PRNP* genotype. The vCJD cases reported to date may therefore represent a distinct genetic subpopulation with unusually short incubation periods to BSE prions. It is possible therefore that a human BSE epidemic will be multiphasic, and that recent estimates of the size of the vCJD epidemic based on uniform genetic susceptibility may substantially underestimate the eventual size (D'Aignaux *et al.*, 2001; Ghani *et al.*, 2000). Genes involved in species barrier effects, which would further increase both the mean and range of human BSE incubation periods, are also likely to be relevant. In this context, it will be very difficult to accurately predict a human epidemic until such loci are identified and their gene frequencies in the population can be determined (Lloyd *et al.*, 2001).

CLINICAL FEATURES AND DIAGNOSIS

With the advances in our understanding of their aetiology it now seems more appropriate to divide the human prion diseases into inherited, sporadic and acquired forms with CJD, GSS and kuru clinicopathological syndromes within a wider spectrum of disease. Kindreds with inherited prion disease have been described with phenotypes of classical CJD, GSS, and also with other

neurodegenerative syndromes including FFI. Some kindreds show remarkable phenotypic variability which can encompass both CJD- and GSS-like cases as well as other cases which do not conform to either CJD or GSS phenotypes (Collinge *et al.*, 1992). Cases diagnosed by PrP gene analysis have been reported which are not only clinically atypical but which lack the classical histological features entirely (Collinge *et al.*, 1990). Significant clinical overlap exists with familial Alzheimer's disease, frontotemporal dementias and amyotrophic lateral sclerosis with dementia. Inherited prion diseases are a frequent cause of pre-senile dementia and a family history is not always apparent: *PRNP* should be analysed in all suspected cases of CJD, and considered in all early onset dementia and ataxias. Although classical GSS is described below the inherited prion diseases should now be subclassified according to mutation. Acquired prion diseases include iatrogenic CJD, kuru and primary and secondary vCJD. Sporadic prion diseases at present consist of CJD and atypical variants of CJD. Cases lacking the characteristic histological features of CJD have been transmitted. As there are at present no equivalent aetiological diagnostic markers for sporadic prion diseases to those for the inherited diseases, it cannot yet be excluded that more diverse phenotypic variants of sporadic prion disease exist and novel phenotypes of human infection with BSE prions are likely to emerge. The key clinical features and investigations for the diagnosis of prion disease are given in Table 39.1.

Sporadic Prion Disease

Creutzfeldt-Jakob Disease

The core clinical syndrome of classic CJD is of a rapidly progressive multifocal dementia usually with myoclonus. The onset is usually in the 45–75 year age group with peak onset between 60 and 65. The clinical progression is typically over weeks, progressing to akinetic mutism and death often in two to three months. Around 70% of cases die in under six months. Prodromal features, present in around a third of cases, include fatigue, insomnia, depression, weight loss, headaches, general malaise and ill-defined pain sensations. In addition to mental deterioration and myoclonus, frequent additional neurological features include extrapyramidal signs, cerebellar ataxia, pyramidal signs and cortical blindness. About 10% of cases present initially with cerebellar ataxia.

Routine haematological and biochemical investigations are normal although occasional cases have been noted to have raised serum transaminases or alkaline phosphatase. There are no immunological markers and acute phase proteins are not elevated. Examination of the cerebrospinal fluid (CSF) is normal; 14-3-3 protein is usually elevated

Table 39.1 Diagnosis of prion disease

Disease	Characteristics
Sporadic CJD	Rapidly progressive ^a dementia with two or more of: myoclonus, cortical blindness, pyramidal signs, cerebellar signs, extrapyramidal signs, akinetic mutism Most aged 45–75 Serial EEG usually shows pseudoperiodic complexes CSF 14-3-3 protein usually positive CT normal or atrophy, MRI may show high signal in the striatum and/or cerebral cortex in FLAIR or diffusion-weighted images <i>PRNP</i> analysis: no pathogenic mutations, most are 129MM (VV and MV may be longer duration, clinically atypical and EEG less often positive) Brain biopsy should be considered in highly selected cases (to exclude treatable alternative diagnoses): PrP immunocytochemistry or Western blot for PrP ^{Sc} types 1–3 ^b
Iatrogenic CJD	Progressive cerebellar syndrome and behavioural disturbance or classical CJD-like syndrome with history of iatrogenic exposure to human prions (pituitary-derived hormones, tissue grafting or neurosurgery) May be young EEG, CSF and MRI generally less helpful than in sporadic cases <i>PRNP</i> analysis: no pathogenic mutations, most are 129 homozygotes Brain biopsy should be considered in highly selected cases (to exclude treatable alternative diagnoses): PrP immunocytochemistry or Western blot for PrP ^{Sc} types 1–3 ^b
Variant CJD	Early features: depression, anxiety, social withdrawal, peripheral sensory symptoms Cerebellar ataxia, chorea or athetosis often precedes dementia Advanced disease resembles sporadic CJD Most in young adults; however, age at onset 12–74 yr seen EEG nonspecific slow waves, CSF 14-3-3 may be elevated or normal MRI: pulvinar sign usually present (particularly using FLAIR sequence) but may be late feature <i>PRNP</i> analysis: no mutations, all 129MM to date Tonsil biopsy: characteristic PrP immunostaining and PrP ^{Sc} on Western blot (type 4t)
Iatrogenic vCJD	Has occurred in recipients of blood transfusion from a donor who subsequently developed clinical vCJD Known recipients of implicated blood or blood products in the UK have been notified of their risk status Clinical features and investigations as for primary vCJD
Inherited prion disease	Varied clinical syndromes between and within kindreds: should consider in all pre-senile dementias and ataxias irrespective of family history <i>PRNP</i> analysis: diagnostic, codon 129 genotype may predict age at onset in pre-symptomatic testing

CSF, cerebrospinal fluid; CT, computed tomography; MRI, magnetic resonance imaging; CJD, Creutzfeldt–Jakob disease.

^aClinical duration typically 6 mo or less but high variability: type 1 PrP^{Sc} associated with short duration (~8 wk); ~10% have duration >2 yr.

^bClassification of Hill *et al.* (2003).

in CJD and is a useful adjunct to diagnosis in the appropriate clinical context (Collinge, 1996). It is also positive in recent cerebral infarction or haemorrhage and in viral encephalitis, although these conditions do not usually present diagnostic confusion with CJD. It may also be elevated in rapidly progressive Alzheimer's disease which may be difficult to clinically distinguish from CJD. Neuronal specific enolase (NSE) and S-100b may be also elevated although also are not specific for CJD

and represent markers of neuronal injury (Otto *et al.*, 1997; Zerr *et al.*, 1995). Neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) is crucial to exclude other causes of subacute neurological illness, but MRI has become increasingly useful in diagnosis of sporadic CJD, showing high signal in the striatum and/or cerebral cortex in FLAIR or diffusion-weighted images (Macfarlane *et al.*, 2007). Cerebral and cerebellar atrophy may be present in longer duration cases.

Figure 39.4 Electroencephalogram in sporadic CJD.

The electroencephalogram (EEG) may show characteristic pseudoperiodic sharp wave activity which is very helpful in diagnosis but present in only around 70% of cases (Figure 39.4). To some extent demonstration of a typical EEG is dependent on the number of EEGs performed and serial EEG is indicated to try to demonstrate this appearance.

Prospective epidemiological studies have demonstrated that cases with a progressive dementia, and two or more of the following: myoclonus; cortical blindness; pyramidal, cerebellar or extrapyramidal signs; or akinetic mutism in the setting of a typical EEG nearly always turn out to be confirmed as histologically definite CJD if neuropathological examination is performed.

Neuropathological confirmation of CJD is by demonstration of spongiform change, neuronal loss and astrogliosis (Figure 39.5). PrP amyloid plaques are usually not present in CJD although PrP immunohistochemistry, using appropriate pre-treatments, will nearly always be positive. Protease-resistant PrP, seen in all the currently recognized prion diseases, can be demonstrated by immunoblotting of brain homogenates. *PRNP* analysis is important to exclude pathogenic mutations. Genetic susceptibility to CJD has been demonstrated in that most cases of classical CJD are homozygous with respect to the common 129 polymorphism of PrP (see section on Aetiology above).

Atypical forms of Creutzfeldt—Jakob disease Atypical forms of CJD are well recognized. Around 10% of cases of CJD have a much more prolonged clinical course with a disease duration of over two years. These cases

may represent the occasional occurrence of CJD in individuals heterozygous for PrP polymorphisms. Around 10% of CJD cases present with cerebellar ataxia rather than cognitive impairment, so-called ataxic CJD. Heidenhain's variant of CJD refers to cases in which cortical blindness predominates with severe involvement of the occipital lobes. The panencephalopathic type of CJD refers to cases with extensive degeneration of the cerebral white matter in addition to spongiform vacuolation of the grey matter and has been predominately reported from Japan.

Amyotrophic variants of CJD have been described with prominent early muscle wasting. However, most cases of dementia with amyotrophy are not experimentally transmissible and their relationship with CJD is unclear. Most cases are probably variants of motor neuron disease with associated dementia. Amyotrophic features in CJD are usually seen in late disease when other features are well established.

Molecular classification of sporadic CJD The marked clinical heterogeneity observed in human prion diseases has yet to be explained. However, it has been clear for many years that distinct isolates, or strains, of prions can be propagated in the same host and these are biologically recognized by distinctive clinical and pathological features (Collinge, 2001). It is therefore likely that a proportion of clinicopathological heterogeneity seen in sporadic CJD and other human prion diseases relates to the propagation of distinct human prion strains. The identification of strain-specific PrP^{Sc} structural properties would thus allow an aetiology-based classification of CJD by typing of the infectious agent itself.

Four types of human PrP^{Sc} have now been reliably identified using molecular strain typing (Collinge *et al.*, 1996b; Hill *et al.*, 1997a, 2003; Wadsworth *et al.*, 1999) (Figure 39.3). Sporadic and iatrogenic CJD are associated with PrP^{Sc} types 1–3, while type 4 human PrP^{Sc} is uniquely associated with vCJD and is characterized by a fragment size and glycoform ratio that is distinct from PrP^{Sc} types 1–3 observed in classical CJD (Collinge *et al.*, 1996b; Hill *et al.*, 1997a, 2003; Wadsworth *et al.*, 1999). The methionine/valine polymorphism at codon 129 of *PRNP* is associated with different PrP^{Sc} types. PrP^{Sc} types 1 and 4 have so far only been detected in methionine homozygotes, type 3 cases are predominantly associated with at least one valine allele, while type 2 is seen in any *PRNP* codon 129 genotype (Collinge *et al.*, 1996a, 1996b; Hill *et al.*, 1999b, 2003; Wadsworth *et al.*, 1999). PrP^{Sc} types 1 and 2 are associated with two clinically distinct subtypes of sporadic CJD and have N-terminal structures determined by the coordination of metal ions (Hill *et al.*, 2003; Wadsworth *et al.*, 1999). Importantly, the identification of strain-specific PrP^{Sc} structural properties has enabled investigation of the influence of human PrP primary structure, in particular polymorphic residue 129, in determining PrP^{Sc} structure. Transgenic mice expressing human PrP with either valine or methionine at residue 129 have revealed that this polymorphism constrains both the propagation of distinct human PrP^{Sc} conformers and the occurrence of associated patterns of neuropathology (Asante *et al.*, 2002; Collinge *et al.*, 1996b; Hill *et al.*, 1997a) (and unpublished data). These data strongly support the biological relevance of molecular strain typing which can now be applied to rapid molecular diagnosis of classical CJD or vCJD and to produce a new classification of human prion diseases. Two such classifications are in use: no internationally agreed classification has yet emerged and it is likely that additional PrP^{Sc} types or strains will be identified (Hill *et al.*, 2003; Parchi *et al.*, 1999).

Molecular strain typing has major implications for epidemiological surveillance of sporadic CJD, whose aetiology remains obscure. While spontaneous conversion of PrP^C to PrP^{Sc} as a rare stochastic event, or somatic mutation of the PrP gene, resulting in expression of a pathogenic PrP mutant, are plausible explanations for sporadic CJD (Collinge, 1997), other causes for at least some cases, including environmental exposure to human or animal prions has not been ruled out by existing epidemiological studies (Collins *et al.*, 1999). Subclassification of sporadic CJD based upon PrP^{Sc} type immediately allows a more precise molecular classification of human prion disease and re-analysis of epidemiological data using these molecular subtypes may reveal important risk factors obscured when sporadic CJD is analysed as a single entity.

For example, it will be important to review the incidence of sporadic CJD associated with PrP^{Sc} type 2 and other molecular subtypes in both BSE-affected and unaffected countries in the light of recent findings, suggesting that human BSE prion infection may result in propagation of either type 4 PrP^{Sc} or type 2 PrP^{Sc} (Asante *et al.*, 2002). Individuals that propagate type 2 PrP^{Sc} as a result of BSE exposure may present with prion disease that would be indistinguishable on clinical, pathological and molecular criteria from that found in classical CJD.

Acquired Prion Diseases

While human prion diseases can be transmitted to experimental animals by inoculation, they are not contagious in humans. Documented case-to-case spread has only occurred during ritual cannibalistic practices (kuru) or following accidental inoculation with prions during medical or surgical procedures (iatrogenic CJD and secondary vCJD).

Kuru

Kuru reached epidemic proportions amongst a defined population living in the Eastern Highlands of Papua New Guinea. The earliest cases are thought to date back to the early part of the twentieth century. Kuru affected the people of the Fore linguistic group and their neighbours with whom they intermarried. Kuru predominantly affected women and children (of both sexes), with only 2% of cases in adult males (Alpers, 1987) and was the commonest cause of death amongst women in affected villages. It was the practice in these communities to engage in consumption of dead relatives as a mark of respect and mourning. Males after the age of 6–8 participated little if at all in mortuary feasting, which is thought to explain the differential age and sex incidence. It is thought that the epidemic related to a single sporadic CJD case occurring in the region some decades earlier. Epidemiological studies provided no evidence for vertical transmission, since most of the children born after 1956 (when cannibalism had effectively ceased) and all of those born after 1959 of mothers affected with or incubating kuru were unaffected (Alpers, 1987). From the age of the youngest affected patient, the shortest incubation period is estimated as 4.5 years, although may have been shorter, since time of infection was usually unknown. The disease has gradually declined in incidence although a small number of cases have been documented in recent years with incubation periods which may exceed 50 years (Collinge *et al.*, 2006). *PRNP* codon 129 genotype has a significant effect on kuru susceptibility and most elderly survivors of the kuru epidemic are heterozygotes (Mead *et al.*, 2003). The marked survival advantage for codon 129 heterozygotes provides

a powerful basis for selection pressure in the Fore. Remarkably, an analysis of worldwide haplotype diversity and allele frequency of *PRNP* coding and noncoding polymorphisms suggests that balancing selection at this locus is much older and more geographically widespread. Evidence for balancing selection (where there is more variation than expected in a gene due to heterozygote advantage) has been demonstrated in only a few human genes. Given recent biochemical and physical evidence of cannibalism on five continents, one explanation is that ancient and worldwide cannibalism resulted in a series of prion disease epidemics in human prehistory, thus imposing balancing selection on *PRNP* (Mead *et al.*, 2003).

Kuru affects both sexes and onset of disease has ranged from age 5 to over 60. The mean clinical duration of illness is 12 months with a range of 3 months to 3 years; the course tends to be shorter in children. The central clinical feature is progressive cerebellar ataxia. In contrast to classical CJD, dementia is much less prominent, although in the later stages many patients have their faculties obtunded (Alpers, 1987). The occasional case in which gross dementia occurs is in contrast to the clinical norm. Detailed clinical descriptions have been given by a number of observers and the disease does not appear to have changed in features at different stages of the epidemic. A prodrome and three clinical stages are recognized:

Prodromal stage Kuru typically begins with prodromal symptoms consisting of headache, aching of limbs and joint pains which can last for several months.

Ambulatory stage Kuru was frequently self-diagnosed by patients at the earliest onset of unsteadiness in standing or walking, or of dysarthria or diplopia. At this stage there may be no objective signs of disease. Gait ataxia however worsens and patients develop a broad based gait, truncal instability and titubation. A coarse postural tremor is usually present and accentuated by movement; patients characteristically hold their hands together in the midline to suppress this. Standing with feet together reveals clawing of toes to maintain posture. This marked clawing response is regarded as pathognomonic of kuru. Patients often become withdrawn at this stage and occasionally develop a severe reactive depression. Prodromal symptoms tend to disappear. Astasia and gait ataxia worsen and the patient requires a stick for walking. Intention tremor, dysmetria, hypotonia and dysdiadochokinesis develop. Although eye movements are ataxic and jerky, nystagmus is rarely seen. Strabismus, usually convergent, may occur, particularly in children. This strabismus does not appear to be concomitant or paralytic and may fluctuate in both extent and type, sometimes disappearing later in the clinical course. Photophobia is common and there may be an

abnormal cold sensitivity with shivering and piloerection even in a warm environment. Tendon reflexes are reduced or normal and plantar responses are flexor. Dysarthria usually occurs. As ataxia progresses the patient passes from the first (ambulatory) stage to the second (sedentary) stage. The mean clinical duration of the first stage is around eight months and correlates closely with total duration (Alpers, 1964).

Sedentary stage At this stage patients are able to sit unsupported but cannot walk. Attempted walking with support leads to a high steppage, wide-based gait with reeling instability and flinging arm movements in an attempt to maintain posture. Hyperreflexia is seen although plantar responses usually remain flexor with intact abdominal reflexes. Clonus is characteristically short lived. Athetoid and choreiform movements and parkinsonian tremors may occur. There is no paralysis, although muscle power is reduced. Obesity is common at this stage but may be present in early disease associated with bulimia. Characteristically, there is emotional lability and bizarre uncontrollable laughter, which has led to the disease being referred to as 'laughing death'. There is no sensory impairment. In sharp contrast to CJD, myoclonic jerking is rarely seen. EEG is usually normal or may show nonspecific changes (Cobb *et al.*, 1973). This stage lasts around two to three months. When truncal ataxia reaches the point where the patient is unable to sit unsupported, the third or tertiary stage is reached.

Tertiary stage Hypotonia and hypo-reflexia develop and the terminal state is marked by flaccid muscle weakness. Plantar responses remain flexor and abdominal reflexes intact. Progressive dysphagia occurs and patients become incontinent of urine and faeces. Inanition and emaciation develop. Transient conjugate eye signs and dementia may occur. Primitive reflexes develop in occasional cases. Brainstem involvement and both bulbar and pseudobulbar signs occur. Respiratory failure and bronchopneumonia eventually lead to death. The tertiary stage lasts one to two months.

Iatrogenic Creutzfeldt—Jakob Disease

Iatrogenic transmission of CJD has occurred by accidental inoculation with human prions as a result of medical procedures. Such iatrogenic routes include the use of inadequately sterilized neurosurgical instruments, dura mater and corneal grafting, and use of human cadaveric pituitary-derived growth hormone or gonadotrophin. It is of considerable interest that cases arising from intracerebral or optic inoculation manifest clinically as classical CJD, with a rapidly progressive dementia, while those resulting from peripheral inoculation, most notably

following pituitary-derived growth hormone exposure, typically present with a progressive cerebellar syndrome, and are in that respect somewhat reminiscent of kuru. Unsurprisingly the incubation period in intracerebral cases is short (19–46 months for dura mater grafts) as compared to peripheral cases (typically 15 years or more). There is evidence for genetic susceptibility to iatrogenic CJD with an excess of codon 129 homozygotes (Collinge *et al.*, 1991a).

Epidemiological studies have not shown increased risks of particular occupations that may be exposed to human or animal prions, although individual CJD cases in two histopathology technicians, a neuropathologist and a neurosurgeon have been documented. While there have been concerns that CJD may be transmissible by blood transfusion, extensive epidemiological analysis in the United Kingdom has found that the frequency of blood transfusion and donation was no different in over 200 cases of CJD and a matched control population (Esmonde *et al.*, 1993). Recipients of blood transfusions who developed CJD had clinical presentations similar to those of sporadic CJD patients and not to the more kuru-like iatrogenic cases arising from peripheral exposure to human prions. Furthermore, experimental transmission studies have shown only weak evidence for infectivity in blood, even when inoculated via the most efficient (intracerebral) route. Iatrogenic (secondary) vCJD related to blood transfusion has, however, been recognized (see below).

Variant CJD

In late 1995, two cases of sporadic CJD were reported in the United Kingdom in teenagers (Britton *et al.*, 1995). Only four cases of sporadic CJD had previously been recorded in teenagers, and none of these cases occurred in the United Kingdom. In addition, both cases were unusual in having kuru-type plaques, a finding seen in only around 5% of CJD cases. Soon afterwards a third very young sporadic CJD case occurred. These cases caused considerable concern and the possibility was raised that they might suggest a link with BSE. By March 1996, further extremely young onset cases were apparent and review of the histology of these cases showed a remarkably consistent and unique pattern. These cases were named 'new variant' CJD although it was clear that they were also rather atypical in their clinical presentation; in fact most cases did not meet the accepted clinical diagnostic criteria for probable CJD. Extensive studies of archival cases of CJD or other prion diseases failed to show this picture and it seemed that it did represent the arrival of a new form of prion disease in the United Kingdom. The statistical probability of such cases occurring by chance was vanishingly small and ascertainment bias seemed most unlikely as an explanation. It was clear that a new risk

factor for CJD had emerged and appeared to be specific to the United Kingdom. The UK Government Advisory Committee on Spongiform Encephalopathy (SEAC) concluded that, while there was no direct evidence for a link with BSE, exposure to specified bovine offal (SBO) prior to the ban on its inclusion in human foodstuffs in 1989, was the most likely explanation. A case of vCJD was soon after reported in France. Direct experimental evidence that vCJD is caused by BSE was provided by molecular analysis of human prion strains and transmission studies in transgenic and wild-type mice (see section on Aetiology above). While it is now clear that vCJD is caused by infection with BSE prions, it is unclear why this particular age group should be affected and why none of these cases had a pattern of unusual occupational or dietary exposure to BSE. However, very little is known of which foodstuffs contained high-titre bovine offal. It is possible that certain foods containing particularly high titres were eaten predominantly by younger people. An alternative is that young people are more susceptible to BSE following dietary exposure or that they have shorter incubation periods. A possible age-related co-factor could be coexistent infection involving lymphoid tissue, for example tonsillar infection. It is important to appreciate that BSE-contaminated feed was fed to sheep, pigs and poultry and that although there is no evidence of natural transmission to these species, it would be prudent to remain open-minded about other dietary exposure to novel animal prions.

vCJD has an insidious clinical onset and its early features are highly non-specific. The clinical presentation is often with behavioural and psychiatric disturbances and in some cases with sensory disturbance. Initial referral has frequently been to a psychiatrist and the most prominent feature is depression, but anxiety, social withdrawal and behavioural change is frequent. Suicidal ideation is infrequent and response to antidepressants poor. Delusions, which are complex and unsustained, are common. Other features include emotional lability, aggression, insomnia and auditory and visual hallucinations. A prominent early feature in some is dysaesthesiae or pain in the limbs or face or pain which is persistent rather than intermittent and unrelated to anxiety levels. A minority of cases have been noted to have forgetfulness or mild gait ataxia from an early stage but in most cases overt neurological features are not apparent until some months into the clinical course. In most patients a progressive cerebellar syndrome develops with gait and limb ataxia. Overt dementia then occurs with inevitable progression to akinetic mutism. Myoclonus is seen in most patients, and chorea is often present which may be severe in some patients. Cortical blindness develops in a minority of patients in the late stages of disease. Uppage paresis, an uncommon feature

Figure 39.5 Neuropathology of sporadic and variant CJD. Mild spongiform vacuolation of the cortical grey matter is a hallmark of Creutzfeldt–Jakob disease. (a) In this case there was no deposition of kuru-like plaques but widespread deposition of abnormal prion protein in a synaptic pattern. (b) This hallmark of variant CJD can be found in several cortical areas and in the cerebellum, and may be associated with vacuolar degeneration. Immunostaining for the pathological prion protein (using monoclonal antibody KG9) highlights the florid plaques but also reveals synaptic staining. (c) In contrast, variant CJD is characterized by frequent so-called florid plaque consisting of a round amyloid core, surrounded by a daisy-like vacuolation. (d) Scale bar 50 μm .

of classical CJD, has been noted in some patients. The age at onset in the initial 14 cases reported ranged from 16 to 48 years (mean 29 years) and the clinical course was unusually prolonged (9–35 months, median 14 months). The age range of cases has since broadened, with ages at onset ranging from 12 to 74 years, although the mean remains around 28 years. The EEG is abnormal, most frequently showing generalized slow wave activity, but without the pseudoperiodic pattern seen in most sporadic CJD cases. Neuro-imaging by CT is either normal or shows only mild atrophy. The most useful non-invasive investigation in advanced cases is magnetic resonance neuro-imaging, particularly the FLAIR sequence (Collie *et al.*, 2003). Early case reports noted bilateral increased signal in the posterior thalamus (pulvinar) on T2 weighted images (Chazot *et al.*, 1996). A retrospective review of 36 histologically confirmed cases of vCJD suggested that the ‘pulvinar sign’ occurred frequently in advanced cases of vCJD (Zeidler *et al.*, 2000) with a sensitivity and specificity of up to 86% and 96% respectively (Figure 39.6). However this sign appears a late feature of the disease process. Histologically confirmed cases of vCJD with minimal or absent pulvinar changes at a mean 10.5 months during an illness of mean 15 months duration were identified in this series. Figures of 81% sensitivity and 94% specificity

have also been reported in a series including 27 cases of vCJD diagnosed by tonsil biopsy (Siddique *et al.*, 2005). As these studies suggest, the pulvinar sign is not specific for vCJD. These MRI appearances are described in sporadic CJD and paraneoplastic limbic encephalitis, both of which are important considerations in the differential diagnosis of patients with suspected vCJD. Pulvinar signal change on MRI is also reported in a number of rare conditions which might otherwise be distinguished from vCJD on clinical grounds, such as benign intracranial hypertension, status epilepticus associated with cat scratch disease, Alpers’ disease and post-infectious encephalitis. The absence of pulvinar sign does not exclude a diagnosis of vCJD.

Tonsillar biopsy remains the most sensitive and specific diagnostic procedure for vCJD (Hill *et al.*, 1997b, 1999b; Hilton *et al.*, 2004b; Wadsworth *et al.*, 2001) (Figure 39.7). Tonsillar PrP^{Sc} is uniformly present in clinically affected cases of vCJD but not in other forms of human prion disease, including iatrogenic CJD associated with use of human cadaveric-derived pituitary hormones, arguing that this distinctive pathogenesis relates to effect of prion strain rather than to a peripheral route of infection (Hill *et al.*, 1999b; Hilton *et al.*, 2004b; Wadsworth *et al.*, 2001). As infection of lymphoreticular tissues is

Figure 39.6 MRI signs in human prion disease: pulvinar sign in vCJD.

Figure 39.7 Tonsil biopsy in vCJD.

thought to precede neuro-invasion, and indeed has been detected in archived surgical samples removed prior to development of vCJD (Hilton *et al.*, 1998, 2004a), it is likely to allow firm diagnosis at the early clinical stage or indeed preclinically (Collinge, 2005b). The PrP^{Sc} type detected on Western blot in vCJD tonsil has a characteristic pattern designated type 4t. A positive tonsil biopsy obviates the need for brain biopsy which may otherwise be considered in such a clinical context to exclude alternative, potentially treatable diagnoses. CSF 14-3-3 protein may be elevated or normal. *PRNP* analysis is essential to rule out pathogenic mutations, as the inherited prion diseases present in younger patients and may clinically mimic vCJD. It is particularly important to exclude mutations prior to tonsil biopsy. Remarkably, to date all clinical cases of vCJD have been of the *PRNP* codon 129MM genotype (see section on Aetiology above).

The neuropathological appearances of vCJD are striking and relatively consistent, generally allowing differentiation from other forms of prion disease. While there is widespread spongiform change, gliosis and neuronal loss, most severe in the basal ganglia and thalamus, the most remarkable feature is abundant PrP amyloid plaques in cerebral and cerebellar cortex. These consist of kuru-like, 'florid' (surrounded by spongiform vacuoles) and multi-centric plaque types. The 'florid' plaques, seen previously only in scrapie, are a consistent feature. There is also abundant pericellular PrP deposition in the cerebral and cerebellar cortex. A further unusual feature is extensive PrP deposition in the molecular layer of the cerebellum. Western blot analysis (molecular strain typing, see section on Aetiology above) of brain tissue demonstrates PrP^{Sc} type 4 which is pathognomonic of vCJD.

Some of the features of vCJD are reminiscent of kuru, in which behavioural changes and progressive ataxia predominate. In addition, peripheral sensory disturbances are well recognized in the kuru prodrome. Kuru plaques are seen in around 70% of cases and are especially abundant in younger kuru cases. The observation that iatrogenic prion disease related to peripheral exposure to human prions has a more kuru-like than CJD-like clinical picture may well be relevant and would be consistent with a peripheral prion exposure.

The relatively stereotyped clinical presentation and neuropathology of vCJD contrasts sharply with sporadic CJD. This may be because vCJD is caused by a single prion strain and may also suggest that a relatively homogeneous genetically susceptible subgroup of the population with short incubation periods to BSE has been selected to date.

Secondary (Iatrogenic) vCJD

The prominent lymphoreticular involvement raised early concerns that vCJD may be transmissible by blood transfusion. Indeed the tissue distribution is similar to that of ovine scrapie, where prionaemia has been demonstrated experimentally. In 2004, two transfusion-associated cases of vCJD prion infection were reported amongst a small cohort of patients identified as having received blood from a donor who subsequently developed vCJD (Llewelyn *et al.*, 2004; Peden *et al.*, 2004). One patient had had a typical clinical course of vCJD although the diagnosis was not made until autopsy, and had the *PRNP* codon 129MM genotype. The second, who died of an unrelated condition, was found to have prion infection at autopsy. This patient had the *PRNP* codon 129MV genotype, which is associated with relative resistance to prion disease. Subsequently two further patients have been diagnosed with vCJD during life from this group of 23 known surviving

recipients of implicated blood. That four out of 23 patients have been infected, three dying of vCJD, in each case following transfusion with a single unit of implicated red cells, suggests the risk to recipients of blood from a silently infected donor is very substantial (Wroe *et al.*, 2006). The incubation period in the clinical cases was six to seven years. Since 2003, all known recipients of implicated blood have been notified of their status. Over 6000 individuals in the United Kingdom have been exposed to blood products prepared from large donor pools containing blood from a donor who went on to develop vCJD. None of these individuals, predominantly haemophiliacs, have yet developed vCJD.

Other Phenotypes of BSE Infection in Humans

The relatively stereotyped clinical presentation and neuropathology of vCJD contrasts sharply with sporadic CJD. This may be because vCJD is caused by a single prion strain and may also suggest that a relatively homogeneous genetically susceptible subgroup of the population with short incubation periods to BSE has been selected to date (Collinge, 1999). A widening of the recognized phenotypic range of vCJD from that based on the earliest patients can be anticipated and indeed is already emerging. Other phenotypic presentations of BSE prion infection in humans, particularly involving other *PRNP* genotypes, are to be anticipated (Hill *et al.*, 1997a; Wadsworth *et al.*, 2004). It will be important to remain open-minded about such phenotypes. Recent studies in transgenic mice expressing human PrP have shown that BSE infection can result in two distinct phenotypes, one with the neuropathological and molecular phenotype of vCJD and a second with the molecular phenotype of the commonest subtype of sporadic CJD (associated with PrP^{Sc} type 2) (Asante *et al.*, 2002). This raises the possibility that BSE infection of humans could also cause some cases of apparently sporadic CJD.

Inherited Prion Diseases

Gerstmann—Sträussler—Scheinker Disease

The first case was described by Gerstmann in 1928 and was followed by a more detailed report on seven other affected members of the same family in 1936 (Gerstmann *et al.*, 1936). The classical presentation of GSS is with a chronic cerebellar ataxia accompanied by pyramidal features, with dementia occurring later in a much more prolonged clinical course than that seen in CJD. The mean duration is around five years, with onset usually in either the third or fourth decades. Histologically, the hallmark is the presence of multicentric amyloid plaques. Spongiform change, neuronal loss, astrocytosis and white matter

loss are also usually present. Numerous GSS kindreds from several countries (including the original Austrian family described by Gerstmann *et al.*, 1936) have now been demonstrated to have mutations in the PrP gene. GSS is an autosomal dominant disorder, which can now be classified within the spectrum of inherited prion disease.

Inherited Prion Diseases

The identification of one of the pathogenic PrP gene mutations in a case with neurodegenerative disease allows not only molecular diagnosis of an inherited prion disease but also its subclassification according to mutation (Figure 39.8). Over 30 pathogenic mutations are reported in the human PrP gene and consist of two groups: (i) point mutations within the coding sequence resulting in amino acid substitutions in PrP or production of a stop codon resulting in expression of a truncated PrP and (ii) insertions encoding additional integral copies of an octapeptide repeat present in a tandem array of five copies in the normal protein (octapeptide repeat insertion (OPRI)). A suggested notation for these diseases is 'inherited prion disease (PrP mutation)', for instance: inherited prion disease (PrP 6 OPRI) or inherited prion disease (PrP P102L). Brief details of the more commonly seen types are given below (for a more comprehensive review see Collinge, 2005a). *PRNP* analysis should be considered in all early-onset dementing or ataxic disorders and is available from the UK National Prion Clinic (see <http://www.nationalprionclinic.org>).

PrP P102L This mutation was first reported in 1989 in a UK and US family and has now been demonstrated in many other kindreds worldwide. Progressive ataxia is the dominant clinical feature, with dementia and pyramidal features. However marked variability both at the clinical and neuropathological level is apparent in some families. A family with marked amyotrophic features has also been reported and cases with severe dementia in the absence of prominent ataxia are also recognized.

PrP A117V This mutation has been described in families from France, the United States and the United Kingdom. The clinical features are pre-senile dementia associated with pyramidal signs, parkinsonism, pseudobulbar features and cerebellar signs. Parkinsonian features may predominate in the early stages and mimic Parkinson's disease.

PrP D178N This mutation was originally described in two Finnish families with a CJD-like phenotype and has since been demonstrated in families in Hungary, the

suggesting a separate UK focus for this type of inherited prion disease.

PrP 6 OPRI This was the first PrP mutation to be reported and was found in a small UK family with familial CJD (Owen *et al.*, 1989) now known to form part of the largest known kindred with an inherited prion disease caused by an OPRI mutation. The diagnosis in the family had been based on an individual who died in the 1940s with a rapidly progressive illness characteristic of CJD. The reported duration of illness was six months. Pathologically there was gross status spongiosis and astrocytosis affecting the entire cerebral cortex, and this case is used to illustrate classic CJD histology in Greenfield's *Neuropathology*. However, other family members had a much longer duration GSS-like illness. Histological features were also extremely variable. This observation led to screening of various case of neurodegenerative disease and to the identification of a case classified on clinical grounds as familial Alzheimer's disease (Collinge *et al.*, 1989). More extensive screening work identified further families with the same mutation which were then demonstrated by genealogical studies to form part of an extremely large kindred (Collinge *et al.*, 1992; Mead *et al.*, 2006; Poulter *et al.*, 1992). Clinical information has been collected on over 80 affected individuals over seven generations. Affected individuals develop in the third to fourth decade onset of a progressive dementia associated with a varying combination of cerebellar ataxia and dysarthria, pyramidal signs, myoclonus and occasionally extrapyramidal signs, chorea and seizures. The dementia is often preceded by depression and aggressive behaviour. A number of cases have a long-standing personality disorder, characterized by aggression, irritability, antisocial and criminal activity and hypersexuality which may be present from early childhood, long before overt neurodegenerative disease develops. The histological features vary from those of classical spongiform encephalopathy (with or without PrP amyloid plaques) to cases lacking any specific features of these conditions (Collinge *et al.*, 1990). Age at onset in this condition can be predicted according to genotype at polymorphic codon 129. Since this pathogenic insertional mutation occurs on a methionine 129 PrP allele, there are two possible codon 129 genotypes for affected individuals, methionine 129 homozygotes or methionine 129/valine 129 heterozygotes. Heterozygotes have an age at onset which is about a decade later than homozygotes (Poulter *et al.*, 1992).

MOLECULAR DIAGNOSIS OF PRION DISEASE

While sporadic CJD can often, following the exclusion of other causes, be diagnosed with a high degree of

confidence on the basis of clinical criteria, atypical forms, which present much greater diagnostic difficulty, are not uncommon (Collinge, 1998). A widening of the recognized phenotypic range of vCJD from that based on the earliest patients can be anticipated and indeed is already emerging. Other phenotypic presentations of BSE prion infection in humans, particularly involving other *PRNP* genotypes, are to be anticipated. Furthermore, current clinically based diagnostic criteria for vCJD used for surveillance require the evolution of disease over at least six months and the development of several signs indicative of extensive cerebral damage. However, early diagnosis, before extensive irreversible brain damage has occurred, is crucial in such patients as they be suffering from an alternative treatable disorder. Brain biopsy may well be considered, particularly in younger patients, to exclude such conditions as cerebral vasculitis. Early tonsil biopsy, if positive, obviates the need for further investigation. The need for early, specific diagnosis is now further emphasized by the arrival of potential therapies and clinical trials for CJD. The early clinical features of vCJD—depression, anxiety, behavioural change and sensory disturbances—are highly nonspecific. Differentiation from much commoner psychiatric causes requires the arrival of overtly neurological features such as ataxia, chorea and cognitive decline, although pre-existing use of neuroleptics and other psychotropic drugs may initially delay their diagnostic recognition. While the diagnostic accuracy provided by a tonsil biopsy has to be balanced against the fact that it is an invasive procedure, early referral for investigation should allow much earlier diagnosis and access to clinical trials before extensive functional loss has occurred.

While neurologists have until recent years had to rely largely on clinical features to differentiate neurodegenerative disorders, the major advances in molecular genetics and in understanding molecular pathogenesis increasingly enable diagnosis using criteria higher in the diagnostic hierarchy of pathology. Around 15% of recognized prion disease is an inherited mendelian disorder associated with one of the more than 30 recognized coding mutations in *PRNP* (Collinge, 2001). For a single gene inherited disorder of high penetrance, such as inherited prion disease, the diagnostic supremacy of direct demonstration of causative mutation by DNA analysis is clear. Indeed, the availability of such definitive diagnostic markers has long allowed diagnosis of inherited prion disease in patients not only atypical on clinical grounds, but in whom classical neuropathological features are absent (Collinge *et al.*, 1989, 1990). Kindreds are documented in which some individuals have the classical syndromes of 'CJD' and 'Gerstmann—Sträussler—Sheinker disease' while others do not fit these rubrics at all (Collinge *et al.*, 1992).

Neuropathology in such patients is no longer the 'gold standard': rather the recognized clinicopathological manifestation of a particular inherited condition simply widens.

The acquired prion diseases, such as vCJD, although not contagious in humans, are infectious diseases. In infectious disease, while again clinical and histopathological features may be key, confirmation of diagnosis, not least in life-threatening conditions, is by identification of the infectious pathogen itself or a specific immune response to it. Isolation and strain typing of the pathogen is at the apex of the diagnostic hierarchy. Strain typing in particular may allow the source of an outbreak to be identified and the best available prognostic and therapeutic advice to be provided. While it is essential to balance the potential risks and discomfort involved in an invasive diagnostic test against the improved diagnostic accuracy, it will only be by progressing steadily to greater use of molecular analysis of neurological disease that we will be able to deliver the diagnostic and ultimately therapeutic advances to patients with neurodegenerative diseases that are so desperately needed.

PRE-SYMPTOMATIC AND ANTENATAL TESTING

Direct gene testing allows unequivocal diagnosis in patients with inherited forms of the disease and pre-symptomatic testing of unaffected but at-risk family members, as well as antenatal testing (Collinge *et al.*, 1991b). Because of the effect of *PRNP* codon 129 genotype on the age of onset of disease associated with some mutations it is possible to determine within a family whether a carrier of a mutation will have an early or late onset of disease. Most of the mutations appear to be fully penetrant, however experience with some is extremely limited. In some families, for example with E200K or D178N (FFI), there are examples of elderly unaffected gene carriers who appear to have escaped the disease. Genetic counselling is essential prior to pre-symptomatic testing and follows a protocol similar to that established for Huntington's disease. A positive PrP gene analysis has important consequences for other family members, and it is preferable to have discussed these issues with others in the immediate family before testing. Following the identification of a mutation the wider family should be referred for genetic counselling. It is vital to counsel both those testing positive for mutations and those untested but at-risk that they should not be blood or organ donors and should inform surgeons, including dentists, of their risk status prior to significant procedures as precautions may be necessary to minimize risk of iatrogenic transmission.

PREVENTION AND PUBLIC HEALTH MANAGEMENT

While prion diseases can be transmitted to experimental animals by inoculation, it is important to appreciate that they are not contagious in humans. Documented case-to-case spread has only occurred by cannibalism (kuru) or following accidental inoculation with prions. Such iatrogenic routes include the use of inadequately sterilized intracerebral electrodes, dura mater and corneal grafting, and from the use of human cadaveric pituitary-derived growth hormone or gonadotrophin. As discussed above, there is now evidence that vCJD prion infection is transmissible by blood transfusion. UK policy for some time has been to leuco-deplete all whole blood and to source plasma for plasma products from outside the United Kingdom.

A further possible route of transmission of vCJD is via contaminated surgical instruments. Prions resist conventional sterilization methods and neurosurgical instruments are known to be able to act as a vector for prion transmission: several cases of iatrogenic transmission of sporadic CJD prions via neurosurgical instruments are documented (Bernoulli *et al.*, 1977; Blattler, 2002). Recent evidence suggests that classical CJD may also be transmitted by other surgical procedures (Collins *et al.*, 1999). In the United Kingdom, all surgical instruments used on patients with suspected CJD are quarantined and not re-used unless an alternate non-prion diagnosis is unequivocally confirmed.

The pathogenesis of vCJD differs sharply from that of sporadic and other forms of 'classical' CJD. In particular, in vCJD there is extensive involvement of the LRS (lymph nodes, tonsil and spleen) with the highest levels of PrP^{Sc} outside the CNS being found in tonsil, where levels are typically 5–10% of brain levels (Wadsworth *et al.*, 2001). PrP^{Sc} is also detectable, at lower levels, in the thymus, rectum, adrenal and retina in vCJD (Wadsworth *et al.*, 2001). This wider tissue distribution raises further concerns about iatrogenic transmission of vCJD via surgical instruments previously used on patients with pre-clinical vCJD prion infection. The number of individuals incubating vCJD, but asymptomatic currently, is unknown but may be substantial. Prions adhere avidly to stainless steel and transmit the disease readily in experimental models (Flechsigs *et al.*, 2001). Tonsillar PrP^{Sc} is readily detectable in all cases of vCJD studied at autopsy and lymphoreticular involvement is a very early feature of natural prion infection in sheep and in experimental scrapie models, where replication in the LRS is detectable early in the incubation period and rises to a plateau, which considerably precedes, and is maintained in, the clinical phase (Fraser *et al.*, 1992). This suggests that tonsillar

PrP^{Sc} has probably been present for a considerable period, perhaps years, before clinical presentation of vCJD in humans and therefore tonsil biopsy should enable diagnosis at the earliest stages of clinical suspicion. In addition, this pathogenesis forms the basis of prevalence screening of the general population for infection. A retrospective study of archived surgical lymphoreticular specimens estimated a much higher prevalence of infection in the UK population of 237 per million (95% confidence interval 49–692 per million) (Hilton *et al.*, 2004b) than the number of clinical cases would so far suggest. This worrying finding led to the Chief Medical Officer commissioning a much larger, prospective, national-scale anonymous screen of discarded tonsillectomy tissue. However, it must be appreciated that the sensitivity of such tests at different points in the prolonged incubation period and in different genotypes is unknown so that such studies may underestimate significantly the prevalence of vCJD prion infection in the community.

Certain occupational groups are at risk of exposure to human prions, for instance neurosurgeons and other operating theatre staff, pathologists and morticians, histology technicians, as well as an increasing number of laboratory workers. Because of the prolonged incubation periods to prions following administration to sites other than the CNS, which is associated with clinically silent prion replication in the lymphoreticular tissue, treatments inhibiting prion replication in lymphoid organs may represent a viable strategy for rational secondary prophylaxis after accidental exposure. A preliminary suggested regimen is a short course of immunosuppression with oral corticosteroids in individuals with significant accidental exposure to human prions (Aguzzi and Collinge, 1997).

PROGNOSIS AND TREATMENT

All recognized prion diseases are invariably fatal following a progressive course. The duration of illness in sporadic patients is very short, with a mean duration of three to four months, although in some of the inherited cases the duration can be 20 years or more. There have been significant recent advances in understanding prion propagation and neurotoxicity and clear proof of principle studies of several therapeutic or secondary prophylactic approaches in animal models, suggesting effective therapeutics for human disease is realistic (Mallucci and Collinge, 2005).

A variety of drugs have been tried in individual or small numbers of patients over many years. There is no clear evidence of efficacy of any agent, and controlled clinical trials are needed. Such trials are highly challenging. Prion diseases are rare, often rapidly progressive and always fatal, which may make randomization to placebo

unacceptable. Patterns of disease overall are extremely variable with clinical durations varying from weeks to more than two years in sporadic CJD, and >20 years in some inherited prion diseases. As ‘first generation’ treatments proposed for prion disease are likely, at best, to have only a modest effect on disease progression, even using survival duration as an outcome measure requires study of large numbers to reliably assess efficacy. There is a lack of systematic natural history studies of disease progression and an absence of biological markers of disease activity. In the United Kingdom, at the request of the Government’s Chief Medical Officer, a clinical trial protocol (www.nationalprionclinic.org) and infrastructure has been developed to rigorously assess the drug quinacrine (Korth *et al.*, 2001) and to provide a framework for assessment of novel therapeutics as these become available: the Medical Research Council (MRC) PRION-1 trial. Importantly under these circumstances, a formal consultation with patient’s representatives was organized to refine the protocol so that it would be acceptable to the majority of potential participants (www.nationalprionclinic.org). Pentosan polyphosphate is another candidate anti-prion drug and has shown some efficacy in animal models. Unlike quinacrine, it does not enter the CNS readily and has been administered by intraventricular infusion in several patients. Major toxicity has been reported by this route in animal studies and such treatment was not supported by the UK’s Committee of Safety on Medicines or CJD Therapy Advisory Group. A report summarizing clinical experience to date with this treatment has been produced (Medical Research Council, 2006).

While the precise molecular events in prion propagation are not clear, it is clear that PrP^C is the essential substrate. Interference with PrP^C expression in adult brain is without serious effect and blocks onset of neurological disease in animal models (Mallucci and Collinge, 2005). It should be possible to identify small molecules which penetrate the CNS to bind to PrP^C and to prevent its recruitment into prions, or to use one of a number of emerging technologies to reduce PrP^C expression in brain. If such methods are able to reduce prion propagation rates to below those of natural clearance mechanisms it ought to be possible to cure prion infection. New methods for early diagnosis—and their timely use—will be crucial, as such methods will not reverse neuronal cell loss which is appreciable or severe by the time clinical diagnosis is typically reached. Proof of principle studies in animal models suggest that humanized anti-PrP monoclonal antibodies could be used for passive immunization in the early pathogenesis to block neuro-invasion. This treatment could be considered for known iatrogenically infected individuals (Wroe *et al.*, 2006).

CONCLUDING REMARKS

Prion diseases appear to be diseases of protein conformation and elucidating their precise molecular mechanisms may, in addition to allowing us to progress with tackling key public health issues posed by vCJD, be of wider significance in pathobiology. Common themes are emerging in neurodegenerative diseases, many of which are also associated with aggregates of misfolded protein. Also, the apparent ability of a single polypeptide chain to encode information and specify distinctive phenotypes is unprecedented and evolution may have used this mechanism in many other ways. While the protein-only hypothesis of prion propagation is supported by compelling experimental data, and now appears also able to encompass the phenomenon of prion strain diversity, the goal of the production of high-titre prions *in vitro* and atomic-level structures of infectious prion strains remains.

Subject Index

Notes:

Entries for the major viruses and the resultant infections have been kept separate for convenience. In such cases, antibodies, diagnostic techniques and vaccines have been listed under the entry relating to the infection, not the virus.

Page numbers in *italics* refer to figures and tables.

This index is in letter-by-letter order, whereby spaces and hyphens between words are excluded from alphabetization (e.g. B lymphocytes comes after blue river virus, and not at the start of the 'B' section)

Abbreviations:

3TC *see* lamivudine (3TC)

CCHF - Crimean-Congo haemorrhagic fever

CMV - cytomegalovirus

EEEV - Eastern equine encephalitis virus

HAM/TSP - HTLV-associated

myelopathy/tropical spastic paraparesis

HBV - hepatitis B virus

HCV - hepatitis C virus

HCWs - health-care workers

HHV - human herpesvirus (e.g. HHV-6)

HIV - human immunodeficiency virus

HPIV - human parainfluenza virus

HPV - human papillomavirus

HSCT - haematopoietic stem cell transplant

HSV - herpes simplex virus

KSHV - Kaposi's sarcoma-associated
herpesvirus (HHV-8)

MCD - multicentric Castleman's disease

PCR - polymerase chain reaction

PIV - parainfluenza virus

PML - progressive multifocal
leukoencephalopathy

PTLD - post-transplant lymphoproliferative
disease

SSPE - subacute sclerosing panencephalitis

TK - thymidine kinase

VEEV - Venezuelan equine encephalitis virus

WEEV - Western equine encephalitis virus
14–13–13 protein 949–950

 viral quasispecies 18, 523
 viral shedding, qualitative detection of virus 16
- viramide, hepatitis C 315
- virologists, communication with physicians
 22
- viroplasm, rotaviruses 339
- 'virtual phenotyping' 20
- virus amplification, in hospitals 43
- viruses
 persistence in environment 49
 physical characteristics 50–51
- virus isolation 2–3, 3
- VITROS ECI assay, HIV 908
- VLA-2, echovirus receptor 605
- VX-950, hepatitis C treatment 316
- ## W
- Wanowrie virus 703, 726
- Warthin–Finkeldy cells 543
- warts
 genital 814, 816, 817
 laryngeal 813, 815
 plantar 813, 817
- Wesselsbron virus 673, 679
- West Caucasian bat virus 779
- Western blotting 6
 HIV infection 906–907
 HTLVs 879, 880
- western equine encephalitis virus (WEEV) 643,
 644, 658–659
 clinical disease 658
 diagnosis 659
 epidemiology and host range 658, 659
 prevention and control 659
- western tick-borne encephalitis virus
 (W-TBEV) 692, 693
- West Nile fever
 clinical features 690
 control 690
 diagnosis and antibodies 688, 690

West Nile fever (*contd.*)
 epidemics and outbreaks 689–690
 epidemiology 689–690
 meningoencephalitis 75
 neuro-invasive disease 688, 690
 rubella differential diagnosis 567

West Nile virus (WNV) 75, 669, 673, 688–690
 characteristics and host range 688–689
 isolation 690
 lineages (I–IV) 688
 NY99 prototype 688
 transmission cycle 689
 vectors 688, 689

Whataroa virus (WHAV) 644

wheezing, recurrent, RSV infection 449–450, 454

Whitewater Arroyo virus 734, 738, 751
 detection 741
 infections 751

whole-genome sequencing, influenza virus 395

whooping cough, vaccination coverage
 reduction 90

winter vomiting disease 54

woodchuck hepatitis virus (WHV) 284

World Health Organization (WHO)
 detection/response on infections 23
 poliomyelitis eradication programme 618
 rabies vaccine recommendations 800
 rubella vaccination recommendations 585, 585–586, 586
 SARS prevention recommendations 62

WU virus 74

Wyeomyia virus 702, 707

X

xenotropic MuLV-related virus (XMRV) 872

xenotropic murine leukaemia related virus (XMRV) 77

X-linked lymphoproliferative syndrome (X-LPS) 216

Y

yattapox virus, host, distribution 626

yeast prions 944

yellow fever 672, 674–678
 abortive infection 676
 age and gender affecting 677
 clinical features 676–677
 control 677–678
 diagnosis 677
 differential diagnosis 676
 ‘enzootic forest cycle’ 674
 epidemics 674
 epidemiology 672, 674–676
 Africa 674, 675
 Americas 674, 675, 677
 haemorrhagic diathesis 676
 history 672
 incubation period 676
 ‘jungle yellow fever cycle’ 674, 676
 mortality 676
 surveillance for 677
 transmission cycles 674, 676
 universal/mass immunization 678
 ‘urban yellow fever cycle’ 676, 677
 vaccine 677–678
 contraindications 678
 French neurotropic 678
 pregnancy 678
 production volume 678
 side effects 678
 viraemia 676

yellow fever virus 672, 674–678
 17D vaccine strain 672, 678
 Asibi strain 672
 detection 677
 distribution and vector 673
 genotypes 676
 isolation/cell lines 677
 prM and E proteins 676
 transmission 672

vector 674
see also flaviviruses

Z

zalcitabine
 HAM treatment 890
 HIV infection 916

zanamivir
 HPIV3 infection 413
 HPIV infection 429
 influenza 60, 398
 structure 397

zidovudine
 adult T-cell leukaemia treatment 890
 HAM treatment 890
 HIV infection 916, 923
 vertical transmission prevention 930
 prophylactic 930, 931
 resistance 923, 924, 930

Zika fever 684

Zika virus 673, 684

zinc preparations, rhinovirus infections 500

Zinga virus 713

zoonotic infections
 influenza *see* influenza A virus; influenza virus
 retroviruses 869
see also individual animals/vectors

zoster *see* herpes zoster

zoster-associated pain (ZAP) 147
 treatment 152, 153

zosteriform herpes simplex (cutaneous HSV) 116

zoster immunoglobulin (ZIG) 154

zoster *sine herpette* 146

Zovirax *see* aciclovir
