Contents

Preface

The human genome project has attracted a great deal of attention in recent years among the general public as well as the scientific community. Although it is likely to be a number of years before many of the expected benefits of the genomics revolution are realized, the impact of these scientific breakthroughs on medicine is likely to become apparent quickly and will transform the entire scene within a generation.

Recent advances in genomic and proteomic technologies open up new avenues in the diagnoses and management of human diseases, and the application of these techniques may initiate a paradigm shift in clinical medicine. Initially, polymerase chain reaction tests were performed only in highly specialized or research laboratories. Presently, routine molecular assays are widely performed in virtually all sections and specialties of the traditional clinical laboratory, including oncology, hematology, immunology, and blood transfusion. Evolving techniques of nucleic acid and protein microarrays may follow a similar path to the clinician in the hospital. In human genetics, molecular techniques have brought forth new procedures for increasingly specific, sensitive, fast, simple, reliable, automatable, and cost-effective diagnostic and predictive DNA analysis. All of these modern nucleic acid technologies have significantly simplified the routine assessment of patients in the genetics clinic. For instance, advances in molecular biology and in genomics have made possible the early identification of persons at increased risk of, e.g., a thrombophilic state, developing certain forms of cancer, or degenerating neurological disorders.

In clinical microbiology, procedures based on nucleic acid analysis offer a more rapid, simple, cost-effective, and universal approach to the identification of microorganisms. The ability to rapidly and unambiguously characterize microbial pathogens suspected of causing a disease can be critical to individual and public health. These molecular techniques are used increasingly in diagnostic laboratories to supplement or replace traditional identification methods, which are mostly based on microbial phenotypic characteristics. Molecular methods for the detection of anti-microbial resistance strains or virulence factors are in development, in field trial, or already in clinical use, and will supplement or replace traditional susceptibility and toxin testing. The expansion of this technology to smaller institutions, hospitals, and point-of-care testing will improve patient care and public health significantly.

Finally, genomics and proteomics will not only transform the diagnosis of diseases, but may radically influence the treatment and even the prevention of diseases in the future. In pharmacogenetics, the molecular analysis of the inherited nature of individual differences in drug metabolism, disposition, and effects will help to optimize drug therapy on the basis of each patient's genetic constitution. Such personalized medicine will allow more effective treatment of illness by using very specific diagnostics to provide actionable information to clinicians and patients, combined with the use of a new generation of targeted and highly effective medicines. Furthermore, identification of individual genetic susceptibility to infectious diseases may have an impact on prevention strategies. There is doubt that in the future, smart molecular diagnostic tools and the growing knowledge of genetic risk factors will lead to improved diagnoses and treatment for the patient and reduced health care costs to the society.

In view of these exciting developments, the *Encyclopedia of Medical Genomics and Proteomics* brings together the state-of-the-art knowledge and practical expertise of leading researchers and clinicians in the field, and provides a comprehensive overview on current medical applications of modern nucleic acid and protein technology. The *Encyclopedia* is a vehicle by which both scientists and the interested public can explore the most recent developments in today's genomic and proteomic medicine, and preview several of the foreseen applications of tomorrow. The subject areas generally include molecular methods and technologies in the diagnosis and management of infectious, neoplastic, and genetic diseases, including predictive genetic and pharmacogenetic testing, as well as tissue typing for transplantation medicine. Each entry includes descriptions and interpretations of state-of-the-art developments, concepts, and applications that will be useful to individuals encountering the field for the first time, or to experienced researchers updating or expanding their knowledge of medical applications of current genomic and proteomic technology. Key references direct the reader to timely and pertinent information sources.

It is the editors' hopes that the *Encyclopedia of Medical Genomics and Proteomics* will help health care providers, researchers, students, and nonprofessionals all better understand and participate in this remarkable emerging field. Its online edition (*www.dekker.com*) is updated regularly, to keep its information current.

The *Encyclopedia of Medical Genomics and Proteomics* resulted from the vision of Russell Dekker and a dedicated and creative Advisory Board of over 25 members, representing countries on all continents. The diligent efforts of this Board are deeply appreciated. We greatly thank the authors of more than 300 entries which, as recognized experts in their fields, lend their credibility and prestige to the *Encyclopedia*. In addition, we are indebted to the many reviewers whose constructive suggestions and insights materially enhanced the quality of individual entries and of the volume in total. We are especially grateful to the staff at Marcel Dekker, particularly Alison Cohen, for superb leadership in the handling of massive correspondence with the authors, reviewers, and the Editors.

To our readers, we offer you this oppurtunity:

- To the extent that you find the *Encyclopedia* useful, we'd like to hear why and how (EDGP@dekker.com).
- To the extent that you find the *Encyclopedia* wanting, we also, and especially, want to hear how you believe we can make it better (EDGP@dekker.com).

The Publisher as well as the Editors are committed to continual updating and refinement of what we believe is a valuable resource for transmitting knowledge and understanding about medical genomics and proteomics.

Jürgen Fuchs, Ph.D., M.D.
Maurizio Podda, M.D.

Accreditation of the Medical Laboratory—ISO 15189/ISO 17025

A

Mario Plebani
University-Hospital of Padova, Padova, Italy

INTRODUCTION

The availability of a new International Standard, ISO 15189:2003, specifically designed for medical laboratories, which contains requirements for both quality systems and competence, should stimulate the adoption of this standard and promote harmonization of accreditation programs at an international level.

The increasing demand for accountability, accessibility, professional excellence, customer satisfaction, and better cost management has underpinned the development of systems for quality assurance and improvement in healthcare, with an increasing focus on certification, accreditation, and several other forms of external review mechanisms. Moreover, many countries have introduced or are about to introduce regulations for quality assessment in laboratory services.

ACCREDITATION OF MEDICAL LABORATORIES

Medical laboratories seek recognition as being compliant with particular standards for a number of reasons. In some countries, accreditation is mandatory and in others it may be voluntary, but in any case it recognizes competence, facilitates exchanges of services, provides a valuable management tool, and ensures that the needs and requirements of all users are met. Moreover, it may be a precondition for a contract and an essential tool for reassuring laboratory professionals who aim to practice in accordance with accepted norms.[1] Table 1 shows the main benefits of accreditation for the medical laboratory, for the health-care system, and for patients.

The term ''accreditation,'' as applied to organizations rather than to specialty clinical training, reflects the origins of systematic assessment of hospitals against explicit standards and began in the United States in 1917.[2] According to the ISO/IEC Guide 2 definition, accreditation is ''a procedure by which an authoritative body gives formal recognition that a body or person is competent to carry out specific tasks.''[3] The distinction between certification and accreditation represented, in the past, a source of debate and concern. Certification activity is based upon standards such as ISO 9001:2000 which delineate the ''requirements for quality-management systems'' and are applicable to any activity. Accreditation systems are based on standards that, in addition to ''requirements for quality systems,'' take care of ''technical requirements'' that relate to achieving competence in all aspects of the specific activity, laboratory medicine in our case. Until the recent publication of the ISO 15189:2003 International Standard ''Medical laboratories—Particular requirements for quality and competence,'' there were no sector-specific ISO standards for quality management and technical competence in medical laboratories.[4] This is the reason why medical laboratories, in the past, had a choice between two separate and distinct lines for achieving recognition. The first line focuses on ''requirements for quality-management systems'' that are, by definition, applicable to any organization, and, generally, it is represented by the ISO 9000:2000 series.[5] The second line, with its origin in assessing the technical competence of a laboratory, is represented by ISO 17025:1999, a generic standard used in the accreditation of testing or calibration laboratory[6] (Fig. 1). Alternatively, other programs for laboratory accreditation are delivered by organization such as Clinical Pathology Accreditation (CPA-UK)[7] or College of Clinical Pathology (CAP) in the United States based on professional standards that basically aim to evaluate and improve technical competence. The availability of an International Standard specifically developed for medical laboratories should overpass any possible dispute and it should harmonize the laboratory approach to quality assessment and improvement. In fact, ISO 15189:2003 recognizes the importance of quality-management systems, as described in ISO 9000:2000, as well as technical requirements contained in ISO/IEC 17025:1999, but, in addition, it contains specific requirements for an organization, such as medical laboratories that, in addition to analytical competence, have to assure consultative and interpretative activities. The relationship between ISO 15189:2003, ISO/IEC 17025:1999, and ISO 9001:2000 is similar to that of a set of three ''Russian dolls'' (Fig. 2):

Encyclopedia of Diagnostic Genomics and Proteomics

Table 1 Benefits of accreditation

a)	*Benefits for the laboratory*
	– Improving quality of the work
	– Perfect documentation of the workflow
	– Total quality management
	– Education and increasing professional competence
	– Focus on patients' outcomes
	– Encouragement to develop interdepartmental cooperation
b)	*Benefits for the health-care system*
	– Improved quality of the system
	– Perfect documentation
	– Results comparability
	– Personnel and equipment specifications
	– Improved efficacy of laboratory services
	– Competition based on quality among different laboratories
c)	*Benefits for the patient*
	– Improving quality of the system
	– Results comparability
	– Transparency in information on laboratory quality
	– Improved safety and trust
	– Value for money

the inner doll being ISO 9001, the middle doll being ISO/IEC 17025, and the outer, ''all embracing doll,'' being ISO 15189.[8]

ISO 9001:2000 ''QUALITY MANAGEMENT SYSTEMS—REQUIREMENTS''

ISO 9001:2000 is one of a family of related quality-management system standards (ISO 9000:2000, ISO 9001:2000, ISO 9004:2000)[5,9,10] that specifies requirements for an organization wishing to establish an effective quality-management system that embraces the concept of continuous improvement and to demonstrate its ability to consistently provide a product that meets the users, needs. This International Standard, however, does not provide specifications for the report (product or service) itself, nor the requirements for assessing the technical competence of the medical laboratory to carry out the preexamination, examination, and postexamination processes necessary to produce the report. Therefore the individual laboratory has to select and implement standards and processes that aim to demonstrate competence and satisfy all users, without any guidance, at least without the guidance of standards recognized in the document itself.

ISO 17025:1999 GENERAL REQUIREMENTS FOR THE COMPETENCE OF TESTING AND CALIBRATION LABORATORIES

The introduction to this International Standard contains two statements of importance to those laboratories making the

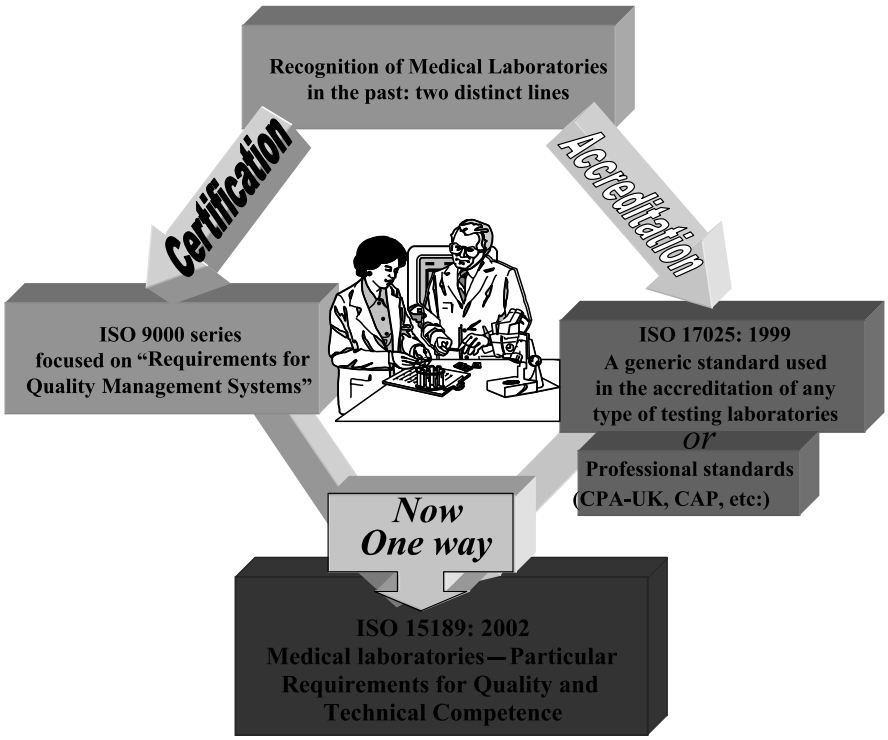

Fig. 1 Accreditation of medical laboratories: old and new standards.

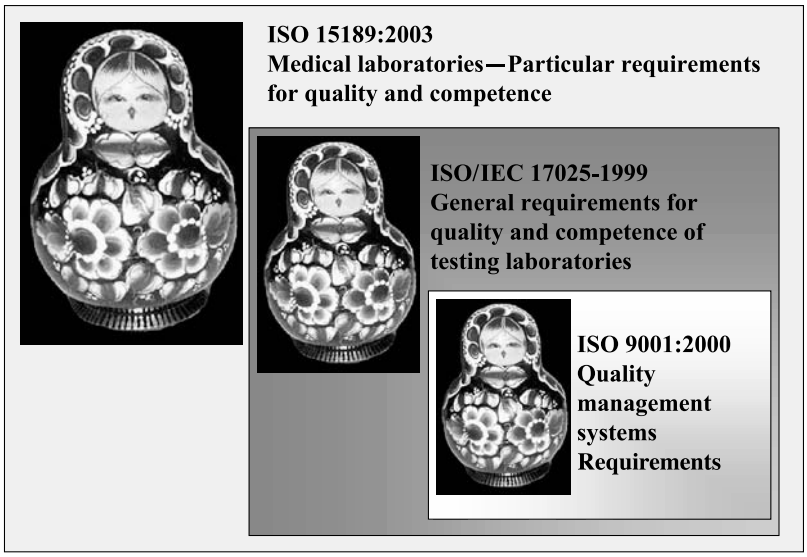

Fig. 2 Relationship between ISO 15189:2003, 180/IEC 17025:1999, and ISO 9001:2000. (*View this art in color at www.dekker.com.*)

choice between pursuing certification and/or accreditation. It states that testing and calibration laboratories that comply with ISO 17025:1999 will also operate in accordance with ISO 9001:2000, but goes on to remind the reader that certification against ISO 9001:2000 does not demonstrate the competence of the laboratory to produce technically valid data and results. The scope of this International Standard includes a number of key issues. In particular, it

1) specifies the general requirements for the competence to carry out tests and/or calibrations, including samples;
2) covers standard, nonstandard, and laboratory-developed methods;
3) is applicable to all testing and calibration laboratories regardless of the number of personnel or extent of the scope of its activities;
4) is for use by laboratories developing their quality, management, and technical systems that govern and improve their operations;
5) is for use by laboratory users, regulatory authorities, and accreditation bodies who wish to recognize the competence of an individual laboratory;
6) does not cover compliance with regulatory and safety requirements for the laboratory activities.

Limitations of ISO 17025:1999 are intrinsically related to the differences between testing/calibration and medical laboratories. Therefore aspects regarding preanalytical phase, which is extremely important for the interpretation and outcome of medical laboratory data, are practically not addressed at all in that document. With regard to the analytical phase, there is no mention in ISO 17025:1999 about requirements for internal quality control and external quality assessment, whereas in the postanalytical phase requirements for turnaround times, as well as for STAT and critical results, are not addressed.

PECULIARITIES OF ISO 15189:2003

ISO 151189:2003 recognizes the major particularities of medical laboratories in comparison to other chemical test laboratories. In contrast to calibration and testing laboratories, the methods applied in laboratory medicine are a compromise between available amount of sample material, turnaround time, test feasibility, and economical reality. Table 2 summarizes the principal differences regarding methods, sample size, validation of results, time span between sampling and the availability of a result (turnaround time), and measurement uncertainty.

Furthermore, there is an increasing relevance of ethical problems related to the use of laboratory samples for examination purposes other than those requested, to the need to obtain informed consent by the individual patient for some procedures, to the need to communicate results to the requesting physician or to other parties with the patient's consent, and the responsibility of the laboratory to ensure that results are correctly interpreted and applied in the patient's best interest.[11,12]

STRUCTURE AND CONTENTS OF ISO 15189:2003

The structure and contents of ISO 15189 follow that of any ISO document. In particular, it contains both normative and informative elements. The normative

Table 2 Main differences between ISO/IEC 17025 and ISO 15189

Issue	Medical laboratories	Test and calibration
1. Patient preparation	Important issue Essential for particular tests	Not relevant
2. Sample volume	Limited, mainly in particular patients (children, neonates, etc.) Methods are adapted to sample size	Sample size adapted to the method
3. Methods	In vitro diagnostics and developed ''in house''	Methods standardized according to national and international standards
4. Results	Results used for patient care and subjected to three (technical, biological, and nosological) validation levels	Pure analytical results and related measurement uncertainty
5. Measurement uncertainty	Related to analytical and biological quality specifications	Related to analytical quality specifications
6. Turnaround time	Extremely important	Not relevant
7. Clinical advice	Appropriateness of test request. Interpretation of results	Not relevant
8. Ethical problems	Increasingly important	Limited to ''state-of-the-art'' measurement

elements describe the scope of the standard and set out its provisions that can be expressed as requirements, recommendations, or statements.[2] Informative elements can be preliminary or supplementary. Preliminary elements are those that identify the document, introduce its content, and explain its background, its development, and its relationship with other documents. Supplementary elements provide information intended to assist with the understanding or use of the document. In the introduction, some essential concepts are explained. Firstly, it declares that laboratory services ''include arrangements for requisition, patient preparation, patient identification, collection of samples, transportation, storage, processing and examination of clinical samples, together with subsequent validation, interpretation, reporting and advice, in addition to the considerations of safety and ethics in medical laboratory work.'' A second important statement is that a second edition of the standard is anticipated, aimed at more closely aligning it with a second edition of ISO/IEC 17025 and with ISO 9001:2000. This emphasizes well the view of accreditation as a dynamic process and the nature of standards as ''a changing world.'' Scope, normative references, and terms and definition are described in

Table 3 Main clauses and primary subclauses of ISO 15189

4. Management requirements	5. Technical requirement
4.1 Organization and management	5.1 Personnel
4.2 Quality management system	5.2 Accommodation and environmental equipment
4.3 Document control	5.3 Laboratory equipment
4.4 Review of contracts	5.4 Preexamination procedures
4.5 Examination of referral laboratories	5.5 Examination procedures
4.6 External services and supplies	5.6 Assuring quality of examination procedures
4.7 Advisory services	5.7 Post-examination
4.8 Resolution of complaints	5.8 Reporting of results
4.9 Identification and control of nonconformities	
4.10 Correction action	
4.11 Preventive action	
4.12 Continual improvement	
4.13 Quality and technical records	
4.14 Internal audits	
4.15 Management review	

clauses 1, 2, and 3, respectively. The most interesting element in these clauses is represented by the definition of medical laboratories that, in turn, represent the structures to which the document is addressed. Medical laboratory is defined as ''laboratory for the biological, microbiological, immunological, chemical, immunohaematological, haematological, biophysical, cytological, pathological or other examination of materials derived from the human body for the purpose of providing information for the diagnosis, prevention and treatment of disease in, or assessment of the health of, human being, and which provide a consultant advisory service covering all aspects of laboratory investigations including the interpretation of results and advice on further appropriate investigation.'' It is clear therefore that ISO 15189 should represent the International Standard for the accreditation of all different types of medical laboratories that operate in the field of laboratory medicine. The main clauses and primary subclauses of ISO 15189 are shown in Table 3.

Very interesting informative elements are finally included in Annex B ''Recommendations for protection of laboratory information systems (LIS)'' and in Annex C ''Ethics in laboratory medicine.''

ACCREDITATION PROGRAMS

As well stated by David Burnett,[2] there are four essential elements in any accreditation system and they are described as:

1. The Standards with which a laboratory has to comply in order to gain accreditation.
2. The accreditation body which oversees the assessment and grants accreditation.
3. The assessors or inspectors who seek to establish compliance with the standards by conducting the assessment.
4. The user laboratory which is required to, or voluntarily seeks to, comply with the standards by being assessed.

An increasing consensus has been reached to recommend the adoption of ISO 15189 as the standard of choice for medical laboratories that seek to receive accreditation. Professional organizations (CPA) have immediately declared the acceptance of the new standards, whereas some accreditation bodies have been reluctant to adopt this standard, but at a recent General Assembly of the International Laboratory Accreditation Cooperation (http://www.ilac.org), endorsed by the European Cooperation for Accreditation (EA), the value of ISO 15189 as an alternative to ISO/IEC 17025 for laboratory accreditation has been established. A recent survey in Europe and elsewhere indicates than an overwhelming majority of accrediting bodies are choosing ISO 15189 as the International Standard against which to accredit medical laboratories.

Regarding the accreditation body, ISO 15189 states that ''...a laboratory seeking accreditation select an accreditation body which operates to appropriate standards and which takes into account the particular requirements of medical laboratories.'' Therefore it can be a specific accreditation body with formal links with existing national accreditation bodies, a subbranch of the national accreditation body, specifically directed to use ISO 15189 for the assessment of medical laboratories, or a professional organization (CPA in the United Kingdom, CCKLTest in the Netherlands, APL in Italy).

One of the major duties of the accreditation body is to take care of the education, training, retraining, and assessment of inspectors. Different types of inspectors exist: full-time ''peers,'' part-time ''peers,'' and external inspectors. The advantages and disadvantages of the different types of inspectors have been described. Taking into consideration the particular nature of ISO 15189, inspectors should assure the evaluation of technical competence in addition to assessment of the quality system.[13] Therefore, they have to demonstrate competence in laboratory medicine and, in particular, in all sectors of activity of the inspected laboratory.

CONCLUSION

The availability of a standard or set of requirements against which practice can be measured is essential in order to create a harmonization of practice in any field of endeavor, but in the case of medical laboratories, the need for harmonization is central to the health and welfare of the individual patient. Therefore the availability of ISO 15189 should promote the harmonization of different accreditation programs for medical laboratories through the adoption of this International Standard and a mutual recognition between the organizers of different accreditation programs.

ACE Genotyping

Michael Rudnicki
Gert Mayer
Medical University Innsbruck, Innsbruck, Austria

INTRODUCTION

The renin–angiotensin system (RAS) is a cascade of enzymatic reactions that finally leads to the formation of angiotensin II (AngII). The protease renin, which is secreted by myoepithelial cells in renal afferent arterioles, cleaves the decapeptide angiotensin I (AngI) from the liver-derived polypeptide angiotensinogen (AGT). AngI serves as a substrate for the dipeptidase angiotensin-converting enzyme (ACE) which not only generates the octapeptide AngII but also degrades vasodilators such as bradykinin and kallidin. Because AngII is a potent vasoconstrictor and sodium-retaining hormone, the activation of ACE is followed by an increase in blood pressure. Therefore, ACE inhibitors are widely used in the treatment of hypertension. They effectively lower blood pressure, reduce cardiovascular events,[1] and reduce morbidity and mortality in congestive heart failure.[2] Furthermore, ACE inhibitors have proven superior to other antihypertensive drugs in protecting kidney function,[3,4] and they are beneficial for the kidney even when systemic blood pressure is normal.[5]

The human ACE gene is located on chromosome 17q23. Exons 4–11 (coding for the N-terminal domain) and 17–24 (coding for the C-terminal domain) of the ACE gene are highly similar, both in size and in sequence, implying that there has been a gene duplication event during evolution. The two forms of ACE are transcribed from the same gene using different promoters, located on exon 1 and on intron 12.

ACE GENE POLYMORPHISMS

The most widely studied polymorphism of the ACE gene is based on the presence (insertion, I) or absence (deletion, D) of a 287-base-pair element in intron 16.[6] Although the intraindividual plasma level of ACE is rather stable, the prominent interindividual variation has been linked to this I/D polymorphism,[6] which accounts for 47% of the phenotypic variance in healthy individuals. It has been shown that Caucasian subjects with ACE–DD genotype have the highest, subjects with ID genotype intermediate, and subjects with II genotype have the lowest concentrations. These findings have been confirmed in diverse populations including French centenarians,[7] Pima Indians,[8] and whites in the United States.[9] However, they could not be replicated for African-Americans, suggesting an important role for ethnic background.[9]

The ACE gene I/D polymorphism genotyping method originally published by Rigat et al.[6] results in a preferential amplification of the D allele with a possible mistyping of approximately 5% of ID heterozygotes as DD homozygotes.[10] One better technique is to use a second pair of primers, which are located inside the insertion-specific sequence as proposed by Lindpaintner et al.[10] Another improved method has been published by Evans et al.[11] and Ueda et al.[12] They used a third primer located in the insertion element that was added to the reaction cocktail together with the first set of primers. Addition of 5% DMSO and the application of a ''hot-start'' (i.e., initial heating at 95°C and using of wax platelets in the PCR tubes) procedure highly improved the specificity of the original protocol.

PHARMACOGENETIC IMPLICATIONS OF ACE GENOTYPING: STUDIES IN ESSENTIAL HYPERTENSION AND CARDIOVASCULAR DISEASE

In patients with essential hypertension, the ACE gene polymorphism and the response to treatment with ACE inhibitors was subject to research in several clinical trials (Table 1). Hingorani et al.[13] and Dudley et al.[14] could not describe any correlation between blood pressure response to an ACE inhibitor and ACE genotype in individuals with essential hypertension. Nakano et al.[15] reported that blood pressure response to a single dose of 50 mg captropril does not correlate with ACE genotype but rather with plasma renin activity. Stavroulakis et al.[16] showed that after treatment with fosinopril, blood pressure reduction was significantly greater in DD

DOI: 10.1081/E-EDGP 120020972

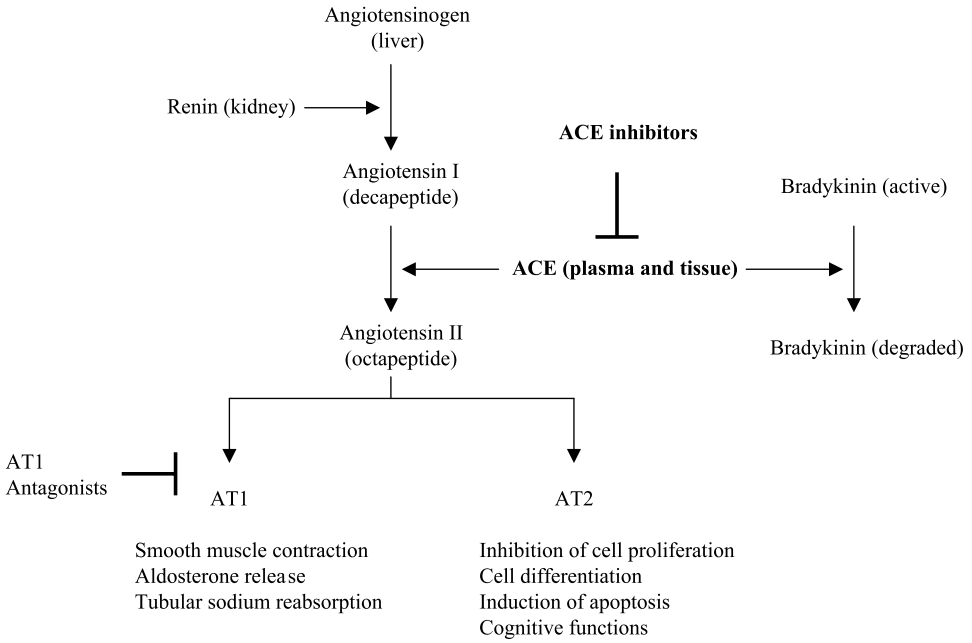

Fig. 1 The renin–angiotensin–aldosteron system (RAS) and the role of the angiotensin-converting enzyme (ACE) with targets for antihypertensive therapy (ACE inhibitors and AT1 antagonists). AT1 = angiotensin II type 1 receptor; AT2 = angiotensin II type 2 receptor.

patients compared to ID or II individuals. On the contrary, Ohmichi et al.[17] found that not only the reduction in diastolic blood pressure was higher in II than in ID or DD patients, but that the reduction in diastolic blood pressure was inversely correlated with plasma ACE activity as well. Sasaki et al.[18] found that regression of left ventricular hypertrophy and improvement in diastolic filling induced by ACE inhibitor therapy was more pronounced in the DD genotype group than in the ID or II group. O'Toole et al.[19] investigated the influence of the ACE genotype on the response to ACE inhibitors in patients with heart failure. They found a higher reduction in blood pressure in patients with the II genotype than in the other groups. Interestingly, this effect was only seen in patients treated with captopril (25 mg t.d.s.) but not in those treated with lisinopril (10 mg o.d.). In summary, the correlation between ACE I/D gene polymorphism and the response to treatment

Table 1 Studies in patients with essential hypertension evaluating the response to ACE inhibitor therapy in relation to ACE genotype

Reference	Study drug	Phenotype
Positive effect in II individuals		
[17]	Imidapril	Reduction in blood pressure
[19]	Lisinopril, captopril	Change in mean arterial pressure (captopril only)
Positive effect in DD individuals		
[16]	Fosinopril	Reduction in blood pressure
[18]	Enalapril	Regression of LVH and improvement in LVDF
No effect of ACE genotype		
[13]	n.s.	Blood pressure response
[14]	Atenolol, lisinopril, nifedipine SR	Blood pressure response
[15]	Captopril	Blood pressure response

LVH = left ventricular hypertrophy; LVDF = left ventricular diastolic filling; n.s. = not specified.

with ACE inhibitors in cardiovascular disorders remains highly controversial.

STUDIES IN RENAL DISEASE

The individual response to treatment with ACE inhibitors is highly variable.[20] Therefore, several studies have been conducted in which the efficacy of ACE inhibitor therapy was studied in relation to ACE genotype in patients with kidney diseases (Table 2). Yoshida et al.[21] studied the response to ACE inhibitor therapy in 21 Japanese patients with IgA-nephropathy, who were treated with lisinopril (10 mg/day). After 4 years of therapy, only patients with DD genotype showed a significant reduction in proteinuria. These results were confirmed by Moriyama et al.[22] in patients with various renal diseases and by Ha et al.[23] in patients with diabetic nephropathy. Those results are also consistent with a study performed by Perna et al.[24] Proteinuria, change of glomerular filtration rate, and progression to end-stage renal disease were effectively reduced by treatment with ramipril in patients with the DD genotype. Interestingly, ethnic background may play a very important role as mentioned before, as three of the four studies showing a more efficient reduction in proteinuria in DD individuals were performed in Asian patients.[21–23]

On the contrary, van Essen et al.[25] compared atenolol and enalapril in 81 Caucasian patients with nondiabetic renal disease. Patients with II and ID genotype showed a significantly higher reduction in urinary protein excretion than patients with DD genotype. These results are consistent with studies performed by Gonzalo et al.[26] and by Haas et al.[27] In the EURODIAB controlled trial of lisinopril in insulin-dependent diabetes mellitus (IDDM) (EUCLID),[5] Penno et al.[28] reported the highest increase in albumin excretion rate in II genotype patients when treated with placebo. However, when treated with lisinopril, patients with the II genotype showed the slowest increase in albuminuria. These results in patients with diabetic nephropathy were confirmed by Jacobsen et al.[29] In an observational follow-up study, patients with IDDM and diabetic nephropathy were investigated during captopril treatment (12.5–150 mg/day).[30] The treatment effect on reduction in proteinuria was similar in all genotype groups. Van der Kleij[31] studied the short-term renal response to ACE inhibition in 61 patients with nondiabetic renal disease and proteinuria >1 g/day. Therapy consisted of either enalapril or lisinopril (10–20 mg/day). The reduction of proteinuria by ACE inhibition was not significantly different between the genotype groups, as has also been shown by Burg et al.[32] in a prospective study and Björck et al.[33] in retrospectively analyzed data. In summary, as in the trials dealing with essential hypertension, the correlation between ACE I/D gene polymorphism and response to treatment with ACE inhibitors in patients with renal diseases remains highly controversial.

Table 2 Studies in patients with various renal diseases evaluating the response to ACE inhibitor therapy in relation to ACE genotype

Reference	Study drug	Phenotype
Improved effect of ACE inhibitor therapy in DD individuals		
[21]	Lisinopril	Proteinuria
[22]	n.s.	Proteinuria
[23]	n.s.	Proteinuria
[24]	Ramipril	Loss of GFR
Improved effect of ACE inhibitor therapy in II individuals		
[25]	Enalapril	Loss of GFR
[26]	Enalapril, Losartan	Proteinuria
[27]	Enalapril	Proteinuria
[28]	Lisinopril	Proteinuria
[29]	Captopril	Proteinuria
[30]	Captopril	Loss of GFR
No effect of ACE genotype on treatment response to ACE inhibitor therapy		
[31]	Enalapril, Lisinopril	Proteinuria
[32]	n.s.	Proteinuria
[33]	n.s.	Proteinuria

n.s. = not specified; GFR = glomerular filtration rate.

CONCLUSION

Several questions regarding the clinical utility of ACE genotyping remain unresolved. The clinical trials studying the correlation of ACE genotype and response to treatment with ACE inhibitors in patients with essential hypertension or kidney disease do not give a clear answer (Tables 1 and 2). Some of the studies have to be dealt with great caution because of small patient numbers and heterogeneous baseline characteristics. Even the choice of ACE inhibitor might have influenced the results of these clinical trials because it has been shown that ACE inhibitors differ in their affinity to ACE.[34] Finally, one has to consider if the ACE I/D polymorphism is the best of the hitherto described genetic markers for pharmacogenomic studies, as its clinical significance and its linkage to pathologies is still controversial.[35] Direct measurement of enzyme activity may not only allow a better estimation of individual risk

but provide a basis for more effective treatment with ACE inhibitors as well.

Actinomyces spp.

Val Hall
University Hospital of Wales, Cardiff, U.K.

INTRODUCTION

Actinomyces species form part of the normal mucosal flora of humans and many animals and are opportunist pathogens involved in periodontal infections, soft tissue abscesses, or actinomycosis. Management of established actinomycosis usually demands surgical intervention and/or long-term aggressive antimicrobial therapy. However, clinical diagnosis and confirmation by microbiological culture and conventional identification methods are each notoriously problematical. In recent years, the application of molecular techniques has greatly improved the classification and identification of members of this genus. In the future, direct detection of *Actinomyces* spp. in clinical materials with specific DNA probes may overcome many of the traditional clinical diagnostic problems.

ACTINOMYCES SPECIES

General Description

Actinomyces spp. are facultatively anaerobic gram-positive bacilli that inhabit mucous membranes, particularly those of the oral cavity, of humans and animals.[1] Cell and colony morphologies, aerotolerance, and growth rates each vary considerably between species. At the time of writing, the genus comprises some 29 species, 17 of which have been classified since 1993 with the aid of modern phylogenetic techniques. Recent studies indicate heterogeneity within some species and the existence of additional, as yet undescribed species.

Causative Agents of Actinomycosis

The principal agents of human actinomycosis are *Actinomyces israelii*, *Actinomyces gerencseriae*, and the morphologically similar *Propionibacterium propionicum*. The cells of these species are filamentous, beaded, and branching gram-positive rods. The organisms in vivo form characteristic microcolonies with radiating filaments and clubbed ends composed of both bacterial and host materials and surrounded by neutrophils and foamy macrophages. In wound exudates, microcolonies may be visible to the naked eye as hard white or yellowish grains, commonly called ''sulphur granules.'' *Actinomyces* spp. are highly susceptible in vitro to a wide range of antimicrobial agents. However, within microcolonies, the organisms are protected from the actions of these and of host defenses, and this is thought to be a major pathogenicity factor. In the laboratory, the above-named species may require up to 10 days of anaerobic incubation on a serum-containing medium before characteristic white or beige ''breadcrumb'' or ''molar tooth'' colonies are visible. Colonies may be very gritty, pitting, and adherent to the agar. These growth characteristics and the almost universal presence of concomitant organisms, commonly members of the oral flora, can result in difficulties in laboratory isolation, identification, and susceptibility testing.

Species Associated with Intraoral Diseases

Actinomyces spp. are early colonizers of various niches within the oral cavity. Species commensal in the mouth include *A. israelii*, *A. gerencseriae*, *Actinomyces odontolyticus*, *Actinomyces meyeri*, *Actinomyces naeslundii/viscosus*, *Actinomyces georgiae* and, probably, *Actinomyces graevenitzii.* Some members of the genus, particularly those of the *A. naeslundii/viscosus* complex, are known to coaggregate with other bacteria and adhere to mammalian cells by means of fimbriae. Consequently, they play an important role in development of dental plaque. However, despite numerous studies, their roles in the highly complex processes of dental caries and periodontal diseases remain somewhat controversial. The recently described species *Actinomyces radicidentis* has been isolated, so far, only from infected root canals.

Other Species

The natural habitats, prevalence, and clinical significance of many recently described *Actinomyces* spp. have yet to be established. For the majority of these species, few isolates have been studied to date. However, it appears that species including *Actinomyces turicensis*, *Actinomyces radingae*, *Actinomyces europaeus*, *Actinomyces funkei*, *Actinomyces neuii*, and *Actinomyces urogenitalis* are principally involved in polymicrobial, superficial soft tissue infections in humans but do not cause actinomycosis. Natural habitats may include the genitourinary and gastrointestinal tracts and lipid-rich areas of the skin. The cell and colony morphologies of these species can be

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120023058

described as ''nondescript'' and may not resemble the well-known forms of the classical *Actinomyces* spp. Therefore, they may be easily overlooked in mixed cultures and, consequently, are probably underreported in clinical specimens.

CLINICAL FEATURES OF ACTINOMYCOSIS

Actinomycosis is a chronic suppurating disease, characterized by cavitating abscess formation and, in the advanced stages, by draining sinus tracts and considerable tissue damage. The disease affects principally the cervicofacial region. Thoracic, abdominal, and pelvic infections occur less frequently but may result in serious, occasionally life-threatening disease.[1] Onset is insidious, early symptoms may be vague, and clinical diagnosis is often difficult until overt signs appear. The medical literature abounds with cases of actinomycosis mistakenly diagnosed as tuberculosis or carcinoma, many of which were correctly diagnosed by histological methods only after surgery. Other sites of infection include the brain, lungs, and hepatic abscess. In cases of lacrimal canaliculitis, the tear duct becomes blocked by concretions of *Actinomyces* or *P. propionicum* and associated flora. Disease of the long bones or joints is rare but may be extremely debilitating, widely disseminated, and intractable. Carriage of *Actinomyces* spp. is strongly associated with intrauterine contraceptive devices (IUCDs) and may progress to pelvic infection.

PREVALENCE

In developed countries, advanced cases of cervicofacial actinomycosis are rare. The incidence of lesser infections and actinomycosis of other sites is difficult to ascertain but may be greatly underreported. The risk of pelvic actinomycosis arising from IUCD usage has remained controversial since the 1980s when the association of *Actinomyces* spp. was first discovered. However, carriage rates averaging 20% in millions of women using IUCDs and few reported cases of disease suggest that *Actinomyces* spp. are rare opportunist pathogens. Conversely, periodontal diseases are widespread in the developed world and *Actinomyces* spp. may play important roles in their development.

PATIENT MANAGEMENT

In simple, promptly diagnosed actinomycotic infections such as dental abscesses following surgery, a short course of antimicrobial therapy may be curative. *Actinomyces* spp. are highly susceptible to a wide range of agents and the pharmacokinetics of penicillin has made this the drug of choice. Various other agents may be used in penicillin-allergic patients, or where broad-spectrum cover for concomitant organisms is required. In advanced cases of actinomycosis, surgical debridement (ranging from drainage of abscesses to removal of major organs) together with long-term (for months or years) antimicrobial therapy and careful monitoring of signs and symptoms may be necessary to effect a cure. Relapses are not infrequent. In cases of lacrimal canaliculitis, manipulation or incision to remove the physical blockage and systemic antimicrobial therapy may be necessary.

Patients with IUCDs should be made aware of the symptoms of pelvic inflammatory disease and advised to consult their doctor if these arise. Asymptomatic patients should be monitored regularly and IUCDs replaced as recommended.

MOLECULAR CHARACTERIZATION

Classification

In common with many other genera, the classification of *Actinomyces* has been revolutionized by the application of 16S rRNA nucleotide sequence analysis. Early results were obtained by laborious reverse transcriptase methods.[2] However, rapid advances in DNA amplification, sequencing techniques, and data analysis software enabled the comprehensive phylogenetic analysis of the genus.[3] As a result, some former *Actinomyces* species have been transferred to other genera (e.g., *Arcanobacterium pyogenes*) and some novel genera (e.g., *Actinobaculum*, *Varibaculum*) and a plethora of novel species have been described. These include, from human sources, *A. radingae*, *A. turicensis*, *A. europaeus*, *A. graevenitzii*, *A. radicidentis*, *A. urogenitalis*, *A. funkei*, and *Actinomyces cardiffensis*. Additional novel species are indicated both from organisms cultivated from clinical materials[4] and from uncultivated clones.[5,6] Furthermore, these and other studies have demonstrated extensive genetic heterogeneity within strains currently assigned to the *A. naeslundii/viscosus* complex and, to a lesser extent, within *A. israelii*, *A. odontolyticus*, and some other species.

The robustness of current classification is ensured by the use of a polyphasic taxonomic approach, whereby phylogenetic divisions are supported by those derived from chemotaxonomic markers and phenotypic characteristics. Determination of cell wall sugars and amino acids, fatty acids, phospholipids, and menaquinones, and whole-cell protein profiling by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) has been utilized. Collectively, these analyses indicate that the

genus *Actinomyces* represents at least three separate genera, as yet to be formally classified.[7]

Many clinicians and clinical microbiologists view taxonomic revisions as purely academic exercises—at best, irrelevant, and, at worst, confusing. However, a robust and discriminatory classification system, coupled with reliable means of identification, is a prerequisite for a meaningful analysis of prevalence, habitats, clinical associations, and potential pathogenicity of microorganisms. In addition, knowledge of genetic specificity and diversity within target species is essential for the development of DNA probes for direct detection of pathogens in clinical materials.

Identification

Identification by genotypic methods is particularly valuable for organisms such as *Actinomyces* spp., which are poorly differentiated in conventional biochemical or serological tests. Species-specific oligonucleotide probes targeting ribosomal DNA have been developed both for identification of cultivars and for direct detection, but their value has been limited by the high degrees of intraspecies genetic diversity occurring within *Actinomyces* spp.[2,8] Conversely, amplified rDNA restriction analysis [ARDRA or polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP)] has proved to be a highly discriminatory, practical, and cost-effective method for differentiation of *Actinomyces* and other facultatively anaerobic gram-positive bacilli to the species or subspecies levels. In two small studies, the restriction endonuclease *Mnl*I was recommended.[9,10] However, in studies of over 600 clinical and some veterinary isolates, banding patterns obtained from separate digestions by *Hae*III and *Hpa*II were analyzed.[11,12] Neither enzyme alone was sufficiently discriminatory, but, in combination, differentiated all currently recognized *Actinomyces*, *Arcanobacterium*, and *Actinobaculum* spp., some to subspecies level, and many *Propionibacterium*, *Lactobacillus*, *Bifidobacterium*, *Gardnerella*, *Mobiluncus*, and *Eubacterium* spp. Results correlated well with those obtained by conventional methods, but the latter lacked discrimination. Several recently described species (e.g., *A. funkei*, *A. urogenitalis*) were recognized as being distinct from existing species prior to their formal description by other workers, and a number of novel species, including *A. cardiffensis*, were detected. This method is now used routinely at the Anaerobe Reference Laboratory of the National Public Health Service for Wales for identification of nonsporing gram-positive bacilli referred from throughout the UK. Unfortunately, although only basic molecular expertise and equipment are necessary to perform this method, it remains impractical for use in the clinical laboratory for identification of occasional isolates.

Methods for PCR-RFLP and 16S rDNA Sequencing of *Actinomyces* Isolates

When an adequate and pure growth of the isolate has been cultured, genomic DNA may be extracted without the need for noxious chemicals or complex procedures. Boil a 1 μL loopful of the organism in 100 μL of Chelex resin (5%) for 8–10 min. Centrifuge at 13,000 rpm for 10 min. Use the supernate as target DNA. The almost complete 16S rRNA gene is amplified by PCR using ''universal'' primers pA (sequence AGAGTTTGATCCTGGCTCAG) and pH′ (AAGGAGGTGATCCAGCCGCA) in 45 μL of reaction mixture containing 1 U of *Taq* polymerase, each deoxynucleoside triphosphate at 200 mM, 20 pmol of each primer, 2.25 mM magnesium chloride, 10 mM Tris–HCl, 50 mM KCl, 0.1% Triton X-100, and 5 μL of target DNA. For amplification, denature at 92°C for 2 min, anneal at 55°C for 1 min, and extend at 72°C for 1.5 min × 30 cycles with final extension for 5 min. Confirm the specific product of approximately 1600 bp by electrophoresis in 1% agarose using an appropriate molecular size marker. For DNA sequencing, purify the amplicon in a commercial PCR purification kit and proceed using a standard *Taq* dye-deoxy terminator sequencing kit and appropriate primers. For identification by PCR-RFLP, no purification step is necessary. Perform restriction endonuclease digestion by mixing 12.5 μL of PCR product with 1 μL of *Hae*III or *Hpa*II (10 U/μL) and 1.5 μL of matched incubation buffer. Mix and incubate at 37°C for 1.5–2 hr. Add 3 μL of loading buffer to the reaction mix and electrophorese 12 μL of sample in a 3.5% Metaphor agarose gel in TAE buffer with ethidium bromide (0.5 μg/mL) at 5 V/cm for 1.75 hr. Run appropriate size markers (e.g., 2 kb; Sigma, Poole, UK) at intervals alongside samples. Destain the gel in deionized water for 10 min and visualize under UV illumination. Analyze banding patterns by visual comparison with those of reference strains or, preferably, in a software package such as GelCompar (Applied Maths, Kortrijk, Belgium).[11]

Molecular Detection from Clinical Material

To date, direct detection of *Actinomyces* spp. has been applied principally to investigations of their roles in intraoral diseases. In a study of the microbial composition of supragingival and subgingival plaques in subjects with adult periodontitis, Ximénez-Fyvie et al.[13] used whole genomic DNA probes and checkerboard DNA–DNA hybridization as described by Socransky et al.[14] to detect the presence and levels of 40 bacterial taxa including

A. israelii, *A. gerencseriae*, *A. naeslundii* genospecies 1 and 2, and *A. odontolyticus*. *Actinomyces* spp. were the most prevalent of the 40 taxa in both supragingival and subgingival habitats, and higher counts were detected in supragingival sites.

Extensive studies designed to detect both cultivable and noncultivable bacteria, including novel taxa, have utilized PCR with all-bacterial or selective primers, followed by cloning in *Escherichia coli* and sequencing of clones. Together with checkerboard DNA–DNA hybridization for selected taxa, this method has been used to determine species identity for the investigation of bacterial diversity in subgingival plaque[5] and tongue dorsa[6] and species associated with childhood caries.[15] Among the large numbers of novel phylotypes detected in these studies, several *Actinomyces* spp.-like clones were recognized. *A. naeslundii* and *A. naeslundii*-like clones and *A. gerencseriae* were detected in cases of refractory periodontitis and in healthy subjects. *A. israelii* and *A. georgiae* were detected in healthy subjects and *A. odontolyticus* was associated with refractory periodontitis. In the study of childhood caries, it was concluded that *A. gerencseriae* and other *Actinomyces* spp. may play an important role in caries initiation.

The wide genetic diversity apparent within *Actinomyces* spp. and particularly in the *A. naeslundii/viscosus* complex has hindered the development of specific riboprobes for detection of pathogenic *Actinomyces* in clinical specimens. Furthermore, such diversity indicates that where investigations of pathogenicity factors, adherence, etc. are based on only one or a small number of strains, results should be treated with caution as these may not be representative of the whole population.

To overcome problems of low sensitivity of specific riboprobes, Kiyama et al.[16] targeted a 756-bp *Actinomyces*-specific fragment of the sialidase gene. As sialidase activity facilitates adherence to buccal epithelial and other mammalian cells, the presence of this gene is relevant to bacteria associated with periodontal disease. The specific DNA fragment was amplified by PCR prior to hybridization with a digoxigenin-labeled probe. Universal detection of a 625-bp highly conserved region of the 16S rRNA gene acted as a control of the method, and it was found to be highly sensitive and specific for the members of the *A. viscosus/naeslundii* complex examined.

CONCLUSION

The application of modern genotypic methods has greatly clarified the phylogenetic status of members of the genus *Actinomyces* and has led to the recognition of many additional species and subspecies. Identification of *Actinomyces* spp. by PCR-RFLP with endonucleases *Hae*III and *Hpa*II has proved to be a highly discriminatory method, far superior to conventional biochemical tests. PCR-RFLP is practical for testing small batches of clinical isolates in the reference laboratory setting. Resulting data will further aid the establishment of the natural habitats, prevalence, and clinical significance of *Actinomyces* spp. Meanwhile, in the field of oral microbiological research, the use of cloning, sequencing, and DNA–DNA hybridization continues to increase the knowledge of the bacterial components of specific oral niches and to aid in the elucidation of the complex etiology of periodontal diseases.

The laboratory cultivation of *Actinomyces* spp. from clinical material remains problematical. The direct detection of the causative agents of actinomycosis, ideally from histological sections as well as microbiological specimens, could greatly improve early diagnosis and patient management. At present, success in this has been limited, principally due to intraspecies genetic heterogeneity. Clearly, this is an area that warrants further research and development.

INTRODUCTION

Leukemia is a neoplastic proliferation of hematopoietic cells. Leukemia can be classified as either myelocytic (myeloid) or lymphocytic (lymphoid) depending on the lineage of the leukemic cells. Leukemia can also be either chronic or acute, depending on the clinical course and on the predominant maturational stage of the malignant clone. In this article, we will focus our discussion on acute myelocytic (myeloid) leukemia (AML), the most common acute leukemia found in adults.

Until recently, the leukemias have been classified using a system proposed by the French–American–British (FAB) Cooperative Group. Under this system, eight subgroups (M0 to M7) have been defined for AML and three subgroups have been designated for the acute lymphocytic leukemias (ALL). This classification also includes the myelodysplastic syndromes (MDS) and the myeloproliferative diseases (MPD). The former category includes the following five subgroups: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEBT), and chronic myelomonocytic leukemia (CMMoL). The MPDs include chronic myelogenous leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), and myelofibrosis with myeloid metaplasia (MMM). The above classification was established on the basis of morphological, cytochemical, and immunological parameters. Several of the above disease entities are more or less associated with specific chromosomal rearrangements, selected examples of which are given in Fig. 1, courtesy of Dr. J. Anastasi.

Although the FAB system has served as the gold standard for classification of malignant hematological diseases for a number of years, cancer centers are increasingly adopting the system proposed by the World Health Organization (WHO), as further discussed below.

THE WHO CLASSIFICATION OF LEUKEMIAS

Harris et al.[1] reported the WHO classification of neoplastic diseases of the hematopoietic and lymphoid tissues in 1999. This system modifies and incorporates the Revised European–American Lymphoma (REAL) classification[2] and extends the principles underlying that schema to the classification of myeloid diseases. Like the REAL system, the WHO system attempts to classify neoplastic lymphohematopoietic diseases into discrete entities with unique clinico-biological features. In this way, the WHO classification is a conceptual improvement over the FAB classification,[3–6] which primarily relied on morphological criteria.

To divide the lymphohematopoietic neoplasms into clinically relevant and biologically discrete entities, multiple diagnostic modalities are employed in the WHO system, including morphology, immunophenotype, clinical history, and cytogenetic abnormalities. With respect to cytogenetic and fluorescent in situ hybridization (FISH) evaluations of AML, the WHO classification has significantly upgraded the role of these modalities in diagnosis, prognosis, and relevance to treatment decisions. Within the acute leukemias, the major WHO categories include therapy-related AML-MDS, AML with multilineage dysplasia, and AMLs with recurrent cytogenetic translocations in addition to AML not otherwise categorized.[1] Thus cytogenetic data define one major group of AMLs. The delineation of specific cytogenetic diseases owes much to studies showing that cytogenetics could predict response to therapy[7–11] and therefore could be used to make treatment decisions.[7,12]

CONVENTIONAL CYTOGENETICS IN DETECTING RECURRING CHROMOSOMAL ABNORMALITIES IN HEMATOPOIETIC DISORDERS

Conventional cytogenetic analysis using G-banding is a powerful technique that enables one to gain a complete picture of the human genome at a glance (Fig. 2). Bone marrow is the tissue of choice for conventional cytogenetic studies of acquired chromosomal abnormalities in most hematological conditions. Nevertheless, a stimulated culture of peripheral blood is sometimes performed besides an unstimulated culture of the bone marrow to ascertain whether an observed chromosomal abnormality, when present in all sampled cells, is constitutional in origin.[13,14]

The first consistent acquired chromosomal abnormality that was associated with a single cancer type, CML, was described by Nowell and Hungerford.[15] The marker chromosome, named the Philadelphia (Ph^1) chromosome, in honor of the city where it was discovered, was later found by Rowley[16] to be a reciprocal translocation between chromosomes 9 and 22 using the G-banding technique. This translocation, in which the c-abl oncogene

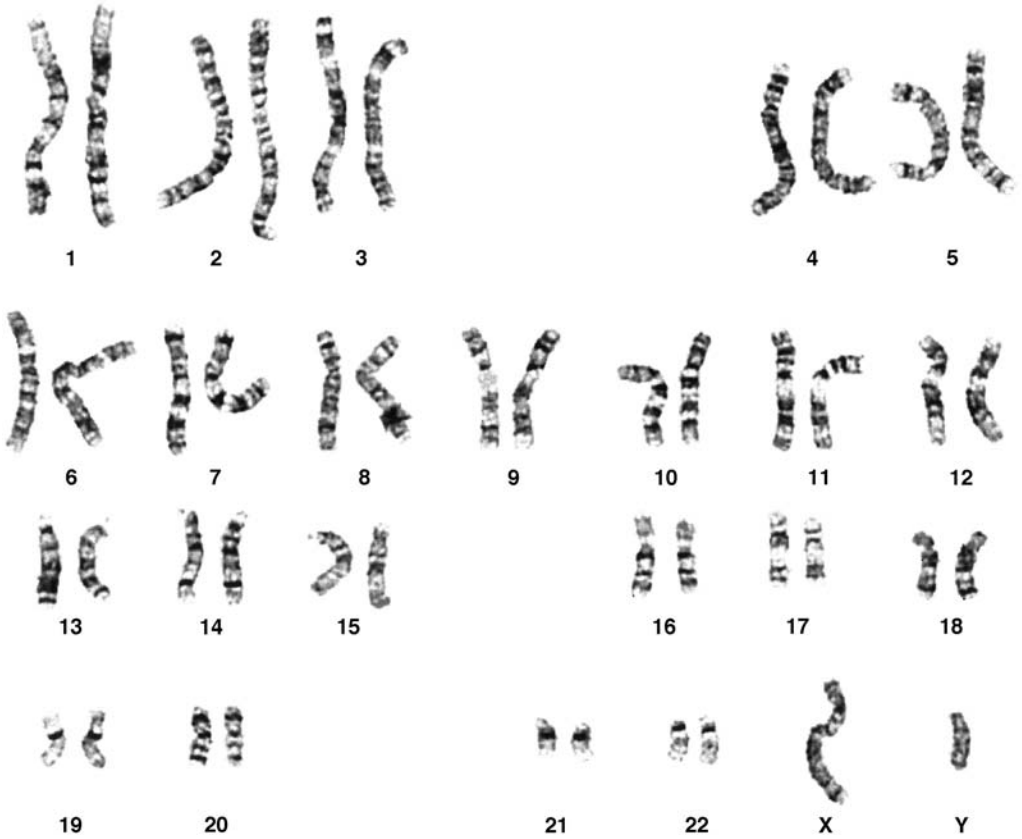

Fig. 2 A normal G-banded male diploid karyotype. [Courtesy of Cytogenetics Department (Dr. H.F.L. Mark, Director), Presbyterian Laboratory Services, Charlotte, North Carolina.]

on 9q34 is fused to the breakpoint cluster region (bcr) locus on chromosome 22, results in a hybrid gene. Subsequently, this gene produces a fusion protein with increased tyrosine kinase activity and eventually leads to myeloid cell transformation. Figure 3 is a simplified illustration of the structural chromosomal rearrangement giving rise to the Philadelphia translocation. It is given special attention here because this reciprocal translocation mechanism was subsequently found to be a common theme: Many of the other structural chromosomal abnormalities found in acute myelocytic leukemia can be explained by the same or similar paradigm. Because of space limitations, the detailed breakage and reunion events leading to the common translocations encountered in the various AML subtypes will not be repeated here. Instead, the reader is referred to the figures provided in the products (probes) section of the Vysis website,[17] as well as in a review by Anastasi and Roulston.[18] Selected examples of the common chromosomal translocations encountered in AML are given in Fig. 1.

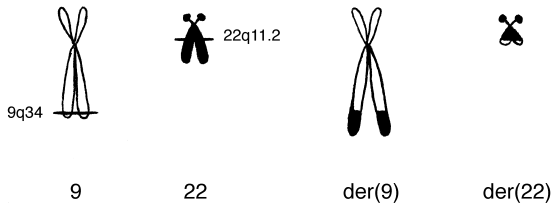

Fig. 3 A simplified illustration of the structural chromosomal rearrangement giving rise to the Philadelphia translocation. Der(22) denotes the Philadelphia chromosome. Chromosomes are not necessarily drawn to scale.

Many patients with AML have characteristic recurring chromosomal abnormalities that were detectable in metaphase preparations by conventional cytogenetics, even before the advent of fluorescent (or fluorescence) in situ hybridization (FISH). FISH is a powerful technique for detecting both numerical and structural cytogenetic abnormalities in nondividing (interphase) as well as dividing (metaphase) cells. On the other hand, conventional cytogenetics can only be performed when the mitotic index is within acceptable limits (i.e., when there is a sufficient number of metaphases to complete a meaningful analysis). Another advantage of FISH is that a large number of cells can readily be scored using the

technique, whereas metaphase cytogenetic analysis is cumbersome and labor intensive when analyzing beyond the standard number of cells.[13,19–22]

FLUORESCENT IN SITU HYBRIDIZATION (FISH)

FISH is a molecular cytogenetic technique that enables the detection of a probe that binds to homologous sequences on a chromosome that is fixed on a glass slide. FISH can be performed on a variety of specimen types such as peripheral blood, bone marrow, and pathological sections.[23,24] Probes used for FISH for cancer applications are most commonly locus-specific DNA probes or alpha-satellite centromere enumeration probes, or a combination of both. The different types of FISH probes and their applications are extensively discussed elsewhere.[25–27]

The technical steps involved in performing FISH are similar to nonfluorescent in situ hybridization techniques. Figure 4 depicts a simplified FISH procedure used in many clinical and research cytogenetic laboratories, whereas Fig. 5 is a simplified schematic representation of the detection of the Philadelphia translocation using FISH. This translocation, characteristic of CML, is used here as an example to illustrate the utility of FISH. Variations of the same basic paradigm enable the detection of most structural chromosomal rearrangements commonly found in AML and other hematopoietic disorders. Other details associated with the principles and techniques of FISH were described by Blancato and Haddad.[25] Research and clinical applications of FISH in cancer cytogenetics include detection of numerical chromosomal abnormalities (aneuploidies), structural chromosomal abnormalities such as translocations, inversions, deletions, duplications, isochromosomes, derivative chromosomes, dicentrics, rings, acentrics, double minutes, amplifications and marker chromosome identification.[28–30] FISH is especially useful in studying a large number of nondividing cells for the determination of clonality, particularly in suboptimal cancer preparations where the mitotic index is low.[31] Additional applications have been summarized elsewhere.[27] Examples of clinical applications of FISH to detect chromosomal abnormalities in AML are further discussed below.

CLINICAL UTILITY OF FISH DETECTION OF RECURRING NUMERICAL AND STRUCTURAL CHROMOSOMAL ABNORMALITIES IN ACUTE MYELOID LEUKEMIA

The convention established by the Fourth International Workshop on Chromosomes in Leukemia[32] serves as the basis for the definition of a clonal abnormality. In clinical cytogenetics, the presence of two or more trisomic or structurally rearranged cells, or three or more monosomic cells, is considered clonal.[4] Following this criterion, a number of recurring clonal cytogenetic abnormalities have been identified in AML based on G-banded studies alone. Selected chromosomal abnormalities found in AML are given in Table 1. The reader is referred to Refs. [6,18] for details and more in-depth discussions.

There are three areas in which FISH is particularly useful in the management of myeloid disease. Perhaps most importantly, FISH is an important part of the diagnostic workup of myeloid malignancy. As noted above, the presence or absence of specific recurrent cytogenetic abnormalities has a major impact on the treatment of AML. Cytogenetically occult lesions, detectable only by FISH, are known to occur,[33] and these could potentially dictate the difference between hematopoietic stem cell transplantation and simple consolidation chemotherapy as postinduction treatment. Moreover, the choice of postinduction chemotherapy is to some extent influenced by cytogenetics, because high-dose cytarabine has been shown to be most effective in the setting of core-binding factor mutations, detected cytogenetically as t(8;21) and inv(16)/t(16;16) chromosome rearrangements.[34] In these diseases, high-dose cytarabine is more strongly indicated than in other types of AML.[35]

Because FISH and traditional cytogenetic banding techniques can have discrepant results,[24,33,36,37] it is important to consider both techniques in the initial cytogenetic assessment of AML. Consideration of the strengths and weaknesses of both cytogenetic techniques (FISH and conventional G-banding) makes it clear how these two assays are complementary in the diagnosis of AML. While FISH has the advantage of being able to evaluate many more cells than conventional cytogenetics, it has the requirement of a prior determination of suspected cytogenetic abnormalities for which one will probe. Because the number of reported cytogenetic abnormalities in AML is large, one cannot search for all such abnormalities at once. In practice, specific FISH probes can be used when the clinical situation and/or morphological criteria suggest specific abnormalities. For example, an FAB diagnosis of acute monocytic leukemia with bone marrow eosinophilia should prompt one to FISH for chromosomes 8, 21, and 16. Acute myeloid leukemia arising after an antecedent hematological disorder should be evaluated with FISH for chromosomes 5, 7, and 8.[37]

FISH is equally important in follow-up of patients treated with either transplant or chemotherapy.[38] For patients relapsing from standard dose consolidation chemotherapy, high-dose antineoplastic therapy with

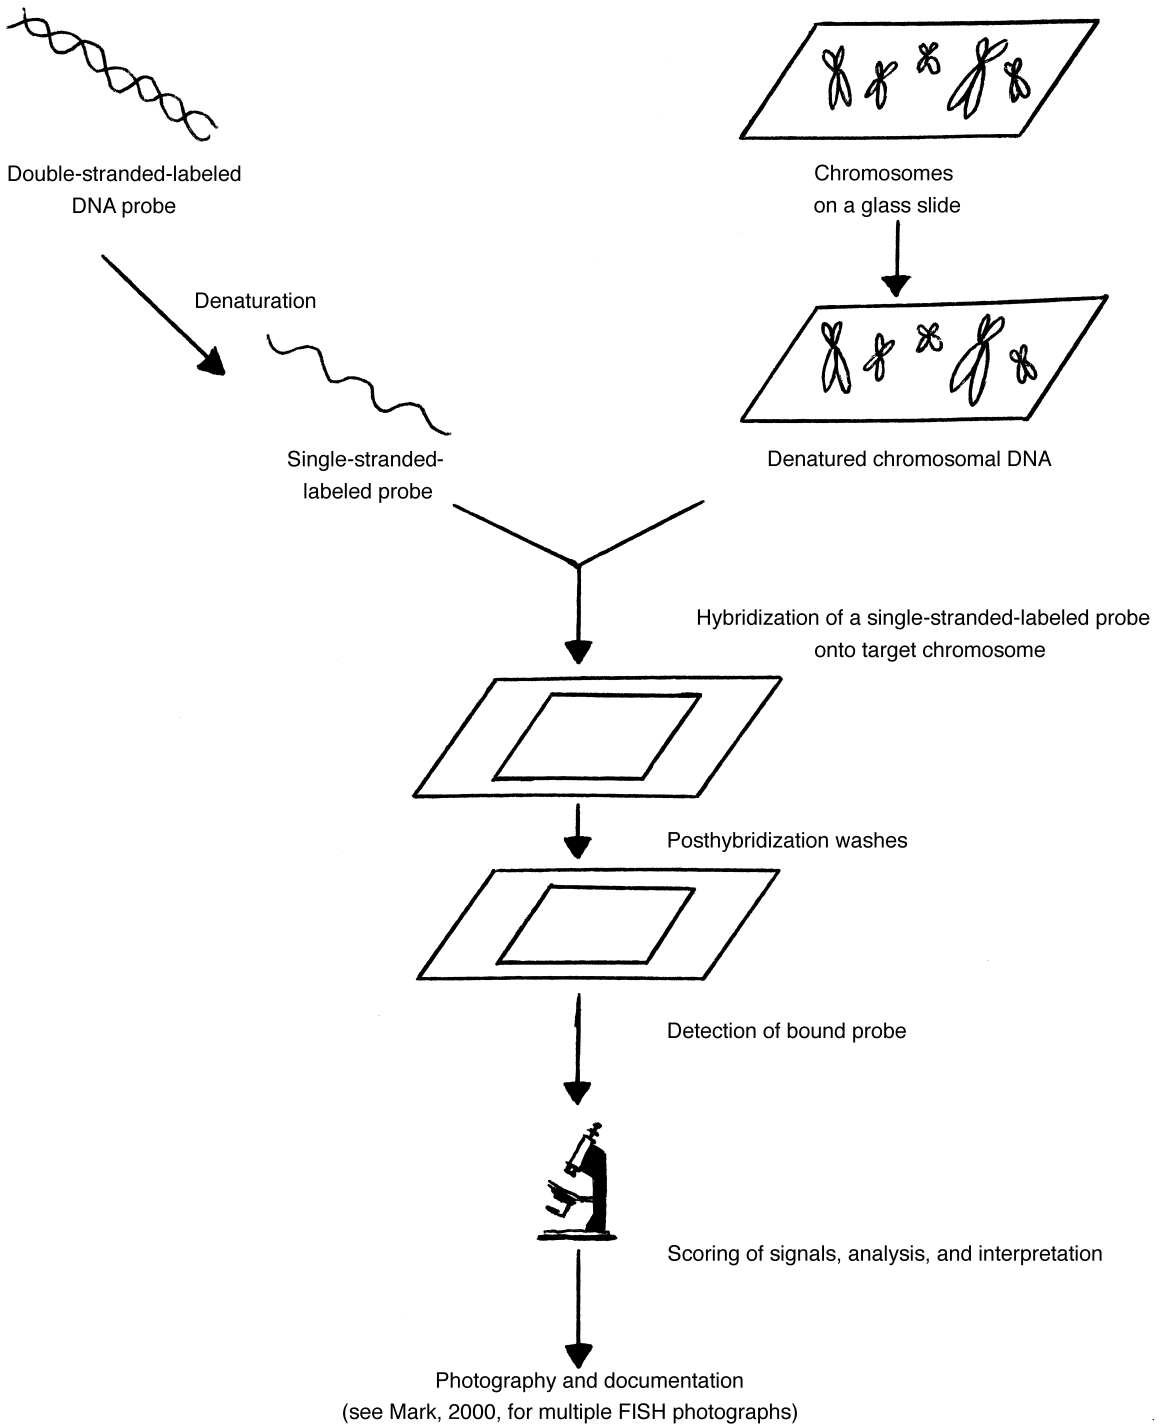

Fig. 4 A simplified illustration of the FISH protocol. (From Ref. [25].)

allogeneic hematopoietic stem cell transplantation is the only known curative modality. Because transplantation is most successful when the disease burden is low, and because FISH is, in general, a more sensitive test than standard cytogenetics, FISH should be a standard part of posttreatment monitoring in all patients with a history of AML with known cytogenetic abnormalities.

In the posttransplant setting, donor lymphocyte infusion (DLI) can be considered to treat relapsed disease. Although this therapy is most useful in CML, it has been

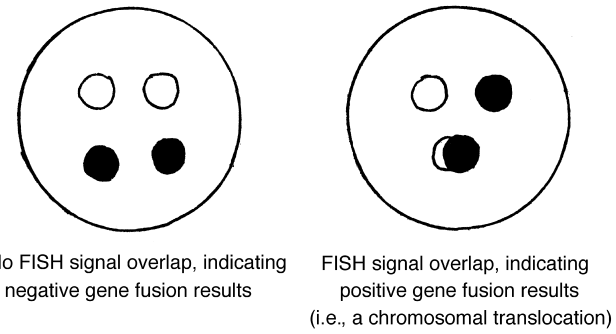

Fig. 5 A simplified schematic representation of the detection of a fusion gene resulting from a translocation using FISH. Variations of the same basic paradigm enable the detection of most structural chromosomal rearrangements commonly found in AML and other hematopoietic disorders.

used in AML as well, wherein, again, treatment with the smallest possible disease burden is felt to be the most likely to succeed. As for postchemotherapy follow-up, cytogenetics and FISH should be standard posttransplant follow-up for all patients with a history of AML with known cytogenetic abnormalities.

There is an additional use for FISH in the posttransplant setting. Because a goal of hematopoietic stem cell transplantation is to completely replace the host's diseased marrow with donor marrow, it is important to demonstrate that this has in fact happened. Donor–host chimerism can be followed by several methods, some of which are labor intensive. In the case in which the donor and host are of opposite sexes, FISH for the X and Y chromosomes can be used to efficiently monitor for persistence, recurrence, or disappearance of host hematopoiesis. This becomes particularly important with the recent development of nonmyeloablative preparative regimens and reduced intensity transplants. Using these strategies, conversion to complete donor chimerism can take up to several months, and DLI may be given simply for persistent host chimerism. In such a clinical setting, an accurate assessment of the levels of donor and host chimerism is crucial and is most simply performed, if the donor and host are sex-mismatched, by FISH.

Finally, one word of caution needs to be mentioned. FISH alone, while more sensitive than conventional cytogenetics, is not a replacement for the standard assay. A clinical error is to order FISH for known chromosomal abnormalities without conventional cytogenetics. This

Table 1 Selected recurrent chromosomal abnormalities found in AML

Selected chromosomal abnormalities	Selected genetic loci	Prognostic significance
inv(3)(q21q26), t(3;3)(q21;q26), ins(3;3)(q26;q21q26)		Intermediate

− Y		Intermediate
No chromosomal abnormalities (normal cytogenetics)		Intermediate
Complex karyotype		Poor

Selected translocations in AML amenable to FISH detection are given in Fig. 1.
[a]Should not be confused with the so-called ''5q-'' chromosome. The latter abnormality, when part of the ''5q-'' syndrome, carries a good prognosis.

will, of course, fail to detect potentially new diagnostic chromosomal abnormalities, thus missing the opportunity for early intervention in the setting of recurrent disease prior to hematological relapse.

CONCLUSION

Cytogenetic analysis of chromosomes in cancer has been exploited as a powerful diagnostic tool, as a means of gaining prognostic information, and as a means of identifying markers for the malignant clone useful in follow-up.[18] Despite the fact that the exact pathogenetic significance of many chromosomal abnormalities is still unknown and that many questions still remain unanswered although clinical cytogenetics has become a formally recognized scientific and medical specialty, cancer cytogenetics has become established as a routine part of the management of patients with leukemia, from diagnosis and prognosis, through treatment, remission, relapse, transplant, and posttransplantation care. In the not-too-distant future, an exact identification of breakpoints and gene loci involved in most, if not all, structural chromosomal abnormalities implicated in cancer should be possible. This will lead to the development and application of more precisely targeted antineoplastic therapy predicated by the results of FISH.

ACKNOWLEDGMENTS

We thank Dr. Roger Mark for reading the manuscript, and Vysis for permission and the option to use some of their beautiful FISH pictures for illustration when needed. We thank Marcel Dekker for their permission to reprint Figs. 11.2, 11.3, and 11.4 in Ref. [18] courtesy of Dr. John Anastasi, the lead author of the Anastasi and Roulston article. The support of colleagues and staff at the Presbyterian Laboratory Services (Cytogenetics Department) in Charlotte, North Carolina, is also acknowledged.

Adeno-Associated Viral Vectors

A

Barrie J. Carter
Targeted Genetics Corporation, Seattle, Washington, U.S.A.

INTRODUCTION

Adeno-associated virus (AAV) vectors have several advantageous features as gene delivery vehicles. Adeno-associated virus does not cause disease or malignancy in any animal species. Adeno-associated virus vectors do not contain viral genes that could elicit undesirable cellular immune responses and appear not to induce inflammatory responses. Adeno-associated virus vectors can mediate long-term gene expression when administered in vivo. They may be best suited for infrequent delivery so that any potential host antibody response to the AAV capsid protein may be less inhibitory. An AAV vector has progressed to phase II trials in cystic fibrosis patients and other AAV vectors have now entered phase I trials for several other clinical indications. The earlier work on AAV vectors and all the current clinical trials used AAV serotype 2 as a prototype. Expanded understanding of AAV biology and other serotypes likely will lead to many more clinical applications of AAV gene therapies in the next several years. Several extensive reviews of the literature are available.

ADENO-ASSOCIATED VIRUS

Adeno-associated virus is a small, DNA-containing parvovirus that has been isolated from humans and other animal species.[1–4] Several serotypes of AAV have been isolated from humans and nonhuman primates.[1,4] Adeno-associated virus is defective and replicates only in host cell nuclei when certain functions are provided by a coinfecting helper adenovirus (Ad) or herpesvirus.[1,2] The mechanism of the helper function is not clearly defined but only a limited set of adenovirus genes, E1, E2A, E4, and the VA RNA are required.[1] Adeno-associated virus has a broad host range but the efficiency of transduction with AAV vectors of different serotypes varies because of differences in cell receptors utilized for entry, cellular trafficking of AAV particles, and uncoating of the viral genome in the cell nucleus. For AAV to replicate, or to function as a gene delivery vehicle, the uncoated single-stranded DNA genome must be converted to a double-stranded molecule to permit transcription and gene expression. Adeno-associated virus infection of cultured cell lines in the absence of helper functions results in persistence of the viral genome as a latent provirus which exhibits a high preference for integration at a specific region on human chromosome 19, but the efficiency and specificity of this process are mediated by the AAV *rep* gene.[5] Adeno-associated virus vectors have no *rep* gene and do not integrate efficiently.[1]

Adeno-associated virus particles are stable to heat and withstand robust purification procedures. Each particle has a protein coat and contains one linear, single-stranded DNA genome, but equal numbers of AAV particles contain a strand of either ''plus'' or ''minus'' complementary sense, and both types of particle are equally infectious. The AAV2 DNA[1] has one copy of the 145-nucleotide-long inverted terminal repeat (ITR) at each end enclosing two open reading frames for the *rep* gene and *cap* gene, respectively. The ITR sequences provide *cis*-acting functions for replication and encapsidation. The family of four rep proteins, Rep78, Rep68, Rep52, and Rep40, and the family of the three capsid proteins, VP1, VP2, and VP3, provide *trans*-acting functions for replication and encapsidation. In the presence of a helper such as adenovirus[1,2] the AAV single-strand genome is converted to a duplex replicating form (RF) then amplified to a large pool of progeny RF molecules that are precursors to encapsidated progeny genomes. In a single growth cycle of several days, AAV may yield in excess of 100,000 particles per cell. This large burst size is important for high specific productivity in vector production.

Design and Production of AAV Vectors

Adeno-associated virus vector production was enabled by the molecular cloning of double-strand AAV DNA into bacterial plasmids followed by transfection into helper virus-infected mammalian cells.[1,6] This results in replication of the AAV genome free of any plasmid sequence to yield AAV particles. For AAV vector construction, the *cis*-acting ITR sequences must be retained and the unique sequence is replaced with foreign DNA.[1,6] There is a limit of about 5 kb of DNA that can be packaged in an AAV vector particle. Production of AAV vectors in host cells can be accomplished entirely by DNA transfection-based methods or by cell-based systems

DOI: 10.1081/E-EDGP 120029815

that do not require DNA transfection.[1,6] Both approaches can give a specific productivity in excess of 10^4 vector particles per cell, but the cell-based systems may be more amenable to scale-up for commercial production.

In DNA transfection-based systems, human 293 cells are transfected with DNA plasmids containing the AAV vector cassette, the rep and cap genes, and the adenovirus E2A, E4, and VA genes. Alternatively, stable producer cell lines that contain the rep and cap complementing genes and the vector genome are infected with Ad. Producer cell lines are readily scalable AAV, but a new producer cell line must be generated for each individual AAV vector. A third approach uses a packaging cell line containing a rep–cap gene cassette that is then coinfected with an Ad/AAV hybrid virus, which is an E1 gene-deleted Ad containing the AAV-ITR vector cassette, and Ad to provide E1. After infection, the rep–cap genes, the AAV-ITR cassette is amplified and packaged into AAV particles. The same packaging cell line can be used for production of different AAV vectors simply by changing the Ad/AAV hybrid virus. Variations of these methods use herpes simplex virus (HSV) in the production of AAV vectors by utilizing a hybrid virus in which the AAV *rep–cap* genes were inserted into the HSV genome. Insect cells may be used with baculovirus vectors containing rep–cap gene cassettes or the AAV-ITR vector cassette to produce AAV vectors. Adeno-associated virus vector purification is generally accomplished by chromatographic methods, including ion exchange and affinity resins.[1] Adeno-associated virus vector amounts and concentrations are measured by the number of vector genomes that are encapsidated, and thus protected from digestion by DNAse, and are expressed in units of DNAse-resistant particles (DRP).

AAV Vector Genome Metabolism

A complex pathway of events[1] impact the function of AAV vectors such as the availability of specific cell-surface receptors, cellular trafficking, and potential diversion of AAV particles into a ubiquitin-mediated proteosome degradation pathway, and delay in uncoating in the cell nucleus. The uncoated single-strand genome must be converted to a duplex molecule. Following this, a succession of additional events result in the vector genome being converted into larger, mostly circular concatemeric molecules.

Single-strand to double-strand conversion step may be rate-limiting, but this can be overcome by using self-complementary vector genomes that are not more than half the size of the AAV genome. These genomes are packaged as a dimeric molecule equivalent to a RF formed during vector genome replication. Upon uncoating, these molecules reassociate (''snap back'') to duplex molecules with pseudo zero-order kinetics.[7] The ability of AAV vectors to form concatemers also extends the capacity of AAV vectors in a ''dual-vector'' system. Expression cassettes up to 9 kb in size can be divided between two AAV vectors, and coinfection forms concatemers to generate an intact expression cassette.[8]

Wild-type AAV, in cell culture, integrates into human chromosome 19, but this process requires the rep gene which is not present in AAV vectors. In contrast, a variety of animal models show that, in the absence of selective pressure, AAV vectors persist predominantly as circular concatemers. The circularization appears to involve recombination between ITRs.[9] The majority of these concatemers are episomal and integrated copies of vector in organs such as liver or muscle may be rare.[10,11] The relative rarity of integration is of importance in assessing the safety profile of AAV vectors for clinical applications.

In Vivo Targets for AAV Vectors

The preferred in vivo targets for AAV vectors are cells that are nondividing or turnover relatively slowly. Early studies using AAV2 vectors demonstrated transgene expression in organs such as lung, muscle, liver, brain, and retina[12–14] with persistence for months to years. The relative hierarchy of transduction efficiencies by individual serotypes is not fully clarified, but several other serotypes show enhanced efficiency in various organs.[1] Additional efforts are underway to modify the AAV capsid sequences to alter or enhance targeting of specific cells.[15]

Clinical Applications

Administration of AAV vectors does not appear to induce significant innate or proinflammatory responses, and in the absence of any viral genes cellular immune responses against the viral components are not readily evoked. Adeno-associated virus vectors may be used mainly for clinical applications requiring only infrequent delivery, but potential humoral immune responses against the viral capsid, either preexisting in the human population or induced by vector administration, must be considered.[1,4] It will require studies in humans to determine how neutralizing antibody responses to AAV vector capsids might impact applications of AAV vectors. There have been few, if any, documented reports or indications of toxicity mediated by AAV vectors in animal studies or human clinical trials.

The toxicity of an AAV vector has been extensively tested for a vector expressing the cystic fibrosis transmembrane regulator (CFTR) protein following delivery of these AAV–CFTR vector particles directly to the lung in rabbits and nonhuman primates.[16] The favorable

safety profile of AAV-CFTR in the preclinical studies was predictive of a similar safety profile observed in the clinical trials. Adeno-associated virus–cystic fibrosis transmembrane regulator was the first AAV vector introduced into clinical trials and it has been tested in a series of trials in CF patients by delivery to the lung, the nasal epithelium, and the maxillary sinus, and has now completed an initial phase II trial in the lung. The phase II multidose, double-blinded, placebo-controlled, and randomized trial was conducted in 37 CF patients with mild CF disease.[17] Patients received three doses (10^{13} DRP per dose) at monthly intervals, administered by inhaled aerosol. Multidose administration was safe and well tolerated, and met the primary endpoint of safety of repeated delivery. There was a significant treatment-related effect of positive increase in pulmonary function as measured by FEV1 at 30 days and a trend to a decrease in the proinflammatory cytokine IL-8 in the lung which was significant at 14 days.

A clinical study of intramuscular injection of an AAV2 vector expressing human FIX in adults with severe hemophilia B was recently completed and showed a low-level expression of FIX in transduced muscle and some possible modest changes in clinical endpoints including circulating levels of FIX and reduced frequency of factor IX protein self-administration by two patients.[18] A second phase I clinical trial with the same AAV2-FIX vector has been initiated in hemophilia B patients, but in this trial the vector is administered via hepatic artery injection to target the liver which may be the natural source of FIX production.

Several clinical trials of AAV vectors in the central nervous system have begun. Patients suffering from Parkinson's disease (PD) are being administered, by coinjection into the subthalamic nucleus (STN) region of the brain, two different AAV2 vectors each expressing one of the isoforms of glutamic acid decarboxylase.[19] Canavan disease is a childhood leukodystrophy that results from an autosomal recessive mutation in the gene for aspartoacyclase (ASPA) that causes accumulation of the toxic metabolite *N*-acetyl-aspartate. A clinical trial is underway in patients aged between 3 months and 6 years who are being administered an AAV2–ASPA vector in up to six sites in the frontal, varietal, and occipital regions of the brain.[20]

Hereditary emphysema results from mutations in the gene for the protease alpha-1-anti-trypsin (α1AT), and a clinical trial of intramuscular administration of AAV2–α1AT vector in patients with this disease has begun.[21] Rheumatoid arthritis (RA) is a chronic autoimmune disorder that causes significant disability including inflammatory joint disease, and TNF-α is a clinically validated target. In an induced arthritis model in Lewis rats, administration of an AAV vector encoding soluble rat TNF receptor:fc fusion gene, either systemically (intramuscular), or locally (intraarticular), resulted in profound suppression of arthritis.[22] Based upon this, a phase I double-blind, placebo-controlled dose escalation trial has begun in patients with rheumatoid arthritis to assess the safety of intraarticular injection of an AAV2 vector expressing a soluble human TNF receptor:fc fusion gene. The long-term durability of transgene expression in the muscle suggested that AAV vectors may have utility as vaccines.[23] An AAV2 vector expressing HIV genes, administered by intramuscular injection, is currently being tested in phase I clinical trials in seronegative subjects in Europe.

CONCLUSION

There is increasingly rapid progress in developing therapeutic applications of AAV vectors. The early clinical testing of AAV vectors for the treatment of CF was extremely important in initiating the regulatory environment for AAV vectors and demonstrating the inherent good safety profile of AAV vectors. As more groups have extended investigations to additional in vivo models, the potential utility of AAV vectors as therapeutic gene delivery vehicles has gained more widespread interest. The development of more sophisticated production systems for AAV vectors has enhanced both the quantity and quality of vectors that can be produced. Additional work to understand the intracellular metabolism of AAV vectors and modify the transduction efficiency by judicious choice of serotype or by modification of the capsid structure will expand the use and potency of AAV vectors. It is likely that in the next few years there will be a significant increase in clinical testing of AAV vectors for additional therapeutic applications.

Adenoviral Gene Therapy

A

Willemijn M. Gommans

Groningen University, Groningen, The Netherlands

INTRODUCTION

Over the last decade gene therapy has evolved as a promising method for the treatment of many diseases. To deliver the genetic material into cells, a viral vector can be utilized. One of the most efficient vectors available at this moment is the adenovirus. Incorporation of specific transgenes into the genome of the adenovirus ensures that the genetic material will be delivered into the nucleus after viral infection. One multigenetic disease which receives much attention in the research area is cancer. Many attempts are made to tackle this still largely incurable disease with gene therapy. The adenovirus may serve as a vector to deliver toxic genes to the malignant cells, but, on the other hand, this virus can also be used as a tool by itself to kill these cells. In the latter approach, the virus may replicate specifically in tumor cells, causing cell lysis and release of new virus progeny.

THE ADENOVIRUS AS GENE THERAPY VECTOR

Our understanding about the biology of the adenovirus has increased enormously in the last decades, and today this virus is commonly used as a vector for gene transfer.[1] This knowledge about the adenovirus has led to a fast progression in the development of new gene therapeutic agents. The adenovirus is known for its efficient infection of dividing and nondividing cells, resulting in an efficient delivery of therapeutic genes to the site of action. Other advantages for the use of adenoviral vectors are the possibility to produce these viruses in very high titers and that they are relatively harmless.

To increase the safety measurements of adenoviral vectors in gene therapy, most adenoviral vectors used are unable to replicate. This elimination of replication is caused by the deletion of the E1A and E1B region of the adenoviral genome. This region is necessary for the adenovirus to replicate. The E3 region of the adenoviral genome may also be deleted to increase the space in the genome available for the insertion of transgenes up to 7.5 kb. The E3 region is not required for replication of the adenovirus, but includes genes that are able to interfere with the defense system of the host cell after infection.

Currently, the realization that clinical applications of adenoviral vectors encounter limitations becomes more and more clear. Although adenoviruses are among the most efficient vectors used in gene therapy, they are not always efficient enough. This is especially true for cancer gene therapy, where it is necessary to kill every tumor cell, otherwise the malignant tissue will reoccur. One intratumoral injected dose of adenoviral vectors will infect maximally 10% of the tumor cells, thus the therapeutic effect will be limited. Another major limitation of adenoviral vectors is the biodistribution of the adenovirus. When administrated intravenously, the majority of the virus ends up in the liver, where it can cause severe liver toxicity. Therefore a large proportion of research is conducted on the untargeting of the liver.

There are two main routes to untarget the liver and to achieve the specific gene therapeutic effect in particular sites of the body. The first one is transductional retargeting and the second one is transcriptional retargeting. Transductional retargeting changes the cell entry route of the virus, whereas transcriptional retargeting restricts the expression of genes to the target cells (Fig. 1).

RETARGETING OF ADENOVIRAL VECTORS

The adenovirus contains a protein capsid with protruding fibers. These fiber proteins form a trimer and the C-terminal region of these fibers is called the fiber knob. The fiber knob recognizes and binds to the host cell via the coxsackievirus–adenovirus receptor (CAR), which is present on many cell types. Upon binding to CAR, secondary interactions between the adenovirus and cell surface receptors cause the internalization of the adenovirus. By shielding or modifying the fiber of the adenovirus, the native tropism can be altered. One possibility is to construct bispecific antibodies that on one side bind to the adenoviral fiber knob and on the other side will bind to an antigen present on target cells. This way, the adenovirus will be retargeted to cells that express this specific antigen. A second possibility is to construct

DOI: 10.1081/E-EDGP 120029811

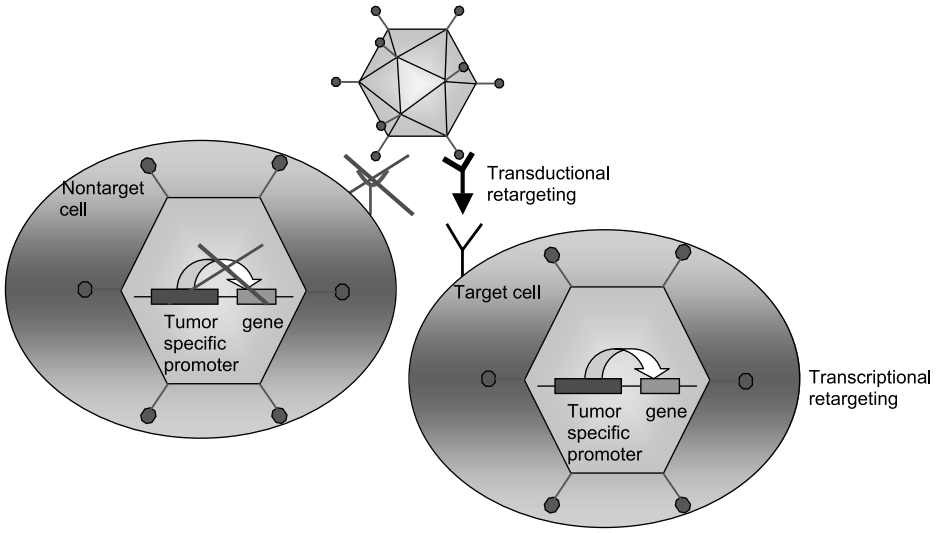

Fig. 1 To achieve transgene expression specifically in the tissue of interest it is possible to either change the homing of the virus (transductional retargeting) or to alter the expression profile of the transgene (transcriptional retargeting). (*View this art in color at www.dekker.com.*)

an adenobody, fusing an antibody directed against the fiber knob with a ligand for a receptor present on the cell type of interest. A third possibility to modify the tropism of the adenovirus is to genetically alter the fiber knob itself. It is possible to genetically insert sequences to be expressed within the fiber knob that are recognized by a certain receptor present on the cell type of interest without modifying the interactions within the trimer itself. However, it has to be noted that although interactions between the CAR receptor and the adenoviral fiber knob play an important role in cell uptake in vitro, these interactions might not play a crucial role in vivo.[2] Adenoviral particles containing a mutation within the fiber knob which abolished binding to the CAR receptor were systemically administrated in nonhuman primates. Surprisingly, the biodistribution of this ablated adenovirus was similar compared to the nonmodified adenovirus. This study showed that other receptors such as the heparan sulfate glycosaminoglycans (HSG) might play an important role in liver uptake. The construction of an adenovirus which is ablated for interactions between the virus and the HSG receptors can be a promising way to untarget the liver. Another approach to prevent uptake by the liver is PEG-ylation of the adenovirus.[3] Coating of the adenovirus by polyethylene glycol (PEG) will shield the adenovirus and prevent uptake by the liver. It is feasible to bind a homing device onto the PEG. This way the PEG-ylated adenovirus will be directed to the site of interest.[3]

Besides transductional retargeting of the adenovirus to the tissue or cell type of interest, it is also possible to transcriptionally retarget the adenoviral vector. Transcriptional retargeting is the modification of the transgene expression profile to increase the specificity of gene transcription towards a certain tissue or cell type. Such increased specificity can be obtained by placing the gene of interest under control of a tumor- or tissue-specific promoter. This way, the gene of interest will only be transcribed in cells where the promoter is active.

ONCOLYTIC ADENOVIRUSES

In the battle against cancer it is very important to kill every tumor cell present; otherwise, the remaining malignant cells will continue to grow and form new tumors. Although adenoviral vectors are one of the most efficient vectors used, one injected dose is thought to infect maximally 10% of the tumor cells. Thus it is necessary to increase the efficiency of adenoviral infection. An approach to increase this efficiency is to allow the virus to replicate, thereby increasing the amount of infectious particles. Replication of the adenovirus inside these cells will eventually lead to cell lysis, thereby releasing newly formed virions within the tumor mass. The subsequent viral generations will continue this cycle of infection, replication, and cell killing, thereby killing more and more tumor cells, resulting in the elimination of the tumor mass. Obviously, adenoviral replication should be confined to the tumor cells. Adenoviruses that can only replicate inside malignant cells are termed conditionally replicating adenoviruses (CRAds).[4]

Two different approaches can be distinguished in constructing CRAds, generating either type I or type II CRAds. Type I CRAds contain a specific deletion in the adenoviral genome based on genes that are differentially expressed between tumor and normal cells. Due to this mutation normal cells are not permissive to adenoviral replication. In tumor cells this host cell defense mechanism is deregulated, thereby creating the perfect environment for the virus to replicate.

A well-known example of a type I CRAd is the adenovirus Onyx-015, also known as *dl*1520.[5] This virus contains a deletion in the adenoviral E1B-region. As mentioned before, the E1A and E1B regions are important for the replication of the adenovirus. The adenoviral E1B 55-kDa gene codes for a protein that inhibits p53 function which is an essential step in viral replication. Onyx-015 is deleted for E1B 55 kDa, and thus unable to inhibit p53. Therefore in normal cells, where p53 is functionally present, Onyx-015 will not be able to replicate as p53 cannot be inhibited by this virus. However, in most tumor cells the function of p53 is already disturbed and the ability of the virus to inactivate p53 is not required anymore. This causes selective adenoviral replication in p53-deficient tumor cells. At this moment, phase I, II, and III clinical trails have been conducted with limited success.

Type II CRAds are adenoviruses where the expression of genes essential for adenoviral replication are under the control of a tumor-specific promoter. When this promoter is active, expression of this gene will result in replication of the virus. These promoters should mainly be active in tumor cells to ensure that replication predominantly occurs inside the malignant tissue. An example of a tissue-specific promoter is the prostate-specific antigen (PSA) promoter which is highly active in PSA-producing prostate cells and shows limited activity in other tissues. Placing a gene essential for replication directly under the control of the PSA promoter directs adenoviral replication primarily to prostate cells that express PSA.[6] Thus this adenovirus will replicate inside prostate (tumor) tissue while sparing the other tissues. At the moment, phase I and II trials are being conducted. Another example of a tumor-specific promoter is the telomerase promoter, which is active in more than 80% of all tumors. An adenovirus which has the expression of a replication essential gene under control of the telomerase promoter can therefore replicate in a broad range of tumor types. Other examples of tissue- or tumor-specific promoters are the epithelial gycoprotein-2 promoter, which is active in most epithelial-derived cancers making it a good candidate for the treatment of many tumor types, and the tyrosinase promoter, which is highly active in melanoma cells.

Although the theoretical idea behind type I and type II CRAds is very attractive, some drawbacks exist. In the case of an adenovirus where the expression of the replication essential gene E1 was restricted to melanoma cells using the tyrosinase promoter, replication was shown to be specific for melanoma cells at low infectious units. However, at a higher dosage replication was also demonstrated in nonmelanoma cells.[7] This loss of specificity might be due to the presence of adenoviral promoter-like sequences upstream of the tyrosinase promoter. These sequences may interfere with the specific regulation of the tyrosinase promoter, causing activation of transcription in cells which lack actual tyrosinase promoter activity. Another possibility is the presence of E1-like proteins inside the cell, compensating for the lack of adenoviral E1 expression in nonmelanoma cells.

DOUBLE-CONTROLLED CONDITIONALLY REPLICATING ADENOVIRUSES

After the systemic administration of adenoviral vectors, most of the virus ends up in the liver. When adenoviral replication is not strictly restricted to certain cell types or tissues, severe liver damage might occur due to adenoviral replication and consequential lysis of the liver cells. Because of this importance to restrict adenoviral replication, solutions have to be found for the observed aspecific replication of CRAds. One solution is a double-controlled conditionally replicating adenovirus (dcCRAd).[8] In a dcCRAd not one but two replication essential genes are controlled by two tumor-specific promoters. For example, both the adenoviral E1A and E1B genes have been placed under the control of two different tumor-specific promoters. Also, studies have already been conducted with both the E1A and the E4 gene under control of two different tumor-specific promoters.[9] E1A, E1B, and E4 are all examples of adenoviral genes that are essential for replication of the adenovirus. The approach of a dcCRAd preferentially includes a more general promoter. For example, the telomerase promoter which has shown activity in more than 80% of all tumors and which is inactive in liver cells. The telomerase promoter might work in concert with a tissue-specific promoter such as the tyrosinase promoter to restrict the expression of two genes essential for adenoviral replication. Only in melanoma cells which contain both telomerase and tyrosinase activity will replication occur.

Another approach for designing a dcCRAd is to combine a type I and a type II CRAd. On one hand, these adenoviruses contain a deletion in the adenoviral genome to prevent replication in cells without a disturbed cell cycle. On the other hand, these viruses also contain a tumor-specific promoter to restrict the expression of adenoviral genes essential for replication to cells where this promoter is active.

CONCLUSION

Adenoviruses can be utilized as a vector for the delivery of genetic material into cells. They possess many valuable characteristics, making them good candidates as gene therapy vectors. However, a major obstacle for clinical applications of adenoviral gene therapy vectors is the biodistribution of the virus. When administrated systemically, over 90% of the administrated adenovirus ends up in the liver where it can cause liver toxicity. Two different approaches are being pursued to deal with this problem, referred to as either transductional or transcriptional retargeting.

Transductional retargeting is focused on preventing the liver uptake. Either by modifying or shielding the fiber knob, thereby inhibiting binding to the CAR receptor, or by shielding the complete adenovirus by means of PEGylation. The next step is the addition of a homing device for retargeting to the tissue or cell type of interest.

Transcriptional retargeting does not prevent liver uptake, but gene expression will only occur in the target tissue or cell type. This can be accomplished by placing the transgene under the control of a tumor- or tissue-specific promoter. When genes essential for adenoviral replication are placed under control of such a promoter selective replication will occur, thereby enhancing the efficiency of infection.

By combining these two fields of expertise it is possible to construct an adenovirus that, on one hand, circumvents the liver because it is transductional retargeted and homes to the tissue of interest. On the other hand, this adenovirus will selectively express the transgene in the targeted tissue.[10] This means that specificity is increased and therefore it is possible to systemically administrate a higher dosage of the adenovirus, increasing the efficiency of adenoviral gene therapy. It is also feasible to transductionally retarget CRAds. In this case more infectious viral particles will reach the tumor environment, increasing the initial infectious dose and subsequent infection efficiency.

Although much progress is made in the transductional and transcriptional retargeting of adenoviral vectors, there are still hurdles to overcome. Success in the clinic using CRAds is not convincing. One problem might be that tumors not only consist of tumor cells but also of connective tissue impairing the spread of the adenovirus throughout the tumor tissue. However, the combination of adenoviral vectors and chemotherapy seems to result in synergistic antitumor effects. Compared to other nonviral and viral vectors, the adenovirus is among the most efficient vectors currently used and is relatively harmless. Progress is made very rapidly and the use of adenoviruses in the clinic is a promising method for the treatment of cancer.

Alagille Syndrome

Michelle Hadchouel
Michèle Meunier-Rotival
Inserm U347, Le Kremlin Bicêtre, France

INTRODUCTION

Alagille syndrome (AGS; Mendelian Inheritance in Man 118450) was described more than 30 years ago as a genetic entity characterized by five major features: chronic cholestasis owing to paucity of interlobular bile ducts, peripheral pulmonary stenosis, butterfly-like vertebrae, posterior embryotoxon, and peculiar facies. Alagille syndrome is inherited in an autosomal dominant manner. The high variability of phenotypic findings led rapidly to a modification of the definition. It is widely accepted that individuals presenting with three of the five main features are considered to have AGS. As initial descriptions, minor less-frequent features were added to the list of criteria including other manifestations involving previously identified targets such as the vascular system, the bones, and the eye, and those involving previously unspecified organs or tissues such as the ear, the pancreas, the kidney, and the intestine. The disease-causing gene is Jagged1 that encodes a protein belonging to the family of Notch ligands. There are now more than 226 described intragenic mutations of the *JAGGED1* (*JAG1*) gene, none corresponding to the intracellular part of the protein. *JAG1* mutations are identified in roughly 70% of patients meeting criteria for AGS leaving 30% of patients with no detectable alteration of the coding sequence. As most often in human disease there is no genotype/phenotype correlation.

The expression pattern of *JAG1* had enabled the manifestations already observed to be explained and to open a field for investigations to evidence other system involvement. The role of the Notch signaling pathway during normal liver and bile duct development is still unclear and the mechanism of action of the mutated *JAG1* gene remains to be elucidated.[5] Haploinsufficiency is supported by the entire deletion of *JAG1* in few patients, but a dominant negative effect of a truncated JAG1 protein cannot be excluded.

CLINICAL DESCRIPTION

The syndrome was initially described as the association of five major features: paucity of interlobular bile ducts, peripheral pulmonary artery stenosis, butterfly-like vertebral arch defect, posterior embryotoxon, and a peculiar facies.[1] However, minor features such as renal abnormalities, skeletal defect, high-pitched voice, and mental and growth retardation were also described. In addition, some patients occasionally present with clinical features including other arterial stenosis, small bowel atresia, deafness, and diabetes.[2]

Because of the variable expressivity of the syndrome, individuals presenting with three of the five main features are considered to have AGS.[1] All associations are observed and liver or heart manifestations may be absent. Liver and heart involvement are present in 95% of the patients, posterior embryotoxon in 80%, and vertebral arch defect in 65%.[2]

Hepatic Manifestations

In a series of 163 children with liver involvement, 132 presented with neonatal cholestatic jaundice, and among the 31 patients who did not present with neonatal jaundice 5 became jaundiced later.[3] Neonatal cholestasis may be complete with acholic stools. The evolution is characterized by persistent or intermittent icterus, but usually biological cholestasis persists. Pruritus, hypercholesterolemia, xanthomas, and fat-soluble vitamin malabsorption are nonspecific consequences of the cholestasis. In some patients, unexplained attenuation or disappearance of pruritus and xanthomas occurs along with decrease in cholesterol level. Bile duct paucity is usually demonstrated by liver biopsy. This biopsy could be unnecessary in patients with complete syndrome.[4]

Cardiovascular Manifestations

Peripheral pulmonic stenosis is the characteristic cardiovascular abnormality of AGS, but complex intracardiac disease especially tetralogy of Fallot is not uncommon. The incidence of more diffuse vascular disease, including aortic coarctation or stenosis of other main arteries, is probably underestimated.[5]

DOI: 10.1081/E-EDGP 120025765

Vertebral Abnormalities

Although vertebral abnormalities have no functional consequences, they are important because they are useful for diagnosis. They consist of a defect of fusion between the two anlagen of the vertebral body giving the aspect of butterfly-like vertebrae. They are mainly observed at the dorsal level.

Ocular Manifestations

The most common finding in AGS patients is posterior embryotoxon, which is the more minor form of eye anterior chamber abnormality. Posterior embryotoxon has no consequence on visual acuity and is present in 10–15% of normal individuals. All the spectrum of eye anterior chamber abnormalities may be observed including glaucoma. Retinal changes such as pigmentary retinitis were formerly ascribed to vitamin deficiency, but progressive blindness may occur even with normal vitamin level.[6]

Peculiar Facies

Although the specificity of peculiar facies has been a matter of debate, there is a facial resemblance among the patients who have a prominent forehead, deep-set eyes, mild hypertelorism, a straight nose, and a small pointed chin without true dysmorphy.

Renal Manifestations

Renal abnormalities are observed approximately in 60% of AGS patients and could be considered as a sixth major feature. Tubular acidosis is frequent during infancy and usually disappears, but renal failure may occur in adulthood. Abnormalities of renal development such as renal cysts are common.[3,7–9]

DIFFERENTIAL DIAGNOSIS

The diagnosis of Alagille syndrome is primarily based on the presence of at least three out of the five main features. The differential diagnosis of each feature of the syndrome will result in a very long and tedious list. Association of butterfly vertebra and cardiac defects has been reported in patients with deletions of 22q11. Atrial septal defect associated with eye anterior chamber anomaly may be observed in Turner syndrome.

The main issue of differential diagnosis concerns diagnosis of neonatal cholestasis. The incidence of neonatal cholestasis is thought to be 1 in 2000 live births; the incidence of extrahepatic biliary atresia is between 1 in 8000, and 1 in 15,000 live births; and AGS incidence is probably between 1 in 70,000, and 1 in 100,000 live births. Complete and permanent acholic stools lasting more than 7 days suggest extrahepatic biliary atresia but may be observed in AGS. Even if biliary hypoplasia has been evidenced by microscopic examination of the biliary remnant of AGS patients, true atresia has never been observed. Moreover, it has been suggested that prognosis is worse in AGS patients who had undergone hepatoportoenterostosmy. Therefore it is important to look for extrahepatic features of AGS before surgery; conversely, cardiac abnormalities may be associated with biliary atresia, and needle liver biopsy is helpful in such situations where timing for surgery is crucial for prognosis of extrahepatic biliary atresia.[4]

MANAGEMENT AND PROGNOSIS

Most of the time the diagnosis is suspected in an infant with heart defect or cholestasis.

The diagnosis relies on:

- Clinical examination: facies, icterus, xanthomas, cardiac murmur, and liver enlargement.
- Chest radiographs: butterfly-vertebrae.
- Ophthalmologic examination: embryotoxon and other anterior chamber anomalies, retinitis.

Further evaluation includes:

Renal ultrasound examination and function tests.
Ear examination and audiogram.

There is no specific treatment, and except for the presence of complex congenital heart diseases the presence or severity of a clinical feature carries no predictive value.

Complex cardiac disease may require surgery; pulmonary stenosis is usually well tolerated and does not progress. When liver involvement is present, careful nutritional management is mandatory especially if liver transplantation is indicated. Supplementary lipid-soluble vitamins must be given regularly either orally or by intramuscular injections. Relief of pruritus is a major problem; ursodeoxycholic acid may be used but rifampicin and opioid-antagonists are more effective. The prognosis of liver disease is worse in children who present with neonatal cholestatic jaundice. However, severe liver complications are possible even after late onset of liver disease, demanding follow-up throughout life. Liver transplantation is eventually necessary in roughly 30% of patients.[3,8,9]

Spontaneous intracranial bleeding is a widely recognized complication, and AGS patients are at special risk for bleeding, either spontaneous or during surgery or other medical procedures. This should be taken into account before deciding on an invasive procedure.[10]

MOLECULAR GENETICS

The autosomal mode of transmission with reduced penetrance suggested by analysis of a limited number of families was confirmed by a segregation analysis. The proportion of sporadic cases when both parents are clinically normal was estimated to be 50%. These findings and the variability of expression of disease within families make genetic counseling difficult until the identification of *JAG1* mutations.[14]

JAG1 Is So Far the Only Responsible Gene

Identification of deletions of the short arm of chromosome 20 allows assigning AGS locus to 20p12. *JAG1* gene was mapped to this region, and mutations in the coding sequence were identified in AGS patients.[11,12]

Catalogue of the Mutations of the *JAG1* Gene

Most of the published data were obtain by SSCP followed by sequencing of exons with modified profile. There are now more than 226 described intragenic mutations of the *JAGGED1* gene, none corresponding to the intracellular part of the protein and there is no clustering or ''hotspots.''[13] Most of the mutations (66%) introduce premature stop codon, but all kinds of mutations including total gene deletion (5%), missense (14%), and splicing (15%) have been observed.[14] A number of polymorphisms have been described and in the absence of a functional study, the distinction between missense mutations and polymorphism relies on the usual criteria. Most of the missense mutations are in the EGF-like repeats, the cysteine-rich region, or affect amino acids conserved in JAG1. *JAG1* mutations are identified in roughly 70% of patients meeting the criteria for AGS, leaving 30% of patients with no detectable alteration of the coding sequence.[14,15]

Transmission and Phenotype–Genotype Correlation

Two thirds of the *JAG1* mutations are de novo. No phenotypic difference is observed between patients with or without visible rearrangement in 20p12, neither between patients with and without an identified mutation in *JAG1*. Furthermore, the number and the severity of the features vary among patients carrying the same mutations even within the same family. A significant frequency of mosaicism for *JAG1* mutations has been reported.[13]

Normal and Abnormal *JAG1* Gene Product

JAG1 gene encodes a transmembrane protein belonging to the family of Notch ligands. Notch signaling pathway seems to control the ability of a broad spectrum of precursor cells to progress to a more differentiated state both during development and oncogenesis.[16,17] Analysis of JAG1 expression during human development demonstrates that renal manifestations and other miscellaneous features previously described were not coincidental.[18]

The mechanism causing AGS may involve haploinsufficiency or a dominant negative effect. Most of the mutations (70%) introduce premature stop codon, which is expected to result in truncated secreted proteins. Such truncated Notch ligands in Drosophila have a dominant negative effect.[19] However, corresponding mRNA may be degraded by nonsense mediated RNA decay, resulting in a haploinsufficiency state comparable to the entire deletion of the gene.[20]

JAG1 mutations are identified in 70% of AGS patients; although alteration outside the coding sequence is still possible, the involvement of other components of Notch signaling pathway either as another disease-causing gene or as a modifier is very likely. This hypothesis is supported by recent demonstration that hypomorphic allele of Notch2 may be both responsible for bile duct paucity and acts as a genetic modifier of Jag1 haploinsufficiency in a mice model.[21]

GENETIC COUNSELING AND PRENATAL TESTING

There is a general agreement for considering that genetic testing is not necessary for the diagnosis of AGS which relies mainly on clinical examination. But genetic testing of the proband is mandatory before genetic counseling. This testing includes karyotyping and fluorescent in situ hybridization (FISH) looking for deletion, and if negative sequencing of *JAG1* gene coding sequence exists.

Genetic Counseling

Risk for the sibs of a proband

If a mutation of JAG1 is present, prenatal genetic testing is available, and testing of the parents will allow to determine whether the mutation is transmitted or de novo.

If the mutation is transmitted, the risk in sibs is 50%.
If the mutation is de novo, the risk for sibs is not null because of possible germline mosaicism (estimated to be 8% in a series) but no figure could be precise.

If there is no mutation, clinical examination of the parents including liver function tests, cardiac evaluation, chest radiograph, and ophthalmologic examination must be undertaken. The presence of AGS peculiar facies in the parents must be considered with caution if isolated.

If one parent is considered as affected, the risk for sibs is 50%.
If there is no affected parent, determined through genetic counseling as mentioned above, the risk for sibs is not null but difficult to assess.

Risk for offspring of a proband

The offspring of an AGS patient has a 50% chance of inheriting the syndrome.

Prenatal testing

Prenatal molecular testing, if available, can be performed on cells obtained by chorionic villous sampling at 10–12 weeks of gestation or amniocentesis at 16–18 weeks of gestation.

Fetal ultrasound examination may show cardiac defects and kidney abnormalities.

In all cases, due to high variable expressivity, it is impossible to predict the number and the severity of the features in affected sib or offspring of a proband.

CONCLUSION

Alagille syndrome was initially described as the association of five major features: paucity of interlobular bile ducts, peripheral pulmonary artery stenosis, butterfly-like vertebral arch defect, posterior embryotoxon, and a peculiar facies. Because of the variable expressivity of the syndrome, individuals presenting with three of the five main features are considered to have AGS. There is a general agreement for considering that genetic testing is not necessary for the diagnosis of AGS which relies mainly on clinical examination. But genetic testing of the proband is mandatory before genetic counseling. This testing includes karyotyping and FISH looking for deletion, and if negative sequencing of *JAG1* gene coding sequence exists. In all cases, due to high variable expressivity, it is impossible to predict the number and the severity of the features in affected sib or offspring of a proband. *JAG1* mutations are identified in 70% of AGS patients, although alteration outside the coding sequence is still possible, involvement of other components of Notch signaling pathway either as another disease-causing gene or as a modifier is very likely and is under study.

Allele-Specific Oligonucleotide Hybridization

Damian Labuda
Maja Krajinovic
Stéphane Bourgeois
Université de Montréal, Montreal, Quebec, Canada

INTRODUCTION

Allele-specific oligonucleotide (ASO) hybridization was first applied to probe genomic DNA samples for the presence of point mutations causing sickle cell anemia and α_1-antitrypsin deficiency. In both cases, the authors used nonadecanucleotides (19-mers) as ASO probes. Although one probe was complementary to the normal allele, the second one matched the mutant allele. Because a mismatched base pair decreases the stability of a nucleic acid duplex, appropriate adjustment of the hybridization and washing temperatures permitted discrimination between the normal, mutant, and heterozygous genotype. With genomic DNA samples, this technique could have been used only for the genotyping of single copy genes. Once the polymerase chain reaction (PCR) has been introduced, this approach could be adapted to almost any genomic fragment by using diverse sources of amplifiable DNA.

Single nucleotide polymorphisms as well as small insertions or deletions (for simplicity, collectively referred to as SNPs) are the greatest source of genomic variability. Most mutations causing hereditary disorders belong to this category as well. Because of their functional impact and/or their usefulness as markers in mapping and association studies, SNPs are frequently typed in the context of population genetic surveys as well as in diagnostic and/or genetic epidemiological analyses. The wide applicability of ASO hybridization (especially in its combination with PCR), the absence of need for costly investments, and straightforward laboratory implementation made this technique very popular as a routine genotyping tool.

EXPERIMENTAL

Genotyping by ASO applies to previously ascertained polymorphisms and/or mutations and is not intended to discover new DNA variants. Through PCR amplification, one aims at a single polymorphic site, but it is also customary to target a number of variant sites residing within a longer amplifiable DNA segment[1] or even those scattered on unrelated genomic fragments that can be simultaneously amplified in a multiplex PCR.[2]

Following PCR, amplicons are immobilized on a solid support by dot blotting and ultraviolet (UV) fixation,[3] usually in duplicates to allow parallel probing of both alleles with the corresponding ASO probes. Typical result of ASO hybridization is illustrated in Fig. 1. SNPs are usually biallelic; even if they are not, the same detection principles apply to triallelic sites or small haplotypes composed of two polymorphic sites, one next to another, except that more than two probes could then be needed. Usually ASO probes are designed as 15-mers to 20-mers, with the polymorphic site in the middle of the sequence and not less than three nucleotides from the end. The shorter is the oligonucleotide probe, the more pronounced is the effect of mispairing at the polymorphic site, thus facilitating discrimination between the alleles. However, an overall duplex stability counts as well; too short a probe could render a signal of a fully matched complex unstable and compromise its detection. In our hands, 15-mer ASO probes worked well, whereas more than 20-mers were also recommended by others.

In a classical ASO protocol, great emphasis is made on the choice of the hybridization temperature to discriminate between fully matched and mismatched probes.[5] Hybridization is carried out a few degrees below the melting temperature (T_m) of the fully matched probe. In practice, the specificity (i.e., discrimination between the alleles) is achieved through posthybridization washes that selectively eliminate the mismatched, less stable probe from the target. The washing temperature, time, and salt concentration are experimentally determined and are typically ''personalized'' in each laboratory. In an alternative dynamic ASO protocol,[6] rather than using constant temperature, the hybridization step covers a temperature gradient, from above the melting point down to room temperature (75–30°C), such that each probe has an opportunity to find its optimal hybridization conditions. To prevent the formation of the mismatched complex between the labelled probe and the opposite allele, the unlabelled opposite oligonucleotide is added in 15-fold or greater excess to the hybridization mixture. Such blocking of the mismatched binding by using the opposite allele probe as a competitor has been used before.[7,8] It appears that the dynamic ASO makes full use of the presence of the competitor. The limitation in

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020723

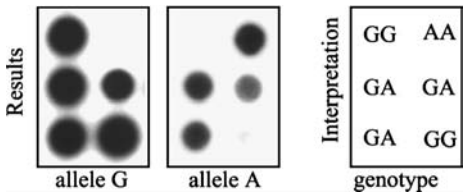

Fig. 1 ASO hybridization of G/A polymorphism at position 80 in RFC1 (reduced folate carrier) described earlier by Laverdiere et al.[4] The PCR product of 207-bp encompassing $G_{80}A$ polymorphic sites was transferred in duplicate to a HYBOND N^+ (Amersham Pharmacia Biotech) membrane. Identical twin membranes were hybridized with the ASO probe specific for the G_{80} (5′ gcacacgaggCgccg) or A_{80} (5′ gcacacgaggtgccg). Hybridization with ASO-specific probe was carried out at 45°C in a ×20 excess of the nonlabeled probe for the other variant allele.

the probe design is that both of them have to be from the same strand, ideally of the same sequence and differing only at the polymorphic site. However, the ASO for one allele serves, at the same time, as the competitor for the second allele, and vice versa. Following hybridization, dot blots are removed from the solution, rinsed at room temperature to wash out excess nonbound radioactivity, and exposed. No additional specificity-increasing washes are required. The most important advantage of dynamic ASO is that the same hybridization conditions work for most of the systems. As a consequence, multiple hybridizations can be simultaneously carried out in the same hybridization oven, disregarding different T_m values of the ASO probes used.

Suggested Protocols

Dot blotting

Twenty microliters of post-PCR mixture is denatured by the addition of 180 μL of 0.4 M NaOH, 20 mM EDTA, which may include 4 μL of 0.02% Orange II (optional spotting dye used to trace the blotting accuracy). Equal portions of the resulting solution are spotted in parallel on two previously water-wet Hybond N^+ nylon membranes (Amersham Pharmacia Biotech), thus creating two exact dot blot replicates of the analyzed DNA segments. Manifold is usually used to transfer DNA onto the membrane but direct spotting can also be used. DNA is then fixed on the membranes by UV irradiation (e.g., using light of 254 nm at 120,000 μJ/cm^2 in Stratalinker 1800; Stratagene) and the membrane is subsequently washed to remove NaOH and excess salt.

Hybridization

Membranes are prehybridized at 75°C for 30 min (Boekel Big Shot hybridization oven) in 25 mL of 1× SSPE [150 mM NaCl, 10 mM NaH_2PO, 1.1 mM EDTA, pH 7.4, 0.75 M NaCl, 70 mM Tris/HCl, pH 7.4, containing 1% sodium dodecyl sulfate (SDS) and 200 μg/mL heparin]. ASO probe (15-mer) is 5′-labeled using γ-[^{32}P]-ATP (6000 Ci/mmol; Amersham Pharmacia Biotech) and T4 kinase (Gibco BRL). Usually the volume of hybridization mixture is increased by 5 mL for each additional membrane. The ASO probe is added to the hybridization mixture to a final concentration of 50 pM accompanied with the opposite allele competitor at 750 pM. Hybridization is then carried out at a decreasing temperature by letting the oven cool down to 30°C and leaving 30 min for equilibration at this temperature. After two brief washings in 2× SSPE containing 1% SDS at room temperature, the membranes are exposed at −80°C with intensifying screens or read by Phosphoimager. Most of the polymorphisms do not require any special adjustment of this protocol and work outright. If the background appears too high and simple shortening of the time of exposure does not help, it can be eliminated: 1) by increasing the competitor/probe ratio; 2) by increasing the probe concentration (keeping the same competitor/probe ratio); or 3) by decreasing the amount of dot-blotted target DNA. Rarely, design of new ASO probes is required.

TECHNICAL COMMENTS

Probe Design

1. It is known that both strands of the DNA are not necessarily equivalent as probes in hybridization. This effect was observed with longer probes[9] but also applies to short oligonucleotides. Purine-rich oligonucleotides have a tendency to be better binders to a longer template than their pyrimidine-rich equivalents.[10] The former would maintain a more rigid structure, stabilized by stacking interactions because of the presence of purines, thus favoring template binding. The latter that are more coiled need additional energy to adopt helical extended structure consistent with double-stranded duplex formation. Note that pyrimidine-rich complement within a longer template is stabilized by stacking with its nearest neighbors from 5′ and 3′ sides through a dangling-ends effect, such that it is less coiled than its isolated/naked oligonucleotide complement. In conclusion, choosing (+) rather than (−) strand for ASO design

may modify the kinetics of duplex formation and its stability, and can be used to improve the test.
2. Although the rule of thumb is to place the probed polymorphic site in the middle of ASO, it is advisable to readjust its position if both flanking sequences differ in stability because of uneven composition in (G+C)/(A+T) and/or unequal redistribution of pyrimidines and purines.

Hybridization Conditions

1. Hybridization of short oligonucleotides is usually very fast, requiring milliseconds rather than minutes to occur. Hybridization times prescribed by the protocol reflect the time needed to equilibrate the temperature and concentrations and to assure the uniform contact of hybridization solution with the membrane.
2. Note that for a 500-nucleotide-long amplification, 100 ng of PCR product, typically found in a 10 μL reaction aliquot, corresponds to 0.32 pmol. When applied per single spot, it leads to about 30 pmol of the target DNA on a single 96-spot membrane. Therefore the probe at 50 pM concentration or 1.25 pmol/25 mL is in shortage as compared to the target. Thus, increasing the number of membranes may require an increase in probe concentration, or decrease in the concentration of spotted PCR products to keep background low and signal-to-noise high.

CONCLUSION

First ASO application in sickle cell anemia[12] and α_1-antitrypsin deficiency[13] were subsequently expanded, since the advent of PCR, to a variety of systems.[14] It was used to analyze disease-causing mutations,[15] study the mechanism of carcinogenesis,[16] or distinguish different haplotypes of the major histocompatibility locus.[17] ASO hybridization also found large application in studies of candidate susceptibility loci in complex disorders,[18,19] as well as in investigations of genetic variants predisposing individuals to adverse drug reaction.[1] ASO takes advantage of the difference in stability between the fully complementary and the mismatched DNA duplex. This difference is used to distinguish between allelic states differing as little as by a single nucleotide. Typically, two oligonucleotide 15-mer ASO probes are designed, each complementary to one of the alleles. In a classical protocol, hybridization is carried out at a temperature favoring the formation of a fully matched duplex, whereas the binding specificity is essentially obtained through stringent post-hybridization washes. In a dynamic ASO protocol, hybridization starts well above the melting point and a decreasing temperature gradient is applied. The labelled probe ''finds'' its target during the cooling of the hybridization mixture. Formation of the mismatched complex is prevented by the presence of the competitor probe that is fully complementary to the opposite allele. ASO hybridization finds application in diagnostic and genetic epidemiological surveys, is reliable, and is easy to implement.

Alpha-1-Antitrypsin Deficiency

Noor Kalsheker
Kevin Morgan
Queen's Medical Center, Nottingham, U.K.

INTRODUCTION

Alpha-1-antitrypsin (AAT), also referred to as SERPIN A1, is the most abundant serine protease inhibitor (PI; serpin) in human plasma. It is a glycoprotein with broad inhibitory capacity against a variety of serine proteases and its main physiological target is neutrophil elastase. The three-dimensional structure of AAT and other serpins has provided major insights into the mechanism of inhibition of cognate proteases. AAT is a globular protein with an exposed reactive center loop (RCL). The protease docks on to the RCL, and cleavage of a methionine–serine bond at positions 358–359 in the loop results in a major conformational change. The loop inserts into a space in the A-sheet as a strand, and the protease then moves to the opposite pole of the molecule. During this translocation process, the catalytic site of the serine protease is distorted so that it is rendered inactive (Fig. 1). The PI complex is then rapidly removed from the circulation. This is a very efficient mechanism for controlling serine protease activity.

GENETIC VARIATION

The *AAT* gene is highly polymorphic. Historically, variants were characterized by gel electrophoresis of serum and initially divided into three groups according to their migration [medium (M), fast (F), and slow (S)], and, conventionally, these variants are preceded by PI. With advances in electrophoresis technology, further variants were identified based on migration characteristics in a pH 4–5 isoelectric focusing (IEF) gel. Anodal variants were assigned letters from the beginning of the alphabet. Several bands are observed on IEF, resulting from the degree of glycosylation. In a pH gradient of 4–5, AAT variants migrate as two major bands designated 4 and 6, and three minor bands 2, 7, and 8.

The migration of these bands is altered by amino acid substitutions (Fig. 2). At least four common M subtypes have been identified (designated M1–M4), with two other rare M subtypes (M5 and M6) and two common deficiency variants (designated S and Z) also arising from single-base substitutions. Other rare deficiency variants are characterized by a combination of the letter of the most closely migrating variant, and the origin of the place of the oldest living carrier. Examples of some of the variants in which the mutations have been characterized are shown in Table 1.

A mean normal plasma concentration of less than 11 μM is classified as deficient, and concentrations for the different common variants are typically in the range of 20–53 μM for MM, 18–52 μM for MS, 24–48 μM for SS, 15–42 μM for MZ, 10–23 μM for SZ, and 3.4–7.0 μM for ZZ.[2] The range of concentrations for PI ZZ falls well below this threshold, as does the very lower end of SZ, and both contribute as risk factors for disease. PI Null variants are rare, and there is considerable heterogeneity of mutations that cause them (Table 1).

THE *AAT* GENE

The 12-kb gene is located on the long arm of chromosome 14 in a cluster of other serpins, and two major promoters have been identified: one for hepatocytes,[3] the cell type accounting for most of the circulating *AAT*, and the other, which is effective in other tissues such as monocytes and lung alveolar epithelial cells.[4] The gene is made up of four coding exons and three noncoding exons, and, during mRNA expression, the noncoding exons are differentially spliced. A diagrammatic representation of the gene is shown in Fig. 3.

AAT GENE REGULATION

AAT is an acute-phase protein, and plasma concentrations can increase two- to threefold during inflammation. These increases are mainly mediated by the cytokines interleukin-6 and oncostatin M.[5] In hepatocytes, basal expression is regulated by the hepatocyte 5′ promoter, but during the acute-phase response, a 3′ enhancer plays a major role in modulating the cytokine-induced response.[6]

AAT DEFICIENCY AND DISEASE

Homozygous Z individuals are predisposed to developing childhood cirrhosis[7] and pulmonary emphysema in early

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120025789

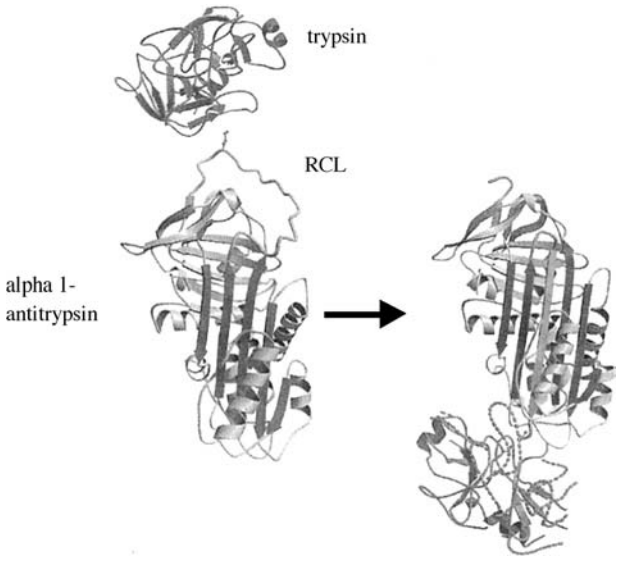

Fig. 1 Interaction of the protease trypsin with AAT. Trypsin docks on to the exposed RCL, cleaves the RCL, and the loop inserts into a sheet. The protease is then translocated to the opposite pole of the molecule and the active site of the protease is distorted. (See Ref. [1].)

adult life, particularly in cigarette smokers.[8] The Z variant is prevalent in northern Europeans, with a frequency of about 1.5% in Sweden and Norway, and greater than 2% in Denmark, Latvia, and Estonia.[9] It is extremely rare in Asian and African populations. The Z protein is synthesized normally, but tends to polymerize in hepatocytes. The polymerization results from an intermolecular interaction in which one RCL inserts into a space in the A-sheet. The Z mutation favors polymerization and the accumulated aggregates cause damage to the hepatocytes, which can result in childhood cirrhosis.[10] Only about 3% of PI Z individuals develop severe liver disease that often requires liver transplantation—the only effective treatment for them.[11] In a prospective screening study carried out in 200,000 newborns in Sweden, 120 children with PI ZZ were followed up.[12] Eighteen percent of the PI Z children developed clinically recognizable liver abnormalities, 7.3% had prolonged obstructive jaundice with marked evidence of liver disease, 4.1% had prolonged jaundice with mild liver disease, and 6.4% had other abnormalities suggestive of liver disease such as hepatomegaly, splenomegaly, or unexplained failure to thrive. The most common presentation is the ''neonatal hepatitis syndrome,'' which is characterized by conjugated hyperbilirubinemia and raised serum transminases. Features of cholestasis generally appear between 4 days and 2 months of age, and can persist for up to 8 months. About 14–29% of individuals with neonatal hepatitis syndrome have been found to have AAT deficiency. Most of these cases resolve without apparent long-term consequences.

The association with pulmonary emphysema is related to cigarette smoking, highlighting an important interaction between genetic and environmental factors. This is thought to arise from the action of neutrophil elastase, a major protease of neutrophils released during an inflammatory state. Deficiency of AAT, its major inhibitor,

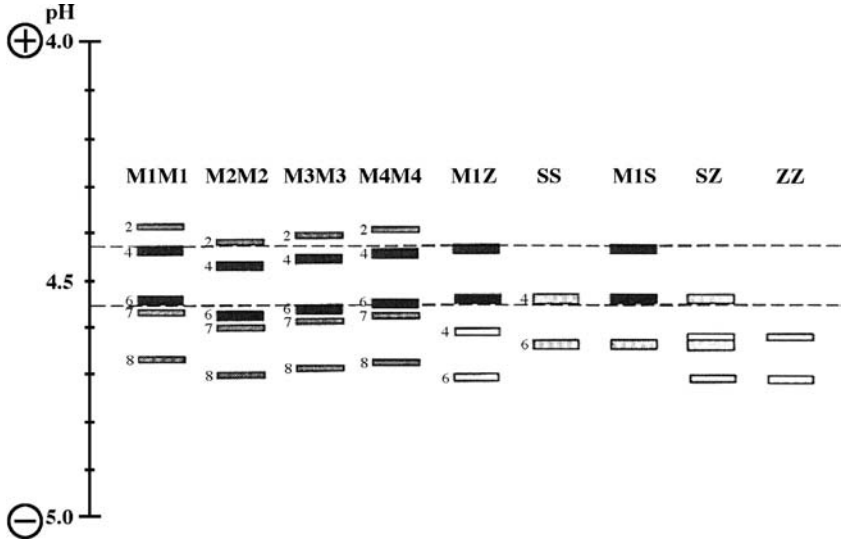

Fig. 2 AAT PI types separated according to their isoelectric point. A pH gradient of 4–5 is used and the variants migrate as two major bands, designated 4 and 6, and minor bands 2, 7, and 8. Variation in migration results from amino acid substitutions. The Z variant migrates toward the cathode and the S variant has an intermediate position to M and Z.

Table 1 Normal and deficiency variants of AAT

The mutations shown are not an exhaustive list of variants, but represent the more common ones described.

results in progressive lung damage, because elastase has the propensity to destroy the connective tissues of the lung, causing destruction of the normal architecture of air spaces, thus reducing the surface area for gaseous exchange. Indeed, it was this association that led to the identification of AAT deficiency as a genetic disease. The methionine residue in the RCL is susceptible to oxidation, resulting in methionine sulphoxide, and the latter is a poor inhibitor[13] of neutrophil elastase, with a potency of 1/2000 that of the native inhibitor. The oxidation is more likely to occur during inflammation, and this may exacerbate genetic deficiency.

Pulmonary function is well preserved in early adult life in nonsmoking PI ZZ individuals. Pulmonary function declines naturally with age, but this rate of decline is markedly accelerated in PI ZZ individuals. Chronic obstructive pulmonary disease (COPD) in AAT deficiency generally occurs in the age range of 25–40 years, although not all PI ZZ individuals develop COPD. Larsson[14] estimated that smoking shortens median survival by 23 years.

A number of other disease associations have been described, although some of these are controversial. There is a well-recognized association with panniculitis, which responds to AAT replacement therapy. Other associations include arterial aneurysms, pancreatitis, and renal disease.

AAT REPLACEMENT THERAPY

The potential to treat lung disease by replacement to augment the lung antiprotease protective screen is available either by the intravenous route or by inhalation

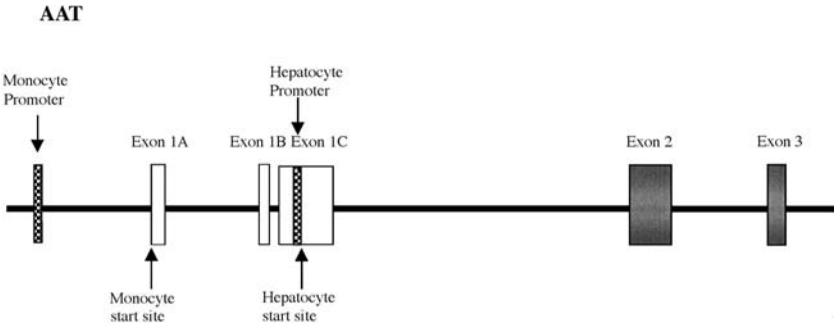

Fig. 3 A diagrammatic representation of the structure of the *AAT* gene. The coding exons are dark-shaded; untranslated exons are in lighter shade; and the location of tissue-specific promoters and a 3′ enhancer is also shown.

through the nasal route. Early studies (by Gadek et al.[15]) demonstrated that intravenous administration of AAT was feasible and biochemically effective. Studies have shown that aerosol administration too is effective.[16]

Although these studies demonstrate biochemical efficacy, it is not yet known whether they influence the outcome of the chronic respiratory disease associated with AAT deficiency. In a large study undertaken in the United States, 1129 subjects with severe AAT deficiency were monitored for 3.5–7 years. The 5-year mortality rate was 19%. The mortality rate was lower in those receiving augmentation therapy,[17] suggesting that long-term replacement therapy may be beneficial. There are anecdotal reports of successful treatment of panniculitis arising from AAT deficiency.

LABORATORY DIAGNOSIS OF AAT DEFICIENCY

Serum Quantification

Immunological methods are used to determine serum AAT concentrations, and serum standards are used to determine the concentration of the antigen in an unknown sample. Neonates have significantly lower serum concentrations compared to adults. In one study, the mean concentration observed in neonates for PI M was 23.8 ± 5.5 μM, compared with the PI M adults, where the concentration was 32.7 ± 8.7 μM.[18] A concentration of less than 11 μM can be used as a cutoff for deficiency states, and provides a useful screening test. It is important to ensure that these concentrations are observed in the basal state in the absence of an acute-phase reaction. It is therefore useful to measure concurrently serum C-reactive protein (CRP), one of the most sensitive markers for the acute-phase response, to exclude an acute-phase reaction. The value of screening newborns and the general population for deficiency remains controversial.

IEF and Genetic Testing

Many laboratories still use IEF to determine protein type.[19] This requires considerable expertise for the interpretation of banding patterns and relies on sample stability for reliable interpretation. The resolution can be improved with ultrathin polyacrylamide gels[20] and sensitivity can be improved by immunoblotting. Many laboratories use DNA-based methods involving polymerase chain reaction and either allele-specific amplification, for example, or the introduction of a restriction enzyme site at the location of the Z variant.[21,22] The DNA-based assays are designed to look for the common deficiency variants, S and Z, and will not detect rare variants. This is a limitation of the tests, as rare variants may be falsely reported as normal, and the use of serum AAT measurements minimizes this likelihood, but does not completely exclude it. DNA-based tests do offer a robust and reliable method for detecting the common S and Z alleles.

CONCLUSION

Much progress has been made in understanding the pathophysiology of AAT deficiency-related disease and its natural history. These developments provide new opportunities for developing specific treatments and may, in the future, result in more widespread screening for deficiency states if early intervention is shown to be effective.

Alpha-Thalassemia

Renzo Galanello
Antonio Cao
Università degli Studi di Cagliari (UNICA), Cagliari, Sardinia, Italy

INTRODUCTION

Alpha-thalassemias are genetic defects, very common among some populations, characterized by the reduction (alpha$^+$) or complete absence (alpha$^\circ$) of alpha-globin chain production. A large number of alpha-thalassemia alleles have been described and their interaction results in a wide spectrum of hematological and clinical phenotypes, ranging from the silent carrier state to the very severe condition of hemoglobin Bart's hydrops fetalis syndrome, which is lethal in utero or soon after birth.

PREVALENCE AND DISTRIBUTION

Alpha$^+$-thalassemia is commonly found in Southeast Asia, China, Africa, reaching a very high prevalence, about 80%, in Papua (New Guinea).[1] In Mediterranean and Middle Eastern countries alpha$^+$-thalassemia carrier state has an incidence of 5–10% (up to 30% in Sardinia).[2] Alpha$^\circ$-thalassemia is found mainly in Southeast Asia; where, as a consequence, the derived clinical relevant genotypes (HbH disease and Hb Bart's hydrops fetalis) are also common. In Mediterranean and African population alpha$^\circ$-thalassemia is rare.

CLINICAL ASPECTS

Four clinical conditions of increased severity have been described (Table 1). The *silent carrier state* results from the presence of a single alpha-globin gene defect (−alpha/alpha alpha) and is characterized in the newborn by a very mild increased percentage (1–2%) of Hb Bart's, a tetramer of globin chains (gamma$_4$), whereas in the adult may be completely silent or associated with a moderate microcytosis and hypochromia with normal HbA_2.

Subjects with two residual functional alpha genes, either in *cis* (− −/alpha alpha) or in *trans* (−alpha/−alpha) clearly show the *alpha-thalassemia carrier state*, characterized in the newborn by a moderate increase (5–6%) of Hb Bart's, and in the adult by thalassemia-like red blood cell indices with normal HbA_2 and HbF.

HbH disease is a clinical condition resulting from the presence of a single functional alpha globin gene (− −/−alpha) or (− −/alpha$^{\text{nondeletion}}$ alpha). As a consequence there is a relative excess of beta globin chains, which form a beta$_4$ tetramer (HbH). HbH is unstable and precipitates inside the red cells and to some extent in erythroid precursors resulting in premature erythrocyte destruction. The syndrome of HbH disease shows a wide variability in clinical and hematological severity. The most significant features are microcytic and hypochromic hemolytic anemia, hepatosplenomegaly, and jaundice. Subjects with HbH disease may have acute episodes of hemolysis, requiring occasional blood transfusions, in response to oxidant drugs, fever, and infections.

The severity of HbH disease correlates with the degree of alpha chain deficiency. Therefore the more severe phenotypes are associated with interactions involving nondeletion alpha-thalassemia defects of the dominant alpha$_2$ gene including − −/alpha C$^{\text{constant}}$ S$^{\text{pring}}$ alpha, − −/alpha$^{\text{NcoI}}$ alpha , − −/alpha$^{\text{HphI}}$ alpha.[3] In general, patients with HbH disease can survive without any treatment. However, folic acid supplementation is recommended by some clinicians. Oxidant drugs should be avoided because of the risk of hemolytic crisis. In the presence of hypersplenism splenectomy may be performed, but the potential complications of severe life-threatening venous thrombosis should be considered. Two peculiar types of HbH disease have been reported. One is acquired, associated with myelodisplasia, and characterized by the presence of classical HbH inclusion bodies in red blood cells, often detectable levels of HbH and a severe microcytic and hypochromic anemia. The structural analysis of the alpha globin genes and of their flanking regions are normal, and a downregulation of the alpha genes by mutation in trans-acting genes has been proposed. The other is the alpha-thalassemia associated with mental retardation syndromes, which includes two different forms.[4] The first is characterized by a relatively mild mental retardation and variable facial and skeletal abnormalities. This form, known as ATR 16 syndrome, is due to extended deletions (1 to 2 Mb) of the short arm of chromosome 16. A second group of patients has a complex phenotype with quite uniform clinical features (hypertelorism, flat nasal bridge, triangular upturned nose, wide

Table 1 Clinical phenotypes and corresponding genotypes of alpha-thalassemia

Clinical phenotype		Genotype
Silent carrier	Normal or mild microcytosis	−alpha/alpha alpha
Alpha thalassemia trait	Microcytosis hypochromia	−alpha/−alpha −−/alpha alpha alphand alpha/alpha alpha
HbH disease	Moderate (rarely severe) microcytic hypochromic haemolytic anemia, hepotosplenomegaly, mild jaundice	−−/−alpha −−/alphand alpha
Hb Bart's hydrops fetalis syndrome	Very severe anemia oedema, hepatosplenomegaly, death in utero or soon after birth	−−/−−

nd = nondeletion.

mouth, genital abnormalities) and severe mental retardation. These patients did not show structural changes of the alpha cluster and the transmission is X-linked (ATR-X syndrome). Mutations in an X-encoded gene, the XH2gene, a member of the SNF2 family of helicase/ATPases. It has been suggested that this gene is involved in a wide variety of cellular processes, such as transcriptional regulation, recombination, replication, and DNA repair.[4]

Hb Bart's hydrops fetalis syndrome is the most severe form of alpha-thalassemia. In most of the cases it is associated with the absent function of all four alpha globin genes (−−/−−). The affected fetus cannot produce any alpha globin to make HbF (alpha$_2$gamma$_2$) or HbA (alpha$_2$beta$_2$). Fetal blood contains only Hb Bart's (gamma$_4$) and small amounts of hemoglobins Portland (zeta$_2$gamma$_2$ and zeta$_2$beta$_2$). The resulting clinical features are those of severe anemia leading to asphyxia, hydrops fetalis, and stillbirth or neonatal death.[5] Other congenital defects have been reported, including cardiac skeletal and urogenital abnormalities. Maternal complications during pregnancy have been reported, including mild preeclampsia (hypertension and fluid retention with or without proteinuria), poly-oligo-hydramnios (increased or reduced accumulation of amniotic fluid, respectively). At present there is no effective treatment for Hb Bart's hydrops fetalis syndrome. Attempts of intrauterine transfusions or in utero hematopoietic stem cell transplantation have been unsuccessfully performed.

DIAGNOSIS

Identification of alpha-thalassemia carriers is difficult because they do not have typical changes in HbA2 or HbF. Carriers with −alpha/alpha/alpha and −−/alpha alpha genotypes have always reduced MCV and MCH, while −alpha/alpha alpha carriers may have normal red cell indices or only slightly reduced MCV and MCH. The hemoglobin pattern is normal.

Reliable diagnosis of the alpha-thalassemia carrier states can only be achieved by DNA analysis with PCR-based methods or globin chain synthesis analysis that shows an alpha/beta ratio lower than 0.9 (see below ''Molecular Diagnosis of Alpha-Thalassemia'').[6] Identification of alpha°-thalassamia carriers is important for the prevention of Hb Bart's hydrops fetalis syndrome. In the newborn the electrophoretic detection of the fast moving band of Hb Bart's is an indication of the presence of alpha-thalassemia. However, in some carriers Hb Bart's may be not detected.

HbH is easily detected as a fast-moving band by cellulose acetate electrophoresis. Another simple and very sensitive test consists in the detection of inclusion bodies in the red blood cells which can be generated by incubating peripheral blood with supravital stains.[6] Determination of alpha globin genotype by molecular methods is useful for prognosis of HbH disease, as the nondeletion forms are more severe than the deletion forms.[3] In the neonatal period subjects with HbH disease genotype can be detected by hemoglobin electrophoresis because they have elevated levels (−25%) of Hb Bart's. Hb Bart's hydrops fetalis syndrome can be prenatally identified by DNA analysis, fetal blood analysis, or using ultrasound (cardiothoracic ratio greater than 0.05).[6,7]

MOLECULAR GENETICS

The human alpha globin genes are duplicated and mapped in the telomeric region of chromosome 16 (16p 13.3), in a cluster containing an embryonic zeta$_2$, three pseudogenes (pseudo zeta$_1$, pseudo alpha$_1$, pseudo alpha$_2$) and one gene (theta$_1$) of unknown function (Fig. 1).[8] The alpha complex is arranged in the order of its expression during the development. There is a remarkable homology

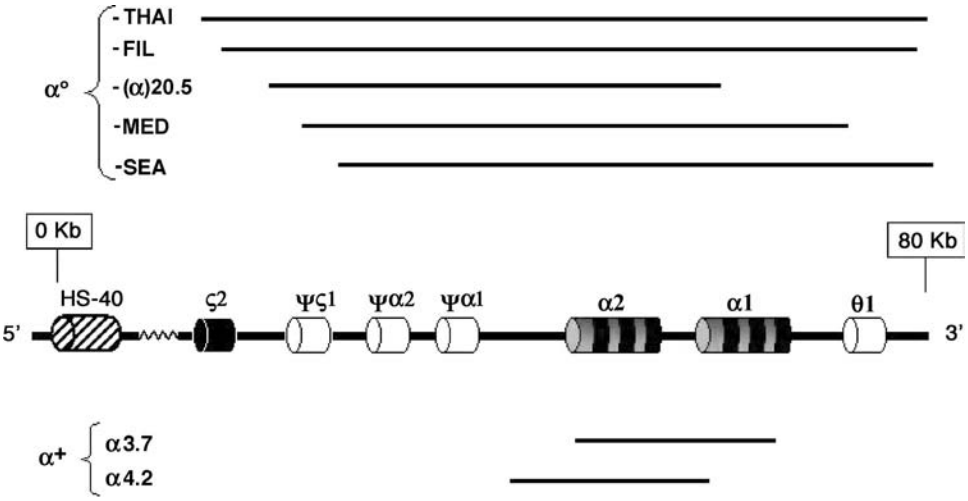

Fig. 1 Structure of alpha globin gene cluster and most common deletion alpha-thalassemia defects. (*View this art in color at www.dekker.com.*)

between $alpha_2$ and $alpha_1$ gene maintained during evolution through repeated rounds of gene conversion.[9] The level of transcription of the two alpha genes differs, encoding the $alpha_2$ gene two to three times more alpha globin than $alpha_1$ gene.[10] The different expression of the two alpha genes has implications for the amount of hemoglobin variant present in carriers of $alpha_1$ or $alpha_2$ globin mutations, and for the pathophysiology of the deletional and nondeletional forms of alpha-thalassemia. The presence and integrity of a DNA region, known as HS40, located 40 kb upstream of the alpha globin gene cluster are critical for the expression of alpha globin genes.[11] Deletions of this regulatory element produce alpha-thalassemia, although both alpha globin genes on the chromosome are intact. A deletion, removing the alpha 1 globin and the theta-globin genes, that results in the transcription of an antisense RNA, leading to silencing of $alpha_2$ gene and in the methylation of its CpG island, has been recently reported as a novel mechanism of human genetic disease.[12]

Deletion Alpha-Thalassemia

Alpha-thalassemia is caused most frequently by deletions of DNA that involve one or both alpha globin genes. The most common deletions remove a single alpha globin gene, resulting in the mild $alpha^+$-thalassemia phenotype ($-$alpha/alpha alpha). These deletions are produced by unequal crossing over within two highly homologous regions, extending for about 4 kb, that contain $alpha_1$ and $alpha_2$ gene.[13] Reciprocal recombination between Z boxes results in a chromosome with a 3.7-kb deletion containing only one alpha gene ($-alpha^{3.7}$), whereas recombination between X boxes produces a 4.2-kb deletion ($-alpha^{4.2}$) (Fig. 1). As a consequence of these recombinational events, chromosomes containing three alpha globin genes are produced.[14] The $-alpha^{3.7}$ and $-alpha^{4.2}$ deletions are the most common $alpha^+$-thalassemia determinants. Other rare deletions totally or partially remove one of the two alpha globin genes.

Extended deletions, from 100 to over 250 kb, removing all or part of the cluster including both alpha globin genes and sometimes the embryonic $zeta_2$ gene, result in $alpha^\circ$-thalassemia and hence no alpha chain synthesis occurs. Illegitimate recombination, reciprocal translocation, and truncation of chromosome 16 are the molecular mechanisms responsible for these deletions. More than 15 different $alpha^\circ$-thalassemia deletions have been described, the most common being the Southeast Asian, Filipino, and Mediterranean types (Fig. 1). Two deletions [$-(alpha)^{5.2}$ and $-(alpha)^{20\text{-}5}$] removing the alpha -2 and partially the $alpha_1$ globin gene also result in $alpha^\circ$-thalassemia.

Several different deletions involving the HS-40 regulatory region but leaving both alpha genes intact have been reported and all result in $alpha^\circ$-thalassemia.[14]

Nondeletion Alpha-Thalassemia

Less frequently, alpha-thalassemia is determined by nondeletion defects, which include single nucleotide substitutions or oligonucleotide deletions/insertions in regions critical for alpha globin gene expression.[14] Several molecular mechanisms (abnormalities of RNA splicing and of initiation of mRNA translation, frameshift and nonsense mutations, in-frame deletions, and chain termination mutations) have been described, the majority

occurring in the alpha$_2$ gene and producing alpha$^+$-thalassemia. Hb Constant Spring, the most common nondeletion defect that is present in Southeast Asian population, results from a mutation in the stop codon of alpha$_2$ globin gene (TAA→CAA, stop→Glu). The change of the stop codon to one amino acid allows mRNA translation to continue to the next in-phase stop codon located within the polyadenilation signal. The result is one alpha chain variant (Hb Constant Spring) elongated by 31 amino acids which is produced in a very low amount (~1%). The instability of the mRNA due to disruption of the untranslated region may be the reason for the reduced production of Hb Constant Spring.[15]

As for beta globin gene, mutations of alpha genes which result in the production of hyperunstable globin variants, such as Hb Quong Sze, (alpha 109 Leu→Pro) Hb Heraklion (alpha 137 pro→0), and Hb Agrinio (alpha 29 Leu→Pro), that are unable to assemble in stable tetramers and are thus rapidly degraded, might produce the phenotype of alpha-thalassemia.[14]

PRENATAL DIAGNOSIS

Prenatal diagnosis is always indicated for the prevention of Hb Bart's hydrops fetalis syndrome for the severity of the disease and even to avoid severe maternal complications during pregnancy.

HbH disease is not considered to be among those hemoglobinopathies targeted for prevention.[1]

MOLECULAR DIAGNOSIS OF ALPHA-THALASSEMIA

The presence of alpha-thalassemia, suspected on the basis of hematological and/or clinical findings [i.e., microcytosis with normal HbA_2 and F and normal serum iron status in carriers; microcytic and hypocromic hemolytic anemia with RBC inclusion bodies and a fast-moving band (HbH) at the hemoglobin electrophoresis; presence of Hb Bart's in the newborn], should be confirmed, if requested, by globin gene synthesis or even better by globin gene DNA analysis.

The exact definition of the genotype with molecular methods is relevant for genetic counseling in carriers and for prognosis in HbH disease patients. In the last few years several approaches based on polymerase chain reaction (PCR) have been developed for the detection of the most common deletional and nondeletional types of alpha-thalassemia (for references, see Ref. [16]).

The common deletion alpha$^\circ$- or alpha$^+$-thalassemias are detected using two primers (specific for each deletion type), which flank the deletion breakpoints. Amplification occurs only in the presence of the deletion, whereas it does not occur in normal subjects because the two primers are separated by too great a distance. This approach is known as GAP-PCR. As a control, DNA from a normal subject is simultaneously amplified using one of the primers flanking the breakpoint and a primer homologous to a DNA region deleted by the mutation. The less common deletion alleles have to be identified by Southern blot analysis.

Nondeletional forms of alpha thalassemia are detected by selective amplification of alpha$_1$ and alpha$_2$ genes, followed by restriction enzyme analysis, when the mutation creates or abolishes a cleavage site [i.e., *Nco*I for T→G alpha$_2$ initiation codon mutation, *Hph*I for the −5 bp (donor) alpha$_2$ IVSI-1 deletion, *Mse*I for Hb Constant Spring] or by Dot Blot analysis or ARMS with specific oligo-probes. A strategy for the diagnosis of all the known point mutations, which involves the combined application of denaturing gradient gel electrophoresis (DGGE) and single-strand conformational analysis (SSCA), followed by direct DNA sequencing, has been reported.[17]

Multiplex PCR assays including up to seven alpha-thalassemia deletional alleles or common Southeast Asian nondeletional alleles have been recently described and seem to give robust and reproducible results.[18–20]

CONCLUSION

Alpha-thalassemias are common hemoglobinopathies, very heterogeneous at clinical and molecular level. Four different clinical conditions of increased severity have been described: the silent carrier state, alpha-thalassemia trait, HbH disease, and Hb Bart's hydrops fetalis syndrome. HbH disease is a moderate, very rarely severe, microcytic, and hypochromic hemolytic anemia, whereas Hb Bart's hydrops fetalis syndrome is a condition not compatible with postnatal life. Deletion defects are more common than nondeletion defects. The carrier state is suspected by hematological methods, but the precise identification is possible with several PCR-based procedures or globin chain synthesis analysis. Prenatal diagnosis is only indicated for Hb Bart's hydrops fetalis syndrome.

Alzheimer's Disease, Familial, Early Onset

Beatriz Marcheco Teruel
National Center of Medical Genetics, Havana, Cuba

INTRODUCTION

Alzheimer's disease (AD; OMIM no. 104300) is a progressive and degenerative disorder that attacks the brain, which was first described by Alois Alzheimer.[1] Alzheimer's disease is the most common type of dementia and is a major cause of death and disability in developed countries. The main symptoms of the disease are memory loss, cognitive impairment, deterioration of motor skills, and withdrawal from social contact. The clinical diagnosis can be difficult to establish and it is only confirmed by postmortem microscopic examination of the brain. The typical features of the neuropathological examination are: cerebral cortical atrophy, the presence of amyloid plaques in the extracellular space composed mainly of β-amyloid (Aβ) peptide, deposition of amyloid in the wall of blood vessels, and the presence of intraneuronal neurofibrillary tangles, consisting of hyperphosphorylated microtubule-associated protein tau.

Alzheimer's disease can be *familial* or *sporadic* and its complex etiology comprises both *genetic* and *environmental* factors. In most cases, the symptoms of the disease appear after 65 years of age (late-onset form); however, around 5% of all AD cases have an early onset (i.e., before age 65 years).[2,3] Sixty-one percent of patients with early-onset AD had a positive family history and 13% had affected individuals in at least three generations. A prevalence of early-onset AD of 41.2 per 100,000 for the population at risk (i.e., persons aged 40–59 years) has been reported.[4] The disease has severe emotional and financial consequences for individuals, families, and society.

CLINICAL DESCRIPTION

The early-onset form of AD generally runs in families with multiple affected individuals and it is mostly inherited as an autosomal dominant trait. The disease usually begins in the 40s or early 50s with a relatively rapid progression.

Alzheimer's disease is characterized by gradual loss of memory, decline in other cognitive functions, and decrease in functional capacity. Other common symptoms include confusion, poor judgment, language disturbance, agitation, withdrawal, and hallucinations. Some patients may develop seizures, Parkinsonian features, increased muscle tone, myoclonus, incontinence, and mutism.[5,6] Survival disease is variable in patients with AD, and they usually die of infections, with death occurring approximately 10 years after the onset of symptoms.

The clinical diagnosis of AD is based on criteria defined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-III-R, American Psychiatric Association 1987) and the criteria of the National Institute of Neurological and Communicative Disorders and Stroke and Alzheimer's Disease and Related Disorders Association Work Group (NINCDS-ADRDA).[7] The NINCDS-ADRDA criteria provide guidelines for a clinical diagnosis of probable and possible AD. A diagnosis of definite AD can be confirmed by neuropathological examination of the brain tissue either from biopsy or autopsy material. The criteria of the Neuropathology Task Force of the Consortium to Establish a Registry for Alzheimer's Disease (CERAD)[8] have been commonly used to set the neuropathologic diagnosis of AD.

Differential diagnosis could be established in the first instance between the familial and sporadic forms of the disease over the basis of the presence of a positive family history and by taking into account that familial and sporadic cases appear (clinically and pathologically) to have the same phenotype. Other genetic causes of early-onset dementia as well as prion disease, fronto-temporal dementia, and CADASIL should be considered.

MANAGEMENT

There is currently no cure or prevention for AD because its basis are still not well understood. Pharmacological agents and psychosocial intervention may help to manage each symptom and provide temporary improvement in cognitive functioning for some patients. Cholinesterase inhibitors such as Tacrine (with hepatotoxic effects), Aricept, Exelon, and Remynil are the most used. Nonsteroidal antiinflammatory drugs (NSAIDs), estrogen replacement therapy (ERT), and lipid-lowering agents are also being investigated.

Effective management of AD also comprises educational information, counselling, and emotional support for patients, caregivers, and other family members.

MOLECULAR GENETICS

Studies focusing on large families with the rare, early-onset, autosomal dominant form of the disease led to the discovery that mutations in the amyloid precursor protein (*APP*)[9] Presenilin 1 (*PSEN1*),[10,11] and Presenilin 2 (*PSEN2*)[12] genes cause AD.

Although these autosomal dominant families represent only a small percentage of the total AD cases, functional studies of the effects of the identified mutations have become an important way to dissect the causes and underlying disease mechanisms leading to AD. Mutations in all three genes produce an increase of plasma amyloid β (Aβ42),[13] which forms the core of neuritic plaques found in brains of people with AD.

The *APP* gene in chromosome 21 (region 21q11.2–q21.1) was the first gene to be associated with early-onset familial AD (AD1).[14] The original clue came from the observation that individuals with Down syndrome, who have chromosome 21 trisomy, invariably develop the clinical and pathological features of AD if they live over 30 years.[15]

The *APP* gene has 19 exons and encodes the amyloid precursor protein (Aβ) of 695–770 amino acids, which is proteolytically cleaved to form Aβ, the major component of amyloid plaques in the brain tissue. All *APP* mutations (16 mutations) occurs in exons 16 and 17.

AD1 accounts for no more than 10–15% of early-onset familial AD.[4] The mean age of AD1 onset is around the early 50s, with a range from 43 to 62 years.[3]

Mutations in *PSEN1* (AD3) located in chromosome 14 (region 14q24.3) are responsible for 30–70% of the AD cases with familial early onset. *PSEN1* gene contains 10 protein-coding exons and is predicted to encode a serpentine protein (467 amino acids) with 7–10 transmembrane domains. To date, at least 130 different mutations have been described in the *PSEN1* gene in more than 200 unrelated families (Fig. 1). Most mutations lie in exon 7 (28 mutations), exon 5 (27 mutations), and exon 8 (23 mutations). The majority of these are missense mutations giving rise to the substitution of a single amino acid (AD mutation database; http://molgen-ww.uia.ac.be/admutations/).

It has been speculated that most AD-related mutations result in a gain of function. Mutations in *PSEN1* alter the processing of βAPP by preferentially favoring the production of potentially toxic long-tailed Aβ peptides ending at residue 42 or 43.[16]

PSEN1 mutations are associated with the earliest age of onset (29–62 years) of the three early-onset form genes.[3] It has been described that families of different ethnic backgrounds with the same mutation also exhibit similar ages of onset.

The *PSEN2* gene (AD4), a rare cause of early-onset AD (2% of all early-onset familial AD), is located on chromosome 1 (region 1q31–q42) and it was found using sequence homology strategy to the PSEN1. The nine mutations in the *PSEN2* gene resulting in AD have been identified in 15 families with a broad range of onset age (40–88 years).[3,12,18,19]

The high similarity in clinical and neuropathological features between the early-onset familial and ''sporadic'' late-onset AD suggests that similar pathophysiological factors are involved.

In the near future, it is probable that other AD genes for early-onset familial AD will be identified because familial pedigrees with several affected members with the early-onset autosomal dominant form and not known mutations in the previously reported genes have been described.[20]

MOLECULAR GENETIC TESTING

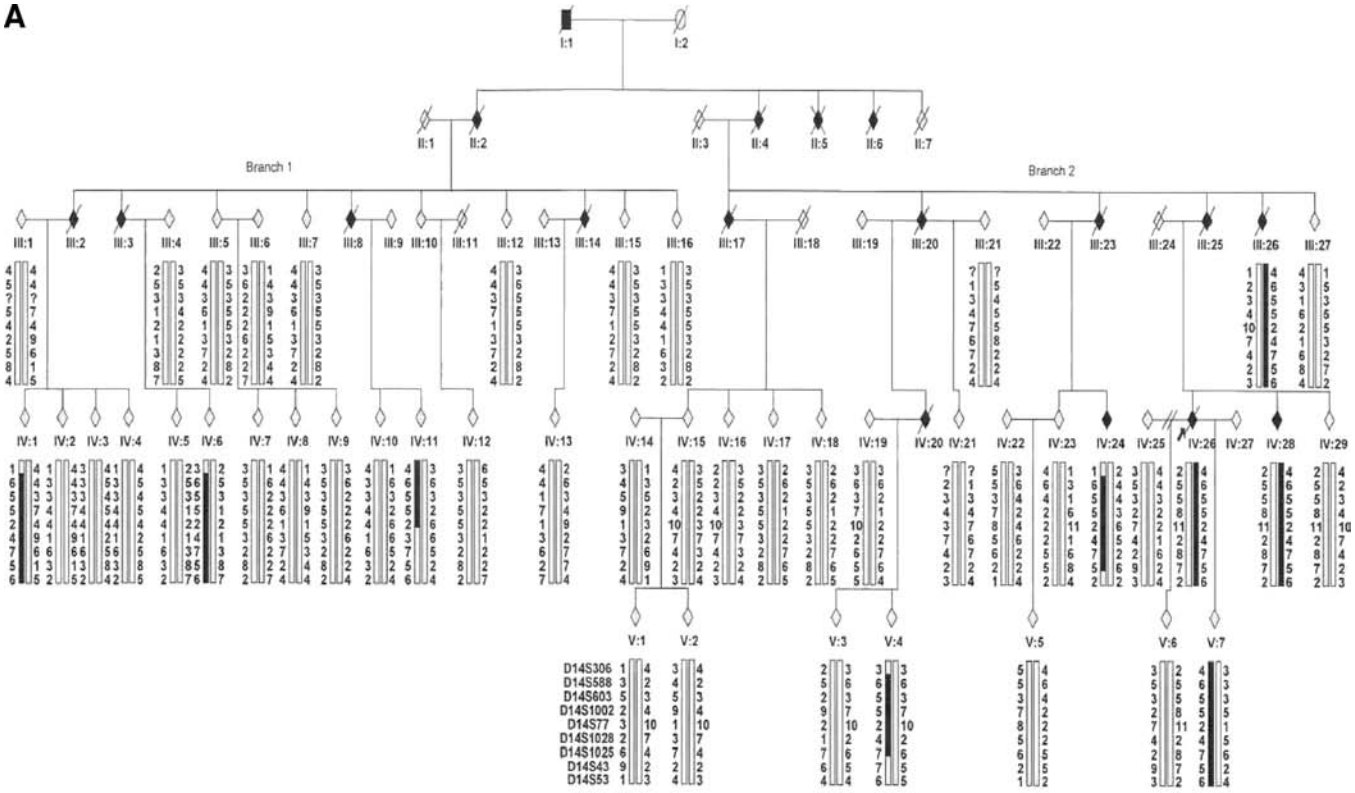
Currently, molecular diagnostic tests are available for AD. With regard to PSEN1 (AD3), it is possible to perform mutation analysis, sequence analysis, and mutation scanning on a clinical basis. For identification of a *PSEN1* mutation, a history of early-onset AD and another family member (principally a first-degree relative) also with early-onset AD is relevant.

The *PSEN2* gene is well characterized, but only nine mutations have been found; most of them are point mutations in the coding region, causing an amino acid change. On one of these mutations (a substitution of an isoleucine for an asparagine at codon 141), the DNA sequence change (AAC vs. ATC) creates a Sau 3a restriction enzyme cleavage site, whose mutation is easy to detect. For PSEN2, sequence analysis and mutation scanning are available on a clinical basis.

Forty-three families with 16 APP (AD1) mutations have been defined. It is probable that because of the limited number of affected individuals, the molecular genetic testing is available only on a research basis by direct DNA study.

GENETIC COUNSELING

In general, genetic testing for AD, diagnosis or disease prediction, is a controversial point and is presently recommended in rare, early-onset familial cases with presumable autosomal dominant inheritance only.[21] Such a testing is not useful in predicting age of onset and severity of symptoms.



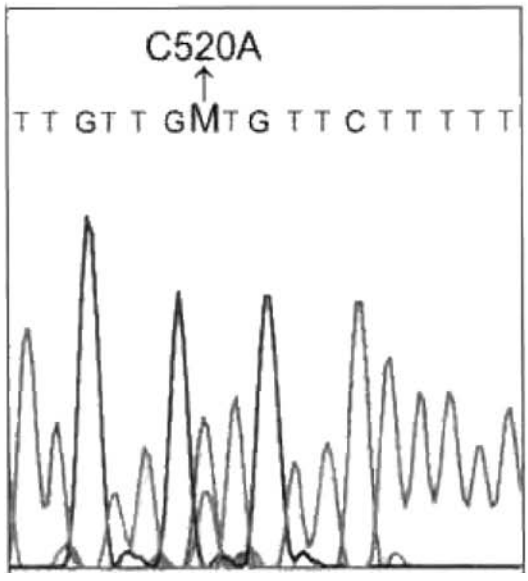


Fig. 1 (A) Pedigree of a large Cuban family with early-onset familial AD. Haplotypes corresponding to the chromosome 14q24.3 region are shown. Filled (black) symbols represent demented individuals. Gender and age are not revealed for reasons of confidentiality. Filled (black) bars indicate disease haplotype. (B) Direct sequencing revealed a heterozygous base change C A (C520A) in exon 6, which is predicted to cause an amino acid change from leucine to methionine in the transmembrana 3 domain (TMIII) of the Presenilin 1 protein. (From Ref. [17].) (*View this art in color at www.dekker.com.*)

Most individuals diagnosed with AD have had an affected parent or at least a second-degree relative with early onset of the disease.

The offspring of an affected individual has a 50% risk of having inherited the altered gene; such a chance is much lower when the parents of probands are clinically unaffected.

Predictive Testing

Many relatives whose family members suffer from the disease wonder about their personal risk of developing AD, but as for Huntington's disease, no prevention or efficient cure is available for AD and predictive testing of AD will become a profound dilemma for individuals at high risk for the disorder. The consequences of providing potentially devastating information to the individual and the family should be weighed against the principles of autonomy and self-determination of the family members.

Prenatal Diagnosis

For AD mutations, if the disease-causing allele of an affected family member has been previously identified, it is possible to carry out prenatal diagnosis by analysis of DNA extracted from fetal cells obtained by chorionic villus sampling or amniocentesis at 10–12 weeks of pregnancy or 16–18 weeks, respectively. In general, request for prenatal testing for adult-onset diseases is not common and many factors affect the uptake of prenatal testing for single gene conditions such as age of onset, severity of the disease, certainty of the test, and, especially, possibility of treatment. The decision is also influenced by legal and social rules of different countries and societies.

CONCLUSION

This review has focused on some of the most important aspects in understanding the occurrence of early-onset familial AD. Genetic factors are of established importance and are being intensively studied. If we are able to elucidate all the mechanisms leading to AD at the molecular level, then it will be possible to develop strategies for prevention and effective treatments either through targeted drugs or other environmental interventions. It will make be possible to improve the use of DNA testing to confirm a diagnosis of AD, or to make predictive statements for an individual about the particular risk of developing AD later in life.

Aminoglycoside-Induced Deafness

Mustafa Tekin
Ankara University School of Medicine, Ankara, Turkey

INTRODUCTION

Our understanding of the genetic basis of aminoglycoside-induced deafness (AID) has greatly improved during the past 15 years. The discovery of the first mitochondrial mutation (A1555G) in 1993, leading to susceptibility to aminoglycoside ototoxicity, was the most remarkable success in this area. Many individuals from different parts of the world have since been identified with this mutation, suggesting that the number of people at risk for ototoxicity may be considerably high, especially in some populations. Two other mutations in the mitochondrial 12S ribosomal RNA (rRNA) gene, C1494T and 961delTinsC(n), have been implicated to cause AID.

OVERVIEW

Aminoglycoside antibiotics are used for the treatment of aerobic gram-negative—and, less commonly, gram-positive—bacterial infections. Streptomycin, the first aminoglycoside introduced in the 1940s, is still in use as first-line antituberculosis drug. Gentamycin, tobramycin, and amikacin are more commonly used in developed countries.[1,2]

The ototoxicity associated with the use of aminoglycosides was recognized soon after they became available, for which a loss of 15 dB or more at any frequency in one or both ears is a commonly used description.[2]

Aminoglycosides can cause deafness in almost all mammalian species when given in massive doses. However, individuals who experienced hearing loss following short-term aminoglycoside use at regular doses, sometimes with a family history of AID, were indicative of a genetic mechanism. It was first suggested in 1989 that the genetic defect might be in the mitochondrial DNA based on the reported pedigrees of AID.[3] It was later clearly demonstrated that the inheritance pattern was matrilineal[4] in a district of China where 167 of 763 (22%) deaf individuals had a history of aminoglycoside exposure. Three Chinese families with histories of AID and an Arab–Israeli family with maternally inherited nonsyndromic deafness (not associated with aminoglycoside exposure) were used to discover the genetic defect in the mitochondrial DNA.[1] As a result of this effort, an A→G transition at position 1555 of the 12S rRNA was identified.[1]

A1555G MUTATION IN THE 12S rRNA GENE

A1555G mutation can induce hearing loss in the presence or absence of exposure to aminoglycoside antibiotics. It was homoplasmic in almost all of the reported cases, although a low level of heteroplasmy has been reported.

There are currently available polymerase chain reaction (PCR)-based screening tests for this mutation. Following are the details of a simple PCR-restriction fragment length polymorphism (RFLP) test:[1]

Primers

Forward 5′-CCGCCATCTTCAGCAAACCCT-3′.
Reverse 5′-TGAAGTCTTAGCATGTACTGCTCG-3′.

Following amplification, PCR products are digested with the *Alw*26I restriction enzyme, of which one cleavage site is abolished when A1555G is present.

Biochemical and Molecular Evidence for the Pathogenicity of A1555G

Because aminoglycosides bind the small rRNA and exert their effect by inhibiting or inducing errors in protein synthesis, it is not surprising that mutations in the corresponding 12S rRNA in humans are responsible for AID.[1] Aminoglycosides bind at, or near, two regions of the *Escherichia coli* small rRNA and these regions, brought together in the secondary and tertiary structures, surround the decoding site of the ribosome (Fig. 1A).

The A1555G mutation introduces a new base pair at a region of the human 12S rRNA (Fig. 1B and C). Disruption of the base pairing at the corresponding region in *E. coli* results in resistance to aminoglycosides.[1] It was experimentally shown that the A1555G RNA analog stoichiometrically binds aminoglycosides with high affinity, whereas the wild type construct does not.[5]

In vitro experiments have confirmed the role of A1555G in AID.[6–8] Lymphoblastoid cell lines obtained from individuals of the original Arab–Israeli family

DOI: 10.1081/E-EDGP 120020975

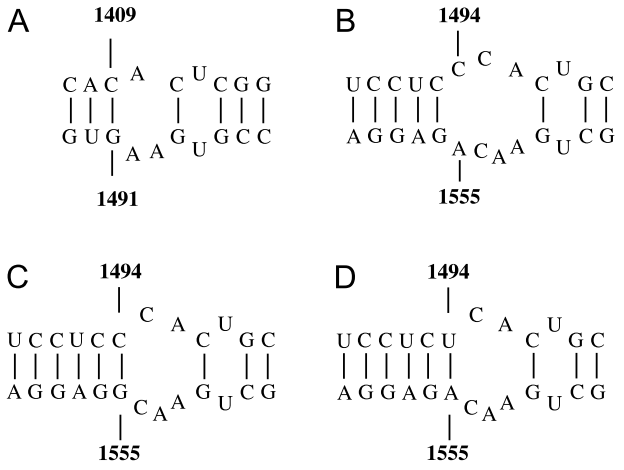

Fig. 1 Wild-type aminoglycoside binding site in *E. coli* 16S rRNA (A) and human 12S rRNA (B) (numbers are in *E. coli* numbering system in A). Positions of the A1555G (C) and C1494T (D) mutations.

showed a lower growth rate, mitochondrial protein synthesis, total oxygen consumption, and respiratory chain complexes-dependent respiration compared with control cell lines.[6] The severity of mitochondrial dysfunction in the mutant cell lines was correlated with the presence or absence of hearing loss in persons carrying the mutation.[6] Exposure of the cells to high concentrations of aminoglycosides significantly decreased the rates of growth and translation.[6,7] When the mitochondria with A1555G was transferred into human mtDNA-less cells, the transformant cells exhibited significantly lower growth rate, mitochondrial protein synthesis, and substrate-dependent respiration compared with control cells. These decreases were very similar in deaf and hearing members of the family with the mutation, suggesting that the nuclear gene(s) plays an important role(s) in deafness phenotype.[8]

Epidemiology

Because A1555G can be found in persons with completely normal hearing, AID, progressive and late-onset high-frequency hearing loss, and congenital- or prelingual-onset severe to profound deafness without aminoglycoside exposure, it is difficult to obtain its true frequency in a given population. Although A1555G was originally described and frequently found in patients coming from families in which other relatives also have AID, sporadic cases with or without AID,[9,10] patients coming from families with hearing loss showing maternal inheritance, or one of the forms of Mendelian inheritance without AID is reported.[11,12]

The proportion of cases with mutation among patients with AID has ranged from 3%[9] to 44%[13,14] in different populations with different ascertainment strategies (Table 1). If there is a family history of AID[14] or maternal inheritance in the pedigree,[11] the possibility of finding this mutation increases. A number of studies have demonstrated that A1555G is associated with different mitochondrial haplotypes,[11,25] although founder effects have also been identified in some families,[25] implying that this mutation has arisen several times in the past and is not limited to a certain ethnic group.

It is important, yet difficult, to find the frequency of A1555G in the hearing population. Based on their results of screening in matrilineal pedigrees, Lehtonen et al.[16] estimated that the minimum frequency of A1555G was 4.7/100,000 in northern Finland. Tang et al.[24] studied anonymized 1173 blood samples obtained for newborn screening in Texas and identified one positive result (9/10,000). Similarly, in a study from New Zealand,[26] A1555G was found in 1 of 206 unselected samples. However, it should be noted that the A1555G mutation was not found in approximately 1500 control samples studied as control in different populations.[1,11,17,21]

Phenotype Associated with the A1555G Mutation

Hearing loss usually manifests itself within 1–3 months following—sometimes even one dose of—aminoglycoside use.[27] The onset and severity of hearing loss are unrelated to age at the time of exposure. The hearing loss is sensorineural (originating from the cochlear lesion) and, in most cases, is symmetrical—almost always involving the high frequencies.[27] The vestibular system appears not to be involved.

A significant portion of individuals with A1555G has normal hearing for their entire life in case they have not been exposed to aminoglycosides. In the absence of aminoglycoside exposure, the probability of an individual possessing the mtDNA A1555G mutation developing hearing loss has been estimated to be 40% by the age of 30 years, and 60% by the age of 60 years.[11]

Genetic Modifiers Implicated in A1555G-Related Deafness

The original Arab–Israeli family and additional families with A1555G without AID suggested the presence of a nuclear modifier gene. Extensive search using different linkage strategies yielded a region on chromosome 8, around the microsatellite marker D8S277.[28]

The common deafness gene *GJB2* and mitochondrial A7444G mutations have been reported to act as modifiers for A1555G in some studies,[21,29] although further

Table 1 Summary of published studies on the frequency of A1555G in different populations (country names in alphabetical order)

Country	Numbers of A1555G-detected/ screened families	Numbers of A1555G-detected/ AID	Numbers of A1555G-detected/ AID	Characteristics of the screened population	Control group	Reference
China	1/36 (3%)	1/36	—	Sporadic cases with AID	—	[9]
China	15/34 (44%)	15/34	15/34	Familial cases with AID	—	[14]
Denmark	2/85 (2.4%)	—	—	Varying degrees of hearing loss	—	[15]
Finland	2/117 (1.7%)	—	2/117	Families with MID	—	[16]
Germany	1/139 (0.7%)	—	—	Severe to profound congenital deafness	0/160	[17]

Indonesia	4/75 (5.3%)	NA	NA	70% profound; 24% severe; 3% moderate to severe; 3% moderate hearing loss	0/100	[18]
Italy	0/80	—	0/16	Moderate to severe hearing loss	—	[19]
Japan	7/138 (5.1%)	2/6	4/8 (without AID)	10% prelingual; 86% postlingual; 4% AID/47% sporadic; 53% familial	—	[20]
Japan	11/319 (3.4%)	7/21	—	18% profound; 10% severe; 34% moderate; 38% mild/92% sporadic; 8% familial	—	[10]
Japan	14/140 (10%)	13/22	—	Profound deafness	—	[10]
Mongolia	37/480 (7.7%)	NA	NA	Severe to profound deafness	0/389	[21]
Poland	3/125 (2.4%)	—	—	Severe to profound congenital deafness	0/89	[17]
Spain	42/209 (20%)	NA	28 (at least seven did not have AID)/30	(Approximately 50% congenital, 50% late-onset in authors' earlier report) 86% familial; 14% sporadic	0/200	[11,12]
Turkey	3/168 (1.8%)	—	—	Prelingual severe to profound deafness/57% familial; 43% sporadic	—	[22]
UK	0/202	0/1	0/10 (possible)	46% familial; 54% sporadic	—	[23]
US	7/41 (17%)	7/41	—	All probands with AID; four had familial AID	—	[13]

MID = Maternally inherited deafness; NA = not available.

studies failed to confirm these results in other populations.[12]

C1494T MUTATION IN THE 12S rRNA GENE

The homoplasmic C1494T mutation was recently identified in a large Chinese family with AID and maternal inheritance.[14] Twenty of 39 matrilineal relatives, who are supposed to carry the mutation, exhibited hearing loss. Clinical data have shown that the treatment with aminoglycosides can induce or worsen deafness in matrilineal relatives. The mutation occurs at a position where the A at position 1555 can make a pair with the mutant base (Fig. 1D). Additional data indicated that the cell lines derived from carriers showed a lower rate of total oxygen consumption and a significant increase in doubling time with the high concentration of aminoglycosides. Nuclear background probably plays a role in the deafness phenotype and AID with the C1494T mutation.[14]

OTHER MUTATIONS IN THE 12S rRNA GENE

Deletion of a T at position 961 and insertion of varying numbers of G were observed in a patient during a search in the mtDNA in 35 sporadic Chinese cases with AID.[30] The same mutation was not detected in 799 control samples.[30] This mutation was later found in an Italian family, in which five maternal relatives became deaf after aminoglycoside exposure.[31] However, in a recent study, 961delTinsC(n) was detected in 7 of 1173 anonymized blood samples in the United States.[24] This result suggests that either the role of this mutation is questionable in AID, or the population at risk for AID is extremely high in the United States.

The T1095C mutation was found in two Italian families.[19,32] In one family, the proband had Parkinson's disease, neuropathy, and a history of AID.[32] The second family with matrilineal inheritance of hearing loss included two maternal relatives of the proband who had histories of AID.[19] More data are needed to draw a firm conclusion about the role of this mutation in AID.

CONCLUSION

The multinational occurrence of the A1555G mutation, with high frequencies in some countries, makes the AID associated with this genetic change a public health problem. Until more precise data are available on the frequencies of this mutation and mechanisms of its action, in coordination with the nuclear or mitochondrial genome, a detailed family history for deafness, especially aminoglycoside-related deafness, will help decrease the number of cases with AID. Currently available PCR-based tests may be used when an aminoglycoside treatment is necessary. Using widely available, precise, less expensive, and rapid molecular screening tests for already known mutations in population screening is open for discussion. Identification of other genetic changes will certainly help create better strategies for large-scale screening.

Amplification Refractory Mutation System PCR

Joannis E. Vamvakopoulos
Biomedicum Helsinki, Helsinki, Finland

INTRODUCTION

Several technologies for probing genetic variation have emerged in the past 20 years, many of which incorporate in vitro enzymatic DNA amplification by the polymerase chain reaction (PCR) in its modern, *Taq*-polymerase-based incarnation. Among them, amplification refractory mutation system (ARMS)-PCR stands out for its speed, simplicity, versatility, and low cost. Since its concurrent inception by six separate groups working independently,[1–6] these features of ARMS-PCR have established it as arguably the single, most popular genotyping technique. Evidence of this abounds in the scientific literature despite some confusing nomenclature issues that persist today (Table 1). The popularity of ARMS-PCR is also apparent by its continuous development over the years (Table 2). Today, ARMS-PCR embraces all formats, from single tube to array, and all conceivable applications, from SNP to universal genotyping.

AN OVERVIEW OF ARMS-PCR: FROM PRINCIPLES TO PRACTICE

Principle and Formats of ARMS-PCR

Accurate genotyping requires stringent allelic discrimination. ARMS-PCR relies on 3′-end primer mismatching to achieve a high degree of allelic specificity. As shown in Fig. 1, the original two-tube incarnation of ARMS-PCR utilizes five primers—two of these are allele-specific and complementary to the polymorphic site at their 3′ terminus, while a common companion primer serves to yield an allele-specific amplification product. Because *Taq* DNA polymerase lacks $3' \rightarrow 5'$ exonuclease activity,[7] allelic specificity is conferred by its inability to efficiently extend 3′ end-mismatched primers. Because most known SNPs are biallelic, two reactions (each containing either one of the allele-specific primers) are required for definitive genotype assignment. An additional pair of irrelevant, fully matched primers, yielding an amplicon of different size serves as internal control to flag false-negative reactions (i.e., those resulting from amplification failure).

Single-Tube ARMS-PCR

Table 2 lists key features of ARMS-PCR and those of numerous subsequent modifications. The initial crucial limitation of having to perform two PCR reactions to establish a single biallelic genotype, along with the associated requirement for an internal control reaction, were soon overcome with the development of various single-tube formats. Here both allele-specific primers are present in the same reaction and allelic discrimination is achieved by either varying the length of these primers[8–10] or by engineering them to amplify on opposite directions and produce amplicons of different lengths.[11–13]

Two-Reaction ARMS-PCR

While single-tube ARMS-PCR arguably represents a more refined, cost-effective, and high-throughput format, it also requires additional expertise, particularly in primer design. It is perhaps for this reason that conventional two-tube ARMS-PCR continued to evolve and has remained popular to date. Substantial modifications have been described that aimed at increasing both assay sensitivity[14] and specificity.[15,16] The concept of multiplex universal genotyping (MUG;[17]), which renders ARMS-PCR applicable to any type of genomic variation and particularly useful for defining mixed (i.e., single-nucleotide and length) polymorphic haplotypes, is the latest addition to an expanding collection of conventional ARMS-PCR formats.

Microarray ARMS-PCR

The advent of microarray technology promises to deliver rapid, high-throughput genotyping through the development of solid-phase, miniaturized assay formats. The forerunner of microarray ARMS-PCR came in the form of allele-specific primer extension, where arrayed allele-specific primers are queried with multiplex preamplified template DNA containing the polymorphisms of interest in the presence of reverse transcriptase and a mixture of ribonucleotides, one of which is fluorescently labeled. Practical difficulties in performing solid-phase PCR, as

Table 1 Alternative designations for ARMS-PCR

Method designation	Reference
Mutation-specific PCR	[1]
Amplification refractory mutation system (ARMS)	[2]
Allele-specific PCR (AS-PCR)	[3–5]
PCR amplification of specific alleles (PASA)	[6]
PCR with sequence-specific primers (PCR-SSP)	[39]

well as the markedly higher signal-to-noise ratio achieved with RT, were the principal reasons for its use here instead of DNA polymerase. These limitations were recently overcome with the development of a two-phase, on-chip PCR platform that achieves simultaneous multiplex amplification of genomic DNA and immobilized allele-specific primer extension using *Taq* DNA polymerase.[18,19]

Design and Optimization of ARMS-PCR Assays

With its numerous formats, ARMS-PCR offers unparalleled flexibility in the design of genotyping assays. Major initial considerations guiding the design process itself include the number and type of genetic variation(s) under study; available equipment, personnel, and expertise in primer design; desired sample throughput; and cost. Once a suitable ARMS-PCR format has been selected, the issue of allele-specific amplicon detection should be separately addressed (reviewed elsewhere in this volume). The design process is complete following customization of the assay to the polymorphisms of interest (primer design), optimization of PCR conditions, and troubleshooting of any problems.

Optimization and Troubleshooting

For all its merits, ARMS-PCR is subject to the same limitations that apply to conventional PCR. Problems such as mispriming and primer dimer formation can be minimized by using suitable software for basic primer design. Complications in basic primer design arising from polymorphisms lying close to the SNP of interest can be overcome by strategically incorporating deoxyinosine (dI) residues into the primer sequence.[1]

Since the original description of ARMS-PCR, several authors have shown that primer 3′-terminal mismatch discrimination with DNA polymerases is not absolute; extension of such mismatches does occur, albeit at a much lower rate than that of a perfectly matched primer. Extension efficiency depends on several factors, primarily the nature of the mismatch[4,20–24] as well as its sequence context,[23] template abundance,[25] and dNTP concentration.[1,21] DNA-dependent DNA polymerases generally achieve better allelic discrimination than reverse transcriptases.[21,22]

While optimization of the PCR reaction itself is typically straightforward, the potential for discrimination failure occasionally necessitates troubleshooting of ARMS-PCR. Initial measures should focus on readily modifiable reaction components and might include reducing the number of amplification cycles,[24] the amount of template DNA,[25] dNTP concentration,[1,8] or performing the reaction under rapid-cycle conditions.[26] In rare instances where these measures would fail or prove difficult to implement (e.g., when running multiplex reactions or pooled DNA),

Table 2 Comparison of different platforms for ARMS-PCR

Method designation	Format	Special features	Reference
ARMS-PCR (AS-PCR; PASA)	Two tube	—	[1–6]
ADPL AS-PCR	Single tube	Seminested design	[8]
PAMSA	Single tube	—	[9]
Asymmetric AS-PCR	Two tube	Seminested design	[14]
Mutagenically separated AS-PCR	Single tube	Intraprimer mismatches	[10]
Competitive blocker AS-PCR	Two tube	CB primers	[15]
Gap-ligase chain reaction	Swo tube	*Taq* ligase	[16]
Bidirectional PASA	Single tube	Tailed AS primers	[11]
PCR-CTPP	Single tube	Tailless primers	[12]
Tetra-primer ARMS-PCR	Single tube	Long, tailless primers; asymmetric design	[13]
Microarray ARMS-PCR	Array	Solid-phase platform	[18,19]
MUG-PCR	Two tube	Universal genotyping platform	[17]

Abbreviations: ADPL = allele discrimination by primer length; PAMSA = PCR amplification of multiple specific alleles; CB = competitive blocker; CTPP = confronting two-pair primer; MUG = multiplex universal genotyping.

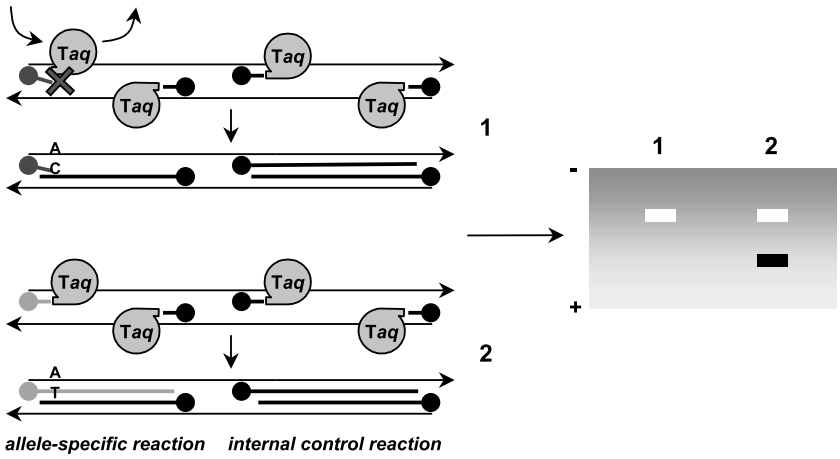

Fig. 1 Principle of ARMS-PCR (see text for details). (From Vamvakopoulos, J.E., 2001. A potential role for interleukin-1 in chronic allograft rejection. PhD thesis. University of Cambridge, U.K.) (*View this art in color at www.dekker.com.*)

further action should involve modification of the allele-specific primers[20,22,25,27–29] or use of depository oligos.[30]

ARMS-PCR relying on intercalating fluorescent dyes for amplicon detection may require additional trouble-shooting aimed at minimizing nonspecific fluorescence from primers and primer dimers. This issue becomes crucial for applications demanding optimal sensitivity, such as genotyping of DNA pools and monitoring minimal residual disease or the emergence of drug-resistant infectious strains in clinical samples. Primer design measures for minimizing primer dimer formation have been described;[31] alternatively, optimal signal-to-noise ratio in these instances can be achieved by simply raising the reaction pH to 11.7 before amplicon detection.[32]

APPLICATIONS OF ARMS-PCR: GENOTYPING AND BEYOND

The versatility and success of ARMS-PCR as a methodological tool can best be judged by its uses. Here I summarize some of the most important, diagnostically oriented applications of this technique.

Clinical Genetics and Cancer Management

ARMS-PCR was originally conceived mainly for the purpose of detecting cancer-related mutations[1] and for studying the genetic basis of heritable disorders.[2–6] In this respect the field of clinical genetics was quick to explore the potential of this technique: rapid, PCR-based assays for several genetic diseases where the causative mutation was known were developed soon after the first description of ARMS-PCR.[33,34] Furthermore, the power of ARMS-PCR to detect mutations with unparalleled sensitivity has revolutionized two key aspects of cancer management, namely molecular diagnosis[35] and the monitoring of minimal residual disease (MRD).[36,37]

Tissue Typing and Cell Therapeutics

HLA typing was one of the very first applications of ARMS-PCR and, in retrospect, the impact of this technique on histocompatibility testing has been momentous. Fugger et al.[38] pioneered the application of ARMS-PCR in this field, while Olerup, Zetterquist, and co-workers are credited with much of the work leading to the routine clinical application of this technique.[39,40] Today, ARMS-PCR is the bedrock of HLA typing. With new HLA specificities being integrated as they are discovered,[41] this situation looks set to persist long into the future.

Also of clinical relevance is the application of ARMS-PCR to the functional and quantitative study of cellular chimerism following cell or solid organ transplantation. Accurate quantitative measurement of cellular chimerism by ARMS-PCR is now feasible[42,43] and should greatly facilitate further advances in this field.

Studies of Interindividual Genetic Variation

The fact that ARMS-PCR is well suited to studying single nucleotide polymorphisms (SNPs), which account for over 80% of interindividual genetic variation, makes it

an ideal tool for related functional and epidemiological studies. Besides conventional, biallelic SNPs, ARMS-PCR is easily adaptable to the study of triallelic SNPs,[44] small insertions, and deletions.[45] Where marker informativeness becomes crucial (e.g., in mapping disease traits), this technique can also accommodate length polymorphisms alongside SNPs;[17] in that same context, it is also unique in allowing direct haplotyping of genetic markers.[17,46,47] Last but not least, the high sensitivity of this method makes it ideal for genotyping of pooled DNA samples.[48,49]

CONCLUSION

Fifteen years after its original description, ARMS-PCR remains an immensely popular and evolving technique. Rapid, reliable, versatile, and accessible to even the smallest laboratory, it is the definitive ''poor man's genotyping method.'' Yet, advanced design features and the integration of new technologies have propelled it to the forefront of large-scale genomic research. Until inexpensive, on-the-fly whole-genome sequencing becomes feasible, this technique is here to stay.

ACKNOWLEDGMENTS

I owe a debt of gratitude to my host and mentor, Professor Pekka Häyry (Transplantation Laboratory, University of Helsinki, Finland); this work owes much to his encouragement, patience, and continuing support. Thanks are also due to Dr. Su Metcalfe and Dr. Craig Taylor (Cambridge, U.K.) for introducing me to ARMS-PCR. Last but not least, generous financial support by the Institute of Biomedical Science (London, U.K.) and the Centre for International Mobility (Finnish Ministry of Education) is gratefully acknowledged.

Amplified Fragment Length Polymorphism (AFLP)—Application for DNA Fingerprinting

G. Ripabelli

J. McLauchlin
Health Protection Agency Food Safety Microbiology Laboratory, London, U.K.

INTRODUCTION

The analysis of nucleic acid markers that reflects similarities in DNA or RNA sequences (DNA or RNA fingerprinting) has become widespread, and has many uses, including identifying progenitors, siblings or paternity, establishing identity of target recovered from different locations, assessing population structure including clonality or degree of recombination, predicting phenotypes, etc. Factors influencing the choice of a fingerprinting technique include the type of application, the target organism under investigation (animal, plant, microorganism), the source of target material available, the resources and skill base to perform tests, and the availability of data for comparative analysis. Ideally, the method should be cheap, rapid, reproducible, discriminatory, independent of other methods, and applicable to all types of samples including to targets without prior sequence or genetic mapping information. Moreover, the method should be amenable to automation, easy to interpret and standardize between different testing sites, capable of comparisons with different methods, and require minimal molecular skills from the operators and those interpreting the data. Currently, no single technique is able to meet all of these requirements.

Initially, the most common DNA fingerprinting techniques were based on restriction fragment length polymorphism, some with subsequent Southern blotting-based analysis. However, polymerase chain reaction (PCR)-based procedures have become more common, one of which is amplified fragment length polymorphism (AFLP) analysis. AFLP has advantages over other similar fingerprinting techniques in terms of reproducibility, discrimination, labor intensiveness, and speed. AFLP is easier to perform and requires simpler and less expensive equipment than pulsed-field gel electrophoresis, which is widely considered as the ''gold standard'' for molecular epidemiological studies of pathogenic microorganisms. Because of the high stringency of the PCR procedure, AFLP is inherently more reproducible than randomly amplified polymorphic DNA analysis. It does not require Southern blotting followed by probing with labeled nucleotides such as is required for ribotyping or insertion sequence typing (IST). Most importantly, AFLP markers have a high multiplex ratio (the number of different genetic loci simultaneously analyzed per experiment) that allows characterization of, at least in part, the entire genome. In contrast, assays characterizing single loci have a multiplex ratio of 1.

AFLP ANALYSIS

AFLP is a PCR-based technique able to provide high-throughput DNA fingerprinting for rapid and accurate screening of genetic diversity, which was correctly originally described as able to ''bridge the gap between genetic and physical maps.''[1] The method comprises of a restriction-enzymatic digestion of genomic DNA followed by ligation of double-stranded oligonucleotide adapters that are complimentary to the restriction sites at the ends of the DNA fragments. The ligated ends are designed not to regenerate the restriction sites, and because the adapters are not phosphorylated, adapter-to-adapter ligation is prevented. Because the adaptors are of known DNA sequences, subsequent PCR amplification under high stringency is performed using primers that have exact complementarity with the template DNA generated by the adaptors. Patterns of amplified product differing in size constitute the final output of the process (Fig. 1). Despite the name, and despite its similarity with restriction fragment length polymorphism, AFLP detects the presence or absence of restriction fragments rather than their length polymorphism.

DNA Extraction

The starting DNA is crucial for successful AFLP analysis. This should ideally be of high molecular weight and as free as possible from contamination by other biomolecules. DNA extraction methods (e.g., those based on

Encyclopedia of Diagnostic Genomics and Proteomics

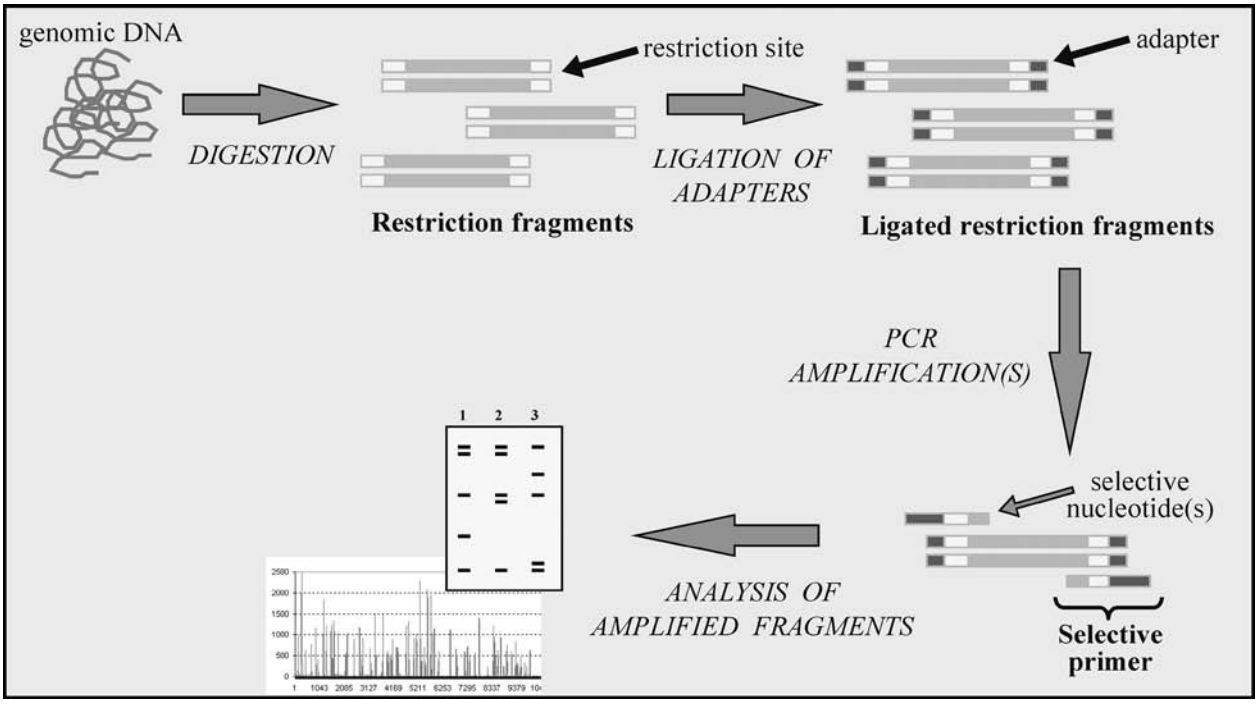

Fig. 1 Amplified fragment length polymorphism procedure. (*View this art in color at www.dekker.com.*)

phenol chloroform, guanidinium thiocyanate, and cetyltrimethyl-ammonium bromide) suitable for AFLP analysis are widely available. Because the PCR primers are not based on specific sequences, target DNA must be free from nucleic acids from other sources and hence, this method is problematic for analysis of microorganisms that cannot be grown in axenic culture or for target DNA that cannot be separated from DNA derived from extraneous sources.

Restriction Digestion and Ligation

Optimal restriction digestion is fundamental for correct AFLP patterns analysis, and the original methods used a combination of two enzymes with rare and frequent cutting sites. Hence, the fragments generated contain a frequent restriction site sequence at one end, plus a rare site sequence at the other. The rationale for this choice, particularly for functional analysis of genomes with very high complexity (e.g., for plant genomes), is that only fragments with combined rare and frequent restriction sites will be amplified, thus limiting the number of selective nucleotides in primers used for subsequent amplifications.[1] Alternative methods using only a single enzyme (sAFLP) are also available.

The availability of many different restriction enzymes with corresponding adapters and primer combinations provides a great deal of flexibility and ''tuning'' of the number of AFLP fragments generated. Theoretically, any restriction enzyme, alone or in combination, could be used to generate DNA profiles, irrespective of the complexity and utility required. However, rarely cutting enzymes will generate few fragments, thus reducing the probability for polymorphism detection, and frequently cutting enzymes are unlikely to generate fingerprints appropriate for interpretation.

Primer Selection and PCR

Because the adaptors are of known DNA sequence, subsequent PCR amplification of all DNA fragments can be achieved using primers that have exact complementarity with the adaptor sequences. Alternatively, the 3′ ends of the PCR primers can include one or more additional ''selective'' nucleotides, thus allowing amplification of a subset of the adapted–restricted fragments; it is usually necessary to test primers with up to three selective nucleotides to obtain satisfactory patterns.[2]

Pattern Analysis and Evaluation of Assays

Depending on the methods used to perform AFLP assay, the amplified fragments can be visualized on denaturing polyacrylamide gels (dPAGE) through autoradiography,[1]

on agarose gel with ethidium bromide staining and UV transillumination,[3] or by using fluorescently labeled primers through a polyacrylamide matrix in an automated sequencer.[4] If comparisons of simple patterns of relatively low discrimination for small numbers of samples are required, these can be adequately achieved by visual inspection. However, once more complex AFLP patterns are analyzed together with the need for intralaboratory and interlaboratory analysis, the application of bioinformatics is essential for analysis: the high reproducibility of AFLP supports the generation of electronic databases.[5] A systematic review of final pattern analysis and its evaluation are outside the scope of this article; however, the fundamental aspects of DNA fingerprinting analysis as developed for other systems[6] must be applied. In addition, the assessment of reproducibility (the repeatability of test results), typability (proportion of targets in a population that can be analyzed), and discrimination (number of different types identified) for each individual system must be evaluated, usually with a degree of empiricism.

APPLICATIONS OF AFLP ANALYSIS

AFLP has been successfully applied to DNA fingerprinting of a very wide variety of biological sample including plants, animals, and both eukaryotic and prokaryotic microorganisms and viruses.[1,7] In plant studies, it has been useful to estimate genetic diversity[8–10] and to resolve phylogenetic relationships.[10–12] Because AFLP markers cover the entire chromosomes, this technique can be successfully applied for breeding analysis including for variety identification, germoplasm management, indirect selection of agriculturally important traits, and backcross breeding.[13] Identification of markers closely linked to resistance genes,[14] construction of plant genetic maps,[15,16] and quantitative trait loci analysis (i.e., QLT analysis is that of traits that do not fall into discrete classes, and are controlled by multiple independently Mendelianly segregating genes) have been achieved by AFLP.

Applications of AFLP to animal genetics and linkage analysis have not been as widespread as in plant genetics, probably because of availability of dense microsatellite maps.[13] However, AFLP analysis has been used to investigate genetic diversity among domestic cattle,[17,18] and for human genome fingerprinting resulting in an efficient and rapid approach for identifying and scoring multiple variants.[19] AFLP-based human mRNA fingerprinting,[20] where the target is cDNA rather than genomic DNA, had been used for analysis of expression of genes involved in cancer development[21] and to evaluate changes in gene expression after exposure to xenobiotics.[22]

AFLP is well suited to the study of eukaryotic parasitic,[23–25] fungi,[26,27] viruses, and bacteria.[1] The power of the technique for comparative genomics is illustrated by the study of Arnold et al.,[28] which showed that AFLP generated >90% of the fragments predicted from the *Escherichia coli* K12 genome. The technique has proven especially useful for analysis of bacteria pathogenic to humans and other animals, and the authors' experience has shown AFLP to be highly suitable for public health microbiology and molecular epidemiological analysis.[29–33] The robustness of the system is illustrated by the successful interlaboratory comparison of AFLP patterns via the internet to identify strains of the bacterium *Legionella pneumophila*, the causative agent of Legionnaires' disease[34] (http://www.ewgli.org/).

CONCLUSION

In summary, PCR-based DNA fingerprinting techniques are becoming increasingly used for a wide range of organisms, and AFLP analysis has considerable advantages for certain applications. The method is robust, relatively easy to perform, sufficiently reproducible to provide the basis for reliable intralaboratory and interlaboratory studies, and can be easily modified (tuned) to provide the desired level of discrimination. AFLP markers have a high multiplex ratio (the number of different genetic loci that may be simultaneously analyzed per experiment), which is of considerable advantage because this allows analysis of, at least in part, the entire genome rather than single locations.[35,36] AFLP has been successfully applied to fingerprint DNA material from a very wide variety of biological sample including plants, animals, viruses, and both eukaryotic and prokaryotic microorganisms.[1,7,37,38] Applications have been particularly successful in the areas of analysis of plant genomes and those from pathogenic bacteria for public health microbiology and molecular epidemiology. Until very high throughput multiple-sequence analysis of whole genomes becomes technically feasible on a wide and rapid scale, AFLP should be seriously considered as the method of choice to investigate genome polymorphisms.

Angelman Syndrome

Milen Velinov
Edmund C. Jenkins
New York State Institute for Basic Research in Developmental Disabilities, Staten Island, New York, U.S.A.

INTRODUCTION

In 1965 Harry Angelman first reported on three patients with severe mental retardation, who had ''flat heads, jerky movements, protruding tongues and bouts of laughter'' that ''gave them specific resemblance to puppets.'' This was the first report on a devastating condition that was for some time referred to as the ''happy puppet syndrome'' but is currently known as Angelman syndrome (AS).

Angelman syndrome is an example of imprinted gene abnormality in humans. The gene, the function of which is deficient in at least 85% of AS cases, E6-AP-ubiquitine-ligase (UBE3A) shows brain-specific imprinting in that only its maternal allele is active in the brain. Four known molecular mechanisms can lead to UBE3A deficiency. For the remaining 15% of patients the underlying mechanism is unknown. Although the recurrence risk for subsequent pregnancies in most affected families is low, in some cases it can reach 50%. As no single laboratory test can identify all AS cases and subtypes, using a sequential diagnostic testing algorithm is suggested.

OVERVIEW

Prevalence

The reported AS prevalence is in the range of 1 in 10,000–20,000.[1,2]

Clinical Features

Angelman syndrome patients[3] have global developmental delay, usually first noticed at 6–12 months of life. Most patients never develop speech, but some may have minimal use of words. All have frequent inappropriate laughter or smiling and significant motor delay—they begin walking at an average age of 4–5 years. Typical neurological manifestations are ataxia and tremulous movements. Most, but not all, have microcephaly. Most develop seizures before 3 years of age and have characteristic abnormal EEG patterns.[4] Features that are present in most cases include characteristic appearance with flat occiput, protruding tongue, prognatia, wide smiling mouth, as well as hypopigmentation and strabismus (Fig. 1). Sleep disturbances and fascination with water can also be present. Clinical diagnostic criteria for AS have been developed by a panel of professionals experienced in the care for AS.[6]

MOLECULAR BASIS AND IMPLICATIONS FOR GENETIC COUNSELING

Angelman syndrome is divided into five major types:

Type I. De novo interstitial deletions of region 15q11q13 are found in about 70% of all AS cases (Table 1).[7] Similar deletions have been reported in association with Prader–Willi syndrome (PWS), a disorder with different phenotype (see Prader–Willi syndrome). The deleted chromosomal area in AS is of maternal origin in contrast to PWS where the origin of the deletions is paternal.[8] These findings suggested the presence of imprinted genes in the PWS/AS region. The common PWS/AS deletion (see also Prader–Willi syndrome) spans about 4 Mb and is routinely diagnosed by FISH analysis.[9] In cases with the common deletion (Type I a) the recurrence risk is lower than 1%.[10] In less than 1% of all AS cases, referred to as Type I b, chromosomal abnormalities are observed in nonaffected parents. Two types of families have been reported: 1) an unbalanced translocation in the affected individual with a balanced translocation in his/her mother. In one such family there were affected children with both AS and PWS depending on the transmitting parent;[11] 2) familial interstitial deletion that is present in the patient, his unaffected mother, and possibly the unaffected grandfather.[12] Such deletions are smaller and do not include the region for PWS—when transmitted from the grandfather to the mother they do not lead to PWS. In Type I b families the estimated recurrence risk is up to 50%.

Type II. Uniparental disomy 15 (UPD-15). About 2–3% of AS cases are the result of paternal UPD-15[13]—inheritance of both chromosomes 15 from the father. It

DOI: 10.1081/E-EDGP 120025780

Fig. 1 Photographs of six 11–33-year-old patients with Angelman syndrome. (From Ref. [5].)

seems that most paternal UPD-15 errors occur during postzygotic divisions.[14] Increased parental age is documented in UPD cases.[15]

Although the recurrence risk for UPD (Type II a) is lower than 1%, cases of AS with paternal UPD-15 have been reported in association with familial translocations involving chromosome 15[16] (Type II b). In such cases the recurrence risk may be increased, but the available information is limited.

Type III. Imprinting defects. Genomic imprinting in the PWS/AS region is associated with specific DNA methylation patterns reflecting the chromosome's parental origin (see ''Laboratory Testing''). The methylation patterns are abnormal in both deletion and UPD–AS cases. About 5% of AS patients do not have FISH-identifiable deletions or UPD, but have abnormal methylation patterns lacking methylated (maternally specific) DNA sequences despite the established biparental inheritance. In some cases this imprinting defect is associated with smaller deletions in the region, involving the 5′ end of the gene SNRPN.[17] This chromosomal locus referred to as an imprinting center (IC) is involved in the imprinting switch process during gametogenesis, which allows the ''resetting'' of the DNA methylation patterns in the gametes to reflect their parental origin. Two physically separated control centers (minimal regions) were identified within the IC region. An 880-bp sequence is believed to be involved in the paternal-to-maternal imprint switch, and when deleted leads to AS. A 4.3-kb sequence is deleted in PWS families with IC mutations and appears to be involved in the maternal-to-paternal imprint switch.[17] Imprinting center deletions are found in about half of the imprinting defect cases. In families with IC deletions (Type III a) the mothers are unaffected carriers of the deletion and have a 50% chance to have another child with AS.[10] In the imprinting defect cases with no identifiable IC deletions (Type III b) the recurrence risk seems to be low as recurrence has not been observed, but the existing data are limited. It seems likely that Type III b abnormalities occur sporadically and are postzygotic.[18] Such abnormalities were recently reported in association with intracellular sperm injection procedures.[19]

Type IV. UBE3A mutations. At least 20% of the AS patients have normal methylation patterns. In up to 50% of those cases single-gene mutations of the maternally derived allele of the gene UBE3A, which is located within the AS/PWS chromosomal region, were identified.[20,21] Mutations of UBE3A can produce the entire AS phenotype in contrast to PWS, where deficiencies of more than one gene contribute to the disease phenotype. UBE3A gene mutations are found more frequently in familial than in sporadic cases.[20,21] In familial cases the mother of the affected individual carries a silent mutation and the risk for subsequent pregnancies is 50%. Cases of gonadal mosaicism for UBE3A mutations that may lead to recurrence have been reported in significant proportion of mothers.[21] Such findings prompt caution while providing genetic counseling for families in which the mutation is not identified in the mother, as the recurrence risk may not be lower than 1%.[22]

Type V. Unknown. There is no confirmatory laboratory test for the last group of AS patients. Their methylation testing and UBE3A mutation screening are normal. Special effort should be made in this group of patients to rule out different etiologies with similar phenotypes.[23]

UBE3A DEFICIENCY

The UBE3A gene encodes E6-AP ubiquitin protein ligase, a protein that takes part of the ubiquitin–proteasome

Table 1 Molecular types of AS

Type	Mechanism	Laboratory testing	Proportion of all (%)	Recurrence risk	Phenotype
Ia	De novo Del 15q11q13	MT[a]+ FISH+	70%	<1%	Severe
Ib	Inherited chromosomal abnormalities	Chromosome analysis–abnormal MT+	<1%	Up to 50%	Unclear
IIa	Paternal uniparental disomy	MT+, FISH−, UPD study+	2–3%	<1%	Mild
IIb	Uniparental disomy and chromosomal aberration	Chromosome analysis–abnormal, MT+, UPD study+	<1%	? Increased, but limited data	Unclear
IIIa	Imprinting defect with IC deletion	MT+, FISH−, UPD−, IC del+	2%	Up to 50%	Intermediate
IIIb	Imprinting defect without IC deletion	MT+, FISH−, UPD−, IC del−	2%	<1%	Intermediate
IVa	UBE3A mutation, mother is carrier	MT−, UBE3A mutation+ (mother+)	2–5%	50%	Intermediate
IVb	UBE3A mutation, mother not a carrier	MT−, UBE3A mutation+ (mother−)	2–5%	? Higher than in general population	Intermediate
V	Unknown defect	All tests negative	15%	Unclear	Unclear

[a]MT = DNA methylation testing.

proteolytic pathway where the proteolysis occurs after conjugation to ubiquitin.[24] This gene is imprinted in the brain where only its maternal allele is functional.[25] A mouse model of AS was developed by generating a UBE3A null mutation. The affected mice show cognitive impairments, inducible seizures, and deficit in long-term potentiation.[26] Still at this time a direct link between the UBE3A deficiency and the clinical features of AS has not been positively established.

Phenotype–Genotype Correlations

The most severe AS phenotype is observed in Type I (deletion) patients. The clinical severity in this group is believed to be due to additional deleted genes in this region. For example, the severity of seizure disorder may be due to the deletion of the GABA receptor gene GABRB3, which is located in the deleted area;[27] the hypopigmentation is linked to the deleted P gene in this area.[28] The UPD patients form the other end of the clinical spectrum with the mildest phenotypes. The severity in patients with imprinting defects and UBE3A mutations seems to fall between the deletion and UPD categories.

Diagnostic Testing

The diagnostic tests bellow are listed in order of their application for diagnostic evaluation (Table 1 and Fig. 2):

- *G-banded chromosome analysis* should be undertaken in every individual with suspected AS for two important reasons: 1) to rule out familial chromosomal abnormalities, associated with increased recurrence risk; 2) to rule out a non-AS chromosomal abnormality that may mimic the AS phenotype.[23]
- *DNA methylation testing* is done as an initial evaluation for all patients with suspected AS and will identify up to 80% of the AS cases: the ones with deletion, UPD, and imprinting defect.[29] DNA methylation is a genomic process that mediates epigenetic regulations of gene expression. It involves the cytosines in the CpG islands and is generally associated with down regulation of gene expression. A CpG area at the 5′ end of the SNRPN gene in the proximal 15q region is methylated if maternally derived and not methylated if paternally derived. This gene region is used to look for DNA methylation abnormalities in AS or PWS. In AS cases of deletions, paternal UPD-15, and imprinting defects the DNA methylation patterns are abnormal reflecting the deficiency of the maternally specific (methylated) 15q region. Diagnostic DNA methylation testing is traditionally done using a Southern-blotting protocol, based on the use of methylation-sensitive restriction enzymes.[17] More recently, PCR-based methylation tests have been developed based on methylation-specific DNA sequence changes introduced by sodium bisulfite modification.[29] Such tests require minimal amounts of DNA and have been used to retest archived patient cells after negative FISH analyses.[30]
- *FISH analysis* using commercially available probes specific for the SNRPN locus is done to look for 15q11q13 deletions after a positive DNA methylation testing,[9] (Fig. 2).
- *UPD analysis* is done in cases of abnormal DNA methylation and normal FISH analysis. This testing protocol uses DNA polymorphisms to trace the inheritance of chromosome 15. DNA specimens from both parents are necessary.[31]
- *IC mutation screening*. In methylation positive, FISH, and UPD-negative cases a search for IC deletion can be done,[17] but is not currently available for routine use.
- *UBE3A mutation screening*. In cases of normal DNA-methylation patterns, the patient phenotype needs reevaluation in order to decide whether UBE3A testing is warranted. If typical AS features are observed UBE3A mutation screening can be considered.[20,21]

CONCLUSION

Angelman syndrome is a devastating condition presenting severe developmental delay, epilepsy, neurological, and

behavioral abnormalities. All various identifiable molecular mechanisms by which the disorder may occur ultimately lead to a deficiency of the UBE3A gene that is involved in ubiquitin-mediated proteolysis. Future research on AS may involve identifying the exact mechanism by which UBE3A deficiency leads to the characteristic clinical manifestations; developing new specific management strategies; establishing the exact molecular basis for the AS patients with negative laboratory testing; studying the possible connection between intracellular sperm injection and the occurrence of sporadic imprinting abnormalities.

Arylamine *N*-Acetyltransferase Gene Polymorphism

A

Neville J. Butcher
Rodney F. Minchin
University of Queensland, St. Lucia, Australia

INTRODUCTION

Acetylation catalyzed by the arylamine *N*-acetyltransferases (NATs; EC 2.3.1.5) is a major biotransformation pathway for arylamine and hydrazine drugs, as well as many carcinogens that we are exposed to on a daily basis found in foodstuffs, cigarette smoke, and the environment. These compounds can either be detoxified (*N*-acetylation) by NATs and eliminated from the body, or bioactivated (*O*-acetylation) to metabolites that have the potential to cause toxicity such as cancer. As a result, NAT levels in the body have clinical importance with regard to drug effect and individual susceptibility to toxicity. In humans, these reactions are catalyzed by two closely related, highly polymorphic enzymes (NAT1 and NAT2), which differ in their substrate specificity and tissue distribution. This article focuses on recent advances in the molecular genetics of the human NATs and their clinical implications.

GENOMIC ORGANIZATION

There are three human NAT genes. Two encode functional proteins and are designated *NAT1* and *NAT2*, and the third is a pseudogene (*NATP1*) that encodes a truncated nonfunctional protein. All are located on the short arm of chromosome 8 and have been mapped to 8p21.3–23.1, a region commonly deleted in human cancers. Both functional NATs are encoded by single intronless exons and the protein-coding regions share an 87% nucleotide homology and are 870 bp in length.

PROTEIN CHARACTERISTICS

Human NAT1 and NAT2 both have an approximate molecular mass of 33 kDa and each consists of 290 amino acids, sharing an 81% homology. NAT1 appears to be ubiquitously expressed, whereas NAT2 expression is restricted to the liver and gut. The active site of NAT enzymes contains the catalytic triad cysteine–histidine–aspartate,[1] which is similar to that of the cysteine protease superfamily of proteins.

SUBSTRATE SPECIFICITY

NAT1 and NAT2 have different but overlapping substrate specificities, although no substrate is exclusively acetylated by one isozyme or the other, and no clear structural motif that determines substrate specificity for the different isoforms has been identified. Substrates preferentially *N*-acetylated by human NAT1 are *p*-aminobenzoic acid, *p*-aminosalicylic acid, sulfamethoxazole, and the folate catabolite *p*-aminobenzoyl glutamate. Substrates primarily *N*-acetylated by human NAT2 include a number of sulfonamides (sulfamethazine, sulfapyridine, sulfadiazine, sulfameridine, and sulfadoxine), isoniazid, aminoglutethimide, amonafide, procainamide, dapsone, dipyrone, endralazine, hydralazine, prizidilol, batracylin, and metabolites of clonazepam and caffeine. Some compounds, such as the carcinogenic aromatic amines 2-aminofluorene, benzidine, 4-aminobiphenyl, 4,4-dichloroaniline and 2-naphthylamine, and the food-derived heterocyclic amines 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine and 2-amino-3,4-dimethyl-imidazo[4,5-*f*]quinoxaline, are *N*-acetylated to varying degrees by both human NAT1 and NAT2. Generally, *O*-acetylation of the *N*-hydroxy metabolites of carbocyclic arylamines is catalyzed selectively by NAT1, whereas NAT2 *O*-acetylates *N*-hydroxy metabolites of the dietary heterocyclic amine carcinogens.

NAT POLYMORPHISM

An international committee has been established to oversee the nomenclature of the NATs[2] and a Web site that provides information about the naming of existing and new alleles for all species can be found at http://www.louisville.edu/medschool/pharmacology/NAT.html.

NAT2 Alleles

Since the human *NAT2* locus was established as the site of the classical acetylation polymorphism, the study of *NAT2* allelic variation has been an area of intense investigation. To date, 36 different *NAT2* alleles have been detected in human populations.[3] Each of the variant alleles is composed of between one and four nucleotide substitutions,

DOI: 10.1081/E-EDGP 120030858

of which 16 have been identified, located in the protein-coding region of the gene. The correlation between NAT2 genotype and phenotype is well established. Moreover, there is a gene-dosage effect. Individuals who are homozygous for slow *NAT2* alleles have a slow acetylator phenotype, individuals heterozygous for slow *NAT2* alleles have an intermediate acetylator phenotype, and individuals who lack slow *NAT2* alleles have a rapid acetylator phenotype.

Molecular mechanisms of NAT2 slow acetylation

The molecular mechanisms responsible for the production of the NAT2 slow acetylator phenotype are not well understood. Initial studies in liver tissue showed that the slow phenotype was due to a marked decrease in NAT2 protein content. In bacterial[4] and yeast[5] expression systems, some base changes caused slow acetylation by producing an unstable protein, whereas others caused slow acetylation by a reduction in NAT2 protein expression.

NAT2 allele frequency

In Caucasian and African populations, the frequency of the slow acetylation phenotype varies between 40% and 70%, whereas that of Asian populations, such as Japanese, Chinese, Korean, and Thai, range from 10% to 30%.[6] This difference reflects slow acetylator allele frequency. Caucasian and African populations have high frequencies of *NAT2*5* alleles (>28%) and low frequencies of *NAT2*7* alleles (<5%), whereas Asian populations have low incidences of *NAT2*5* alleles (<7%) and higher incidences of *NAT2*7* alleles (>10%). Also, *NAT2*14* alleles are almost absent from Caucasian and Asian populations (<1%), but are present in African populations at comparably higher frequencies (>8%).

NAT1 Alleles

Historically, NAT1 was thought to be genetically invariant. However, wide interindividual variability in NAT1 activities was suggestive of a genetic polymorphism. The first reported allelic variation at the *NAT1* locus was in 1993[7] and marked the beginning of a systematic survey of *NAT1* genotypes. To date, 26 different *NAT1* alleles have been detected in human populations.[3] However, only a small number of these alter phenotype.

A genotype/phenotype relationship involving the slow acetylator alleles *NAT1*14*, *NAT1*15*, *NAT1*17*, and *NAT1*22* in human blood cells exists. Individuals heterozygous for these alleles have approximately half the activity of individuals who are wild-type (*NAT1*4*). Similar to NAT2 in the liver, low activity was caused by a parallel decrease in NAT1 protein content.[8] A gene-dosage effect similar to that seen for NAT2 alleles also exists for the low activity *NAT1* alleles. The *NAT1*10* allele has been associated with increased activity in bladder and colon tissue, compared to wild-type.[9] In addition, higher levels of DNA adducts have been detected in bladder tissue from *NAT1*10* heterozygotes. The functional significance of this allele is controversial, as several recent studies do not support the idea that *NAT1*10* is associated with elevated NAT1 activity.[10–14]

Molecular mechanisms of altered NAT1 acetylation

The molecular mechanism for slow acetylation caused by the *NAT1*14*, *NAT1*15*, *NAT1*17*, and *NAT1*22* alleles has been recently elucidated. These alleles produce mutant proteins that are rapidly polyubiquitinated and targeted for degradation by the 26S proteasome. Moreover, degradation correlates with the nonacetylated state of the mutant proteins.[8] It is likely that this same mechanism exists for the slow NAT2 acetylator phenotype. *NAT1*10* contains nucleotide substitutions located in the 3′-untranslated region that alter the consensus polyadenylation signal (AA**T**AAA → AAA**A**AA), leading to the suggestion that increased activity may be due to enhanced mRNA stability.

NAT1 allele frequency

The frequency of slow acetylator alleles for NAT1 is low. The most common low activity allele, *NAT1*14*, has been identified in Caucasian populations ranging from 1.3% to 3.7%. Interestingly, a much higher frequency of the *NAT1*14* allele (25%) was reported for a Lebanese population. This indicates that NAT1, like NAT2, shows considerable interethnic variability.

NAT AND DISEASE

The role of NATs in human disease has recently been extensively reviewed.[3] The following is a summation of findings to date. The association between acetylator status and the risk of various diseases has been extensively reported. Altered risk with either the slow or rapid phenotype has been observed for bladder, colon and breast cancer, systemic lupus erythematosis, diabetes, age-related cataracts, Gilbert's disease, Parkinson's disease, and Alzheimer's disease. These associations imply a role for environmental factors that are metabolized by the NATs, in particular NAT2, in each disorder. However,

identifying those factors has remained elusive. Humans are exposed to many toxic NAT substrates including the food-derived heterocyclics present in the diet as well as arylamines such as 4-aminobiphenyl and β-naphthylamine present in tobacco smoke. Moreover, occupational exposure to arylamine carcinogens such as benzidine has also been reported.

Because of the role of acetylation in the metabolic activation and detoxification of arylamine and heterocyclic carcinogens, acetylator status and cancer risk have been widely investigated. Unlike the relatively rare but highly penetrant genes involved in familial cancers, those genes responsible for metabolic polymorphisms have low penetrance and cause only a moderate increase in cancer risk. Nevertheless, their widespread occurrence in the general population suggests they are a significant contributor to individual risk. However, few diseases have consistently demonstrated a relationship between phenotype and risk. For example, several studies have implicated the rapid phenotype as an increased risk factor for colon cancer,[15–17] whereas others have been unable to confirm this finding.[18–20] Geographical differences, ethnicity, lack of study power, dietary differences, and differences in other risk factors between study groups have been suggested as reasons for variable results from independent laboratories. Recent reports suggesting that NAT activity may be altered by environmental factors and substrate-dependent downregulation may also explain why inconsistent associations have been seen.

When acetylator phenotype has been linked to carcinogen exposure, more consistent results have been reported. For example, the rapid phenotype has emerged as a strong risk factor for colorectal cancer in those individuals who have a higher exposure to the food-derived heterocyclic amines. These observations provide strong circumstantial evidence that the heterocyclic amines have an important role in colorectal cancer, and extensive animal studies support this. They also illustrate the importance of establishing associations between genetic polymorphisms and disease risk. From such studies, it should be possible to pursue the causative agent(s) of the disease where no obvious candidate agent is evident.

Recently, the NAT2 acetylator phenotype has been linked to increased risk associated with neurodegenerative diseases such as Parkinson's disease and Alzheimer's disease. For late-onset Alzheimer's disease, an odds ratio of 3.0 (95% CI 1.3–7.3) has been reported for the rapid phenotype in non-apoE epsilon carriers.[21] By contrast, the slow phenotype appears to increase the risk of Parkinson's disease with an odds ratio of 3.58 (95% CI 1.96–6.56).[22] Although these results need to be confirmed with larger epidemiological studies, they point to environmental factors that are substrates for the NATs having a role in the onset of these diseases. Alternatively, the different alleles for NAT2 that produce the rapid or slow phenotype may cosegregate with unrelated genes that are the causative agent for the different neurodegenerative diseases.

NAT AND DRUG RESPONSE

The genetic polymorphism in *N*-acetyltransferase activity was first discovered in patients treated with isoniazid for tuberculosis. This drug is primarily excreted following acetylation catalyzed by NAT2. Many other therapeutic

Table 1 Effect of acetylator status on drug response and toxicity

agents are now known to be polymorphically acetylated in humans. However, the incidence of failed or less effective clinical response as a consequence of acetylation polymorphism is uncommon. This is because most drugs that are metabolized by the NATs have a wide therapeutic window or because acetylation is a minor metabolic pathway. An exception is hydralazine. Early studies showed that the antihypertensive activity of hydralazine was less in rapid acetylators and that a 40% higher dose was necessary for a similar therapeutic effect compared with slow acetylators.[23] This difference appeared to be due to a change in the bioavailability of the drug, which decreased from 33% in slow acetylators to less than 10% in rapid acetylators.

A more common consequence of the polymorphic acetylation of therapeutic agents is an increase in the frequency and severity of side effects associated with either the rapid or slow phenotype (Table 1). These adverse effects often arise as the result of a shift in the metabolic pathways responsible for the activation and detoxification of the drug. This is best illustrated by the amine-containing sulfonamides, such as sulfamethoxazole, that undergo hydroxylation to a reactive *N*-hydroxy metabolite capable of covalently binding to macromolecules and giving rise to idiosyncratic adverse reactions. These drugs can also be acetylated by NAT2 to nonreactive *N*-acetyl metabolites. In slow acetylators, a higher proportion of the drug is *N*-hydroxylated and, consequently, these individuals are at a greater risk of sulfonamide-induced toxicity. However, the incidence of severe adverse side effects to sulfonamides is much less than the incidence of the slow acetylator phenotype suggesting that other factors predispose individuals to idiosyncratic adverse reactions.

Risk of developing side effects, such as neurotoxicity or hemolytic anemia, to dapsone therapy is very similar to that described for the sulfonamides. The most severe incidence of toxicity occurred in individuals with a slow acetylator phenotype who are rapid hydroxylators, which is consistent with the role each pathway has in the activation and detoxification of the drug.

While slow acetylators are at a greater risk of toxicity from sulfonamides and dapsone, other therapeutic agents exhibit increased incidence of adverse reactions in rapid acetylators. Amonafide is a novel arylamine that has previously been in clinical trials for the treatment of various cancers. It undergoes *N*-acetylation to an active metabolite that contributes to systemic toxicity. Several studies have shown that myelosuppression is greater in rapid acetylators (white blood cell nadirs of 500/μL) than in slow acetylators (white blood cell nadirs of 3400/μL) following a standard dose of 300 mg/m^2 daily for 5 days.[35] This has led to different recommended doses for the two groups.[34]

CONCLUSION

Although considerable allelic variation exists for both *NAT1* and *NAT2*, our understanding of the molecular mechanisms and functional significance of many of these alleles, particularly for NAT1, is still limited. Much of the research in the area of NATs has involved identifying relationships between allele frequencies and disease, particularly different forms of cancers. Although several studies have reported associations between different *NAT* alleles and various cancers, other studies have failed to do so. While these inconsistencies may be due to several factors, such as differences in exposure to arylamine carcinogens, it may well be that genotype does not necessarily accurately reflect phenotype.

Astrovirus

C. Anthony Hart
Rachel L. Hart
The University of Liverpool, Liverpool, U.K.

INTRODUCTION

Astroviruses cause diarrheal disease in a number of different animal species (humans, pigs, sheep, turkeys) and hepatitis in ducklings. Astroviridae are a family of small (27–30 nm), round, unenveloped viruses with a characteristic star-shape on their capsid surface. Their genomes are single-stranded linear positive sense RNA of 6.8 to 7.9 kb. The genome encodes three open reading frames (ORF). ORF1a encodes a serine protease; ORF1b, an RNA-dependent RNA polymerase; and ORF2, the viral capsid protein. There are currently eight known human astrovirus serotypes. All cause diarrheal disease predominantly in infants which is usually mild. Nosocomial outbreaks and outbreaks of infection in adults can occur.

THE VIRUS

The family Astroviridae encompasses small nonenveloped viruses that infect a variety of animal species. They were originally classified among the small round structured viruses (SRSV) causing diarrhea in humans. They are round with icosahedral symmetry and 27–30 nm in diameter. They were first described by Madeley and Cosgrove[1] as a potential cause of diarrheal disease in human infants and named for the characteristic five- or six-pointed star (astron is Greek for a star), visible on the capsid surface by negative stain electron microscopy (Fig. 1). There are small surface projections consisting of 30 dimeric spikes protruding some 50 Å from the virus surface. In 1981, serial passage of human astrovirus was achieved in primary human embryo kidney (HEK) cells by Lee and Kurtz,[2] but astrovirus is more conveniently cultured in CaCo-2 cells. However, trypsin must be included in the culture medium.[3] Astrovirus particles are stable at pH 3, but disassemble at pH 10.5 and are resistant to chloroform, detergents (nonionic or ionic), and lipid solvents such as ether. At 60°C astrovirus retains infectivity for 5 but not 10 min. It is stable for years at −70°C but is disrupted by repeated freeze–thaw cycles.[4] Human astroviruses (HuAst) survived for 5–6 days when dried at 20°C in fecal material onto porous or nonporous material. Survival was significantly longer at 4°C. Its survival was equivalent to that of adenoviruses but less good than that of rotaviruses.[5]

The genome is positive sense single-stranded linear unsegmented RNA and 6.8 to 7.9 kb long.[6] It has a poly-A tail at the 3′ end. During infection both genomic (6.8 kb) and subgenomic (2.4 kb) RNA are produced. The genome encodes three ORFs. At the 5′ end of the genome are encoded ORF1a and ORF1b. The third ORF (OFR-2) is found at the 3′ end as is the subgenomic fragment in infected cells. ORF1a and ORF1b encode nonstructural proteins whereas ORF2 encodes the capsid proteins. At the 5′ end there is an untranslated region of 80–85 nucleotides depending on the astrovirus serotype. ORF1a varies in size from 2763 to 2784 nucleotides also depending upon the serotype. There is an area of overlap between ORF1a and ORF1b of between 61 nt (for HuAst serotype 3) and 73 nt (for serotypes 1 and 2). Similarly, ORF1b varies in length from 1548 to 1560 nt depending upon serotype. ORF1a encodes a putative protein (nsp1a) of 920 to 935 amino acids in length.[6] It contains a serine protease motif similar to that seen in other positive sense RNA viruses such as feline calicivirus (FCV). However, a major difference between it and FCV is the substitution of a serine for a cysteine residue at the third catalytic amino acid residue.[7] Downstream of the protease motif is a nuclear localization signal which directs ORF1a protein to the nucleus of infected cells as has been determined by immunofluorescence and immunoprecipitation.[8,9] The 920-amino acid nsp-1a is itself proteolytically cleaved into smaller proteins and in particular, cleavage around amino acid 410 appears to be mediated by the polypeptide itself.[10] ORF1b encodes a polypeptide containing 515–519 amino acids and contains motifs suggestive of an RNA-dependent RNA polymerase most closely resembling those of plant viruses, bymovirus, and potyvirus.[11] There is an overlap between the end of ORF1a and the beginning of ORF1b which is highly conserved. This suggests there is a ribosomal frameshift mechanism involved in the translation of the polypeptides.

ORF2 encodes a viral structural protein varying in length from 782 to 794 amino acids depending on serotype.[6] The polypeptide is conserved for the first

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021400

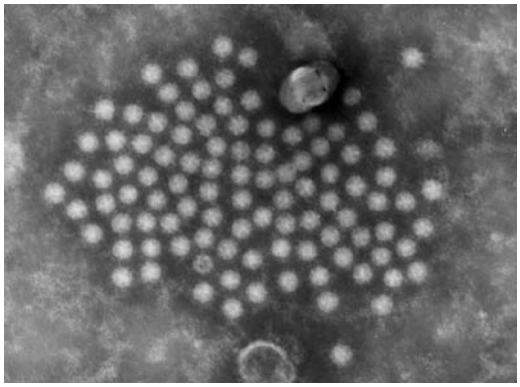

Fig. 1 Negative stain electron micrograph of astrovirus in feces.

415 N-terminal amino acids but shows variability thereafter. The polypeptide is cleaved proteolytically to 20–40-kDa structural proteins, and, for example, the 26-kDa structural protein expresses a neutralization epitope.

Currently, eight serotypes of human astrovirus are recognized (HuAst 1–8) based upon epitopes on ORF2. It is also possible to genotype HuAst by examination of sequence data of ORF1a, ORF1b, and the 5′ end of ORF2,[12] and genotypes equivalent to the eight serotypes have been defined. Recently, evidence for a novel recombinant HuAst has been uncovered.[13] There is no cross-reactivity between the HuAst serotypes, and immunity to one does not give immunity to the others. Astroviruses have been detected in diarrheic animals and as a cause of hepatitis in ducks. Phylogenetic analyses of a large collection of sequences from a variety of astroviruses showed that all the HuAst clustered together separate from the nonhuman strains; however, the branching order of the astroviruses was the opposite of their host species indicating the possibility of cross-species transmission.[14]

PATHOGENESIS AND IMMUNITY

HuAst are transmitted by the feco-oral route,[15] either directly person-to-person or indirectly via contaminated food or water. During infection, between 10^8 and 10^{13} genome equivalents are shed per gram of feces.[16] The infectious dose is not known but thought to be low. Little is known of how HuAst cause diarrheal disease. However, in experimental infection in gnotobiotic lambs, ovine astrovirus caused infection of mature enterocytes in the upper two thirds of the villi resulting eventually in transient villous flattening and crypt hypertrophy.[17] In turkeys, astrovirus causes diarrhea in the absence of inflammation and of enterocyte death,[18] but intestinal maltase activity decreases suggesting an osmotic mechanism for diarrhea.[19]

The major determinants of astrovirus immunity are as yet unclear. Serum antibody does seem to correlate with immunity in volunteer studies,[15] and specific T cells that could recognize astrovirus antigen have been found in the adult lamina propria.[20]

There seems to be an association between HIV infection and astrovirus infection and diarrhea.[21,22] Similar associations between astrovirus infection and other forms of immunodeficiency have been described.[6]

EPIDEMIOLOGY AND CLINICAL FEATURES

HuAst have been detected in all countries where they have been sought and thus have a worldwide distribution. In temperate countries, HuAst infection peaks in winter usually 4–6 weeks prior to the rotavirus peaks.[23] In general, HuAst diarrhea is predominantly a disease of infants with an age-specific incidence of 0.38 for those under 6 months and 0.40 for those aged 6–12 months.[24] However, further episodes of infection with different astrovirus serotypes do occur subsequently. These are usually milder than the first infection. Astrovirus is the second or third most important cause of diarrheal disease in children being responsible for 5–10% of cases in hospital-based studies and for 10–25% of cases in community-based studies.[25] Globally, serotype 1 is most frequently detected.[22,26–28] Recently, HuAst serotype 3 has been associated with higher stool viral levels and increased incidence of persistent diarrhea.[16] Outbreaks of astrovirus infection have been described involving the rarer serotypes.[29]

The incubation period was 3–4 days in adult volunteers but in children in Egypt was 24–36 hr.[24] The illness which consists of acute watery diarrhea with or without nausea and vomiting is usually milder than that due to rotavirus. It lasts on average 5–6 days.[30]

DIAGNOSIS

Astroviruses were first detected by negative stain electron microscopy (Fig. 1), but the characteristic star-shaped capsid is found in only 10% of the viral particles in fecal samples. It is now clear that electron microscopy is less sensitive than antigen detection or RT-PCR.

An antigen-capture ELISA was developed in 1990.[31] The lower limits of detection sensitivity of such an ELISA are estimated to be 10^5 to 10^6 particles per gram. A commercial kit version of this is available which can

Table 1 Primers for RT-PCR detection and genotyping Astrovirus

Primer	Region	Nucleotides	Sense	Sequence (5′–3′)
Mon 340	ORF1a	1180–1202	+	CGT CAT TAT TTA TAT CAT ACT

Mon 244	ORF2	4560–4541	–	GGT GTC ACA GGA CCA AAA CC

detect each of the eight astrovirus serotypes (IDEIA Astrovirus, Dako Diagnostics, United Kingdom), and this has been shown to have a sensitivity of 100% and specificity of 98.6%.[31]

Detection of virus genome by RT-PCR is estimated to detect as few as 10 to 100 astrovirus particles.[32] A number of different targets have been used. One strategy employs primers (Mon244 and Mon245) which amplify a 413-nt fragment of ORF2 (Table 1), and if this is negative, primers Mon340/348 which amplify a 289-nt fragment of ORF1a are used.[22,29,33] For genotyping, fragments of ORF1a, ORF1b, and ORF2 are amplified by RT-PCR and sequenced.[29] A novel hanging drop single-tube nested RT-PCR method has recently been devised.[34] Recombinant antigens have been used to determine the seroprevalence of astrovirus infections.[35] This is of little value for acute diagnosis.

MANAGEMENT AND PREVENTION

Astrovirus gastroenteritis is usually mild, but if the patient is dehydrated, appropriate rehydration therapy should be given. In hospital, appropriate infection control measures must be used to prevent nosocomial spread. Methanol 90% v/v is a better disinfectant than ethanol.[36] There are no vaccines available for preventing astrovirus infection in humans.

CONCLUSION

Astrovirus is the second or third commonest cause of infantile gastroenteritis. There are eight serotypes with little cross-immunity between serotypes. Outbreaks of infection can occur in children and adults. The positive sense single-stranded RNA genome encodes three open reading frames: ORF1a (nonstructural: protease), ORF1b (RNA polymerase), and ORF2 (capsid protein).

Automated DNA Sequencing

Alexandre Izmailov
Visible Genetics, Inc., Toronto, Ontario, Canada

INTRODUCTION

DNA sequencing is an important tool for molecular biology, genetic studies, pharmacogenomics, and other areas of fundamental and applied science where information is required about unknown DNA, mutations, DNA fragment size, for DNA fingerprinting or prediction of drug resistance of viruses. Originally suggested, and widely used, manual sequencers cannot satisfy a growing demand for throughput increase, high reliability, and ease of use. This necessitates the development of automated DNA sequencers. Automation may include data collection and analysis, or as in the case of fully automated sequencers, also sample loading and sieving matrix replacement. The output of automated DNA sequencers is a base calling report, which represents the sequence of the nucleotides in the fragment of a DNA molecule. Different applications may require specific features of a DNA sequencer, but base calling accuracy and read length remain major figures of merit for all sequencers. Clinical applications and research, which involves large volumes of data, require high throughput and a high level of automation. However, automated DNA sequencers targeted to research laboratories must also provide flexibility in their features. Careful assessment of the user requirements allows an optimum selection of DNA sequencer from the wide variety of existing instruments.

SEQUENCING CHEMISTRIES

The goal of DNA sequencing is to obtain information about the sequence of nucleotide bases—adenine (A), guanine (G), cytosine (C), and thymine (T)—which constitutes a particular DNA molecule. In order to obtain this information, the sample under investigation is modified in DNA sequencing reactions, which can be based on one of two approaches: enzymatic synthesis of DNA fragments with chain termination by dideoxynucleotides ddNTP (terminators)[1] or by chemical degradation method.[2] The first method is faster, easier to implement, and it is currently the method of choice. Terminators (ddNTP) lack a 3′OH group that is necessary for the extension of DNA's sugar phosphate backbone. Thus the DNA chain cannot be extended beyond the incorporated ddNTP. A mixture of all four dNTPs and one ddNTP is used in each reaction. For example, in a T-terminated reaction a ddTTP is added to a mixture of dNTPs. This allows elongation of the DNA chain until ddTTP is occasionally attached to the growing molecule, which stops the reaction. This process is random and as a result, fragments of different lengths are produced, each terminated at a T-position, for all T's from the primer to the end of the sequence. Four reactions are required for complete description of the DNA sequence, each representing an A-, C-, G-, or T-terminated ladder. In order to enable observation of DNA bands, the fragments are labeled with a tag (radioactive or fluorescent) attached to either the primer (primer chemistry) or ddNTPs (terminator chemistry).

STRUCTURE OF A DNA SEQUENCER

A DNA sequencer is composed of an electrophoresis system, which includes a sieving matrix (e.g., polyacrylamide gel), buffer, a high-voltage power supply, and a detection system. When a high voltage (1000 V to 10 kV) is applied to the gel, an electric field forces negatively charged fragments of DNA molecules to move through the mesh created by polymer molecules constituting the gel. The difference in the friction for the DNA fragments of different sizes leads to their spatial separation. Groups of molecules of the same size propagate through the gel as a set of confined bands with the width defined by such factors as diffusion, injection conditions, sample volume, field, and temperature gradients, etc.

Manual and automated instruments, in their principle of operation, mainly differ by the method of detection. In manual sequencers the electrophoretic run is stopped as soon as the first base of interest (typically a primer) reaches the end of the gel. Then, information about DNA sequence is obtained by determining the relative position of the bands in the gel. In automated sequencers, the detection system records variations of the output intensity over time at a fixed location in the gel. The difference in the migration times of various DNA chain lengths results in a set of electrophoretic peaks.

Automated DNA sequencers can be divided into three major categories based on the method used for

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020747

sieving matrix support: slab gel, capillary, and microarray sequencers.

SIEVING MATRIX

A polymer most frequently used as a sieving matrix in automatic DNA sequencers is polyacrylamide. It can be used in linear or cross-linked form. The porosity of the gel is defined by the concentration of acrylamide and cross-linking agent (typically *N*,*N*′-methylene-*bis*-acrylamide). The concentration of acrylamide may vary from 3% to 10%.[3] The concentration of a cross-linker is ~3% to 5% of the total acrylamide concentration. An increase in the acrylamide concentration suggests a higher resolution of the DNA bands and allows calling more bases, but this leads to slower runs. Linear polyacrylamide (LPA), which is more fluid, is typically used in capillary electrophoresis (CE) where the sieving matrix is replaced after each run so the capillary can be reused. The last requirement is a result of the high cost of the capillary arrays and complexity of alignment required after their replacement. Other types of polymers used in CE include hydroxyethyl cellulose (HEC), poly(ethylenoxyde) (PEO), polyvinyl pyrrolidone (PVP), and others.[4]

One of the major figures of merits in the DNA sequencers is the resolution of the DNA bands. A reduction in the width of the DNA band improves resolution, allowing base calling of longer DNA chains. Resolution depends also on the distance which DNA molecules migrate in a sieving matrix. Separation lengths of 10 to 50 cm are typical but they may be longer for higher resolution. However, there is a trade-off between increase in resolution and run time: for a given voltage, velocity of DNA molecules in the gel is inversely proportional to the separating length, L, resulting in a migration time proportional to L^2.

For analysis of single-stranded DNA, denaturants such as urea (concentration 4–8 M) or formamide (up to 10%) are added to a gel. Additionally, the electrophoretic runs are conducted at elevated temperature (40–70 °C), which helps to prevent self-hybridization.

METHODS OF DETECTION

Radiolabeling

DNA molecules separated by the sieving matrix need to be detected. In the manual sequencers an autoradiographic method is used[3] where either a primer or terminators contain a radioisotope (typically ^{32}P or ^{35}S). After completion of the electrophoretic run, the gel is dried and placed in contact with an X-ray film. Exposed film is developed and manually analyzed. Lack of automation in the data analysis and risk associated with using radioactive materials are the most serious drawbacks of this method. Also, the resolution at high base numbers in manual sequencers is lower than that in automatic sequencers because of the much shorter migration distance.

Laser-Induced Fluorescence (LIF)

Laser-induced fluorescence is a standard detection method in a majority of the automated sequencers. This method is extremely sensitive, allows automation of base calling, avoids using radioactive materials, and promotes a throughput increase by using several spectrally distinct labels simultaneously. Laser-induced fluorescence is based on the excitation of a dye label attached to a DNA molecule by laser light. Resulting fluorescence is collected and converted to an electrical signal by a photosensitive element [photomultiplier tube (PMT), photodiode, or charge-coupled device (CCD) element]. The output signal (trace) represents a series of peaks each corresponding to a DNA chain of a certain size. One trace provides information about one of the four bases (A, C, G, or T). Therefore, in order to obtain information about a complete sequence, four traces are required. This is achieved either by using four physically separated lanes (or capillaries) or by running four differently labeled samples in a single lane.

If a single laser is used in the sequencer, different parts of the gel or different capillaries are illuminated through a scanning objective lens. Alternatively, a sheath cell[5] can be used with simultaneous illumination of several DNA traces. Some DNA sequencers contain several lasers either with different wavelengths improving excitation[6] or with the same wavelength providing excitation of multiple samples without using moving parts.[7]

Collected fluorescence is converted into digital form and processed by a computer. Software packages used in different sequencers vary in their functionality and efficiency, but all of them involve the following common steps: noise reduction, base line subtraction, color cross-talk compensation, trace alignment, and peak recognition. A typical example of the resulting base calling is shown in Fig. 1.

Dye Labeling

Dye labeling is typically used for sample identification in the automatic DNA sequencers. The properties of a dye shall satisfy the following major requirements: 1) Dye structure shall allow attachment to a primer or ddNTP with a reasonable yield. 2) Absorption spectrum shall match the laser wavelength. 3) Extinction coefficient and quantum yield shall be high enough to provide acceptable sensitivity. 4) Dyes shall be chemically and thermally

stable in order to withstand cycle sequencing conditions 5) Dyes shall be photo stable. 6) Mobility of the DNA fragments labeled with different dyes shall be equalized, which can be achieved by optimization of the labeling process.[8]

Both emission and absorption spectra of the organic dyes employed in DNA labeling are broad (typically 20–50 nm). This relaxes the requirement for spectral content of the excitation light.

Overlapping absorption spectra of several dyes used for labeling allows excitation of all these dyes with a single laser source. However, efficiency of excitation drops off quickly as the laser wavelength deviates from the absorption maximum of the dye and results in a significant drop in sensitivity. To avoid these losses, energy transfer (ET) dyes were introduced.[9]

In the case of multicolor sequencers (when two or more dyes are used for DNA labeling), collected radiation must be spectrally separated by means of a diffractive element or a set of interference filters and is registered by separate PMTs or by a CCD. Alternatively, a single PMT can be used with a set of replaceable filters (a ''color wheel''). A more sophisticated detection method used for sensitivity increase is based on single-photon detection.[10]

A complication arises because the emission spectra of the dyes used for labeling different samples overlap and color cross-talk correction of the collected data is required. Improper compensation of the cross-talk results in false peaks in the processed data.

Both visible and near IR dyes can be used for DNA labeling in automated DNA sequencers. The advantage of using red and near IR dyes is lower background

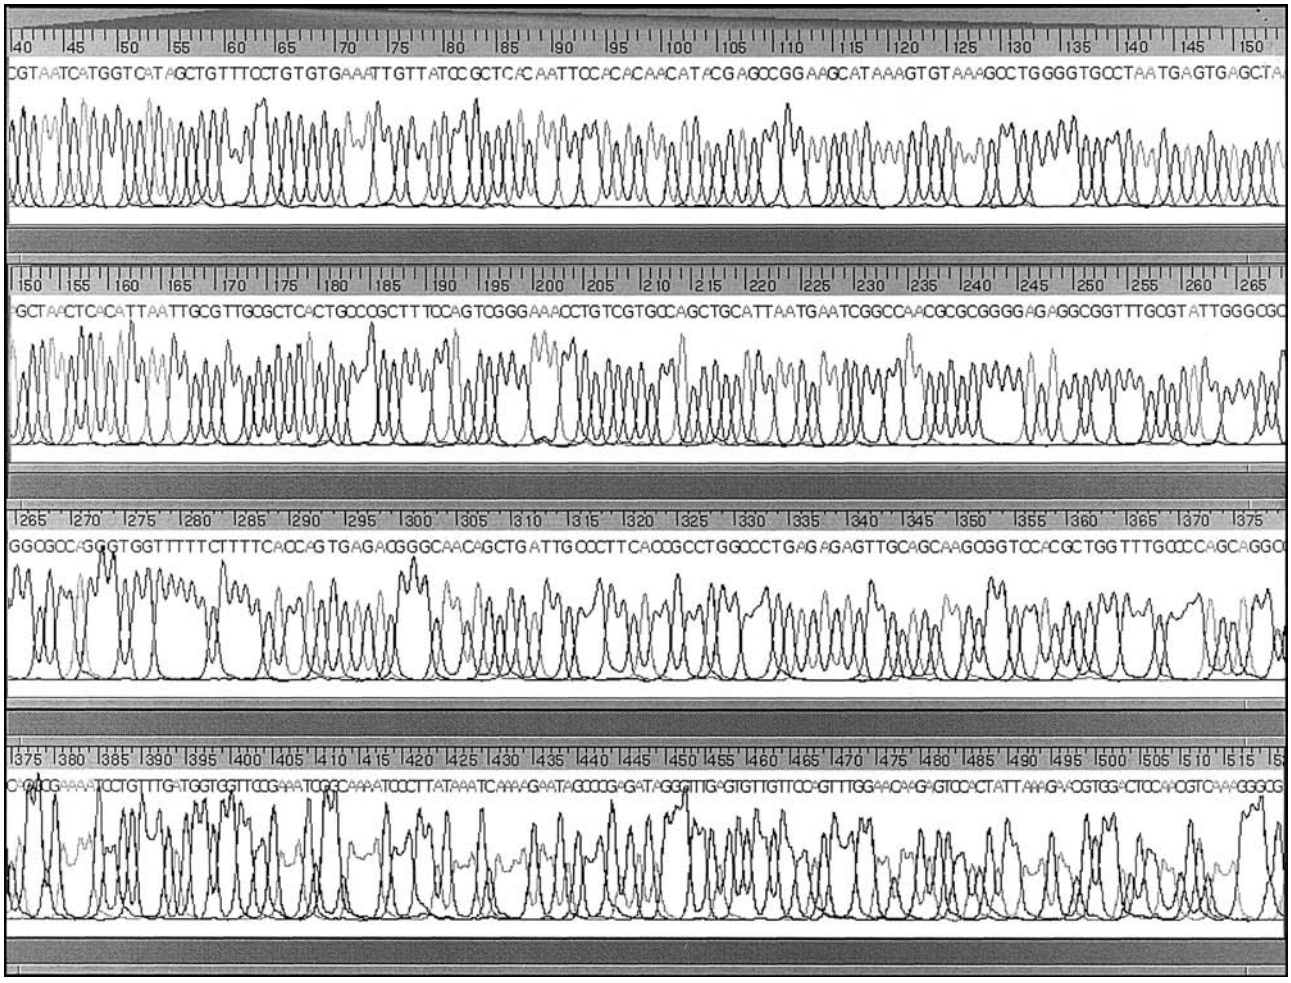

Fig. 1 A typical result of base calling obtained with an automated DNA sequencer. The Ml3 sequencing by ultrathin slab gel electrophoresis. The signal obtained with the Long-Read Tower™ sequencer has been base called with GeneObjects software. (From Ref. [7].) The accuracy of base calling is 98.5 % up to 500 bases. Similar results are typically produced with other types of automated DNA sequencers, including CE instruments.

fluorescence and decreased laser light scattering at longer wavelengths. This results in better sensitivity. IR dyes can be excited by laser diodes (LD) resulting in a reduction of instrument design complexity.[6,7]

Dye labels can be covalently linked either to a primer or to each of four types of ddNTPs.[11] In the last case, all four sequencing reactions can be carried out in one tube instead of the four used in primer-labeled chemistry. However, dye-labeled terminators may introduce significant variability in the peak intensity resulting in decreased base calling accuracy and reliability. For clinical applications dye primer chemistry may be preferred because of the higher reliability of the results. Terminator chemistry provides more flexibility, which may be advantageous for the research laboratories.

In some automated sequencers less than four colors are used for DNA labeling. For example, a two-dye approach is used in the Long-Read Tower™ and LICOR sequencers. The sample is prepared by running two sequencing reactions in the same tube with differently labeled forward and reverse primers. This approach enables the increase of the read length, accuracy, and reliability of base calling.

TYPES OF DNA SEQUENCERS

Slab Gel Sequencers

Initially, automated DNA sequencers were based on slab gel electrophoresis with low throughput and automation limited to data collection and analysis. Gel filling and sample loading are done manually. The support glass plates require cleaning after each run. Poor dissipation of heat generated in a slab gel through relatively thick glass plates limits the electric field strength and prevents short run times. Both of these problems are eliminated in the disposable ultrathin slab gels (50 μm thick), which can withstand higher electric field strength, E (100 V/cm), resulting in shorter run times.[7]

Capillary Electrophoresis Sequencers

Capillary electrophoresis (CE) DNA sequencers were introduced to increase analysis throughput. This is a direct result of high electric fields (100–250 V/cm) and multiple capillaries (up to 384 capillaries). Both sieving matrix replacement and sample loading can be automated. The small diameter of capillaries (internal diameter is 50–100 μm) allows for good heat dissipation. Capillaries having smaller diameters (2–10 μm) are not practical as they do not provide enough signal intensity, are difficult to fill with acrylamide, and do not provide reproducible performance.[12] The ability to use replaceable sieving matrices makes CE systems practical as repetitive runs are possible with the same capillary up to 200 times or more.

Electra-kinetic sample loading allows high automation of CE sequencers. But optimization of loading conditions and sample purification is required. These are critical for reducing variability of peak intensity, suppressing decay in gel current and bubble formation, increasing capillary lifetime. Salt concentration, ratio of labeled DNA to unlabeled DNA, and total volume of loaded sample all affect the success of CE analysis.

Typical read length in CE DNA sequencers is 400–600 bases in several hours, but can be as high as 1100 bases.[13] Run conditions can be optimized for faster runs, if necessary, by reducing separation lengths, decreasing polymer concentration, increasing voltage or/and gel temperature.

Examples of commercial automated DNA sequencers are shown in Table 1.

A variety of automated DNA sequencers is available, providing similar performance characteristics but

Table 1 Automated DNA sequencers

Model	Read length (nt)	Number of lanes	Run time (hr)	Type
Al31 3731377	850	48/64/96	10	Slab
LI-COR 4300 L	1000–1200	48/64	10	Slab
LI-COR 4300 S/ L	800		6	
	500		1.5–3	
Long-Read Tower™	300/500/700	16	0.51/14	Ultrathin slab
ABI 310	500–600	1	3	Capillary
ABI 3700	550	96	5	Capillary
ABI 3730 (xl)	550–1100	48/96	0.5–2	Capillary
CEQ™ 2000	500	8	2	Capillary
CEQ™ 8000	700	8	2	Capillary
MegaBACE™ 1000	550	96	2	Capillary
MegaBACE™ 4000	550	384	2	Capillary

Source: From Refs. [6,14–17].

differing in throughput, flexibility, complexity, and cost. Although generally higher throughput is desirable (especially for clinical labs), for some applications the major requirement may be short run time, flexibility of characteristics, or low cost of analysis. In this case smaller DNA sequencers may be advantageous.

Microarray Sequencers

Capillary microarray and microfabricated sequencers are still under development and promise a significant size reduction of automated sequencers providing high throughput and base calling accuracy.[18,19] A 96-channel radial capillary array was demonstrated in Ref. [20]. The microchannel plate provides high resolution due to the use of tapered turns that provide an effective separation length of 15.9 cm on a compact 150-mm-diameter wafer. An average read length of 430 bases was obtained on this device. In general, miniaturization typically leads to a reduction of separation distance causing poor resolution, insufficient read length, low base calling accuracy, all of which currently limit the application of these devices.

CONCLUSION

Automated DNA sequencers provide important information about DNA structure. Plurality of existing instruments can satisfy a variety of requirements, which may arise in a particular experiment. Although modern automated DNA sequencers are well developed, continuous improvement of their structure, components, and run conditions is still ongoing. The development of new approaches is focused on throughput increase, reduction of sequencer size, and improvement of accuracy, reliability, and read length.

Automated Nucleic Acid Extraction

A

Juergen Loeffler
Kathrin D. Schmidt
Holger Hebart
Hermann Einsele
Eberhard-Karls-Universität Tuebingen, Tuebingen, Germany

INTRODUCTION

In the past, the extraction and purification of nucleic acids had been a complicated, time-, and labor-intensive process. Manual extraction of nucleic acids requires repeated centrifugation steps followed by removal of supernatants and, depending on the type of specimen, additional mechanical treatment, e.g., for the lysis of blood cells, organ biopsies, or bacterial and fungal cell walls. In addition, many extraction methods suffer from the presence of strong inhibitors that are present in different clinical specimens, such as sera and stool, and may lead to false-negative results. Furthermore, many manual protocols rely on the use of toxic chemicals, such as guanidinium thiocyanate or phenol–chloroform.

Robotic workstations for the extraction and purification of nucleic acids should fulfill a true walk-away automation. The technology should allow a high throughput of samples; the yield, purity, reproducibility, and scalability of the RNA and DNA as well as the speed, accuracy, and reliability of the assay should be maximal, whereas the risk of cross-contamination must be minimal.

Here we give an overview of commercially available workstations for an automated extraction of nucleic acids.

BioRobot WORKSTATIONS

The BioRobot EZ1 workstation (Qiagen, Hilden, Germany) purifies nucleic acids from many clinically relevant specimens; one to six samples can be processed within 15 min of time. This rapid purification is feasible using a magnetic particle technology: nucleic acids in sample lysates are isolated in one step through their binding to the silica surface of magnetic particles. The automated protocols for nucleic acid purification are provided on special preprogrammed cards.

The BioRobot M48/M96 workstations run the identical magnetic particle technology, but the pipet tips function as reaction chambers. However, up to 48/96 samples can be processed per run in increments of six samples. The pipettor head contains six syringe pumps, which operate simultaneously to allow aspiration or dispensing of volumes between 25 and 1000 μL. The workstation uses UV light to decontaminate surfaces in-between runs.

Finally, the BioRobot 9604 workstation allows automated nucleic acid purification for up to 2×96 samples in parallel.

Xu et al.[1] describe an automated assay for the extraction of HIV RNA by using the BioRobot 9604. They conclude that this procedure yields comparable results to a manual RNA extraction method with improved precision. The assay was found to be linear down to 50 copies.

For the extraction of hepatitis C virus RNA, it was shown that it is possible to achieve a detection level of 12.8 IU/mL (95% confidence). Cross-contamination studies have confirmed that the use of the BioRobot 9604 does not pose a detectable contamination risk.[2]

For hepatitis B virus detection, Mitsunaga et al. describe that it was possible to quantify DNA in all samples extracted by the BioRobot 9604 which contained more than 500 genome equivalents/mL. Extraction of 96 samples could be completed within 2 hr.[3]

COBAS AmpliPrep

The COBAS AmpliPrep robotic workstation (Roche Diagnostics, Mannheim, Germany) is a fully automated system which isolates DNA and RNA targets. It is based on silico-coated glass particles which bind the extracted nucleic acids. Internal controls allow target recovery monitoring. Up to 72 samples (three racks of 24 specimens each) can be loaded on the system simultaneously. Reagents are delivered in sealed, bar-coded, ready-to-use cassettes. The pipetting integrity check ensures the accurate pipetting of samples and reagents, and a clot detection reduces the risk of incorrect results. Besides kits for the extraction of generic DNA, introductory kits for hepatitis C virus and human immunodeficiency virus type 1 detection can be acquired. This product is not available in the United States.

DOI: 10.1081/E-EDGP 120020669

In a preliminary study, the COBAS AmpliPrep was evaluated for the preparation of human immunodeficiency virus RNA and was compared to a manual sample preparation protocol.[4] The authors assessed the reproducibility by analyzing 584 plasma samples from infected patients. They achieved an interassay coefficient of variation between 39.4% and 48.4% and an intraassay coefficient of variation from 6.2% to 58.0%. The mean viral load of 152 samples, which were found to be in the linear range of both tests, was 3.7 log(10) HIV copies/mL by the COBAS AmpliPrep compared to 3.73 log(10) copies/mL by the manual test (no significant difference). The authors concluded that the COBAS AmpliPrep assay is reproducible and sensitive.

Miyachi et al.[5] evaluated the COBAS AmpliPrep protocol for hepatitis C virus RNA extraction. Assay linearity was observed to range between 500 and 850,000 IU/mL by using serial dilutions. Comparison of the COBAS AmpliPrep test results to those obtained by a manual extraction method showed a good correlation [$R(2)=0.972$, $n=86$]. When known PCR inhibitors such as heparin, dextran sulfate, hemoglobin, and bilirubin were added to the samples prior to extraction, the automated assay successfully eliminated the inhibitory effects.

KingFisher mL

The KingFisher technology (Thermo Electron, Waltham, USA) uses shifting of magnetic particles through the different phases of the purification process. Volumes from 50 to 1000 μL can be processed, and because of the 3×5 fixed magnetic rods and the 3×5 separate disposable tube strips, a maximum capacity of 15 samples per run can be achieved. Besides RNA and genomic DNA, the KingFisher instrument enables the isolation of proteins from a variety of starting volumes.

Saukkoriipi et al.[6] compared the KingFisher instrument to a manual DNA extraction method for the purification of *Streptococcus pneumoniae* DNA from 50 nasopharyngeal swab samples. All pneumococcal culture-positive samples (44%) were PCR-positive regardless of the extraction method. Additionally, from the culture-negative specimens, 71% of the manually extracted and 82% of the samples purified with the KingFisher instrument were PCR-positive.

m1000

The m1000 sample preparation platform (Abbott Laboratories, Abbott Park, USA) uses a magnetic particle technology for the extraction and purification of RNA and DNA. It provides a fully automated sample preparation and is capable of processing 48 samples within 2 hr for a sample volume of 1 mL. Analyte-specific reagents (ASR) may be used for the preparation of samples for hepatitis C virus analysis as well as for the extraction of human DNA for HLA typing. The robot contains liquid-level sensing and a clot detection system. Standard primary bar-coded tubes are used.

Silva et al.[7] evaluated the performance of the m1000 instrument for the extraction of genomic human DNA from frozen blood specimens followed by HLA-DRB sequencing-based typing. Their results showed that the DNA yield was consistently high with an average concentration of 20 ng/μL (from 0.2 mL blood). The average (260:280 nm) ratio was 1.7, and the purified DNA was free of inhibitors; all DNA samples could successfully be amplified and sequenced.

MagNA Pure LC INSTRUMENT

Magnetism is the underlying principle of the automated nucleic acid isolation performed by the MagNA Pure system (Roche Diagnostics, Mannheim, Germany). The instrument has a completely closed housing as well as an automatic clot and tip loss detection. No filtration, centrifugation, or vacuum pumps are necessary, which minimizes the risk of cross-contamination. Up to 32 nucleic acid isolations (the eight-nozzle pipette head allows a variable number of samples from 1 to 32 per run) can be performed within one run. Extraction of human, viral, bacterial, and fungal DNA, RNA, and mRNA is possible. The protocol is applicable to a broad variety of samples such as blood, cultured cells, biopsies, sputum, urine, stool, plant tissue, and food products. After the extraction procedure, isolated nucleic acids and PCR mixes can be pipetted automatically into PCR tubes, 96-well plates, LightCycler capillaries (Roche Diagnostics), or COBAS A-Rings (Roche Diagnostics). Sample information can be entered manually or via a barcode reader. Samples are loaded into nuclease-free sample cartridges with a capacity of 4×8 wells. The initial sample volume is 20–1000 μL (or up to 5×10^6 cells or 10 mg of homogenized tissue); the dispensable volume is 5–1000 μL with a 2–3% variance.

For the isolation of DNA or total nucleic acids, the sample material is initially incubated with a lysis buffer and proteinase K, and then magnetic glass particles are added. Nucleic acids bind to the surface of the magnetic glass beads and are thus separated from the sample remnants. For the extraction of mRNA, DNA is removed by DNase digestion. Streptavidin-coated magnetic beads and biotin-labeled oligo (dT) nucleotides are added to the lysed sample. The mRNA binds specifically to the glass beads through the oligo (dT) nucleotides.

In addition, since 2003, a smaller version named MagNA Pure Compact System is available. This system

allows the extraction of nucleic acids from eight samples in parallel using bar-coded prefilled reagent cartridges and assembled tip trays.

Comparison of the MagNA Pure and a manual extraction protocol (phenol/chloroform) showed equivalent detection sensitivities for the extraction of *Borrelia burgdorferi* DNA from a variety of specimens such as urine, blood, and cerebral spinal fluid. All 80 positive samples (as determined by an independent method) were also tested positive by MagNA Pure extraction.[8]

Wolk et al.[9] describe a protocol for the extraction of DNA from *Encephalitozoon* species. These species cause microsporidiosis, a disease of which the prevalence is likely to be underestimated because of the labor-intensive, insensitive, and nonspecific conventional methods used for the diagnosis of the spores in feces. The detection limit of the assay was 100–10,000 × lower compared to microscopy with trichrome stain.

Our group[10] demonstrated that the MagNA Pure technique provides rapid automated DNA isolation from numerous pathogenic fungi revealing high sensitivity and purity. Although the fungal cell wall is highly resistant to mechanical, chemical, and enzymatical treatment, we could achieve a sensitivity of 1 colony forming unit/mL blood for *Candida albicans*.

In addition, there is a need for simple and sensitive assays for mRNA detection, e.g., to assess innate and adaptive immune responses[11] or to determine different subpopulations of cells.[12] The MagNA Pure protocol allowed extraction of mRNA from 32 samples in parallel within 1.5 hr, compared to at least 3 hr using manual methods. The amount (3–6 μg RNA from 10^6 PBMC) and purity (260:280 nm ratio in spectral photometer 1.8–1.9) of RNA were comparable or higher than those achieved by manual extraction.[12]

Finally, Williams et al. compared the BioRobot 9604 workstation to the MagNA Pure instrument, extracting genomic DNA from 106 blood samples followed by genotyping for factor V Leiden.[13] The comparison showed that both methods were similar in DNA yields (8.1 ± 2.3 μg by MagNA Pure, 7.1 ± 2.3 μg by BioRobot), although the DNA purity was higher in samples extracted by MagNA Pure (ratio 1.9 ± 0.11 vs. 1.6 ± 0.24). The extraction failure rate was 0.7% by MagNA Pure and 2.0% by BioRobot. Furthermore, with both assays the analysis of DNA extracted from sodium citrate and heparin anticoagulated blood samples was feasible. Finally, five heterozygous samples were analyzed in two separate runs. Statistical analysis using an *F*-test indicated that the ΔT_ms for the MagNA Pure were more consistent ($p < 0.001$) which may be due to differences in sample purity.

NucliSens EXTRACTOR

This instrument (bioMérieux, Marcy 1'Etoile, France) is able to extract DNA and RNA, and has been designed for a highly variable initial sample volume from 10 up to 2000 μL. The concentration factor can be up to 55-fold, e.g., a 2000-μL sample volume input can be eluted in 35 μL. The closed system minimizes carryover and environmental template contamination. Plasma, serum, whole blood as well as urine, semen, feces, and sputum can be analyzed within 45 min per run, and up to 10 samples can be processed within one run.

The extraction protocol is based on a method described by Boom et al.[14] After lysis of the samples and addition of silica, nucleic acids bound to the silica are captured on a filter by applying air pressure on the closed sample

Table 1 Comparison of eight different workstations for automated nucleic acid extraction concerning assay duration, maximal number of samples, processing volume, and price

Workstation	Duration per run (maximal sample load)	Maximal number of samples per run	Processing volume	Approximate price of workstation
EZ1 (Qiagen)	15 min	6 samples	25–1000 μL[a]	U.S.$35,000
BioRobot 9604 (Qiagen)	2 hr	2 × 96 samples		U.S.$100,000
COBAS AmpliPrep (Roche)	3 hr	3 × 24 samples	200–1000 μL	U.S.$50,000
KingFisher mL (Thermo Electron)	45 min	15 samples	50–1000 μL	U.S.$15,000
m1000 (Abbott)	2 hr	48 samples	200 or 1000 μL	U.S.$110,000
MagNApure LC (Roche)	1.5 hr	32 samples	20–1000 μL	U.S.$90,000
MagNAPure Compact (Roche)	30 min	8 samples	100–1000 μl	U.S.$35,000
NucliSens Extractor (bioMérieux)	45 min	10 samples	10–2000 μL	n.a.

n.a. = not available.
[a]Depending on the workstation.

chamber. The silica particles remain on top of the filter. Through a hollow air-pen, multiple wash cycles are performed. After drying of the silica at 56°C, the nucleic acids are eluted into an elution tube by means of air pressure.

Jongerius et al.[15] used this technology for the extraction of hepatitis C virus RNA. They found a cutoff value of 16 genome equivalents (geq)/mL with a 100% hit rate, demonstrating a high sensitivity of this assay for the extraction of RNA.

Comparison of the BioRobot 9604 to the NucliSens Extractor for the isolation of hepatitis C virus RNA showed a lower detection limit of 82 vs. 12 geq/mL.[16]

CONCLUSION

Current manual methods for the extraction of nucleic acids are suitable for low-throughput analysis.[17] However, these methods are unable to cope with the increasing demand for molecular diagnosis of infectious diseases and genetic analysis, necessitating the development of new, fully automated, and reliable methods. All automated workstations described reveal high yield, purity, reproducibility, scalability, accuracy, and reliability for the extraction of nucleic acids (Table 1). However, as different laboratories may claim unique performances of a workstation, the individual choice of an instrument should depend on the type and volume of samples to be analyzed and on the throughput of samples per day.

Barriers to Integrating New Genetic Knowledge into Daily Medical Practice

B

Carol Isaacson Barash
Genetics, Ethics & Policy Consulting, Inc., Boston, Massachusetts, U.S.A.

INTRODUCTION

The expectation that diagnostic genomics and proteomics, along with toxicogenomics, chemicalgenomics, and BIO IT, will revolutionize health care is big and widely held. New knowledge emerging from these fields promises an understanding of gene function thorough enough to enable the mitigation of adverse effects of genetic risks, therapies that are more effective and safer, and the opportunity to ameliorate health risk factors in the context of environmental and socioeconomic risk factors. In other words, they promise a deeper understanding of disease and its causes, and with it strategies to promote health, prevent disease, and lower overall mortality and morbidity. Achieving these ends requires translating this new genomic knowledge into daily medical practice. Adoption of genomic innovations is, however, not an automatic given or foregone conclusion. Rather, it is a formidable challenge. The expected benefits of diagnostic genomics and proteomics cannot be realized unless practitioners accurately understand new genetic knowledge, apply that understanding appropriately in daily practice, and work with patients to ensure that they can make voluntary informed choices about their care. Adoption (or successful incorporation of innovation into practice) of genomics innovations (diagnostic genomics, proteomics, or toxicogenomics) requires ensuring that practitioners spontaneously think about the possibility of genetic involvement, when appropriate, and pursue that possibility accurately and efficiently.

THE CHALLENGE OF INTEGRATING GENOMIC INNOVATION

It is commonly believed that innovations succeed on their own merit. Those without real merit fail in the market place; those with superior merit succeed simply on the basis of their superiority over existing alternatives. *However*, experience shows otherwise. Technological capability and superior engineering do not, in fact, guarantee acceptance (Table 1). Great innovations themselves are often insufficient to ensure usability, effectiveness, or user satisfaction. In other words, good technology does not equal adoption. Why? (Fig. 1) Because factors integral to users' experiences, such as intuitive approaches to problem solving, environmental factors or underlying beliefs, values or attitudes, play an integral role in adoption. More specifically, these factors can facilitate or thwart integration of new knowledge and thus bar acceptance. For example, the problem-solving logic inherent in IT tools may well serve a developer's needs, but prove incoherent with end users' intuitive problem-solving processes, thereby failing to be a useful solution for the employee.[1]

Similarly, physician lag in adopting innovation is well known. The history of medical practice, in particular, is replete with examples of un- and underutilized innovations, whether new IT solutions, devices, diagnostics, clinical guidelines, or therapeutics.[2–5] This history suggests the very real possibility that genetics innovations will not be readily or accurately integrated into daily practice without an identification of and remedy to barriers (Table 2).

A central goal of genetics educational initiatives, indeed, has been to promote adoption and accomplish the primary aim of effecting a change in medical practice. The desired behavioral change is to improve physician decision making about potential genetic involvement in the face of uncertainty. Existing educational programs have increased clinician *awareness* of advances in molecular medicine.[6] Clinical competency in problem solving about potential involvement depends on more than mere awareness[7] (Table 3). Despite the high quality of many current genetics education curriculum, education assessments confirm that practitioners remain unconvinced about the relevance of genetics advances to their practices as well as *uneasy about how to integrate* this new information into point-of-care service.[8–10] Education alone, then, has been less than fully successful and changing clinician behavior so that practice reflects the appropriate incorporation of innovation. The shortcomings are due far less to the quality and delivery of educational programs than they are to a lack of understanding of practitioner diagnostic problem-solving strategies, and both the environmental and internal factors (i.e., cognitive, attitudinal, and normative factors) that influence those strategies. Researchers in continuing medical

Table 1 Predicting innovation

1943	IBM, Chairman (Thomas Watson)	''I think there is a world market for about 5 computers''
1977	Digital Equipment Co., President (Ken Olson)	''There is no reason for any individual to have a computer in their home''
1981	Microsoft, CEO (Bill Gates)	''640K [of memory] ought to be enough for anybody''

education show that such factors, hidden within the day to day of medical practice, nonetheless can pose significant obstacles to acceptance.[11–14]

Cognitive barriers represent a particularly difficult hurdle, primarily because they are embedded in clinical problem-solving strategies that become deeply engrained over time in one's practice.[15] For example, clinicians rarely use formal probabilistic modes as they engage in diagnostic reasoning. Instead, they use induction and heuristics as problem-solving tactics because heuristics[16] (i.e., rules of thumb or shortcuts), in particular, drastically reduce the number of steps needed in a search for solutions to a problem, or a diagnosis. Heuristics, reasoning shortcuts, and other thinking habits aid physicians in accurately and efficiently solving clinical conundrums, making diagnoses, or determining medical decisions. Although these tactics are neither precise indicators of prevalence nor other probability associations, heuristics are convenient and frequently correct. As such they serve a practitioner well, given time, and other practice, constraints. Furthermore, their accuracy reinforces their continued use. In fact, they are typically learned in medical school, refined to one's idiosyncratic ways of framing and solving diagnostic puzzles and continually reinforced in daily practice. As such, they become more ingrained in a clinician's intuitive diagnostic approaches.[17]

Fig. 1 Innovativeness doesn't ensure adoption. (*View this art in color at www.dekker.com.*)

The ''availability'' heuristic is used to judge frequency and probability but relies on the cases brought to mind as a basis for judgment. As such, it can impede focus on case specifics. The ''representative'' heuristic assumes that a present case so closely resembles a well-defined case that the probability of the disease occurring in this case is that of the well-defined case. Resemblances between a patient's features and a classic disease pattern can produce exaggerated estimates of the likelihood that present disease as in fact the classic one. In other words, the class of things retrieved most easily leads subjects to believe that *that* class is more frequent than those classes less easily retrievable. As such this tactic can result in failure to consider either prior probability or factors that limit predictive accuracy of thought generated.

Applied to genetic issues, however, these techniques are less useful and may even contribute to failure to detect genetic involvement or appropriately consider genetic influences, thereby resulting in misdiagnosis or mistreatment. Specific characteristics of genetics thwart the clinical utility of these clinical reasoning strategies that are designed to identify observable pathology (phenotype), determine a proximate cause (diagnosis), and prescribe appropriate treatment and management. In particular, scientists determined that one gene can affect more than one trait (pleiotropy), that any single trait can be affected by more than one gene, and that the majority of traits are affected by environmental factors as well as by other genes. Identifying the cause of a clinical symptom (or trait) is then far more complicated than identifying a symptom or determining that a number of symptoms indicate the presence of disease. Furthermore, determining the clinical significance of any genetic findings (that is, what do the genetic findings mean in the context of the patient's biochemical, hormonal and other biological processes) is more complicated than many general medical diagnoses, such as detecting the presence or absence of an otitis media or strep throat. The utility of heuristics and clinical reasoning shortcuts in the context of complicated genetic involvement is thus compromised.[18–20]

Constructing, understanding and problem solving are cognitively similar activities. Expertise in clinical problem solving has been shown to consist of highly automated, yet highly accurate perceptual and cognitive processes. For example, expert behavior is characterized by rapid recognition of key aspects of problems. Experts

Table 2 Indicators of physician receptivity to genomics innovations

''I've taken CME in the new genetics, but I shy away from it. It takes lots of time, is changing so fast and is so complicated. But, I have the working consciousness of a geneticist. I look for things.''	(Primary Care Physician recently trained in genetics advances)
''Several doctors (at a bioethics conference) admitted they had never heard the pharmacogenomics until the conference and weren't quite sure what they would do with a genetic test if they had one.''	(AMA News, Sept. 2000)
''Teachers open the door, but you must enter by yourself.''	(Chinese Proverb)

in any domain, for example in primary-care delivery, are known to use more elaborate but more flexible schemas for conceptualizing, understanding, and reasoning through problems, as well as domain-specific conceptual and procedural knowledge. These skills enable clinicians to identify critical cues within data presented and reason using data-based hypothesis generation, both of which are considered marks of expertise.[21]

Research into classical genetics problem solving shows that domain-specific and procedural knowledge is crucial to successful problem solving.[22] Knowledge-based and procedural errors in reasoning typically include knowledge deficits, factual errors, recall failure, fallacies of inference, fallacies of availability, metajudgments about the importance of pieces of information, and misapplied knowledge. Research into the effectiveness of genetics education programs indicates that clinicians have displayed a proclivity for confirming genotype solely on the basis of phenotypes ascertained through physical exam. Family history characteristics, which could trigger suspicion of possible heritable involvement, were not spontaneously considered by clinicians.[23] This tactic, which is a very narrow approach to genetics thinking, represents problematic genetic reasoning competency. Clinicians are trained to diagnose on the basis of observed phenomenon, (phenotype) and biochemical tests indicated what has most likely caused the physical finding. This approach, however, motivates practitioners to consider genetic involvement from the physical (phenotype) to the internal (genotype) and therein lies a major potential for error in clinical judgment. Research further indicates that clinicians with recent training in advances in genetics did not perform as well as clinicians lacking specific genetics training but known to be outstanding clinical problem solvers.[24]

Table 3 Genetics' barriers to adoption

Complicates typical strategies to ensure innovation adoption
Challenges the efficiency and efficacy of the usual clinical reasoning strategies involved in medical problem solving
Ethical concerns increase the stakes in using genetics in practice

Assimilation of new genetic knowledge occurs when the possibility of genetics involvement is continually brought to mind, entertained, pursued, and rigorously tested for validation or falsification. Deriving genetic suspicions solely from phenotypic characteristics does not achieve the desired clinical competency in identifying or making medical decisions about potential genetic involvement because pleiotropy, phenotypic variability, and other aforementioned characteristics of genetics introduce considerable room for error in clinical judgment. Physicians will become clinically competent genetic thinkers when their clinical thinking attends to the particular characteristics of genetics.

In particular, clinicians will display competence in genomic medicine when they apply more substantive genomic knowledge, a higher level of inquisitiveness, a broader range of diagnostic hypotheses and interpretations of clinical findings, as well as a more methodical manner of testing candidate hypotheses. A lower threshold for considering possible genetic involvement and consulting a geneticist to validate a suspicion will also serve clinicians well. In addition, family history gathering focused on identifying possible inheritance patterns and recurrence risk will serve clinicians well in refining possible genetic involvement. Reliance on textbook definitions and diagnostic criteria may contribute to a failure to appreciate phenotypic variability. Furthermore, as research suggests that clinicians view a ''genetic'' diagnosis as unfortunate and associated with dire medical and social consequences, they will continue to be reluctant to confer a genetic diagnosis. As knowledge increases and positive actions are proven to mitigate genetic risks, and the ill effects of a genetic diagnosis, clinicians are likely to shed this reluctance.

CONCLUSION

Genomics, as we now understand it, has, and will continue to have, a major role in health care as each of us carries roughly five to six mutations capable of causing significant disease. The major causes of death in the United States are now known to involve genetic influences. The

full extent of those influences, including the interactions between genes and genes, and genes and environments, is not yet known. Increasingly, we are learning that genetic mutations influence both the development and expression of disease. We expect that as these influences and interactions become better known we will be able to more precisely understand disease development and expression and so better able to target and manage root causes and effects. Furthermore, as our knowledge increases, we are likely to learn that some traits, which cause disease in certain environments, confer protection against disease development in other environments. Such traits are likely to be similar to sickle cell trait in contributing to sickle cell disease in particular contexts but affording immunity to malaria in other contexts.

Identifying genetic influences and understanding what they mean in the context of a patient's other risk factors is further complicated by features of genetics and heritability that complicate clinicians' usual approaches to categorizing symptoms into candidate diagnoses. Unless or until clinicians' medical decision-making processes trigger suspicion that a genetics factor may be present and pursue a thorough testing of that genetics hypothesis, ''learning'' about advances in human genetics will not be fully integrated into daily practice, and patients will not realize the benefits of genomic medicine.

Medical education research shows that knowledge, skill, and motivation, while necessary to physician acceptance, are, nonetheless, insufficient to bring about performance change.[25] This is largely because the practice of medicine, while anchored in the basic sciences, is itself an applied science but importantly also a normative activity. In other words, it is not so much what the physician knows, can do, or wants to do as much as what the physician *actually does* to (and for) patients that is of primary importance. What physicians do in practice has implications for their ability to incorporate innovation into daily activities; those daily activities, and habits, give rise to experience that in turn is a powerful determinant of behavior. Medical problem-solving literature, for example, supports this contention, indicating that what physicians actually do in practice is more related to their previous clinical experience than to their fund of medical knowledge.[26] Further, experts have shown that by understanding what needs to be done, how it is to be done, with awareness of potential barriers to successful implementation, physician learners are primed to apply new knowledge (or technological innovation) to a particular problem. Integrating innovation into practice gives rise to a new experience and, ultimately, it is the new experience that gives rise to the potential for learning.

The nature of genetics poses particularly difficult challenges to integration into daily medical practice. Continuing medical education courses, as well as strategies for adopting innovation, often fail to attend to key elements of clinical experience, and in so doing fail to address key parts of an individual's learning process and the relationship between those parts. The end result is the failure of education to effect the desired performance change. In regard to adoption of genetics innovation, unless or until educators know more about clinicians' thinking habits, which are used to assimilate new knowledge, much new knowledge may go underutilized, and potential patient benefits go unrealized. Identifying features of clinical reasoning that promote and thwart accurate and efficient medical decision making about potential genetic involvement can inform the development of future genetics education as well as specific strategies for changing physician behavior. Acceptance can then keep pace with genomic innovation.

Basal Cell Nevus Syndrome

A. S. High
University of Leeds, Leeds, U.K.

INTRODUCTION

This disorder, caused by mutations in the human homologue of the *Drosophila* ''patched'' gene (OMIM 601309), is inherited in an autosomal dominant manner and shows high penetrance and variable expressivity. It produces a bewildering array of clinical appearances including the following: *Face*: broad facies; frontal and biparietal bossing; mild mandibular prognathism; odontogenic keratocysts of jaws. *Eyes*: strabismus; lateral displacement of the inner canthi; hypertelorism; subconjunctival epithelial cysts; iris coloboma; glaucoma. *Nose*: broad nasal root. *Mouth*: cleft lip; cleft palate. *Cardiovascular*: cardiac fibroma. *Respiratory*: congenital lung cyst. *Abdomen*: lymphomesenteric cysts, often calcified; hamartomatous stomach polyps. *Genitourinary*: ovarian fibromata; ovarian carcinoma. *Skeletal*: bifid ribs; synostotic ribs; hypoplastic ribs; scoliosis; kyphoscoliosis; abnormal cervical vertebrae; brachydactyly. *Skin*: basal cell nevi; basal cell carcinoma (BCC); pits of palms and soles. *Neurological*: mental retardation; desmoplastic medulloblastoma. Other rare lesions are also reported.

It is associated with a paternal age effect and abnormal sensitivity to therapeutic radiation. Diagnosis using clinical phenotype or genotype is still problematic and there is no universally accepted ''gold standard.''

DIFFERENTIAL DIAGNOSIS

Most clinicians still rely on a set of criteria originally formulated by Kimonis et al.[1] Table 1 shows a current list of qualifying criteria. It is worth noting that a number of other related but apparently distinct disorders are recognized. Rombo syndrome[2] is a familial disorder with vermiculate atrophoderma, milia, hypotrichosis, trichoepitheliomas, basal cell carcinomas, and peripheral vasodilation with cyanosis, whereas Bazex–Dupré–Christol syndrome[3] combines major characteristics of basal cell nevus syndrome (BCNS) with follicular atrophoderma, hypotrichosis, hypohydrosis, and minor skin defects. Occasionally, acquired BCCs develop after contact with arsenic and exposure to radiation, and even burns, scars, vaccinations, or tattoos are rare contributing factors.

BASAL CELL NEVUS SYNDROME

In basal cell nevus syndrome (BCNS) there is an increased frequency of neoplasms, the result of excessive activation of segments of the Hedgehog pathway.

Patched is a target gene in the Hedgehog signalling network. *Patched* (*Ptch1*) encodes a transmembrane protein that acts as a negative regulator of *hedgehog* (*Hh*) signalling (Fig. 1). [Note: There is a general move toward abandoning the acronyms *Ptc* and *PTC* in favor of *Ptch* and *PTCH*, thereby avoiding confusion with phenylthiocarbamide tasting (PTC; OMIM 171200)]. The 1500-amino acid glycoprotein has 12 hydrophobic, membrane-spanning domains, intracellular amino- and carboxy-terminal regions, and two large hydrophilic extracellular loops where Hh ligand binding occurs.

Ptch has dual roles in sequestering and transducing Hh. When the second large extracellular loop, essential for ligand binding, is deleted by a *Ptch1* mutation, Hh binding to Ptch cannot occur, but repression of Smoothened (Smo) by Ptch is unaffected. When a C-terminal truncation is caused by a *Ptch1* mutation, Ptch can no longer repress Smo, but Hh binding to Ptch is unaffected.

In the Hedgehog signalling network, mutations result in various phenotypes, including, among others, holoprosencephaly, BCNS, Pallister–Hall syndrome, Greig cephalopolysyndactyly, Rubinstein–Taybi syndrome, isolated BCCs, and desmoplastic medulloblastoma.

Human *PTCH1*, a tumor suppressor gene, maps to 9q22.3. Most mutations in *PTCH1* result in protein truncation. However, four rare *PTCH* missense mutations have resulted in holoprosencephaly—two in the extracellular loops required for SHH binding and two in the intracellular loops that may be involved in PTCH–SMO interaction.[4]

Four features of Hedgehog signalling are noteworthy. First, autoprocessing generates an active Hedgehog ligand with a C-terminal cholesterol moiety. Then, palmitoylation results in an N-terminal palmitate. The active Hedgehog ligand therefore becomes double lipid modified. Second, most membrane-bound receptors activate downstream signalling on ligand binding. However, Ptch is *repressed* by its Hedgehog ligand, freeing Smoothened for downstream signalling.

Table 1 Diagnostic criteria for BCNS

Diagnosis of BCNS made in the presence of two major, or one major and two minor criteria
Major criteria
1. >2 BCCs or one at <20 years old
2. Histologically confirmed odontogenic keratocysts of jaw
3. ≥3 palmar or plantar pits
4. Bilamellar calcification of falx cerebri
5. Bifid, fused, or markedly splayed ribs
6. First-degree relative with BCNS syndrome
7. Desmoplastic medulloblastoma
Minor criteria
Any two of the following features:
1. Macrocephaly determined after adjustment for height
2. Congenital malformations: cleft lip or palate, frontal bossing, ''coarse face,'' moderate or severe hypertelorism
3. Other skeletal abnormalities: Sprengel deformity, marked pectus deformity, marked syndactyly of digits
4. Radiological abnormalities: bridging of the sella turçica vertebral anomalies such as hemivertebrae, fusion or elongation of the vertebral bodies, modeling defects of the hands and feet, or flame-shaped lucencies of hands or feet
5. Ovarian fibroma

Third, Ptch and Smoothened may shuttle oppositely between plasma membrane and endocytic vesicles in response to Hedgehog ligand. They may not interact physically, Ptch working catalytically rather than stoichiometrically.[5] In contrast, Incardona et al.[6] suggested that Ptch and Smoothened colocalize in the absence of Hedgehog and both proteins endocytose on ligand binding, after which Smoothened subsequently segregates from the Ptch–Hedgehog complex.

Fourth, the network has a bifunctional transcription regulator, Cubitus interruptus. In the absence of Hedgehog ligand, a truncated transcription repressor is generated that binds target genes and blocks transcription. With Hedgehog ligand, a full-length transcriptional activator binds target genes and up-regulates transcription.

Hedgehog is proficient at both short- and long-range signalling. It is tightly regulated on many levels. Cholesterol-modified Hedgehog, which should be anchored to the cell membrane, can be further modified at the lipid rafts where it multimerizes and becomes soluble and diffusible.[7] Dispatched (OMIM 607502; another 12-pass transmembrane protein) functions to release multimeric Hedgehog, making it available for long-range signalling.

The up-regulation of Ptch expression, resulting in Ptch protein at the cell membrane, sequesters Hedgehog and limits its spread beyond the cells in which it is produced. Thus, a balance is created by the antagonism of Hedgehog and Ptch, whose relative concentrations alternate with regard to each other. Many other factors including Megalin, Rab23, Hip, GAS1, PKA, GSK3, CK1, Slimb, SAP18, and CBP are essential for the Hedgehog signalling network (see review in Ref. [8]).

Besides Ptch, Megalin can also bind Hedgehog with high affinity.[9] Megalin-mediated endocytosis of multimeric Hedgehog may perhaps regulate its availability to Ptch by competing with Ptch to limit the levels of multimeric Hedgehog. Alternatively, Megalin may deliver multimeric Hedgehog to vesicular pools of Ptch.

Hedgehog binding to Ptch alleviates Ptch-mediated repression of Smo by a conformational change that frees Smo for downstream signalling. Kalderon[10] reviewed four models for the regulation of Smo by Ptch and Hh. The classical model has already been discussed. A second model postulates that Hh activates Smo by causing dissociation of the Ptch/Smo complex. In a third model, Ptch inhibits Smo through a diffusible intermediate and Hh binding to Ptch alters the activity of the intermediate, allowing Smo to become activated. In a fourth model, Ptch acts catalytically via a small molecule to suppress Smo, and on Hh binding to Ptch, Smo is activated by becoming dissociated from Ptch and the small molecule.

Intracellular localization of Ptch was demonstrated by Capdevila et al.,[11] who induced a mutation in *Shibire* [OMIM 602377] that affects endocytosis. Incardona

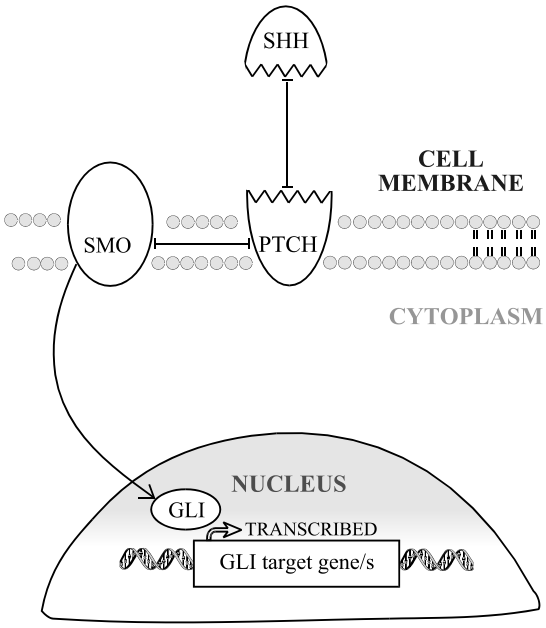

Fig. 1 Sonic Hedgehog pathway. SHH acts on the receptor complex of Ptch and Smo to inhibit repression of Smo by Ptch. Smo then signal activates gli intracellularly, resulting in downstream transcription of target genes. (*View this art in color at www.dekker.com.*)

et al.,[12] noting that M-Shh-N and Ptch colocalize in subcellular vesicles, suggested that internalization of M-Shh-N is mediated by Ptch. At present it is unclear whether Ptch eventually separates from M-Shh-N, with M-Shh-N being directed to lysosomes for degradation and Ptch returning to cell surface. It has been suggested that Ptch and Smo shuttle oppositely between the plasma membrane and cytoplasmic vesicles in response to M-Hh-N ligand.

In the absence of M-Hh-N binding, Ptch may be found principally at the cell membrane. At the same time, Smo may occupy intracellular vesicles. The binding of M-Hh-N to Ptch triggers a dynamin-mediated internalization into endosomes[13] and this results, indirectly, in the migration of vesicular Smo to the cell membrane.

Caveolae and caveolin-1 protein, which coats caveolae, may play a role in M-Hh-N uptake by Ptch.[14] However, only Ptch interacts specifically with caveolin-1 whereas Smo does not.

Ptch mediates the posttranslational modification of the C-terminal domain of Smo. Modification may include potential enzymatic candidates such as a phosphatase, Protein kinase A, or cyclin Bl that alter the phosphorylation status of Smo, affecting its stability, activity, and subcellular localization.[15] When Smo moves to the cell surface, hyperphosphorylation takes place, a putative Smo kinase increasing its activity. How closely linked phosphorylation of Smo is to its transport to the cell surface is not known at present. Unstimulated Ptch may promote dephosphorylation of Smo, a putative Smo phosphorylase decreasing Smo's activity.

Denef et al.[16] provided some evidence that Ptch and Smo do not interact physically in transducing M-Hh-N signals. They suggested that the regulatory interaction between Ptch and Smo need not be stoichiometric. It has been found[5] that Ptch and Smo are not significantly associated together within responding cells. They demonstrated that Ptch, unbounded by M-Hh-N, acts substoichiometrically to suppress activity of Smo. Extremely low levels of Ptch were sufficient to substantially reduce Smo activity. For example, a Ptch:Smo ratio of 1:45 suppressed nearly 80% of Smo activity. They suggested that in the absence of M-Hh-N, Ptch may translocate a small molecule across the lipid bilayer that regulates the activity state of Smo.

In contrast, Incardona et al.[6] provided some evidence that supported a model in which colocalization of Ptch and Smo occurs in the absence of M-Shh-N. On M-Shh-N binding to Ptch, both Ptch and Smo may undergo simultaneous transport into the endocytic pathway where Smo is subsequently segregated from the Ptch/M-Shh-N complex, which is destined for lysosomal degradation. Possibly, late endosomal sorting may control the generation of active Smo.

Whether Ptch eventually separates from M-Shh-N, with M-Shh-N being directed to lysosomes for degradation and with Ptch returning to the cell surface, is unclear at present.

To date, NBCS has not been reported with mutations in *PTCH2*, *SHH*, *SMO*, or *GUI*, but there are reasons for believing that such mutations may be found. *PTCH2* has been reported with a mutation in a medulloblastoma, whereas medulloblastoma is a feature of NBCS in about 3–5% of cases. A disputed mutation in *SHH* has been reported in one isolated BCC. Furthermore, BCCs and skeletal malformations are reported in hypersonic transgenic mice. Mutations in SMO have been reported in isolated basal cell carcinomas, and expression of *GLIl* has been found in almost all isolated BCCs studied.

Target genes for this disorder include *Ptch* (*PTCH*), the *Wnt* (*WNT*) family, and the *bone morphogenetic proteins* (*BMPs*) of the TGFβ superfamily. These are essential for normal embryonic development and differentiation of many adult tissues. Experiments in mice, chicks, and flies have shown that modification of genes or exposure to teratogens causes interesting and similar changes to reported human phenotypes. For example,

Ptch +/− in mice results in skeletal defects and neoplasms, but changes can be inhibited by cyclopamine. [This plant steroidal alkaloid induces cyclopia in vertebrate embryos and has been shown to act by inhibiting the cellular response to the Shh signal (see below)].

Ptch −/− in mice is lethal, producing overgrown and open neural tubes.

$Ptch^{1130X}$ in flies causes C-terminal truncation and abolishes Smo repression, but not Hh binding.

$Ptch^{\Delta loop2}$ in chicks cannot bind Shh ligand.

$Ptch^{sterol\ sensor}$ mutations in flies abolishes Smo repression, but not HH binding.

Taipale et al.[17] showed that cyclopamine or synthetic derivatives with improved potency block activation of the Hh response pathway and abnormal cell growth associated with both types of oncogenic mutation. The substance was discovered through epidemiological investigations of cyclopia in sheep in the Western United States. Cyclopia was found to result when pregnant females ate the lily *Veratrum californicum*. The ''active'' ingredient was named ''cyclopamine.'' Although cyclopamine has no apparent effect on adult animals, it consistently leads to severe holoprosencephaly in developing embryos. Because this condition can be caused by either mutations in human *hedgehog* or exposure to cyclopamine, it was proposed that cyclopamine suppresses Hedgehog. Taipale et al.[17] demonstrated that cyclopamine acts by affecting the balance between active and inactive forms of

Smoothened and may therefore have a role in treating BCCs and BCNS.

As epidemiological studies have shown, adult sheep tolerate cyclopamine well, and the results are encouraging. They do not directly address the question of whether switching off the Hedgehog pathway will cure basal cell carcinomas or prevent BCNS. BCCs, like most other human cancers, have mutations in many genes, and it is probably the accumulation of mutations that results in malignancy. Perhaps the Hedgehog pathway must be activated to kick-start tumor development, but may not need to be kept activated to maintain a fully malignant state. Indeed, in naturally occurring BCCs, shutting off this pathway might be too little, too late! Treating basal cell carcinomas with cyclopamine might be expected to suppress the development of neoplastic cells and perhaps limit growth, but not automatically kill them. There is some early evidence that tumor cells that have been suppressed in this way might undergo programmed cell death or be eradicated by the body's natural defenses. If not, then tumors treated with cyclopamine may eventually reappear when the drug is stopped.

MUTATION DETECTION

Blood samples are taken for straightforward DNA sequencing to assess the exact PTC gene mutation carried, but novel approaches including a protein truncation assay are being increasingly used to improve the yield of mutation detection. Standard sequencing detects minor changes in DNA [e.g., single-strand conformation polymorphism (SSCP) analysis, heteroduplex analysis, and denaturing gradient gel electrophoresis (DGGE) analysis], including those that are not pathogenic (polymorphisms) or are of questionable pathogenicity (missense mutations). The protein truncation test[18] specifically uncovers certain disease-causing mutations, namely, those causing premature translation termination. Initially developed for use with Duchenne muscular dystrophy, PTT is now used for screening many different disease genes and is proving useful in BCNS diagnosis.

TREATMENT

Treatment of BCCs includes surgical excision, curettage and electrodesiccation, cryosurgery, Mohs' micrographic surgery, and ultrapulsed CO_2 laser treatment. These methods, although effective, have economic, physical, and psychological implications, primarily because of the risk of scarring and recurrence. New, more inclusive selection criteria for surgery, combined with more effective neoadjuvant chemotherapy based on 5-fluoruracil and topically applied 5% imiquimod, are proving useful in reducing scarring. Radiotherapy is now avoided completely.

CONCLUSION

There is, however, much cause for optimism in this field. Fortunately, there is a good mouse model for BCNS that will help answer questions about the effects of cyclopamine on tumors in vivo. If this, or a related compound, progresses to clinical trials, investigators should not forget its source, and to avoid women of childbearing age in any study! However, the drive to understand the biology and behavior of BCCs—the world's commonest human cancer—will ultimately lead to spin-offs that will undoubtedly help NBCS sufferers.

The routine clinical implementation of genomics-based diagnosis and outcome predictors, as reported with desmoplastic medulloblastoma and *PTCH*[19] must await confirmation in independent data sets, and models may need to be modified as diagnostic and treatment regimens evolve.

For patients predicted to have a favorable outcome, efforts to minimize toxicity of therapy might be indicated, whereas for those predicted not to respond to standard therapy, earlier treatment with experimental regimens might be considered. Genomic technologies have the potential to advance treatment planning beyond the empirical, toward a more molecularly defined, individualized approach.

Bead-Based Technology in Nucleic Acid Testing

B

Mario C. O. Probst
University of Regensburg, Regensburg, Germany

INTRODUCTION

Further development and improvement of molecular diagnosis depends on the development of robust, automatable, and cost-efficient technologies. In addition to conventional methods, a variety of homogeneous amplification assays that are based on fluorescence are available and facilitate detection of amplicons and characterization of mutations, single nucleotide polymorphisms (SNPs), and other sequence variations in DNA. Especially, SNPs have recently gained great attention, being markers for susceptibility to disease or response to therapeutic drugs.

To serve the increasing request for the simultaneous determination of larger numbers of parameters, DNA arrays (DNA chips) of different densities are available that allow high throughput and multiplex sequence and gene expression analysis. They require dedicated automation that may not be available in routine laboratories and their capabilities exceed by far what is currently required for diagnostic purposes. These conventional DNA and oligonucleotide arrays consist of a variable number of spatially arranged spots with nucleic acids on solid supports. The production of such arrays in small numbers for specific questions may be time consuming and costly. In addition, high-density arrays may not be necessary for many diagnostic purposes.

An interesting alternative to DNA chips is bead-based technology. The main advantage of this technology is that different species of beads are coated with the desired oligonucleotides prior to mixing the distinct populations together. A so-called suspension array for multiple analyses can be generated and modified according to the individual needs. Such suspension arrays can be supplemented with additional bead populations any time.

TECHNOLOGY

Beads are homogenous microspheres produced from polymer by special synthesis techniques. The most common material used is polystyrene and available bead sizes range from 0.4 to 200 μm. In order to function as carriers for binding interactions, beads have to be ''sensitized'' by attaching biological ligands such as antibodies or single-stranded nucleic acids to their surface. The first bead-based assay was reported in 1956, when Singer and Plotz introduced their rheumatoid factor agglutination test.[1] Later, beads were introduced in flow cytometry, which is a powerful combination, because here, like cells, several hundreds of beads can be discriminated by fluorescence intensity and spectral diversity in a couple of seconds. As a large number of each distinct species are measured, a mean signal with high precision is obtained. The increasing request for the simultaneous determination of complex parameter profiles in small sample volumes brought up the idea of multiplexing with microspheres as carriers for tests and assays, which can be analyzed and discriminated by flow cytometry. First, attempts to use microspheres of different size have been made, then beads were impregnated with fluorescent dyes, to make them spectrally distinctable. The maximum number of such populations depends on the availability of fluorescent dyes, the technologies to impregnate the beads, and the number of suitable fluorescent channels available in a flow cytometer. By color-coding beads with a blend of different amounts of only two fluorescent dyes, a set of 100 distinct bead populations can be generated (Fig. 1), which are commercially available as LabMAP Beads (Luminex Corporation, Austin, TX). Numerous companies have licensed the LabMAP technology as platform for the development of their bead-based assays especially in immunology and microbiology. Now that the conquest of bead-based assays over the traditional microtiter plate ELISA has begun, beads have been discovered as carriers for nucleic acid testing. Here, like antigens or antibodies, oligonucleotides of interest can be attached to beads using simple chemical reactions. Thus each bead population corresponds to a specific oligonucleotide. In a suspension hybridization, amplicons that carry another fluorescence can be immobilized to the beads by hybridization. Analysis is performed in the flow cytometer, where this additional fluorescence, that was brought to the bead by successful hybridization, is also detected. A conventional flow cytometer with three fluorescence channels measures two dyes that specify the bead population and a reporter dye that specifies hybridization events. By using more sophisticated flow cytometers with additional fluorescent channels (e.g., FACSCalibur, BD Biosciences, San Diego, CA), it would be possible to use more dyes for

DOI: 10.1081/E-EDGP 120024826

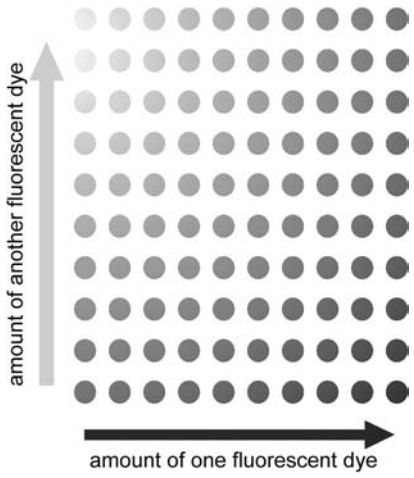

Fig. 1 By impregnating beads with a blend of two fluorescent dyes, a set of 100 color-coded species can be generated, which can be discriminated in a flow cytometer.

color-coding of beads or more colors for the test reaction. However, flow cytometers are expensive and their capabilities exceed what is required for bead-based analysis. With the Luminex100 (Luminex), a low-cost flow cytometer is available that is specifically adapted to the measurement of color-coded beads.[2,3]

ASSAY FORMATS

Direct Hybridization

Several formats of wet-ware were adopted to bead-based nucleic acid testing. The simplest method is the direct hybridization of labeled nucleic acids to beads carrying a sequence-specific oligonucleotide.

An assay for gene expression analysis using color-coded microspheres was developed using this technique. In Ref. [4], labeled cRNA was generated which was hybridized to a set of 20 bead populations carrying specific capture sequences of 25 bp for 20 *Arabidopsis* genes. The obtained expression profiles were similar to those obtained by Affymetrix GeneChip Analysis.[4]

In addition to expression profiling, sequence-specific hybridization of labeled PCR product to microspheres has been performed. A sensitive multiplexed bead assay for the detection of three viral nucleic acids (HIV, HSV, and HCV) was developed. Here labeled primers were used in the amplification of the relevant viral nucleic acids, which were hybridized to sequence-specific oligonucleotides bound to the beads.[5]

A third test applying the format of direct hybridization was a screening test for mutations in the CFTR gene, which can cause cystic fibrosis. A set of 10 bead populations, each carrying a sequence-specific oligonucleotide for 10 common mutations, and 10 bead populations, each carrying the according wild-type sequence, were used. The relevant DNA segments were amplified by PCR using labeled primers prior to hybridization to the beads.[6]

Competitive Hybridization

As hybridization of longer PCR products to microspheres results in significant cross-talk and decreased sensitivity, a different assay format, the competitive hybridization, was applied. With this technique, allele-specific, fluorescently labeled oligonucleotides (reporter oligonucleotides) are hybridized to the target amplicon. Afterwards, microspheres coated with oligonucleotides complementary to the reporter oligonucleotides are added and capture the remaining nonhybridized oligonucleotides. A decrease in fluorescence intensity compared to the negative control (inhibition of fluorescence) will report a positive test result. This assay format was used, for example, for a multiplexed hybridization assay to perform HLA-DQA1 tissue typing of PCR-amplified human genomic DNA.[7]

Zip Code Techniques

The simultaneous and efficient hybridization of oligonucleotides with different lengths and GC contents is still a problem, even when using special hybridization buffers. In addition, the allelic discrimination of single nucleotide polymorphisms by hybridization is problematic because of the similarity of the sequences. To this end, the idea of using so-called zip codes was brought to light. Here, probes for allelic discrimination carry a 5′-dangling end with an artificial unique DNA sequence for hybridization to beads subsequent to allelic discrimination. These zip codes are designed with identical length and GC content and limited cross-talk in simultaneous hybridization to their complementary sequence bound to the bead. An additional advantage is that the development of novel assays no longer requires production of differently coated beads. With this assay format, three different techniques have been evaluated: the oligo ligation assay (OLA), minisequencing (also called single-base chain extension, SBCE), and the allele-specific primer extension (ASPE).

In the OLA, two adjacent hybridized oligonucleotides are enzymatically ligated to each other using DNA ligase. This reaction only takes place when the nucleotides next to the ligation position are fully complementary. The first (capture) oligonucleotide is designed to hybridize to the target amplicon with its 3′ base complementary to the polymorphic base. It also carries a 5′-dangling end with the zip code. The second (reporter) oligonucleotide

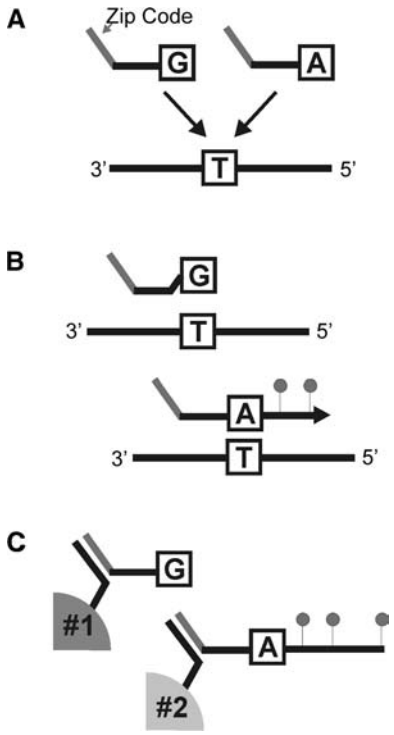

Fig. 2 Principle of the ASPE reaction. A) For each allele, one primer is designed carrying a 5′-dangling end with a unique zip code sequence. B) Only a primer hybridized with a perfect match at the 3′ end will be elongated and labels will be incorporated. C) Subsequent to allelic discrimination, primers are captured by color-coded beads carrying complementary zip code sequences.

hybridizes to the target sequence just adjacent to the 3′ end of the capture probe and carries a fluorescent tag at its 3′ end. If the capture probe matches exactly the SNP query position, the probes are ligated to each other, bringing a fluorescent tag to the capture oligonucleotide, which is detected by flow cytometry subsequent to hybridization to the bead populations. Two detection probes with different zip codes are required to cover each of the two possible alleles. This method has been successfully applied in the analysis of nine SNP markers located near the ApoE locus on chromosome 19.[8]

In OLA, one additional labeled reporter oligonucleotide is required for each variation. In minisequencing, only one primer for each allele is necessary, which is extended by one single-labeled nucleotide terminator. The SBCE primer, carrying a zip code at its 5′-dangling end, hybridizes to the target amplicon with its 3′-end one base upstream of the SNP query position. The primer is elongated by DNA polymerase using labeled dideoxynucleotide triphosphates (lacking a 3′ hydroxyl group), so that only a single base—complementary to the polymorphic base being analyzed—is incorporated. The disadvantage of the SBCE format is that up to four different labels are required in multiplexing assays to cover each ddNTP, and hence a sophisticated flow cytometer with six fluorescence channels would be necessary. The alternative is to use a separate reaction for each type of terminator nucleotide. Then the analysis can be performed on a standard flow cytometer, but up to four different reactions are required in a multiplex assay to cover all possible nucleotides. This method has been successfully performed with 55 randomly selected SNPs near the ApoE locus.[9]

In allele-specific primer extension only one reaction is required for genotyping. Here, like in OLA, one oligonucleotide is designed for each allele to hybridize to the target amplicon with its 3′ base complementary to the polymorphic base and a 5′-dangling end with a unique zip code. Standard deoxynucleotides are used, with one type of them (e.g., dCTP) being labeled. A DNA polymerase lacking 3′–5′ exonuclease activity is used to elongate primers with a perfect match at their 3′ end. During elongation, dependent on the sequence, several labels are incorporated which increases sensitivity compared to formats incorporating only one label (like OLA or SBCE). After the genotyping reaction, the zip-coded primers are hybridized to color-coded beads (Fig. 2). Only one fluorescent channel is required for detection of each possible genotype and no labeled oligonucleotides are required, which are expensive. This format seems to be the most suited and cost-efficient method for bead-based nucleic acid testing of SNPs and mutations. For evaluation, 20 randomly selected SNPs have successfully been analyzed in 633 probands applying this method.[10]

A set of 100 color-coded beads carrying unique zip codes (FlexMAP Beads) is available as platform for the development of bead-based nucleic acid tests (Luminex). Several commercially available kits (Tm Bioscience, Toronto, Canada) have been developed with this platform, applying the ASPE format, including multiplex tests for screening of sequence variations in genes relevant for blood coagulation (Factor V, Prothrombin, MTHFR), drug metabolism (CYP450-2D6), and cystic fibrosis (CFTR).[3,11]

CONCLUSION

At this time, bead-based nucleic acid testing might not be able to compete with high-density DNA arrays in gene expression profiling and with the determination of more precise expression levels using homogeneous real-time PCR methods. However, it has been shown that bead-based assays produce accurate results in low-density gene expression profiling and sequence detection. In terms of the analysis of sequence variations, especially genotyping

of single nucleotide polymorphisms and point-mutations, bead-based technology provides a real alternative to conventional methods because of its flexibility and high multiplexing capability. The individual combination and the simultaneous determination of complete parameter profiles might be more cost-efficient than conventional single-analysis methods and so could find their way into laboratory diagnostics. Flow cytometry is a robust and automatable platform for bead-based testing. A large set of commercially available zip code beads (Luminex FlexMAP beads) provides an ideal condition for the development of new bead-based nucleic acid tests. With allele-specific primer extension (ASPE), an optimal wetware has been established, allowing high specificity, increased sensitivity, and thus requiring a less sophisticated platform at the same time.

Becker Muscular Dystrophy

B

Masafumi Matsuo
Kobe University Graduate School of Medicine, Chuo, Kobe, Japan

INTRODUCTION

Becker muscular dystrophy (BMD) is an X-linked recessive inherited disease with a worldwide incidence of 1 in 35,000 male births. Becker muscular dystrophy is characterized by progressive muscle wasting but is distinguished by delayed onset, later dependence on wheelchair support, and longer life span from Duchenne muscular dystrophy (DMD) that follows severe progressive muscle wasting.

Dystrophin, the gene defective in not only BMD but also DMD, was isolated in 1986. Since then, genetic diagnosis of BMD has been done leading to better understanding of the disease process, and the difference between DMD and BMD can be explained at the molecular level by the reading frame rule.

CLINICAL DIAGNOSIS

Becker muscular dystrophy patients show normal growth and development in their early childhood. In BMD, affected men start to show disturbance of walking due to muscle weakness at 20s or over. He maintains to walk but his muscle strength gradually decreases. Dilated cardiomyopathy is sometimes an initial clinical sign for the diagnosis of BMD. The muscle weakness involved in BMD follows a mild downward course with patients living near normal lives.[1]

Serum creatine kinase (CK) is markedly increased. This marked elevation of serum CK is the most important hallmark for the diagnosis of BMD, but the level of elevation of serum CK is not so high compared to DMD. During the asymptomatic period, elevation of serum CK is the sole sign for BMD. Some BMD patients are identified accidentally because of elevations of AST or ALT which are commonly examined for liver function as serum CK elevation is accompanied with elevations of AST and ALT.

Becker muscular dystrophy should be included in the differential diagnosis of moderately elevated serum CK in males. Pathological examination of biopsied muscle consolidates the diagnosis of BMD.

GENE DIAGNOSIS

Becker muscular dystrophy is caused by mutations of the dystrophin gene that is also mutated in DMD.[2] Therefore, both DMD and BMD are sometimes called as dystrophinopathy. Furthermore, not only types but also locations of mutations identified in both BMD and DMD are quite similar.[3] For gene diagnosis of BMD both multiplex PCR and Southern blot analysis have been employed as in the genetic diagnosis of DMD.[4–6] Nearly two-thirds of mutations identified on the dystrophin gene are deletions or duplications occupying a single or multiple exons. Every mutation identified in BMD cases would be examined based on the following reading frame rule.[3] In the rest of the BMD cases it is rather difficult to identify the responsible mutations on the dystrophin gene as a single nucleotide change is supposed to be present. However, some point mutations that induced exon skipping have been reported.[7,8]

READING-FRAME RULE OF DMD/BMD

Although both DMD and BMD patients have been shown to have deletion or duplication mutations of the dystrophin gene, the extent of the deletion does not always correlate with the severity of the disease: some BMD patients with mild symptoms have deletions encompassing numerous exons, whereas some DMD patients with severe symptoms lack only a few exons. In some cases, the long deletions resulting in BMD and the short deletions resulting in DMD may even overlap. The reading-frame rule explains the difference between DMD and BMD as follows: in DMD the translational reading frame of the dystrophin mRNA is shifted after a deletion or duplication mutation whereas it is maintained in BMD.[3] According to the reading-frame rule, BMD patients with long deletions are able to produce dystrophin mRNA that would still direct the production of an internally truncated semifunctional protein. Shorter deletions harbored by severe DMD patients, on the other hand, would bring together exons that, when spliced, would change the translational reading frame in the mRNA, such that a

DOI: 10.1081/E-EDGP 120025799

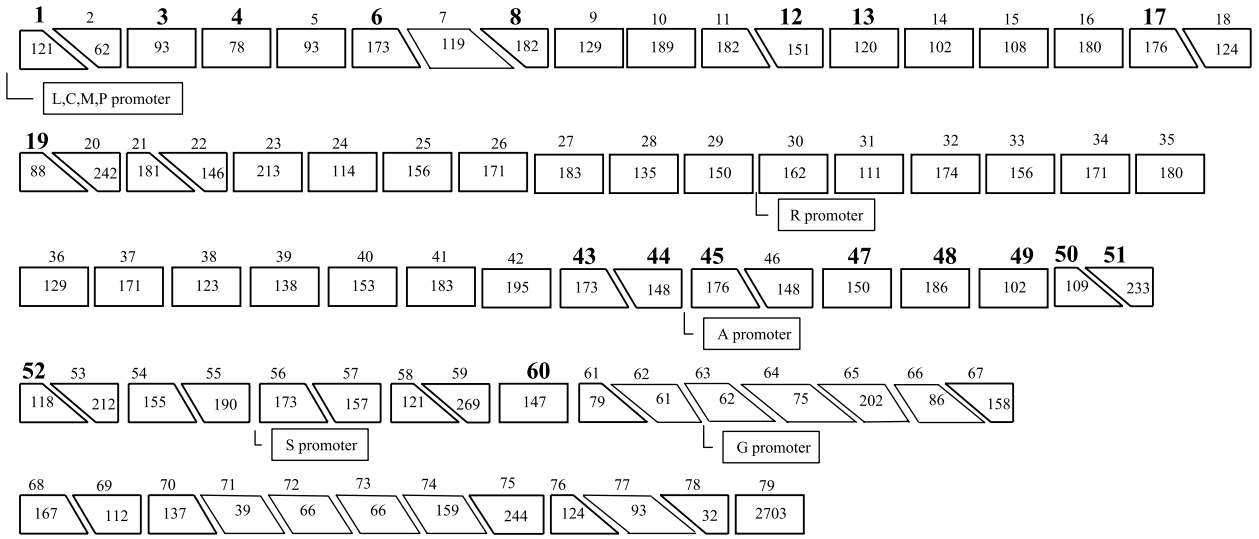

Fig. 1 Schematic description of the exon structure of the dystrophin gene. The dystrophin gene consisting of 79 exons (boxes) and at least eight alternative promoters (boxes under the lined boxes) is schematically described. Numbers over the box indicate exon number, the bold numbers being the exons that are examined by multiplex PCR. Quadrilaterals and parallelograms indicate in-frame exons (type 0 exons). Trapezoids indicate out-of-frame exons (type 1 or type 2 exons).

premature stop codon is created. This rule predicts that milder BMD patients would produce a smaller semifunctional protein whereas DMD patients would either produce a severely truncated dystrophin lacking the entire C-terminal region or would not produce dystrophin at all.

Subsequent gene analyses have shown that over 90% of the deletion–duplication mutations that cause BMD maintain the dystrophin mRNA reading frame whereas those causing DMD are frameshifts.[9] Accordingly, point mutations identified in DMD are nonsense mutations[10] except in rare DMD cases with missense mutations.[11,12]

Considering that molecular therapy for DMD to change the reading frame from out-of-frame to in-frame has been proposed,[13,14] it is important to see the resulting translational reading frame of dystrophin mRNA after the identification of a deletion or duplication mutation. Exons of the dystrophin gene are classified into three types according to the number of nucleotides encoded in the exon (Fig. 1): 1) in-frame exon that encodes nucleotides of multiples of 3 (type 0 exon); 2) two out-of-frame exons that have nucleotides of multiples of 3+1 or 2 (type 1 exon or type 2 exon, respectively). Among the 79 exons, 40, 18, and 21 exons are classified into types 0, 1, and 2 exons, respectively. In cases with deletion/duplication of the dystrophin gene the reading frame can be determined as described in Fig. 1. Cases having a deletion of a type 2 exon, e.g., exon 45, should be DMD based on the reading frame rule. Although gene diagnosis of DMD/BMD has been conducted, not all DMD/BMD cases have been examined for its reading frame.

In other types of mutations, nonsense mutations are expected to be identified in DMD. However, nonsense mutation that should result in DMD phenotype has been identified in BMD cases,[8,15] where exon skipping is shown as a mechanism that modified clinical phenotype. Furthermore, BMD has been shown to have a nonsense mutation in in-frame exons.[16–18] Detailed analysis of genotype–phenotype correlation would lead a better understanding of molecular mechanism of dystrophinopathy.

PATHOLOGICAL DIAGNOSIS

The pathological examination of biopsied skeletal muscle confirms the diagnosis of BMD. Immunohistochemical analyses of normal muscle demonstrate that dystrophin is present along with muscle cell membranes. Muscle from BMD patients contains reduced amounts of dystrophin that is stained discontinuously and patchy along the muscle cell membranes.[19] Western blot analysis using dystrophin antibody reveals a band corresponding to 427 kDa, close to the predicted size of dystrophin, in extracts of normal muscle tissue. Shorter or lower amount of dystrophin is detected in muscle extracts from patients with BMD.

Dystrophin contains 3685 amino acids organized in four domains: N-terminal actin binding, triple helical rod, cystein-rich, and C-terminal domains. The internally truncated dystrophin identified in BMD maintains both N-terminal and C-terminal domains, but lacks some of the 24 repeat sequences of triple helical rod domain. Therefore, dystrophin is stained when antibody recognizing either N-terminal or C-terminal domains is used, but in

some cases no dystrophin is stained as in DMD when antibody recognizing rod domain is employed.[20]

TREATMENT

For BMD patients, supportive therapies such as rehabilitation or ventilator support are clinically employed, but no effective way to improve the clinical course is available. Gene therapy has been considered a cure for BMD but no clinically applicable way has been established.

CONCLUSION

Becker muscular dystrophy is a mild muscle wasting disease and characterized by dystrophin abnormality in skeletal muscle. Currently, no effective treatment is available although a molecular understanding of BMD developed well.

Beta-Thalassemias

Antonio Cao
Renzo Galanello
Università degli Studi di Cagliari (UNICA), Cagliari, Sardinia, Italy

INTRODUCTION

The β-thalassemias are a markedly heterogeneous group of autosomal recessive disorders resulting from reduced (β^+) or absent (β°) production of the β-globin chains. The resulting shortage of β-globin determines an excess of unassembled α-globin chains that precipitate on the red blood cell membranes causing premature destruction by apoptosis of the erythroid precursors and consequently markedly ineffective erythropoiesis.

PREVALENCE AND DISTRIBUTION

The β-thalassemias are prevalent in populations in the Mediterranean area, Middle East, Transcaucasus, Central Asia, Indian subcontinent, and the Far East. The highest incidences are reported in Cyprus (14%), Sardinia (12%), and Southeast Asia. However, because of population migration and partly to the slave trade, β-thalassemia is now common also in Northern Europe, North and South America, the Caribbean, and Australia.[1]

CLINICAL ASPECTS

At the clinical–hematological level, the severity of the β-thalassemias depends on the extent of α-chain/non-α-chain (β+γ) imbalance. Clinically, we distinguish four conditions of increasing severity, i.e., silent β-thalassemia, the β-thalassemia carrier state, thalassemia intermedia, and thalassemia major. Silent β-thalassemia is produced by heterozygosity for extremely mild β-thalassemia mutations. This develops a clinical, hematologically silent phenotype and can only be recognized by a moderate imbalance of the α/non-α-chain synthesis. The β-thalassemia carrier state results from heterozygosity of typical β-thalassemia mutations and is clinically asymptomatic and hematologically defined by microcytosis (low MCV), hypochromia (low MCH), increased percentage of the minor fraction of adult Hb, namely, HbA_2, and mild unbalance of the α/non-α-chain synthesis. Thalassemia intermedia most commonly results from homozygosity for β-thalassemia and is clinically characterized by microcytic anemia of variable severity, for which regular transfusions are not required. Thalassemia major, the most severe form, also results from homozygosity for β-thalassemia and is characterized by a severe transfusion-dependent anemia.[2]

From the genetic point of view, β-thalassemia can be classified as a simple β-thalassemia, where only the β-globin gene is affected, and a complex β-thalassemia one in which also the γ and δ genes are involved.

Thalassemia Major

The clinical picture of β-thalassemia major is characterized by presentation with pallor and spleen and liver enlargement at 6–24 months of age. Typical skeletal changes resulting from expansion of the bone marrow are evident only in patients in whom transfusions were initiated late or are undertransfused. At the age of 10–11 years, regularly transfused thalassemia major patients are at risk of developing severe complications related to iron overload. These complications include growth retardation, failure of sexual maturation, dilated myocardiopathy, liver fibrosis or cirrhosis, diabetes mellitus, and insufficiency of parathyroid, thyroid, and pituitary glands. Other complications are hypersplenism, B or C virus chronic hepatitis, HIV infection, venous thrombosis, and osteoporosis. Survival of well-transfused patients treated with appropriate chelation extends beyond the third decade.[2,3]

Thalassemia Intermedia

Clinical features are pallor, jaundice, cholelithiasis, liver and spleen enlargement, moderate to severe skeletal changes, leg ulcers, extramedullary masses of hyperplastic bone marrow, and tendency to develop osteopenia, osteoporosis, and thrombotic complications. Compared to thalassemia major, iron overload occurs later and is a result of increased intestinal iron absorption caused by ineffective erythropoiesis.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020564

Diagnosis

Besides the picture described above, diagnosis of both β-thalassemia major and β-thalassemia intermedia is based on the following hematological features:

1. Typical peripheral blood smear showing microcytosis, hypochromia, anisocytosis, poikilocytosis, and nucleated red blood cells.
2. Hb pattern (by cellulose acetate electrophoresis or HPLC), characterized by HbF, and trace of HbA_2 (β°-thalassemia) or 10–30% HbA, 70–90 HbF, and trace of HbA_2 (β^+-thalassemia).
3. Complete absence (β°-thalassemia) or extreme reduction (β^+-thalassemia) of β-chains by in vitro synthesis of radioactive-labeled globin chains.[2,3]

Management of Thalassemia Major

Patients affected by thalassemia major are treated with regular blood transfusions and iron chelation therapy with desferrioxamine B (DFO). Life expectancy with this treatment extends to the third decade. The alternative oral iron chelator deferiprone (L1) is indicated only in patients with proven allergy or toxicity from DFO. Alternative chelation strategies and drugs, including the combination of deferiprone and DFO or ICL670 alone, are under investigation.

Bone marrow transplantation (BMT) or cord blood transplantation from HLA-identical siblings represents an alternative to traditional transfusion and chelation therapy. In patients without liver fibrosis and low level of iron accumulation, the disease-free survival is over 90%. However, BMT from HLA-identical but unrelated donors has a lower (60%) disease-free survival.[4–6]

Management of Thalassemia Intermedia

The treatment of patients with thalassemia intermedia is symptomatic and based on splenectomy, folic acid supplementation, and chelation therapy. The treatment of extramedullary masses is based on radiotherapy, transfusions, or hydroxyurea.

Other Therapies

Attempts to increase HbF production through the administration of a variety of agents have produced variable but not substantial effects. These agents have included 5-azacytidine, erythropoietin, butyrate compounds, and hydroxyurea.

The possibility of correction of the molecular defect in hematopoietic stem cells by transfer of a normal gene via a suitable vector or by homologous recombination is being actively investigated.

Encouraging results have been obtained recently with the lentivirus mediated transfer of a normal human γ- or β-globin gene.[7]

MOLECULAR GENETICS

β-Thalassemias are very heterogeneous at the molecular level. More than 200 different disease-causing mutations have been identified so far (Table 1).[2,3,8] The large majority of mutations are simple single nucleotide substitutions or deletion/insertions of one nucleotide or oligonucleotides leading to frameshift. The β°-thalassemias are rarely a result of a mechanism of gross gene deletion involving the β-globin gene or the LCR. The β°-thalassemias result from nonsense mutation, frameshift, or splicing mutations involving the invariant dinucleotides. The β^+-thalassemia mutations are produced by mutations of the promoter area (CACCC or TATA box), the polyadenylation signal, conserved sequences in the 5′ or 3′ untranslated regions, or by splicing abnormalities resulting from mutation of the consensus sequences around the GT/AG invariant dinucleotides. An interesting category of β^+-thalassemias is that associated with a consistent residual output of β-globin chains or constantly associated with a high γ-chain production rate, thereby determining a mild phenotype (Table 2). The most common mild mutations are β+ IVS1 nt 6 (T→C), which is found in the Mediterranean area, and β codon 26 (G→A), which gives rise to HbE that prevails in Southeast Asia. Finally, silent alleles result from mutations of the distal CACCC box and from conserved sequences in the 5′ untranslated region, in the polyadenylation signal, or within consensus sequences affecting the splicing process (Table 3). The complex β-thalassemias (δβ or γδβ-thalassemias) result from deletion of a variable extent of the β-globin gene cluster.

Several nucleotide substitutions (polymorphisms) in the β-globin cluster have been found not randomly associated, but grouped in subsets (in linkage), called haplotypes. In each population, different specific β-Thalassemia mutations are associated with different haplotypes. However, the same mutation can be contained in different haplotypes.

For example, in Mediterranean countries, most of the patients with haplotype I have the mutation IVS1–110 G→A. More rarely, the frameshift mutation at codon 6 (-A) and the β° 39 C→T mutation are also associated with haplotype I.

Table 1 Most common β-thalassemia mutations in populations at risk

Genotype–Phenotype Correlations

Any inherited or acquired condition that reduces the α/non-α-globin chain imbalance results in a lesser degree of globin α-chain precipitation and leads to a mild β-thalassemia phenotype. One of the most common and consistent mechanisms is homozygosity or compound heterozygosity for mild and silent β^+-thalassemia mutations. In contrast, compound heterozygosity for mild/silent β^+ and severe mutations produces a variable phenotype, ranging from thalassemia intermedia to thalassemia major. Compound heterozygosity for β-thalassemia and hemoglobin E (HbE) results in a wide range of clinical phenotypes, often severe, although sometimes mild and even clinically asymptomatic. HbE is a thalassemic structural variant, characterized by the presence of an abnormal structure as well as a biosynthetic defect. The nucleotide substitution at codon 26, producing the HbE variant ($\alpha_2\beta_2$26 Glu→Lys), activates a potential cryptic RNA splice site resulting in alternative splicing at this position. The homozygous state for HbE results in a mild hemolytic microcytic anemia. The clinical picture resulting from homozygosity for β°- or severe β^+-thalassemia may be ameliorated by coinheritance of mutations in the gene encoding the α-globin chain (deletion of two α-globin genes or point mutations in the major α_2 gene in β°-thalassemia and even a single α-globin gene deletion in β^+-thalassemia) associated with α-thalassemia, which reduces the output of the genes encoding the globin α-chains and therefore decreases the α/non-α-globin chain imbalance. However, the presence of coinherited α-thalassemia does not always produce a consistent effect, thus precluding its use to predict phenotype. The coinheritance of some genetic determinants capable of sustaining a continuous production of globin γ-chains (HbF) in adult life may also reduce the extent of α/non-α-globin chain imbalance.[2,3,9] This effect may be related to the β-thalassemia mutation per se which increases the globin

Table 2 Mild β-globin gene mutations causing β-thalassemia

γ-chain (HbF) output. This occurs in δβ°-thalassemia, which is caused by deletions of variable size in the β-globin gene cluster, and in deletions removing only the 5′ region of the β-globin gene promoter, which also result in high levels of HbA_2. High γ-chain output may also depend on cotransmission of hereditary persistence of fetal hemoglobin (HPFH), resulting from single-point mutations of the Aγ or Gγ promoter. The most common is a single-base C to T substitution at position −158 upstream from the Gγ gene, which is silent in normal subjects and β-thalassemia heterozygotes, but leads to increased HbF production in patients with erythropoietic stress, as occurs in homozygous β-thalassemia. The −158 Gγ mutation is in linkage disequilibrium with the IVSII-I (G→A), frameshift 8 (-AA), and frameshift 6 (-A) mutations. This explains the mild phenotype that may result from the inheritance of these mutations. Another point mutation of the Aγ promoter (−196 C→T) is in linkage with the β° 39 nonsense mutation in Sardinians. Homozygosity for this chromosome is associated with a clinically silent phenotype. Finally, also coinheritance of heterocellular hereditary persistence of fetal hemoglobin (HPFH), which may be linked or unlinked to the β-globin gene cluster, may lead to a mild phenotype. To date, three loci have been mapped: one at Xq22.2–q22.3, one on 6q22.3–q23.1, and one on 8q (which interacts with the Gγ −158 C→T mutation), but many others are very likely to exist. In some cases, heterozygous β-thalassemia may lead to the phenotype of thalassemia intermedia instead of the asymptomatic carrier state. Known molecular mechanisms include the following:

1. Heterozygosity for mutations in the β-globin gene that result in hyperunstable hemoglobins (dominant β-thalassemia), which precipitates in the red cell membrane together with unassembled α-globin chains, resulting in markedly ineffective erythropoiesis. Most of these β-globin gene mutations lie in the third exon and lead to the production of a markedly unstable Hb variant often not detectable in peripheral blood. Up to now, 32 dominant β-thalassemias have been described; all of them, but one, i.e., Cd121 G→T described in several families, are private mutations reported in single families.
2. Compound heterozygosity for typical β-thalassemia mutations and the triple or (less frequently) quadruple α-globin gene arrangement (ααα/αα, ααα/ααα, or αααα/αα), which may increase the imbalance in the ratio of globin α/non-α-globin chains.

Other Modifying Factors

The clinical phenotype of homozygous β-thalassemia may also be modified by the coinheritance of other genetic factors mapping outside the β-globin gene cluster. The best known of these modifying genes is the Gilbert mutation [i.e., the presence of the $(TA)_7$ configuration instead of the $(TA)_6$ in the TATA box of the gene encoding uridin-diphosphoglucuronyltransferase], which, when combined with thalassemia major or thalassemia intermedia or the β-thalassemia carrier state, leads to increased jaundice and increased risk of gallstones. Less defined modifying factors are genes coding for hereditary hemochromatosis and genes involved in bone metabolism.[10]

β-Thalassemia Phenotype With Normal β-Globin Gene Sequences

A limited proportion of individuals with the β-thalassemia carrier phenotype show completely normal β-globin gene sequences as well as normal LCR sequences. Recently, mutations in the general transcription factor TFIIH coding for a specific helicase have also been shown to be associated with β-thalassemia carrier phenotype besides tricothiodystrophy. Furthermore, depending on the site of mutation, mutations in GATA-1 resulted either in dyserythropoietic anemia and thrombocytopenia or thrombocytopenia and β-thalassemia carrier phenotype. The results indicate that the β-thalassemia carrier phenotype may result from mutation in a transcription factor regulating the function of the β-globin gene.

CARRIER IDENTIFICATION

β-Thalassemia carriers are identified by analysis of red blood cell indices, which show microcytosis and reduced MCH and Hb analysis, which displays high HbA_2 (>3.5%). Pitfalls in carrier identification may result from several molecular mechanisms. Coinheritance of α-thalassemia (two α-globin gene deletions or point mutations of the major α_2 globin gene in β°-thalassemia, or even a single α-globin gene deletion in β^+-thalassemia) may

normalize the red blood cell indices of the β-thalassemia carrier. Nevertheless, the HbA_2 concentration remains in the β-thalassemia carrier range and therefore has diagnostic value. Coinheritance of δ-thalassemia, which reduces the increased HbA_2 levels typical of the β-thalassemia carrier state to normal, may cause confusion with the α-thalassemia carrier state. Differentiation of the double heterozygote state for δ- and β-thalassemia from the α-thalassemia heterozygote may be accomplished by globin chain synthesis analysis or globin gene analysis. Heterozygotes for mild β-thalassemia mutations (β^+ IVS-I nt 6 mutation, γδβ-, and δβ-thalassemia) may have normal HbA_2 levels. However, δβ-thalassemias are characterized by high HbF levels.[1,11]

Based on these features, screening for β-thalassemia should be carried out by red cell indices analysis, Hb electrophoresis, and HbA_2 quantitation. Molecular genetic testing to identify the β gene mutation is usually performed in the couples at risk for β-thalassemia and when the hematologic tests are not conclusive (i.e., borderline HbA_2, microcytosis with normal A_2 and F and normal iron, increased HbF). In some cases, molecular diagnosis may be helpful in patients to predict the clinical severity. Mutations are detected by several PCR-based procedures, such as reverse dot blot analysis or primer specific amplification using probes or primers complementary to the most common mutations present in the population or denaturing high-performance liquid chromatography. Sequence analysis is used if the previous methods fail to detect the mutation. Because of the high carrier rate, population screening is ongoing in several populations at risk (Sardinians, Continental Italians, Greeks, Cypriots) in Mediterranean area. In these populations, screening in combination with prenatal diagnosis has led to a marked reduction of the birth rate of homozygous β-thalassemia.

PRENATAL DIAGNOSIS

Prenatal diagnosis may be carried out for couples of whom both members are β-thalassemia carriers and for whom β-globin gene mutations have been identified by DNA analysis. Molecular genetic testing can be performed either on fetal DNA extracted from cells obtained by chorionic villi sampling (CVS) at about 10–12 weeks gestation or by amniocentesis at 14–18 weeks gestation. Diagnosis by DNA analysis of polar bodies and preimplantation diagnosis by analysis of cleavage embryo biopsy are also possible. Prenatal diagnosis by analysis of fetal cells in maternal blood is not yet available. However, analysis of fetal DNA in maternal plasma for the presence of the father's mutation may lead to prenatal exclusion of homozygous β-thalassemia.

CONCLUSION

β-Thalassemias are very heterogeneous at the clinical and molecular level. Clinically, we distinguish four clinical-hematological conditions of increasing severity, i.e., silent β-thalassemia, the β-thalassemia carrier state, thalassemia intermedia, and thalassemia major. At molecular level, β-thalassemias result from more than 200 different molecular defects. Molecular detection is possible with several PCR-based procedures. Preconception and prenatal diagnosis is available. Carrier screening and genetic counseling in the Mediterranean population at risk have led to a dramatic decrease in the birth rate of homozygous β-thalassemia. Treatment, based on periodic transfusion and iron chelation, has resulted in extended survival. Bone marrow transplantation from HLA identical siblings results in a >90% disease-free survival in patients in good clinical conditions. The lentivirus-mediated transfer of the β-globin or γ-globin gene in a thalassemic mouse has recently produced encouraging results.

Biosensors—DNA-Based Sensor Technology

B

Wenonah A. Vercoutere
NASA Ames Research Center, Moffett Field, California, U.S.A.

INTRODUCTION

Biosensors link biological probes to a signal transducer to convert chemical recognition into recordable data, ideally in real time. For medical genomics, biosensor technology focuses on recognizing nucleic acid sequences. The biosensor probes are typically single strands of DNA complementary to a target. The probes may be in solution or associated with a surface. Signals from probe–target recognition are converted by a variety of techniques. Recognition may be measured, for instance, as a change in fluorescence, color, acoustic wave resonance, optical resonance, electronic signal, or magnetic field. Medically useful genomic variations extend from broad-range gene expression patterns to single point mutations. This review summarizes DNA-based biosensor technology that is being developed to provide fast, simple, and inexpensive methods for measuring medically important genomic information.

CURRENT TECHNIQUES USED IN MEDICAL GENOMICS

Genomic variations that influence disease predisposition or response to pharmaceutical therapies (see pharmacogenetics) are not simple to characterize. Clinically useful techniques must be able to detect a few mutations, such as associated with hereditary hemochromatosis (two single nucleotide polymorphism sites), or many mutations, such as associated with cystic fibrosis (>1000 mutations). Differences in drug response can be monogenic, but more typically they are caused by a combination of several genes.[1] Recognition of onset of disease such as cancer, and monitoring treatments, depends on identification of neoplastic markers. Research continues with the goal to identify genetic mutations and gene expression changes associated with disease, disease progression, and response to treatment.

An assortment of methods is currently used in genomic research and for molecular diagnostics. DNA microarrays are the first widely used research tool to couple signal generation directly to DNA hybridization to measure genomic variations. For example, recent research using microarrays has identified gene expression changes associated with breast cancer stages.[2] However, microarray use as clinical tool is limited by the number of manual steps involved, the time required, cost, and often by the variability between samples and between laboratories.[3] Current clinical techniques frequently use ''home-brew'' assays and commercial instruments that require analyte-specific reagents (ASRs). In-house validation is essential and all laboratories are required to be CLIA (Clinical Laboratory Improvement Amendments) certified (http://www.cms.hhs.gov/clia).[4] Clinical laboratories currently identify single nucleotide polymorphisms (SNPs) and other diagnostic mutations using platforms that include allele-specific amplification, chemiluminescent forward dot blot assay, dot blot hybridization, gel-based restriction fragment length polymorphism (RFLP) analysis, oligonucleotide ligation, primer extension, multiplex PCR. Also in use are commercial kits such as mDx platform for hereditary hemochromatosis and Factor V_{Leiden} from Bio-Rad Laboratories (Hercules, CA) and the Amplichip CYP450 Array that identifies common mutations associated with poor or rapid drug metabolisms from Roche Diagnostics (Indianapolis, IN). Solution-based biosensors have debuted in the clinical laboratory in the form of fluorescence resonance energy transfer (FRET) probes used in real-time PCR. Systems using TaqMan™, molecular beacon, or Scorpion™ primers fluoresce as DNA target replication proceeds, and results can be generated within 20 min to 2 hr.[5] However, typical laboratory turnaround times using these tools are on the order of weeks; as with DNA microarray analysis, multiple manual steps are involved that take time and can introduce human error. Depending on the particular test, concerns also include sample size, cost, scalability, and limited adaptability.

DNA BIOSENSORS

The ideal biosensor for clinical use would be robust, simple and rapid to use, cost-effective, require minimal sample preparation, use small volumes, and have low nonspecific interference. It would also produce results that are nonbiased, and with low false positives or negatives.

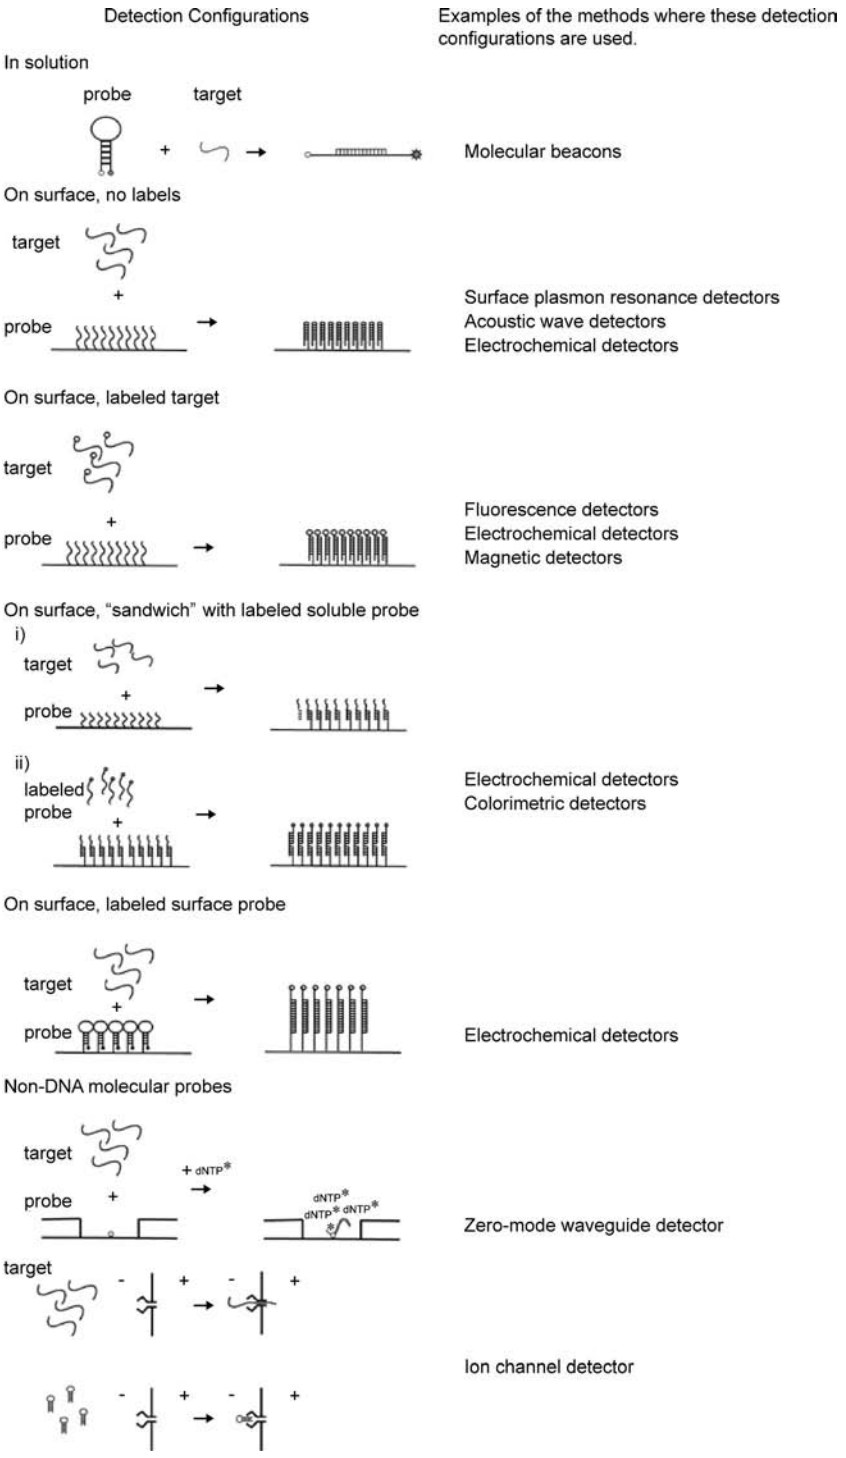

Fig. 1 Schematics showing different detection configurations with examples of the methods where they are used.

This device would potentially integrate multiple steps and be flexible enough to handle a broad spectrum of applications. Some biosensors are beginning to meet these criteria; most are still in development.[6,7] Currently, almost all DNA biosensors use DNA/DNA hybridization to obtain specificity (Fig. 1). Several novel methods use nonspecific proteins including enzymes and ion channels to detect sequence information from single molecules of DNA. The following are examples of DNA biosensors with a comparison of sensitivity and stage of development.

Evanescent and Acoustic Wave Sensors

A common form of evanescence wave detection used for biosensor applications is surface plasmon resonance (SPR). Ligand association (and dissociation) to surface-bound probe molecules is detected by changes in the refractive index of evanescence waves within a thin metal-coated quartz sensor adjacent to the sample flow chamber. This method is primarily used to study kinetics of protein–protein and protein–DNA interactions. Several reports demonstrate that SPR can also be used to monitor DNA and RNA hybridization. For example, Feriotto et al.[8] showed that SNPs associated with thalassemia could be distinguished by using PCR-amplified samples from normal, heterozygous, and homozygous thalassemia patients as the surface-bound molecule. Probe–target hybridization took 5 min per sample to read, and 1 to 3 μg of each PCR product was used. Surface plasmon resonance has also been applied in a microfluidics array format to detect 20 fmol of 1731-nucleotide RNA transcribed in vitro from the *uidA* gene of a transgenic *Arabidopsis thaliana* plant (20 nM in 1 μL).[9] The shift to array format and the significant reduction in sample size are improvements for SPR use as a tool to examine genetic mutations or gene expression. The requirement for specialized equipment, however, may limit the applicability for clinical use.

Acoustic wave biosensors measure mechanical wave propagation at the surface of a piezoelectric sensor that is sensitive to changes in mass, surface charge, and viscoelasticity. As a demonstration of concept, Furtado and Thompson[10] showed that eight synthesized 25-mer target DNAs each with a different single nucleotide mismatch could be discriminated in less than an hour. Increasing sensitivity to DNA hybridization or observing transcription at single nucleotide resolution may be achievable with these real-time resonance detection methods if they were coupled to a second detection method such as fluorescence microscopy.[11]

Fiber-Optic Sensors

Fiber-optic biosensors use total internal reflectance to measure fluorescent-labeled targets captured at the glass fiber surface. Fibers have been configured for use in large or small clusters. Large clusters of ~6000 fibers are used in an array format with probe-coated beads seated at the tip of each fiber (Illumina, San Diego, CA.). With this system, Epstein and colleagues[12] showed that zeptomole levels of fluoroscene-labeled 21-mer containing the cystic fibrosis F508C mutation could be identified within an hour (0.1 fM in 10 μL). Small (~4-fiber) clusters are individually coated with probes. Using 19-mer probes, this configuration was used to distinguish between two gene mutations associated with spinal muscular atrophy using Cy5-labeled 202-bp PCR products amplified from patient samples. When a time-derivative of the signal was applied, the difference was identified in less than 2 min.[13]

Colorimetric Sensors

There is emerging interest in sensitive colorimetric biosensor methods that do not require specialized instruments for signal detection. Nanoparticles, nanovesicles, and optical thin film have been used to transduce complementary hybridization into a color change. Aggregation of probe-labeled nanoparticles in the presence of complementary target is associated with a color shift that can be monitored using a UV–VIS spectrophotometer. This system was coupled in an array format with a chemoresponsive diffraction grating detector to show real-time detection of a synthesized 27-mer DNA target. The experimental detection limit was 0.8 fmol (1 pM in 800 μL), and an extrapolated detection limit of 33 attomol was calculated.[14] In a system using a dye-encapsulated nanovesicle label, Baeumner and colleagues[15] showed that sandwich hybridization in solution could be detected simply and with high sensitivity. Target DNA, capture probe, and labeled probe were mixed for 20 min, sampled with a membrane strip for 10 min, and then read with a reflectometer. This method showed sensitivity to 1 fmol (1 nM in 10 μL). Using an optical thin-film biosensor, Zhong and coworkers[16] printed DNA arrays that detected PCR products with a lower limit less than 5 fmol. The signal is visible to the naked eye, and data can be recorded using a digital camera, a dissecting microscope, and a standard light source. In this system, a 30–40-min oligo sandwich detection method was used, facilitated by a *Thermusthermophilus* ligase modified to have a 10-fold increase in efficiency. To compare accuracy with standard methods, DNA samples from 100 human subjects were tested for SNPs associated with increased risk of venous thromboembolism, and DNA samples from 50 individuals were tested for SNP genotyping. Results were as good as or better than TaqMan™ or RFLP results.

Electrochemical Sensors

Electrochemical detectors measure potential, resistance, or capacitance using electrodes functionalized with DNA probes. Techniques include using labeled second probes for sandwich hybridization or labeled surface probes for simultaneous target hybridization and signal generation. In an application of nanoparticles for electrochemical detection, Park and colleagues[17] used specific target–probe association to align nanoparticle-labeled probes across a gap. A final step of silver treatment to coat the

adhered gold particles completed a conducting bridge, and SNPs were distinguished at femtomolar levels. Park's research group is continuing to investigate applications of DNA-coated nanoparticles for low-level gene (and protein) detection.

Bernaki and coworkers[18] tested the accuracy of a low-density biosensor array called eSensor (Motorola Life Sciences, Pasadena, CA). This device uses a sandwich detection method on a pair of gold electrodes, with probes labeled with two different conducting ferrocenes. DNA samples from six B-lymphocyte cell lines were tested as part of an ongoing clinical validation process, four with hereditary hemochromatosis (*HFE* gene) mutations and two with cystic fibrosis (*CFTR* gene) mutations. After a 2-hr hybridization, the array was tested for conductance of the ferrocene conductance pairs representing wild-type and single nucleotide mutant. A signal of 6 to 40 nA indicated hybridization, showing reasonable selectivity from noncomplementary DNA, below 1 nA. Five molecular genetic laboratories tested the samples other than Motorola Life Sciences and used standard techniques including direct DNA sequence analysis, RFLP, and conformational gel electrophoresis. The electrochemical biosensor results concurred in all cases.

By labeling a surface-bound probe with an electrically active moiety, electronic detection can take place with a unimolecular reaction. Mao et al. electrochemically detected target 15-mers using a self-assembled monolayer of DNA hairpin probes end-labeled with redox-active thionine.[19] Binding of 2.5 pmol (50 nM in 50/μL) target DNA to the complementary loop sequence dissociated the hairpin stem and moved the active label away from the detection surface, reducing the potential measurably within about 25 min. Readings at two temperatures allowed detection of single nucleotide differences representing a p53 mutation with at least 10% change in signal. A similar system used hairpins labeled with ferrocene. In this system, 5-fmol (10 pM in 500/μL) target 17-mers were detected within 30 min.[20]

Magnetic Sensors

Magnetic biosensors detect hybridization using a signal probe labeled with a metal microbead. Miller and colleagues showed that the material used in hard-drive read heads, giant magnetoresistance (GMR) sensors, could be modified with DNA probes to detect target DNA.[21] Using commercially available chips, they showed eight DNA samples from pathogenic bacteria could be read within 30 min. Similar work compared probe concentrations and magnetic microbeads, and showed detection of 100 nmol (10 ng/μL) target DNA.[22] This technique has been studied by only a few groups, but shows promise because the GMR microchips and readers are already developed, and because each GMR sensor is capable of detecting a single magnetic bead, so that a single target molecule may be detectable.

Single Molecule Sensors

All DNA biosensors discussed so far use DNA as the biological recognition probe to obtain specificity. Several novel methods use nonspecific proteins such as ion channels or enzymes to detect sequence information from single molecules of DNA. The most commonly employed ion channel is the α-hemolysin ion channel reconstituted in an artificial bilayer. Using a 120-mV applied potential, the channel samples unlabeled DNA from solution. Capture of a DNA molecule is observed as an ionic current blockade. Blockade durations can last from 20 μsec to minutes depending on the length and stability of the molecule. Real-time identification using machine-learning analysis requires up to a 50-msec read of each molecule.[23] Watson–Crick base-pair differences at the termini of 9-bp DNA hairpins were distinguishable using this analysis method.[24,25] Standard experimental conditions were 10-μM target DNA in 70 μL. A reduction in volume would lower the concentration needed to maintain an adequate acquisition rate. However, identification of comparable sequence information from single-stranded DNA is not possible with the current system. Up to 12 nucleotides contribute to blocking current through the transmembrane compartment at a time, and the translocation rate of 2 μsec per nucleotide is at the limit of electronic instrument noise. A nanopore device capable of reading sequence from target DNA will likely incorporate an enzyme that reduces translocation speed from microseconds to milliseconds.

Another method to observe DNA, a single nucleotide at a time, used a surface-bound DNA polymerase. Levene and colleagues[26] used a 50-nm-wide well in a metal film as a zero-mode waveguide to restrict excitation light to the immediate vicinity of the enzyme. They observed real-time synthesis of a single DNA polymerase by monitoring the incorporation of fluorophore-labeled dCTP into a growing cDNA strand. If dNTPs with different fluorophores on each were used, it would be possible, in principle, to monitor the order of nucleotide incorporation and reconstruct the sequence.

CONCLUSION

The biosensors reviewed here each show improvement to some aspect of current mutation detection. A number have utility as research tools, including the nanovesicle-based colorimetric sensor and the α-hemolysin nanopore. A few DNA biosensors are beginning to meet the requirements

for clinical use, such as the eSensor. A key component to facilitating transition of DNA biosensors into clinical use will be the establishment of a set of reference samples such as used by Bernaki and colleagues to use for validation and calibration. In addition to being reliable, the most successful DNA biosensors will be flexible and scalable. This may be accomplished with biosensors that can be assembled into array format or that have interchangeable probe-coated surfaces. This may also be achieved using probes other than DNA that can give sequence information without specific base-pair hybridization, such as the DNA polymerase captured in a zero-mode waveguide, or a nanopore detector.

Bladder Cancer—Identification of Bladder Cancer Biomarkers by Microarrays

Marta Sänchez-Carbayo
Memorial Sloan Kettering Cancer Center, New York, New York, U.S.A.

BLADDER CANCER

Bladder cancer is one of the most common malignancies in developed countries, ranking as the fourth most common cancer in men and the seventh most common in women.[1] Bladder cancer constitutes a spectrum of diseases that have been classified into three main groups with distinct clinical behavior, prognosis, primary managements, and molecular profiles: superficial (stages Ta-Tis-T1), deeply invasive (stages T2–4), and metastatic disease (N+/M+).[2] Most superficial cases are treated conservatively by transurethral removal of the tumor, followed by adjuvant intravesical therapy, without removal of the bladder. Muscle-infiltrating tumors are generally treated by cystectomy, plus systemic adjuvant chemotherapy or radiotherapy. Approximately 20% of the superficial tumors are cured by surgical removal of the presenting lesion, 50–70% recur one or more times, but never progress into invasive disease, and 10–30% progress to invasive and potentially lethal disease. In contrast, approximately 50% of patients with muscle-infiltrating tumors already harbor or will develop metastatic disease, and ultimately, the vast majority of patients with metastatic tumors die from their disease.

Bladder cancer, including some superficial lesions, has been reported to carry a significant number of genetic alterations at the time of diagnosis. A substantial body of work has suggested that superficial papillary tumors (pTa) differ from flat carcinoma in situ lesions (TIS) and muscle-invasive tumors in their molecular pathogenesis and pathways of progression. At least, these two major molecular pathways of bladder tumor development and evolution that can be followed are recognized (Fig. 1). The first, represented by papillary superficial tumors, is associated with chromosome 9 losses, including inactivation of CDKN2A (p16) on 9p and still unknown genes associated with telomeric 9q loci.[3,4] The second pathway includes inactivation of p53 on chromosome 17 (17p11.3) and RB on 13q14, adscribed to flat carcinoma in situ and pT1 tumors.[2–5] The number of genetic alterations is substantially higher in the invasive lesions, but there also appears to be a difference in the specific alterations present.

THE NEED FOR BIOMARKERS IN BLADDER CANCER

Bladder tumors are pathologically stratified based on stage, grade, tumor size, presence of concomitant carcinoma in situ, and multicentricity.[2] The chances of tumor progression are augmented with the increase of these pathological variables. Pathologically, most bladder tumors are transitional cell carcinomas. There is, however, increasing recognition of the prognostic importance associated with the metaplastic variants displaying squamous and glandular differentiation as part of their clonal evolution. The power of these histopathological variables and the tumor node metastases (TNM) categorization, in defining the clinical subtypes of bladder cancer and predicting the clinical outcome of individual patients, has certain limitations. Within each stage, it has been very difficult to identify clinically useful parameters that can predict risk of disease recurrence or progression. Numerous biological markers have been described for bladder cancer, some correlating with tumor stage and prognosis in patients affected with these neoplasms. Phenotypic features associated with tumor aggressiveness include cell cycle and apoptosis regulators, as studied by appropriate sensitive molecular techniques.[2–5] Remaining challenges are not only the identification of biomarkers of early diagnostic utility combining high sensitivity and specificity, but also progression and outcome-predictive markers in bladder cancer.

MICROARRAYS AS TARGET IDENTIFICATION TOOLS IN CANCER

Microarrays constitute a group of technologies characterized by the common availability of measuring hundreds or thousands of items, including DNA sequences, RNA transcripts, or proteins, within a single experiment using miniaturized devices. Hybridization-based methods and the microarray format constitute together an extremely versatile platform provided for both static and dynamic views of DNA structure, as well as RNA and protein expression patterns in cultured cancer cells and tumor

Encyclopedia of Diagnostic Genomics and Proteomics

tissues. The most widespread use of this technology to date has been the analysis of gene expression. There is an increasingly broad range of additional applications for microarrays, including genotyping polymorphisms and mutations, determining the sites of DNA-binding proteins, and identifying structural alterations using arrayed comparative genome hybridization (CGH). Powerful methods for comprehensive analysis of gene and protein expression patterns utilize not only microarray formats, but also differential display,[6] serial analysis of gene expression (SAGE),[7] protein composition-based approaches such as antibody microarrays,[8] high-throughput mass spectral analysis, or 2-D gel analysis.[9] Among these high-throughput techniques, DNA microarrays are the most utilized tools for target identification.

The development and implementation of high-throughput array technologies to primary human tumors is changing clinical management of patients with cancer. The histopathological diagnosis and classification of tumors are now being complemented by these comprehensive procedures, providing novel diagnostic, predictive, and therapeutic targets for the cancer patient. To the simplicity of the study of a single molecular marker, we may be able to integrate the complexity of multiple biological determinants, participating in signaling pathways and biological networks. Comprehensive information may, in turn, modify empirical clinical treatments for individualized mechanism-based therapies, as well as diagnostic and predictive molecular signatures for the management of patients with bladder cancer. The concept of individual biomarkers of diagnostic and/or prognostic utility is being progressively changed by the concept of cluster of genes or gene profiles characteristic of recurrence, progression, or survival.

IDENTIFICATION OF MOLECULAR TARGETS AND BIOMARKERS FOR BLADDER CANCER USING DNA MICROARRAYS

Microarray-based gene expression profiling to the study of bladder cancer can be divided into those analyzing in vitro systems and those centering on clinical material, with the objectives of achieving gene and pathway discovery, functional classification of genes, and a new classification based on tumor subtypes. Molecular profiling using DNA microarrays of in vivo models on bladder cancer has not been reported to date.

Bladder Cancer Studies Using In Vitro Models

Expression profiling using bladder cancer cell lines has been used to gain insight into the molecular events associated with clinical disease states, assigning potential functional roles to novel genes in both tumorigenic and tumor progression processes. Certain studies have focused on *gene and pathway discovery* associated to genistein[10] or 5-aza-2′-deoxycytidine[11] exposure. Other reports describe the *functional classification of genes* comparing the expression patterns of p53-mediated apoptosis in resistant tumor cell lines versus sensitive tumor cell lines using cDNA arrays,[12] or the expression patterns of a metastatic variant cell line to the respective parental

invasive cells.[13] Many molecular targets involved in bladder cancer progression have been identified in these studies. Comprehensive analyses using clinical specimens will also elucidate the clinical utility of these targets as biomarkers for patients with bladder cancer. An attempt to *tumor subtypes classification* of bladder cancer cell lines by means of gene expression analyses has rendered identification of biomarkers of clinical utility. Gene profiling identified novel biomarkers from in vitro analyses that were proven to be associated with clinical and histopathological variables when validated on tumor specimens using tissue microarrays at the protein level, using well-characterized antibodies and immunohistochemistry. Caveolin-1 and keratin 10 were differentially expressed in a squamous carcinoma cell line and certain invasive tumor cell lines. Cells clustered also based on their p53, RB, and INK4A status revealing E-cadherin, zyxin, and moesin as targets differentially expressed in these clusters. The expression of all these proteins in primary bladder tumors spotted on tissue microarrays was significantly associated with histopathological stage and tumor grade.[14]

Bladder Cancer Studies Using Clinical Specimens

Microarray analyses have been used to correlate changes in the expression of specific genes and groups of genes within distinct bladder subclasses. Such signature genes would ideally provide a molecular basis for classification, yielding insight into the molecular events underlying different clinical bladder cancer phenotypes.

The first report monitored the expression patterns of superficial and invasive tumor cell suspensions prepared from individuals and pools of normal and bladder tumors of tumors of different stages such as from pTA grade I and II and pT2 grade III and IV bladder cancer specimens.[15] Hierarchical clustering of gene expression levels grouped bladder cancer specimens based on tumor stage and grade. The most significant functional genes included those involved in cell cycle, cell growth, immunology, adhesion, transcription, and protein metabolism. Superficial papillary tumors showed increased transcription factor and ribosomal levels, as well as proteinase encoding genes up-regulation. In the invasive tumors, increased levels of cell cycle, growth factor networks, immunology-related and oncogene transcripts, and loss of cellular adhesion genes were observed.[15]

The combination of separate expression profiling studies of bladder tumors and bladder cancer cell lines has allowed the identification of the tumor suppressor role of KiSS-1 in bladder cancer progression.[16] Lower transcript levels of KiSS-1 were observed in cells derived from advanced bladder tumors and bladder carcinomas as compared with superficial tumors, and these ratios provided prognostic information. The expression patterns of KiSS-1 analyzed by in situ hybridization on tissue microarrays were associated with tumor stage, grade, and overall survival. Thus gene expression profiling identified a novel target involved in bladder cancer progression with clinical relevance.[16]

The most extensive expression profiling study of bladder tumors reported to date has dealt with the development of a predictive classifier of Ta, T1, and T2+ bladder carcinoma subclasses. The use of a support vector machine algorithm allowed prediction with 75% accuracy of these tumor subclasses in an independent set of patients, using cross-validation strategies to evaluate the clinical impact of the classifier defined using independent series of tumors. Smad6 and cyclin G2 were also identified as Ta/T1 classifier genes and their immunostaining patterns were validated on tissue microarrays by immunohistochemistry.[17] This study represents the first attempt to predict recurrence within 2 years for patients with bladder cancer.

Gene profiling has also successfully classified bladder tumors based on their progression and clinical outcome. Early-stage tumors showing gene profiles similar to invasive disease were identified. More importantly, carcinoma in situ from papillary superficial lesions and subgroups within early stage and invasive tumors displaying different overall survival were separated. Different techniques were used to identify molecular biomarkers of clinical significance. For example, p33ING1 was found to be significantly associated with pathological stage, tumor grade, and overall survival using tissue microarrays. Analysis of the annotation of the most significant genes revealed the relevance of critical genes and pathways during bladder cancer progression.[18]

BIOMARKER DISCOVERY USING OTHER MICROARRAY PLATFORMS

In addition to transcriptome expression microarrays, specific oligonucleotide microarrays have been applied to the study of DNA variation in clinical material. Multiple probes of short length that differ in sequence at a single base have been designed to identify simple polymorphisms and allelic variations in DNA. The primary applications of these types of microarrays have dealt with automated high-throughput identification of mutations in critical genes such as *TP53*, a valuable predictor for bladder cancer outcome,[19] and in the genotyping of single nucleotide polymorphisms (SNP).[20] High-throughput CGH arrays can also confirm chromosomal gains and losses alterations found at the genomic level in a comprehensive detailed manner. This provides a significant advantage over laborious pregenome mapping

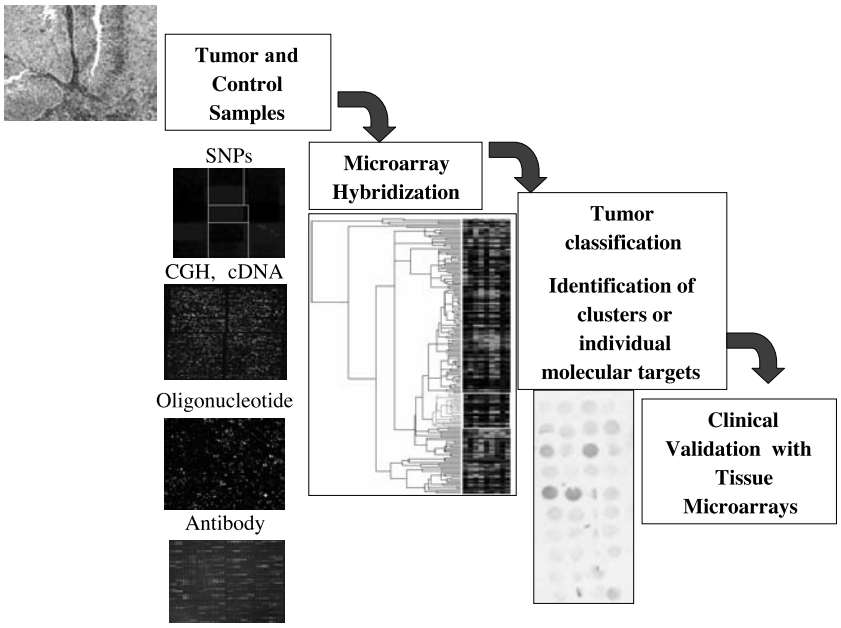

Fig. 2 General strategy used in tumor expression profiling for target identification. RNA isolation from cell lines, tumor biopsy, and control samples is followed by preparation of the hybridization probe, hybridization with the DNA microarray, data acquisition, and analysis. Verification of the results can be performed using different approaches, such as tissue microarray analysis. (*View this art in color at www.dekker.com.*)

and transcript identification strategies and allows study of genetic changes in tumor progression.[21]

It should be noted that microarrays technology is a convenient platform for assays involving biomolecules other than nucleic acids not widely utilized for patients with bladder cancer yet. Arrays of tissues, peptides, antibodies, proteins, and even cells have been developed.[8,9] This is further evidence of the strength and

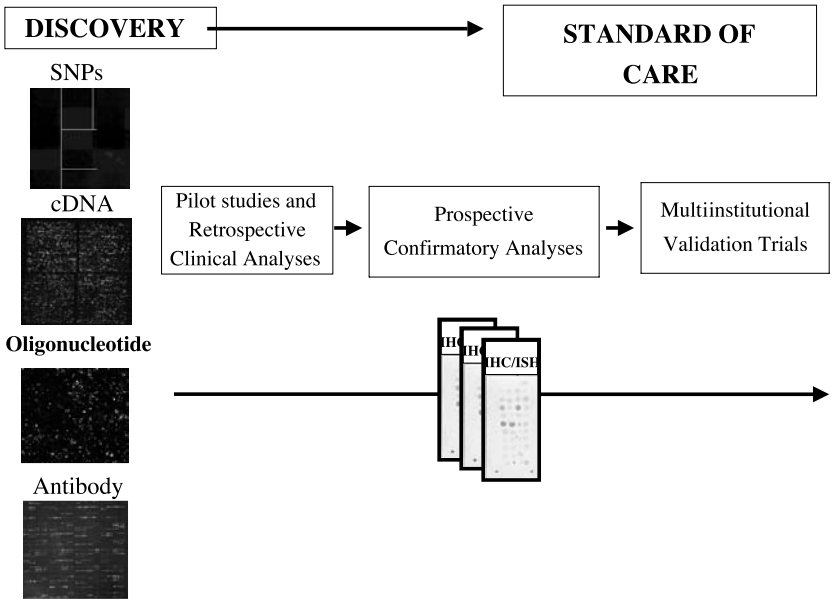

Fig. 3 The use of high-throughput technologies provides novel targets that might be developed into biomarkers of diagnostic and prognostic utility. The tumor marker development requires several steps before acceptance into clinical routine. (*View this art in color at www.dekker.com.*)

versatility for high-throughput screening for biomarker discovery using, for example, mass spectrometry. Protein microarrays also provide means of rapidly validating the genes identified by expression profiling using DNA microarrays at the protein level.

TISSUE ARRAYS FOR VALIDATION OF BIOMARKERS IDENTIFIED USING MICROARRAYS

Genomic analysis tools for biomarker identification can be complimented by the use of array-based high-throughput approaches to survey tumor biopsies for a large number of individual patients. In combination with the associated clinical data for these patients, this technology is ideally suited to a genomics- or proteomics-based discovery project and has the ability to significantly accelerate the transition of basic science findings into clinical applications (Fig. 2). The application of tissue microarrays represents a high-throughput approach for validation of potential novel markers for bladder cancer by immunohistochemistry or fluorescence in situ hybridization in paraffin blocks. Focus is intensified within this field to automate construction of tissue microarrays and generate arrays from frozen blocks.

CONCLUSION

The studies summarized here and others indicate that expression profiling provides a molecular means of identifying clinically important tumor subtypes and molecular targets not identified using standard methods. Gene expression profiling could define, at the molecular level, the individual clinical and histopathological phenotypes of bladder tumors. Reports using different microarray platforms and analyzing specific cancer subgroups are warranted to find consensus on subclasses and signatures of the disease with diagnostic and predictive utility (Fig. 3). Creation of international tumor banks represents an option that might facilitate interactive research among different laboratories. Further efforts using in vitro and in vivo models are warranted to characterize functionally the pathways by which many of the targets already identified to be involved in tumorigenesis or bladder cancer progression. The utility of the application of microarrays has not estimated yet many clinical issues in bladder cancer. Identification of Ta-T1-IS subtypes within superficial disease and patients more likely to develop positive lymph nodes or distant metastases are critical subclassification questions to be answered. Another area that will provide critical targets for clinical intervention is that of pharmacogenomics. In the near future, gene profiling will provide effective means to predict the response against specific therapeutic regimes based on the molecular signatures of the tumors associated with their chemosensitivity or resistance to anticancer drugs. Moreover, the discovery of molecular pathways altered in cancer progression as well as the identification of molecule-susceptible targets would lead to the development of novel alternative therapies. The combined information revealed by these studies also allows the identification of new molecular determinants involved in the progression of the disease with clinical diagnostic or predictive utility. The classical tumor marker concept of an individual biological determinant will be substituted by the use of cluster of genes as predictive classifiers. These genetic signatures will allow a better chance of cure by opting for individualized therapies and development of biomarkers of diagnostic and predictive value for patients with bladder cancer.

Blood Group Genotyping

Lilian Castilho
Hemocentro Unicamp, Campinas, Brazil

INTRODUCTION

Accurate phenotyping of red blood cells (RBCs) can be difficult in transfusion-dependent patients such as those with thalassemia and sickle cell anemia because of the presence of previously transfused RBCs in the patients' circulation. Recently, the molecular basis associated with the expression of many blood group antigens was established. This allowed the development of a plethora of polymerase chain reaction (PCR)-based tests for the identification of blood group antigens by testing the DNA.

The determination of blood group polymorphism at the genomic level facilitates the resolution of clinical problems that cannot be addressed by hemagglutination. They are useful to 1) determine antigen types for which currently available antibodies are weakly reactive; 2) type patients who have been recently transfused; 3) identify fetuses at risk for hemolytic disease of the newborn; and 4) to increase the reliability of repositories of antigen-negative RBCs for transfusion.

BLOOD GROUP GENOTYPING

Blood group antigens are polymorphisms of proteins and carbohydrates on the outside surface of the red blood cell (RBC) (Fig. 1) and are defined by serum alloantibodies produced in response to an immunizing event such as transfusion or pregnancy. It is the antibody that causes clinical problems in transfusion incompatibility, maternal–fetal incompatibility, and autoimmune hemolytic anemia.

The major risks of transfusions are unexpected incompatibility reactions[1] and the transmission of infectious agents. Iron overload and alloimmunization are also frequently observed among some categories of chronically transfused patients. Alloimmunization leads to an increased risk of transfusion reactions, reducing the available pool of compatible blood for transfusion in subsequent crises. Alloimmunization is the source of a variety of problems during long-term medical and transfusion management, with the main problem being the identification of appropriate antigen-negative RBCs for transfusion.[2]

Thus in transfusion medicine much time and effort are expended in detecting and identifying blood group antibodies. Next to ABO, the most clinically significant antibodies are those in Rh, Kell, Duffy, and Kidd blood group systems.[3]

Red blood cell phenotyping is essential to confirm the identity of suspected alloantibodies and to facilitate the identification of antibodies that may be formed in the future. Accurate antigen typing of transfused patients is often a difficult task because of the presence of donor RBCs in the patients' circulation. Thus in these patients phenotyping can be time consuming and difficult to interpret. It is also complicated to type cells when a patient's RBCs have a positive direct antiglobulin test and no direct agglutinating antibody is available.

DNA technology led to the understanding of the molecular basis of many blood group antigens. The genes encoding 28 of the 29 blood group systems (only P remains to be resolved) have been cloned and sequenced[4–7] (Table 1), which has permitted the elucidation of the molecular basis of many common blood group antigens. There are many molecular events that give rise to blood group antigens and phenotypes (Table 2); however, the majority of genetically defined blood group antigens are the consequence of a single-nucleotide polymorphism (SNP). (For current information regarding blood group antigen SNPs, the following website is recommended: www.bioc.aecom.yu.edu/bgmut/index.htm). This knowledge allows the use of DNA-based assays to detect specific blood group SNPs and that can be used to overcome the limitations of hemagglutination assays.[8,9]

Several assays for blood group genotyping of patients have recently been developed to predict the blood group antigen profile of an individual, with the goal of reducing risk or helping in the assessment of the risk of hemolytic disease of the newborn (HDN);[10–16] they include PCR-RFLP, allele-specific PCR, sequence-specific PCR as single or multiplex assays, real-time quantitative PCR.

These assays can be applied for blood group antigens to type patients who have recently received transfusion; to type patients whose RBCs are coated with immunoglobulin; to identify a fetus at risk for HDN; to determine which phenotypically antigen-negative patients can receive antigen-positive RBCs; to type donors for antibody identification panels; to type patients who have an antigen that is expressed weakly on RBCs; to determine *RHD*

zygosity; to mass screen for antigen-negative donors; to resolve A, B, and D discrepancies.

APPLICATIONS TO TRANSFUSION MEDICINE

For Multiply Transfused Patients

The ability to determine a patient's antigen profile by DNA analysis when hemagglutination tests cannot be used is a useful adjunct to a serological investigation. Blood group genotyping in the transfusion setting is recommended for multiply transfused patients, as part of the antibody identification process.

Determination of a patient's blood type by DNA analysis is particularly useful when a patient who is transfusion-dependent has produced alloantibodies.[3] This is because identification of the patient's probable phenotype allows the laboratory to determine to which antigens the patient can and cannot respond to make alloantibodies.

We have demonstrated the relevance of genotype determination of blood groups for the management of multiply transfused patients with diseases such as sickle cell disease (SCD) and β-thalassemia[15,16] by allowing the determination of the true blood group genotype, and by assisting in the identification of suspected alloantibodies and the selection of antigen-negative RBCs for transfusion. Furthermore, we have observed that taking genotype into account allowed better selection of compatible units for patients with discrepancies between genotype and phenotype, leading to increased cell survival and a reduction of the transfusion frequency.

For Patients Whose RBCs are Coated with IgG

Patients with warm autoimmune hemolytic anemia (WAIHA), whose RBCs are coated with IgG, cannot be accurately typed for RBC antigens, particularly when directly agglutinating antibodies are not available, or IgG removal by chemical treatment of RBCs is insufficient. We have shown that blood group genotyping is very important for the determination of the true blood group antigens of these patients.[17] After genotyping, the patients received antigen-matched RBCs that had better in vivo survival, as assessed by increases in hemoglobin levels and diminished frequency of transfusions.

The possibility to have an alternative to hemagglutination tests to determine the patient's antigen profile should be considered for multiply transfused patients and for patients with WAIHA by allowing the determination of the true blood group genotype and by assisting in the identification of suspected alloantibodies and in the selection of antigen-negative RBCs for transfusion. This ensures more accurate selection of compatible donor units and is likely to prevent alloimmunization and reduce the potential for hemolytic reactions.

Table 1 Blood group systems with gene names and chromosome location

ISBT number	System name	Gene name	Number of antigens	Chromosome location
001	ABO	*ABO*	4	9p34.1–q34.2

For Blood Donors

DNA-based typing can also be used to antigen type blood donor both for transfusion and for antibody identification reagent panels. This is particularly useful when antibodies are not available or are weakly reactive. A good example is the Dombrock blood group polymorphism where DNA-based assays are used to type patients and donors for Do^a and Do^b to overcome the dearth of reliable typing reagents.[18,19] Furthermore, the newer technologies have the potential to screen pools of DNA for rare blood types. The molecular analysis of a variant gene can also assist in resolving a serological investigation.[20]

ABO Genotyping and Resolution of A and B Discrepancies

ABO blood grouping is crucial for safe blood transfusion. Since the cloning of the *ABO* gene in 1990,[21] progress has been made in the structural and functional analyses of the *ABO* genes and A and B transferases at the molecular level. A proportion of blood donors and patients who historically have been typed as group O are now being recognized as group A or group B with the use of monoclonal antibodies capable of detecting small amounts of the immunodominant carbohydrate responsible for A or B specificity. A typing result that differs from the historical record often results in time-consuming analyses. Because the bases of many weak subgroups of A and B are associated with altered transferase genes, PCR-based assays can be used to define the transferase gene and thus the ABO group.[22] A majority of the mutations are nucleotide substitutions, resulting in amino acid substitutions or a single nucleotide deletion/insertion, and correlate well with the presence of specific subgroup alleles.

Table 2 Molecular events that give rise to blood group antigens and phenotypes

Gene conversion or recombination events (MNs, Rh, Ch/Rg blood group systems)
Duplication of an exon (Gerbich)
Deletion of a gene, exon, or nucleotide(s) (ABO, Rh, MNS, Kel, Duffy, Dombrock)
Insertion of a nucleotide(s) (Rh, Colton)
Single nucleotide substitutions (most blood group systems)

Resolution of RhD Typing Discrepancies

A proportion of blood donors that historically have been typed as RhD-negative are now reclassified as D-positive, because of monoclonal reagents that detect small and specific parts of the D antigen. The molecular basis of numerous D variants can be used to identify the genes encoding altered RhD protein in these individuals.[23,24,33]

APPLICATIONS TO MATERNAL–FETAL MEDICINE

Alloimmunization against the RhD antigen during pregnancy is the most frequent cause of hemolytic disease of the newborn (HDN). Immunization occurs when fetal cells, carrying antigens inherited from the father, enter the mother's circulation following fetal–maternal bleeding. The mother, when not expressing the same antigen(s), may produce IgG antibodies toward the fetal antigen, and these antibodies can pass through the placenta causing a diversity of symptoms, ranging from mild anemia to death of the fetus. Apart from antibodies in the RhD blood group antigen, other specificities within the Rh system and several other blood group antigens can give rise to HDN, but RhD is by far the most immunogenic.[25]

Prenatal determination of fetal RhD status is desirable in pregnancies to prevent sensitization and possible hydrops fetalis in fetuses of RhD-negative mothers with RhD-positive fathers. Fetal DNA has been detected in amniotic cells, chorionic villus samples, and, as recently reported, in maternal plasma.[26–32] Polymerase chain reaction amplification of *RHD* in maternal plasma may be useful for the management of RhD-negative mothers of RhD-positive fetuses and for the study of fetal–maternal cell trafficking.

Before interpreting the results of DNA analysis, it is important to obtain an accurate medical history and to establish whether the study subject is a surrogate mother and whether she has been impregnated with nonspousal sperm.

The discovery of fetal DNA in maternal plasma has opened up new and exciting possibilities for the noninvasive prenatal determination of fetal blood group status. However, a number of technical issues still need to be addressed and large-scale multicenter clinical trials need to be carried out. When these issues are resolved, it is likely that the prenatal testing of fetal blood group type will be carried out routinely and safely.

LIMITATIONS AND FUTURE

It is important to note that PCR-based assays are more prone to different types of errors than those observed with hemagglutination assays. For instance, contamination with amplified products may lead to false-positive test results. In addition, the identification of a particular genotype does not necessarily mean that the antigen will be expressed on the RBC membrane.

A large number of people from a variety of ethnic backgrounds need to be studied to determine the occurrence of particular genotypes and to establish more firmly the correlation between blood group genotype and phenotype.

Advances are ongoing in the automation of SNP and DNA sequence analysis, and the success of sequencing the human genome has shown that the potential for phenotyping large numbers of samples has already been realized.[34] It should soon be possible to analyze major and many minor blood group alleles on a single synthetic chip. Indeed, it will be possible to test for many genetically defined conditions.

As automated procedures attain higher and faster throughput at lower cost, blood group genotyping is likely to become more widespread. We believe that the PCR technology may be used in a transfusion service in the next few years to overcome the limitations of hemagglutination.

CONCLUSION

The identification of the molecular basis of blood group antigens provides an insight into the generation of gene diversity in humans. A molecular understanding of blood groups has enabled the design of simple assays that may be used to facilitate the provision of blood to patients who require antigen-matched red cells, both by phenotyping the patients to determine their requirements and by phenotyping red cell units.

Transfusion-dependent patients have sickle cell disease, thalassemias, and aplastic anemias, and frequently become alloimmunized. Blood group genotyping contributes substantially to the safety of blood transfusion in these recipients. Although it is unlikely that molecular genotyping will replace hemagglutination any time in the near future, together these techniques have substantial value in the resolution of clinical laboratory problems and, consequently, in the quality of patient care.

Blotting Techniques

Philip Lewis White
Sam Hibbitts
University of Wales College of Medicine, Cardiff, U.K.

INTRODUCTION

The capacity to separate nucleic acids and proteins by their molecular weight and identify fractions of interest by the hybridization of specific labeled probes is known as blotting. It was originally developed for the analysis of gel-fractionated DNA and was termed the Southern blot. Northern blotting was soon to follow and permitted the investigation of RNA templates by using an identical procedure. Since then, Western blotting was designed to analyze proteins and a procedure known as Dot/Slot blotting was developed to detect and quantify any nucleic acid sequence without the necessity of processing [restriction fragment length polymorphism (RFLP) and/or separation by electrophoresis] the nucleic acids.

The development of blotting techniques has helped revolutionize molecular biology. One of the benefits of detecting nucleic acids using a blot/probe system, rather than ethidium bromide staining, is that it provides an enhanced sensitivity and confirms the identity of the polymerase chain reaction (PCR) amplicon or target sequence. Initially, targets were visualized by hybridization with a radiolabeled (^{32}P) probe, but because of apprehensions over user safety/exposure and the difficulty with disposal of radioisotopes, a number of nonisotopic alternatives are now available allowing colorimetric, chemiluminescent, or fluorescent detection.

TECHNICAL OVERVIEW

The basis of all blotting techniques (Southern,[1] Northern[2] and Western blotting[3]) is the transfer of nucleic acids/proteins to a solid inert support/filter followed by hybridization with a specific labeled probe. The process involves depurination (for nucleic acids >5 kb) to allow a more efficient transfer and denaturation of double-stranded nucleic acids to provide a suitable target for the probe. Neutralization is required for nitrocellulose filters because nucleic acids are not retained on these supports at pH values above 9.0. Usually, transfer to the support is by capillary diffusion, although apparatus are available that enhance the transfer by using suction and fixation onto a nitrocellulose/noncharged nylon solid support by baking or UV cross-bonding, respectively. Hybridization of the specific probe is performed under optimal conditions, and washing to remove excess (non-specific) hybridization is necessary before the degree of hybridization is determined.

BASIC PROTOCOL FOR SOUTHERN BLOTTING

Using a Nitrocellulose Filter

Southern blotting is the term given to the procedure of transferring DNA from a gel matrix to a solid inert filter. DNA samples, fragmented by restriction digests or PCR amplified, are separated by agarose gel electrophoresis (0.5–2.5% agarose), stained with ethidium bromide (0.5 μg/mL) and photographed to record the position of molecular weight markers and the fragments of interest. The gel is rinsed, the DNA depurinated by a HCl (0.25 M) wash, and denatured by washing twice in a denaturing buffer (1.5 M NaCl, 0.5 M NaOH). For the DNA to be transferred to the nitrocellulose filter, it is necessary to neutralize it by washing twice in a neutral, high-salt buffer (1.5 M NaCl; 0.5 M Tris–HCl, pH 7.0). For all the washes, use 5- to 10-fold gel volumes of each buffer and incubate at room temperature for 20–30 min with gentle shaking.

To transfer the DNA to the filter, assemble the blot apparatus as shown in Fig. 1. Fill a tray/sandwich box with transfer buffer (20× SSC; 3 M NaCl, 0.3 M trisodium citrate) and place a 20× SSC-soaked wick (three sheets of Whatman 3MM paper) onto the glass support so that each end dips into the 20× SSC reservoir. The nitrocellulose filter should be cut to the exact size of the gel and wetted by floating on distilled water prior to soaking in 20× SSC. Expel any air bubbles trapped beneath the wick with a gloved hand before placing the gel on to the saturated wick. Apply the 20× SSC-soaked filter to the top of the gel and remove any bubbles as instructed earlier. To prevent the filter from touching the wick, use saran wrap to form a barrier around the edges of the gel. Place five sheets of dry 3MM paper onto the filter and stack paper towels (4–5 cm) on top, cover with a glass plate, and place

DOI: 10.1081/E-EDGP 120020705

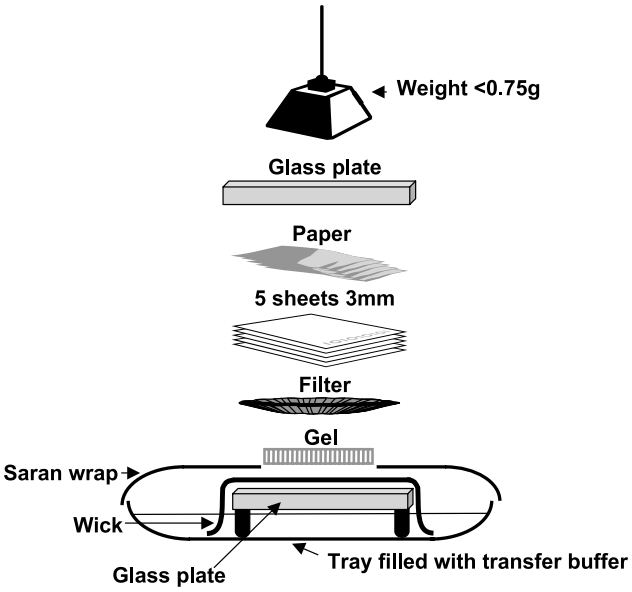

Fig. 1 Overview of nucleic acid blotting procedure.

a small weight (up to 500 g) at the top. The apparatus should be left overnight for optimal DNA transfer.

Disassemble the blotting apparatus, leaving a compacted gel/filter amalgamation. It is paramount to mark the position of the wells on the filter and to nick one of the corners to allow correct orientation. To remove excess salt and prevent the filter from becoming brittle, peel the filter from the gel and soak in a 6× SSC solution for 3 min before drying it on 3MM paper. It is recommended to confirm the DNA transfer by restaining the gel with ethidium bromide. After the filter has dried, sandwich it between two sheets of 3MM paper and bake it for 2–3 hr at 80°C under a vacuum to immobilize the DNA by expelling any water. The filter is now ready for probe hybridization, although it can still be stored for several months in a dry, dark location.

Using a Nylon Filter

Many groups now prefer the use of nylon filters, and varieties of charged (Hybond-N+) and noncharged nylon filters (Hybond-N) are commercially available. They have a high binding capacity for single-stranded nucleic acids; however, unlike nitrocellulose, nylon filters are capable of efficient double-stranded DNA retention. It is believed that nucleic acids bind to nitrocellulose in a noncovalent manner and baking will noncovalently bind nucleic acids to a nylon filter. Alternatively, a covalent association can be achieved by the UV irradiation of noncharged nylon filters and by simple alkaline treatment of positively charged filters. Further advantages of nylon-based filters include their ability to bind smaller oligonucleotides and their enhanced structural strength permits secure long-term storage and further analysis such as multiple reprobing.

The techniques for blotting on to a nylon filter are similar to those for nitrocellulose supports; however, when using commercially acquired filters, it is recommended that manufacturers' instructions are followed. In general, when performing Southern transfers to a nylon membrane, alkali blotting is the method of preference. Compared to high-salt blotting, alkali blotting allows quicker transfer of DNA molecules (within in 2 hr) while minimizing the possibilities for DNA reassociation. Furthermore, on transfer to positively charged nylon filters, the DNA becomes covalently linked—thus removing the need for baking or UV treatment.

The method is fundamentally the same; however, no neutralization stage is necessary and the blotting apparatus only requires a few minor alterations from what was previously described (Fig. 1). The 20× SSC transfer buffer is replaced with NaOH (0.4 mM) or NaOH (0.25 M) and NaCl (1.5 M) for positively charged and uncharged filters, respectively.[4] Because of its hydrophilic nature, it is not necessary to prewet the nylon filter; it can be placed on the gel without any pretreatment and left for a minimum of 2 hr for DNA transfer—after which the apparatus are disassembled, the filter marked as described, probed, and stored for reference or further use.

Alkali-induced covalent linking of DNA to nylon filters works most efficiently for positively charged supports, and although it does work for uncharged nylon filters, UV treatment is the preferred method when using the latter.[4] However, overexposure to UV irradiation may reduce the ability of the nylon membrane to hybridize a probe[5] and this limitation is enhanced when using positively charged filters.[4]

Alkali blotting is not suitable for DNA transfer to nitrocellulose filters as these supports require a neutral pH to retain nucleic acids, and furthermore, their lack of structural stability is accentuated by alkali treatment. Performing Northern blots by alkali transfer is not recommended, because RNA is hydrolyzed by prolonged (overnight) alkaline exposure;[4] however, the use of lower (0.2 M) NaOH concentrations for shorter (1 hr) transfer times has generated successful Northern blotting techniques.[6]

BASIC PROTOCOL FOR HYBRIDIZATION

The expression hybridization refers to the (re)association of complementary nucleic acid strands (DNA, RNA, or synthetically produced primers or probes) to form double-stranded complexes. The process starts with the

association of two short regions of complementary nucleic acid sequences, followed by a rapid and progressive linking of the base pairs on either end of the duplex region. The rate of hybridization and the stability of the complexes, once formed, are dependent on a number of factors. Temperature has an important role in both the rate and stability of the hybridization complex. Optimal hybridization occurs at 20–25°C and 10–15°C below the melt temperature of DNA and RNA complexes, respectively.[7,8] At suboptimal temperatures, reaction rates will be slowed and nonspecific hybridization may occur; however, if temperatures exceed the optimal range, then although stringency of the reaction may improve there may be a degradation of accurately associated dimers.

Hybridization time is also important and long incubation times may not provide the optimal results. There is a balance between achieving an optimal bind between the target and probe and the development of a nonspecific background signal or the hybridization of the probe to sequences similar to the target. Generally, incubations for less than 24 hr should not result in a high background signal, providing the probe concentration is not in excess. If the probe is in excess of the bound target, then binding to similar nontarget sequences may become problematic in the latter stages. For an overnight reaction, a usual probe concentration is 10 ng mL^{-1}.

Mismatches between the probe and target sequence will compromise the stability of the association and this may lead to a reduction in the optimal temperature to overcome the discrepancy. Even so, a 10% mismatch is usually tolerated. However, mismatches will also have a detrimental effect on the rates of hybridization and a 10% mismatch will reduce the hybridization rate.[7]

Other factors that need to be considered include the following:

1. Salt concentrations—generally concentrations of 1.0–1.5 M Na^+ (or equivalent, 5× SSC) are considered optimal.[9]
2. pH—reactions are usually performed at a neutral or weakly acidic pH.[4]
3. Dextran sulphate—the addition of dextran sulphate (10%) concentrates the nucleic acids by expelling them from the volume that it occupies, thus increasing the chances for the interaction between the probe and target sequence.[10]
4. Viscosity—the use of solution with a low viscosity will reduce the opportunity for the interaction between the probe and target sequence. The introduction of polyethylene glycol (PEG 8%) will increase the viscosity of less viscous solutions.[11]
5. Probe length—when probing a filter, the hybridization rate is directly proportional to the probe length when there is excess target DNA bound. Probes are usually >15 bp and <1.5 kbp[4] in length.

When performing hybridization, three steps are followed. The first stage is prehybridization, where the filter is washed with a protein, polymer, and sheared carrier DNA mix to block nonspecific binding. The next stage is hybridization and involves denaturing the probe before adding it to fresh, warm prehybridization solution, which is then applied to the filter and agitated overnight at the desired temperature. The filter is then washed for 30 min to remove any unbound or weakly bound probe using 0.2× SSC, 0.1% SDS solution. The stringency of the wash is temperature-dependent, with washing at room temperature and close to the probe Tm considered to be moderate and high, respectively.

The most common detection methods originally utilized ^{32}P radiolabeling of the oligonucleotide with autoradiography. The use of fluorescent dyes or lanthanide chelates, biotin-labeled nucleotide analogs, cross-linked enzymes such as horseradish peroxidase, or acridinium esters that can be detected by enhanced chemiluminescence are just some of the currently available alternatives.[12]

BASIC PROTOCOL FOR NORTHERN BLOTTING

Northern blotting is the transfer of RNA from a gel to a filter, and the method is comparable to that for Southern blotting with only a few modifications. By adding formaldehyde to the agarose gel, the RNA is denatured and secondary structures are prevented. Soak the gel in transfer buffer to dilute out the formaldehyde, cut off the marker lane for ethidium bromide staining, but do not stain the main body of the gel because this reduces RNA transfer.[13] Proceed as described earlier, although denaturing and neutralizing treatments are not essential if the RNA fragment is less than 5 kb. After the overnight transfer, the RNA can be cross-linked to the filter by baking or UV treatment prior to hybridization.

When compared to Southern blots, Northern blots, because of the ubiquitous nature of RNases, are highly variable in terms of sensitivity. As the presence of RNases is common, it is important to ensure all solutions are diethyl pyrocarbonate (DEPC)-treated, all plastics are baked prior to use, and, if possible, individual apparatus should be provided for RNA use. These preparations may help to provide more consistent results.

BASIC PROTOCOL FOR DOT/SLOT BLOTS

Dot blotting, also known as Spot or Slot blotting depending on the shape of the applied blot, is a rapid and simple alternative to Southern or Northern blotting procedures. It involves the direct application, either

manually (by pipette) or automatically (by suction apparatus), of the denatured nucleic acid to the filter. If DNA is being analyzed, usually 10–100 pg will be applied and can be resuspended in 0.4 M NaOH, high-salt solutions, or 6× SSC depending on which filter is being used. As soon as the sample has dried on the filter, it is exposed to the usual denaturing and neutralizing conditions before it is immobilized by baking or UV cross-linking. Positive and negative DNA controls must be included in these experiments, and it is further recommended to include standards that can be used for quantification. After application, the sample is air-dried and immobilized without any further treatments.

The major applications of Dot blotting are the rapid detection of specific nucleic acid sequences and the ability to quantify sequences in a complex sample, e.g., viral load in human blood. However, as Dot blotting does not utilize any fractionation methods, it is unable to differentiate true hybridization from nonspecific hybridization, and therefore it is essential to include the correct controls and standards, especially if accurate quantification is required.

BASIC PROTOCOL FOR WESTERN BLOTS

Western blots, otherwise known as Immune blots, have a method analogous to the one outlined above. In brief, proteins are fractionated and denatured by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis (PAGE). The size-fractionated proteins are then blotted onto a nylon or nitrocellulose filter, where—once fixed and blocked—they are probed by antibodies specific for the target protein. This primary antibody can be labeled, but most often the filter is probed with a labeled secondary antibody raised against the first (primary antibody rabbit, secondary antibody antirabbit goat antibody), and it is this secondary antibody that is detected. The primary antibodies should be specific for a single protein, and bind to an amino acid sequence rather than any posttranslational modifications, e.g., phosphorylation, that may have been applied.[14] It is also beneficial for the antibody to be able to detect any epitopes of the protein, and so polyclonal antibodies are widely used, although they may create unsatisfactory high background levels.[14] Monoclonal antibodies do not have this problem, but being specific for a single epitope could be problematic if the targeted epitope has not renatured after electrophoresis.

CLINICAL AND GENETIC APPLICATIONS

Blotting techniques have widespread uses as both research and diagnostic tools:

1. They are essential in sequencing strategies for screening cosmid/phage clones and libraries.
2. They can be used to screen populations for polymorphisms.[15]
3. They can also be utilized for the mapping of unknown genes or sequences, e.g., to locate restriction sites for cloning[16] or inverse PCR.
4. Blotting techniques can be used to confirm the identity of PCR amplicons, which is especially useful if coamplification has occurred or is required.
5. They have various applications in medical molecular biology, e.g., screening for mutations,[17] confirming culture results,[18] or providing early diagnosis of infections where the alternatives are slower, less sensitive, and reproducible.[19]
6. Further medical applications involve the ability to quantify levels of nucleic acids[20] (e.g., the RNA copy number of infectious agents such as HIV) and proteins (e.g., hormones) or proteoglycans.[21]

CONCLUSION

The widespread and extensive applications of blotting techniques are undoubted. However, the development of real-time amplification systems has replaced their usage for diagnosing many infections and conditions. They will still be used for many applications in protein analysis, or where nucleic acids are not preamplified and blotting techniques will still provide a low-cost alternative.

Molecular Detection and Epidemiological Typing of *Bordetella pertussis* and *Bordetella parapertussis*

Johanna Mäkinen
Matti K. Viljanen
Jussi Mertsola
Qiushui He
National Public Health Institute, Turku, Finland

INTRODUCTION

Pertussis has been classified by the American Centers for Disease Control and Prevention as one of the reemerging infectious diseases. The increase in the incidence of pertussis, the fact that other agents can cause a pertussis-like syndrome, and the possible adaptation of *Bordetella pertussis* populations to vaccine-induced immunity underscore the need for simultaneous detection, identification, and genetic typing of *B. pertussis* to enable rapid, sensitive, and specific diagnosis for treatment and prevention. This article discusses recent developments in the laboratory diagnosis of *Bordetella* infections and the epidemiological typing of *B. pertussis* as well as future prospects in the field.

BORDETELLAE

Bordetellae are small, gram-negative coccobacilli causing respiratory infections in humans and animals. The genus *Bordetella* comprises eight species; six of which have been isolated from humans. *B. pertussis* is pathogenic only for humans and causes pertussis (whooping cough), a contagious respiratory disease with severe clinical manifestations in infants. *Bordetella parapertussis* and *Bordetella holmesii* cause milder pertussis-like disease. In addition to these species, *Bordetella bronchiseptica* has been occasionally isolated from the human respiratory tract, *B. holmesii* and *Bordetella hinzii* from blood cultures of immunocompromised patients and *Bordetella trematum* from wound and ear infections. The remaining *Bordetella* species, *Bordetella avium* and *Bordetella petrii*, are not pathogenic in humans.[1]

DESCRIPTION OF THE INFECTION SPECTRUM

Whooping cough is acquired by inhalation of aerosols containing *B. pertussis*. The infection is characterized by bacterial colonization of ciliated respiratory epithelia in the trachea and bronchi. The incubation period is 6–20 days. Classical pertussis is an illness of three stages. It starts with a catarrhal stage, with nonspecific symptoms similar to those of the common cold (duration 1 to 2 weeks). At the paroxysmal stage (duration 2 to 6 weeks), the cough becomes more prominent with staccato attacks, postussive whooping, and vomiting. At the convalescent stage (duration several weeks), the frequency and severity of coughing attacks gradually decrease. The most severe cases of whooping cough occur in unvaccinated children under 1 year of age. This group accounts for most deaths.[1,2]

B. parapertussis and *B. pertussis* are almost identical at the DNA level and produce many similar virulence factors. However, *B. parapertussis* does not secrete pertussis toxin (PT).[3] In patients infected with *B. parapertussis*, the symptoms of whooping cough occur at lower frequencies and are of shorter duration than those of typical pertussis. A striking difference is the lack of lymphocytosis in children with *B. parapertussis* infections. Lymphocytosis during pertussis is thought to be caused by PT.[4]

PREVALENCE

Whooping cough is presently one of the 10 most common causes of death from infectious disease. The WHO estimates it to cause 50 million illnesses and over 350,000 deaths worldwide each year. After the introduction of whole-cell vaccines in the 1950s, its morbidity and mortality were significantly reduced in the developed world, whereas in the developing countries whooping cough has remained a major cause of infant mortality. In recent years, however, the incidence of pertussis has increased in a number of countries with high vaccination coverage.[5–7] Thus, the Centers for Disease Control and Prevention have classified pertussis as one of the reemerging infectious diseases.[8] This reemergence may be due to several factors such as waning vaccine-induced

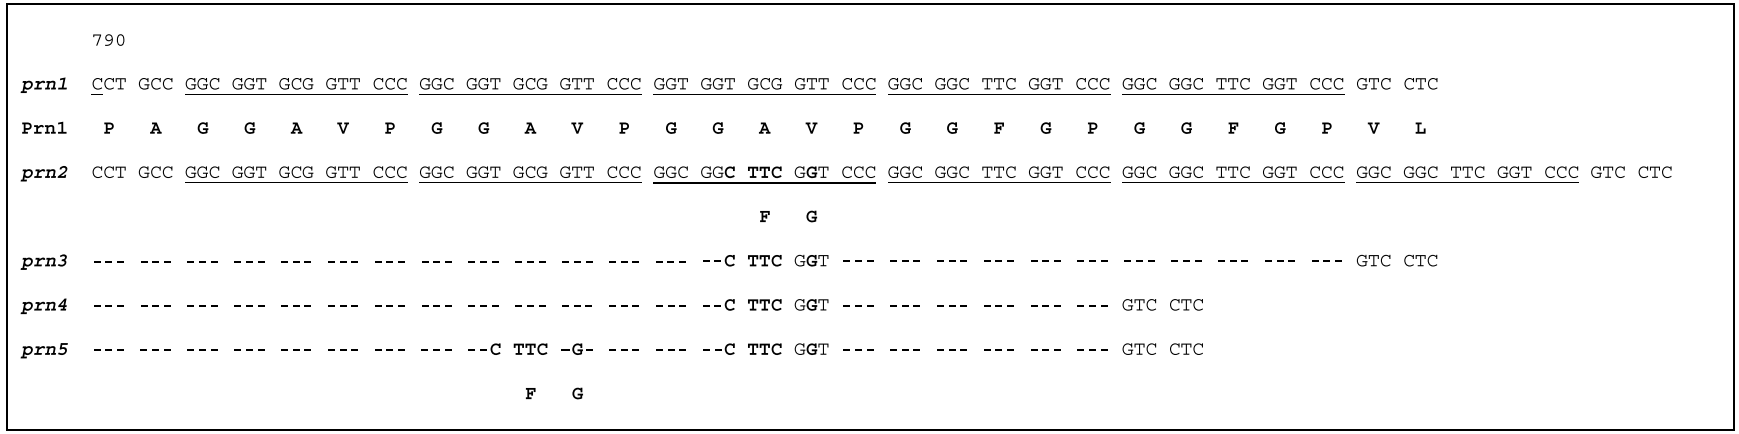

Fig. 1 Variable region 1 of the most common *B. pertussis* pertactin variants, Prn 1–5. Depicted are the nucleotide sequences of the pertactin genes and the corresponding amino acid sequences of the pertactins. The number in the upper left corner refers to the underlined residues and marks the start of an open reading frame. The dashes indicate identical bases relative to the vaccine-type pertactin, Prn1. Most clinical isolates collected in the 1990s expressed Prn2. (From Refs. [9,16,17].)

immunity, changes in vaccine production processes, improved surveillance, more sensitive laboratory diagnostic methods, or, possibly, expansion of strains antigenically distinct from the vaccine strains.[9]

In highly vaccinated communities, *B. pertussis* and *B. parapertussis* infections often go undiagnosed because pertussis is thought to be rare and adequate laboratory diagnostic tests are not used or available.[10] Infections caused by *B. parapertussis* are also more common than usually thought. In acellular vaccine efficacy trials, 2% to 25% of all isolates were *B. parapertussis*.[4,11] In addition to *B. pertussis* and *B. parapertussis*, *B. holmesii* has also been isolated from the respiratory tract of patients with pertussis-like symptoms.[12] However, its significance as a respiratory pathogen remains to be determined.

MANAGEMENT

The treatment of pertussis is primarily supportive, and adequate control of the disease depends on effective immunization. Currently, acellular pertussis vaccines, consisting of only a few antigens, are replacing whole-cell vaccines in many countries. These new vaccines are less reactogenic than the whole-cell vaccines. Several antibiotics eliminate *B. pertussis* from the respiratory tract, but erythromycin is recommended as first-line treatment because of the high concentration attainable in the serum and respiratory tract. Treatment during the catarrhal stage shortens and ameliorates the disease, and the onset of therapy even during the early paroxysmal stage has benefit. Erythromycin therapy terminates infectivity, and prophylaxis is recommended for prevention of household and school transmissions.[13] Patients should remain isolated as long as they are infectious, i.e., 5–7 days after the onset of erythromycin therapy. Infants under 1 year of age are at the greatest risk of complications and permanent sequelae.[2]

MOLECULAR CHARACTERIZATION OF *B. PERTUSSIS* AND *B. PARAPERTUSSIS*

Molecular characterization and typing of *B. pertussis* and *B. parapertussis* are used to obtain information on the changes in the phenotype and genotype of circulating isolates and in epidemiological studies. When polymorphisms in a number of *B. pertussis* genes encoding for virulence factors and surface-associated proteins as well as in housekeeping genes were studied, *B. pertussis* proved to be a rather conserved bacterium. Polymorphisms in recent isolates are restricted to genes encoding tracheal colonization factor, pertactin (Prn), and the S1 subunit (*ptxS1*) of PT.[9,14] Pertussis toxin and pertactin are important virulence factors and protective antigens. Pertussis toxin is a component of all and Prn of many new acellular vaccines and, thus, the degree of allelic variation in genes encoding these proteins has been studied intensively in many countries. The majority of the currently circulating isolates express PT and Prn types that are different from types included in the vaccines (Figs. 1 and 2).[9,15,16] It has been suggested that the reemergence of pertussis in highly vaccinated populations could be due to inadequate protection by currently used vaccines against these antigenic variant strains. For a better understanding of the causes for the reemergence of pertussis, population-based studies are necessary. Several molecular methods, such as serotyping, Western blotting, polymerase chain reaction, pulsed-field gel electrophoresis (PFGE), restriction fragment length polymorphism, ribotyping, and multilocus sequence typing have been applied to the characterization of *B. pertussis* isolates. The use of the various techniques hampers the comparison of typing data between countries. To make the data comparable, recommendations for standardized epidemiological typing of *B. pertussis* have been given. Currently, PFGE using the restriction enzyme *Xba*I (and *Spe*I when needed), serotyping using monoclonal

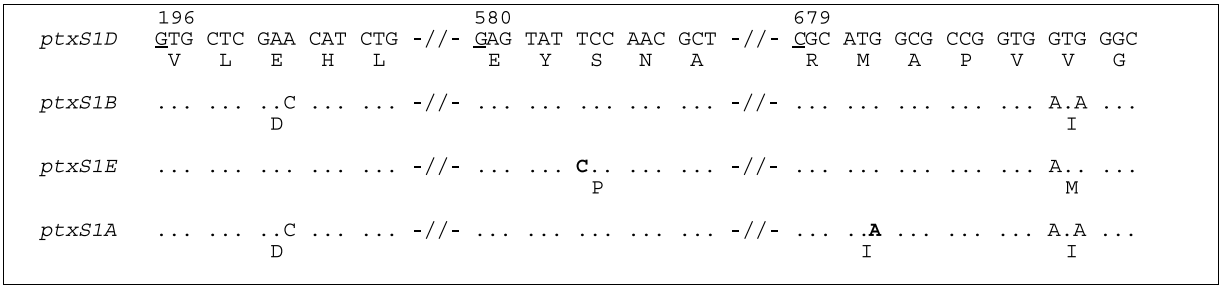

Fig. 2 Polymorphic region of *B. pertussis* pertussis toxin. Depicted are the nucleotide sequences of the toxin genes (*ptxS1*) and the corresponding amino acid sequences of the toxins (*ptxS1*). The numbers refer to the underlined residues and mark the start of open reading frames. The dots indicate identical bases relative to *ptxS1D*. The strains used for vaccine production express ptxS1B or ptxS1D, whereas the majority of currently circulating isolates express ptxS1A. (From Refs. [9,16,17].)

antibodies to fimbriae 2 and 3, and determination of PT and Prn encoding alleles are recommended for the standardized epidemiological typing of *B. pertussis*[17] *Xba*I PFGE is also recommended for the epidemiological typing of *B. parapertussis*.

MOLECULAR TESTS IN THE CLINICAL DIAGNOSTICS OF *BORDETELLA* INFECTIONS

Older children and adults often present with mild or atypical pertussis that easily goes unrecognized. In addition, other pathogens[18] can cause pertussis-like illnesses. These factors complicate the clinical diagnosis of pertussis and make the laboratory diagnosis a vital component of effective strategies against the disease in the community. Laboratory diagnosis requires isolation of *B. pertussis* or *B. parapertussis* from respiratory secretions, demonstration of specific antigens or nucleic acids in the above secretions, or detection of a serological response to infection. Culture and detection of antigens or nucleic acids yield positive results at the early stages of pertussis, whereas serology is usually the only diagnostic method that can be used at later stages, when microbial antigens and nucleic acids have disappeared from the infected host.

Bordetellae are fastidious organisms. Sampling time, sample collection and transportation methods, and culture conditions affect the sensitivity of culture. Furthermore, culture is a slow procedure; it may take up to 3 weeks before culture results are available for the physician. The direct fluorescence antibody test (DFA) uses polyclonal fluorescein-labeled antibodies to *B. pertussis* and *B. parapertussis* for the detection of organisms in nasopharyngeal smears.[19] The method is compromised by inadequate sensitivity, specificity, and subjectivity and should be used only in parallel with culture. The diagnostic sensitivity of serology is very much dependent on the timing of sample collection, choice of antigen, and the immunoglobulin class.[1,20] Assessments of IgG and IgA antibodies to PT and filamentous haemagglutinin (FHA) are the most useful assays. Only antibodies to PT are specific for *B. pertussis*, antibodies to FHA and Prn may be elicited by *B. parapertussis* and other bacteria.[21] The diagnostic efficacy of serology is rather low in the acute phase of the disease. At the later stages of pertussis, diagnosis is primarily based on serology. Without serology, adolescent and adult pertussis cases are largely overlooked, as the patients do not usually contact a doctor until after a long duration of symptoms.

Molecular diagnostic methods such as PCR have been widely applied to the direct detection of the DNA of fastidious pathogenic bacteria from clinical specimens. PCR has proved a rapid, sensitive, and reliable tool for the diagnostics of pertussis.[10] A variety of regions in the *B. pertussis* genome have been successfully used as targets, including the PT promoter region, repeated insertion sequence IS481, a DNA region upstream from the porin gene and the adenylate cyclase toxin gene. IS1001-based PCR has been applied to the diagnosis of *B. parapertussis* infections.[10]

The recent application of fluorescence techniques to in vitro nucleic acid amplification allows simultaneous amplification and sequence-specific detection of PCR products using hybridization probes.[22] The advantages of these real-time PCR methods are that PCR amplification can be carried out in less than an hour and no further analysis of the PCR amplicons (such as gel-electrophoresis and Southern blotting) is required. Because no PCR products need to be handled, contamination risk is minimized. Like with conventional PCR, the crucial issue of the use of these real-time PCR methods is finding good amplification targets allowing sensitive and specific detection of a given pathogen. The target gene region should have sufficient sequence variation to allow differentiation between *B. pertussis* and *B. parapertussis* and *B. holmesii*. However, the gene region should be conserved without any variation on the subspecies level in the regions where the probes bind. Further, multiple copies of the target gene region in the genome increase the sensitivity of the assay. Multiple copies of repeated insertion sequences IS481 and IS1001 are present in the genomes of *B. pertussis* and *B. parapertussis* and, therefore, IS-based PCR assays are widely used in diagnostic laboratories. The first diagnostic real-time PCR assay developed for simultaneous detection and identification of *B. pertussis* and *B. parapertussis* also targeted at IS481 and IS1001.[23] However, IS481 is also present in the genome of *B. holmesii*, and the major drawback of the IS-based assays is that *B. holmesii* and *B. pertussis* infections cannot be differentiated. The major limitation of the other target genes tested so far is that they are present singly or in low copy numbers and their amplification may not allow as good analytical sensitivity as that of IS-based assays.

Currently, rapid real-time PCR assays are gradually replacing conventional PCR assays in clinical diagnostic laboratories. One of the major challenges in pertussis diagnostics is finding new target gene regions for sensitive and specific detection and identification of Bordetellae directly from clinical specimens. However, PCR can probably never fully replace culture, as the collection of clinical isolates for research purposes is an important task for diagnostic laboratories.

MOLECULAR TESTING IN THE EPIDEMIOLOGICAL TYPING OF *B. PERTUSSIS* ISOLATES

The finding that the currently circulating strains harbor *ptxS1* and *prn* alleles different from those in strains used for vaccine production emphasizes the importance of monitoring the molecular evolution and antigenic variation of clinical isolates. In epidemiological studies, PFGE is used for the determination of the overall genotype of the isolates. Serotyping and the determination of *ptxS1* and *prn* alleles provide information about the expression and polymorphism of these virulence factors at a single-gene level.

To date, the only way to determine alleles encoding for important antigens has been PCR-based sequencing, a relatively time-consuming and expensive method. Thus, new simple methods suitable for large-scale screening of isolates are needed. Recently, real-time PCR using fluorescent-labeled hybridization probes has been applied to the determination of *prn* and *ptxS1* alleles of *B. pertussis*.[24,25] These assays proved a good alternative to sequencing as they correctly identified all *prn* and *ptxS1* gene variants, data analysis was uncomplicated and both *prn* and *ptxS1* typing results could be obtained within one working day. The disadvantage of the assays was that the PT encoding gene alleles of the two vaccine subtypes could not be differentiated. The main shortcoming of all hybridization probe-based methods, however, is that novel genotypes are missed and, therefore, these methods can never fully replace sequencing.

Studies have suggested that antigenic divergence between vaccine strains and circulating strains of *B. pertussis* affects the efficacy of pertussis vaccines and may have contributed to the disease burden as well as to recent pertussis epidemics.[9] Population-based studies should therefore be continued to ensure that antigenic shift among *B. pertussis* populations does not result in decreased efficacy of pertussis vaccines. Well-standardized, rapid, and reliable techniques are needed that further simplify typing procedures in pertussis research laboratories and facilitate the comparison of typing results from different countries.

CONCLUSION

The Sanger Centre had sequenced the genomes of *B. pertussis*, *B. parapertussis* and *B. bronchiseptica*, and thorough analysis of the genomes will undoubtedly improve the understanding of the molecular pathogenesis of *Bordetella* infections. In the near future, novel analytical tools such as DNA microarrays, amplification on a chip, and direct sequencing of the amplicon will probably enable simultaneous detection, identification, and genetic typing of Bordetellae. The genomic information obtained may also promote the identification of new specific antigens to be used in pertussis vaccines as well as in diagnostic approaches and therapeutic interventions.

Borrelia spp.

Maurice M. Exner
Quest Diagnostics Nichols Institute, San Juan Capistrano, California, U.S.A.

INTRODUCTION

The genus *Borrelia* comprises approximately 40 species that belong to the family Spirochaetaceae. Borreliae are vector-borne pathogens that cause Lyme disease and relapsing fever in humans, and spirochetosis/borreliosis in birds, cattle, sheep, and horses. Louse-borne relapsing fever epidemics appear to be decreasing over the years, with occasional outbreaks still occurring in parts of Africa. Endemic tick-borne relapsing fever still surfaces regularly in the Americas and Europe, although the number of reported cases remains low. Lyme disease, on the other hand, appears to be rapidly spreading on a global scale. This may be due to the ''promiscuous'' nature of Lyme borreliae, which have a wide variety of reservoirs and vectors compared to relapsing fever *Borrelia* species. While there are relatively few fatalities associated with Lyme disease or relapsing fever, significant morbidities can result from both, especially in the case of Lyme disease, in which chronic infection can last for years. An early and accurate diagnosis of either disease is extremely important, considering that both diseases respond well to early administration of antimicrobial agents. While a clinical diagnosis of relapsing fever can be relatively simple based on recurring febrile events, it is still confounded by the rarity of the disease, which often leaves it out of differential diagnoses (particularly in nonendemic areas). Diagnosing Lyme disease poses a particularly daunting challenge because of the protean manifestations of the disease, the variable stages of the disease, and the lack of sensitive, specific, and accurate diagnostic tools. Although the disease syndrome still relies on clinical findings for diagnosis, with confirmation by serological testing, molecular testing is proving to be sensitive and specific. Such tests are gradually gaining acceptance, and new molecular techniques may, in combination with serology, provide better insights into both diagnosis and treatment of the disease.

THE GENUS *BORRELIA*

The borreliae are motile, helical rods that range from approximately 5 to 30 μm in length and 0.2 to 0.5 μm in width.[1] They are similar in structure to other spirochetes, although *Borrelia* are generally longer and less tightly coiled. The organisms are highly motile, and they have 7 to 30 periplasmic flagella, which are partly responsible for maintaining the shape of the organism. The flagella are attached to the protoplasmic cylinder, which is enclosed by a cytoplasmic membrane and bounded by the periplasmic space and an outer membrane.

Borreliae are unique with respect to their genetic composition in that they possess a linear chromosome, along with a complement of linear and circular plasmids. The chromosome comprises approximately 950 kbp, whereas the plasmids may consist of another 40–50% more genetic material. The linear plasmids tend to encode surface proteins, whereas the circular plasmids encode proteins related to transmission and pathogenesis. Sequencing of the *Borrelia burgdorferi* genome has indicated that the organism possesses genes involved in replication, transcription, translation, and metabolism, although genes for biosynthetic pathways are lacking.[2]

Borrelial diseases are caused following the transmission of organisms to the host by means of an arthropod vector. All *Borrelia* species are vector borne; *Borrelia recurrentis* is transmitted by the human body louse, *Pediculus humanus humanus*, whereas all other species are transmitted by ticks. Hard-bodied ticks, predominantly of the genus *Ixodes*, are the vectors that are principally responsible for the transmission of Lyme disease-causing *Borrelia* species, whereas soft-bodied ticks of the genera *Ornithodoros* and *Argas* are typically responsible for the transmission of relapsing fever species.

RELAPSING FEVER

Relapsing fever is an acute, febrile illness that can be transmitted through lice or ticks. Disease is characterized by the sudden onset of high fever, chills, myalgia, delirium, joint pain, and nausea. The initial fever may occur 2 days to 2 weeks following infection, with symptoms that last 3–9 days. Successive relapses can occur after as little as 2–3 days, or as long as 2 months after the primary infection, and relapses can occur from 1 to 13 times. Secondary spirochaetemia and fever relapses occur because of antigenic variation in the variable major surface protein (vmp) of the organism. Rearrangement of

DOI: 10.1081/E-EDGP 120025614

silent and expressed genetic loci alters the *vmp* gene, and the result is an altered antigenic surface structure that allows the organism to temporarily evade the immune response.[3]

Louse-borne relapsing fever is caused by *B. recurrentis*, which enters the host through skin abrasions or through mucous membranes that have made contact with hemolymph from crushed lice. *Borrelia* are not transmitted through a louse bite, as they are not present in the louse saliva. *B. recurrentis* is the only *Borrelia* species for which humans are the sole host; all other species are maintained in various wild-animal reservoirs. Because of the nature of the vector, including the increased prevalence in regions with poor hygienic practices, louse-borne relapsing fever can result in epidemics, and it is often referred to as epidemic relapsing fever. Mortality rates can be greater than 50% for untreated cases, although this drops to less than 5% following antibiotic treatment. Currently, disease outbreaks are relatively rare, and they are primarily found in Africa, although historically, cases have been reported throughout Europe and Asia as well.

Tick-borne relapsing fever, or endemic relapsing fever, is isolated to regions containing the vectors and their reservoir hosts. Infection is a result of the direct transfer of *Borrelia* from the tick saliva to the host. The soft-bodied ticks, which are implicated as vectors, feed for only a short duration, and infection of the host occurs very rapidly, as opposed to the extended feedings that are required for transmission of Lyme-disease-causing spirochetes. Relapsing fever is caused by a number of different characterized *Borrelia* species, and most are associated with a species-specific vector. As with louse-borne relapsing fever, cases of the tick-borne variety are uncommon. For example, less than 1000 cases have been reported in the United States in the past 40 years. Nevertheless, it is not likely that tick-borne relapsing fever will ever be eradicated, considering that there are a number of natural reservoirs, and that vertical transmission can occur in ticks.

While the documentation of recurring febrile episodes in a patient is diagnostic for relapsing fever, the rarity of the disease, the variable pattern of recurrences (or the lack of recurrences), and the fact that patients may not recall being bitten by a tick can make diagnosis difficult. Laboratory diagnosis can be helpful in some instances. Organisms can be visualized by microscopy (using Giemsa or Wright stains) in blood smears obtained during a spirochaetemic/febrile phase, or they may be directly viewed using darkfield microscopy. It has been estimated that the detection sensitivity of microscopy is approximately 70%.[4] In addition to direct observation, organisms can be cultured from specimens, and the cultures can then be monitored by microscopy for the growth of *Borreliae*. Aside from microscopic techniques, there have been few advances in relapsing fever diagnosis. This is, for the most part, due to the relatively few outbreaks that occur, and the consequent lack of utility for such tests. Serology is generally not used in diagnosis, and although molecular detection methods involving amplification of specific *Borrelia* genes using the polymerase chain reaction (PCR) have been devised,[5] they are rarely utilized. The low disease prevalence coincides with a low demand for these tests, and it also means that such tests are not considered to be useful for routine differential diagnoses of febrile illnesses.

LYME DISEASE

The causative agent of Lyme disease, *B. burgdorferi*, was first identified in 1982,[6] five years after the description of an epidemic of arthritis cases among children in Lyme, Connecticut. Lyme disease occurs following the transmission of *B. burgdorferi* to a patient via the bite of an infected tick. Infection is often accompanied by a distinctive bulls eye rash, erythema migrans (EM), which occurs in 60–80% of cases, or it may occasionally be associated with acrodermatitis chronicum atrophicans (ACA), which is a rash found on the legs and hands. The disease originally manifests itself with flu-like symptoms, including low-grade fever, myalgia, fatigue, headaches, and arthralgia. In the early stages of the disease, antibiotic therapy is usually successful, but without treatment, the organisms disseminate to a number of different tissues, including joints, neural tissue, and the heart. Chronic disease can then develop, causing a variety of neurological/cognitive malfunctions, along with severe arthritis, which may be exacerbated by autoimmune reactions in the host.[7]

The identification of Lyme borreliae throughout the world has led to the creation of three different genospecies of *B. burgdorferi* sensu lato. All have been implicated with Lyme disease, although each appears to have distinct pathologies. *B. burgdorferi* sensu stricto is found in North America and parts of Europe, and is most often associated with arthritis and disseminated disease. *Borreliae garinii* is most commonly found in western Europe and is more associated with neurological symptoms, whereas *Borreliae afzelii*, which is associated with ACA, is most commonly found in central Europe, Scandinavia, and Asia.[8] In addition to the three major genospecies, there are a number of other emerging species that are phylogenetically related and that have been isolated from ticks, but none has been proven to cause disease in humans.

The antigenic structure of *B. burgdorferi* has similarities to that of relapsing fever borreliae in that they all

undergo antigenic variation. *B. burgdorferi* normally express two major surface lipoproteins, OspA and OspB, while they are within a tick, but upon transfer to a mammalian host, these proteins are down regulated, and a new lipoprotein, OspC, begins to be expressed.[9] *B. burgdorferi* also possesses a number of paralogous gene families, including the *vlsE* genes, which consist of a number of silent cassettes that can be inserted into an expression site. This results in antigenic variations that increase in frequency throughout the duration of infection.[10] The combination of antigenic variation with the paucity of organisms present in late stages of infection may contribute to the establishment of chronic infection.

Lyme disease, which was originally thought to be confined to the northeastern United States and parts of Europe, is now being reported in North and South America, Europe, Asia, and even Australia. This geographical spread brings a concomitant increase in disease prevalence. According to the Centers for Disease Control, in the United States alone, reported incidences of Lyme disease have increased from 2386 cases in 1987, to 12,901 cases in 1997, and to 23,763 in 2002.[11] With such a rise in prevalence, and with the serious sequelae of untreated disease, proper diagnosis becomes increasingly important. Lyme disease diagnosis is still, for the most part, based on clinical findings, including the presence of EM, ACA, and history of a tick bite. Laboratory diagnosis during the early stages of the disease can confirm clinical observations, and considering that organisms are most abundant in host tissues during the production of EM, it is at this time that laboratory confirmation by culture, biopsy examination, or molecular detection is most successful. Although culture is the ''gold standard'' for detection, it is rather insensitive and impractical, particularly during disseminated disease. At this stage, serological and molecular tests gain increased utility. Serological analysis is currently the most commonly used method for laboratory diagnosis, since established recommendations have been set forth for such tests. Despite the utility of serology, false positive results may occur, and false negative results can be common, because a number of patients do not develop immune responses following infection.[12] In addition, serological testing cannot distinguish past from current infections, nor can it indicate clearing of organisms following therapy.

In many instances, PCR is being used as an alternative to serological testing, as it has been shown to be more sensitive and specific. Polymerase chain reaction has been used to detect organisms in skin biopsies, spinal fluid, urine, synovial fluid, and joint tissue. Studies indicate that PCR analysis of biopsies from EM or ACA lesions provides up to 80% and 92% detection sensitivity, respectively.[13] Furthermore, urine specimens from patients with EM show 13% to 100% sensitivity for the detection of *B. burgdorferi* DNA.[14–16] For patients with symptoms of neuroborreliosis, detection of *B. burgdorferi* DNA in CSF has a sensitivity of 17% to 79%, along with 7% to 45% sensitivity from urine specimens from the same patients.[15,17] With respect to patients diagnosed with Lyme arthritis, detection sensitivities from synovial fluid and urine are 85% and 79%, respectively.[15,18] For all disease manifestations, increased detection sensitivity is achieved when analyzing multiple specimen types from a single patient.

The variability in observed assay sensitivities between studies is in part due to the lack of PCR assay standardization. There is currently no consensus regarding which PCR target provides the best sensitivity, but in general, detection methods using chromosomal targets, such as the flagellin gene, appear to be more effective than those targeting plasmid encoded genes, such as the *ospA* gene. Further variation in sensitivity can be caused by differences in the disease stage at which specimens are drawn, as the number of organisms present in the host tends to decrease with extended lengths of infection. Assay sensitivity can also be affected by the disposition of the patients, particularly with respect to administered treatment. Studies have consistently demonstrated decreased detection of organisms following antibiotic therapy. Despite variations in assay sensitivity, most described PCR assays show specificities approaching 100%. False positive results are always a concern with PCR assays, because of the target amplification and the ensuing possibility for contamination, but, nevertheless, PCR has become a routine technique for many laboratories, such that specificity problems resulting from cross contamination can be minimized.

CONCLUSION

While relapsing fever is generally in decline, or is at least limited to a few endemic areas, Lyme disease appears to be rapidly spreading across the globe. The geographical spread coincides with the inception of a variety of new reservoirs and vectors, which is in turn initiating the evolution of new Lyme disease-causing *Borrelia* species. Corresponding with the incidences of each disease and the impact on public health is the fact that only a modest amount of research is being done with respect to treatment and diagnosis of relapsing fever, whereas Lyme disease research is burgeoning. Despite the volume of study being conducted on Lyme disease, both clinical and laboratory diagnosis are far from perfect. The multitude of different symptoms presented, combined with the variety of emerging strains, complicates diagnoses. Neither clinical findings nor serological or molecular laboratory diagnosis is able to detect all forms of disease. Established

serological tests are often challenged by conflicting clinical findings, and molecular testing, while often specific, has yet to be standardized, despite being in use for the past 15 years. Because of the changing face of this disease and its causative agent, it is likely that an accurate and sensitive laboratory diagnosis will always be elusive, and it will take a combination of both serology and molecular detection techniques to provide the greatest chance for success.

Branched DNA Signal Amplification

R. Stefan Ross
University of Essen, Essen, Germany

INTRODUCTION

Techniques for detection and quantitation of a given nucleic acid sequence can be divided into three categories: 1) approaches for target amplification including polymerase chain reaction (PCR), nucleic acid sequence-based amplification (NASBA), transcription-mediated amplification (TMA), or strand displacement amplification (SDA), 2) probe amplification systems such as ligase chain reaction (LCR), and 3) methods that do not alter the number of target molecules but dramatically increase the signal generated by nucleic acid sequences present in the original specimen. One of the signal amplification strategies involves the so-called branched DNA (bDNA) and the following article will attempt to provide a short overview of the basic principles as well as specific clinical and research applications of this technology.

PRINCIPLES OF bDNA TECHNOLOGY

The basic principles of bDNA technology will be described here taking the commercially available VERSANT™ assays (Bayer Diagnostics, Berkeley, CA) for determination of viral loads as an example. After release of genomic DNA or RNA by a lysis reagent, capture of the target nucleic acids to the bottom of a microtiter plate well is mediated by probes termed capture extenders (Fig. 1). Then, a second series of target-specific probes hybridize to various sites of the captured DNA or RNA. These label extenders are designed in such a way that two of them must be bound to adjacent regions of the target to enable efficient hybridization of the preamplifier molecule. The resultant cruciform label extender–preamplifier complex and the incorporation of nonnatural, synthetic nucleotides (i.e., iso-C and iso-G) into selected target and amplification probes significantly reduce the assay background by minimizing nonspecific probe interactions. The bDNA amplifiers as the key element of the whole technology finally hybridize to the preamplifiers. Every bDNA molecule has 15 arms, and three sites for hybridization of alkaline phosphatase-labeled probes are located on each of the branches resulting in a tremendous enhancement of the generated signal. The enzyme catalyzes the dephosphorylation of the chemiluminescent substrate Lumi-Phos Plus™, and the intensity of the light emission is directly proportional to the original amount of target sequence present in the sample. Quantitation is possible by a standard curve defined from preparations containing known concentrations of recombinant DNA.[1–4]

bDNA technology, in principle, can be used for detection and quantitation of every known nucleic acid sequence. The specificity and sensitivity of the methodology, however, largely depend on the judicious design of the probe sets. This task is partly facilitated by a commercial software application (ProbeDesigner™), which allows for the recognition of unwanted nonspecific hybridization events and provides an algorithm for the simultaneous design of probe sets for multiple targets.[5] Because bDNA amplification is a nonenzymatic process that does not change the original amount of target nucleic acid sequences, this technique, in comparison to enzymatically mediated amplification systems, is less prone to contamination, sample-to-sample variation, and the influence of inhibitory substances contained in clinical specimens. On the other hand, target amplification in general still has greater analytical sensitivity than bDNA and provides greater feasibility in design when novel targets are approached because only one appropriate pair of primers and not a whole set of hybridization probes is needed.

INFECTIOUS DISEASE APPLICATIONS

The development and ongoing improvement of bDNA technology during the past decade was mainly driven by the increasing demand for quantitation of nucleic acids in clinical virology. Understanding the natural history and pathogenesis of chronic viral infections caused, for instance, by hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV) has been greatly supported by accurate determinations of viral load. Consequently, measurements of HBV DNA, HCV RNA, and HIV RNA are extensively used in today's clinical practice to monitor the efficacy of antiviral treatment, predict the outcome of therapeutic strategies,

assess disease progression, and detect the potential emergence of drug-resistant viral strains.[6]

HBV DNA Quantitation

For quantitation of HBV DNA, a commercial third-generation assay is available from Bayer Diagnostics (VERSANT HBV DNA 3.0). Results of a multicenter evaluation showed that the specificity of this test was 99.3% using 600 HBV seronegative samples at four different sites. Quantitation was possible between 2×10^3 and 1×10^8 copies HBV DNA/mL and the assay proved to be linear throughout its entire dynamic range. Mean coefficients of variations of 7.5% and 13.6% were established for intra- and interassay imprecisions, respectively. Furthermore, studies revealed that HBV DNA concentrations obtained by bDNA 3.0 differed by less than threefold from the expected values for HBV isolates of genotypes A to F, suggesting that quantitation is not significantly affected by HBV genotypic variability.[7]

Because HBV DNA quantitative units reported by the various commercially available assays currently do not represent the same actual amount of HBV DNA in a given sample, these tests cannot be used interchangeably in the clinical laboratory. Therefore, like bDNA 3.0, all quantitative assays should in future be calibrated against the WHO HBV DNA standard[8] to achieve better comparability of the results and aid in the establishment of reliable, clinically relevant thresholds for HBV DNA loads that are yet poorly defined.[9] bDNA technology in the format of the VERSANT HBV 3.0 assay meets most of the clinical demands for HBV DNA quantitation, but is still not sensitive enough to answer all analytical questions in this field; for example, it is not suited to decide whether healthcare workers who are HBV carriers can be allowed to perform exposure-prone procedures under the strict guidelines recently issued by the UK Department of Health (decision threshold: 1000 copies HBV DNA/mL[10]).

HCV RNA Quantitation

Quantitation of HCV RNA by bDNA technology is possible with the commercial VERSANT HCV RNA 3.0 assay. The performance characteristics of this test were established in our laboratory during the so-called ''beta trials'' before licensing and are given in Table 1.[4] Our findings were essentially confirmed by other studies,[11,12] and showed that the assay, from an analytical point of view, can be used as a routine tool for HCV RNA quantitation in clinical laboratory settings.

Table 1 Analytical performance characteristics of VERSANT HCV RNA 3.0 assay

Specificity (%)	98
Sensitivity (IU/mL)[a]	1000[b]
Reproducibility	
Intraassay [CV (%)][c]	6.8
Interassay [CV (%)]	11.2
Dynamic range (IU/mL)	1×10^3 to 7.7×10^6 [b]
Influence of HCV genotype[d]	None for types 1 to 4

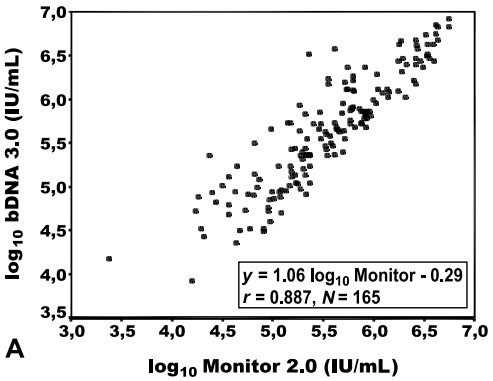
[a]International units/mL (IU/mL) of the first international WHO standard for HCV RNA.[13]

[b]Detection limit stated by the manufacturer: 615 IU/mL.

[c]Mean coefficients of variation (CVs) calculated from non-$\log_{10}$-transformed results.

[d]Two hundred samples were included in statistical analysis: 129 with HCV genotype 1, 21 with genotype 2, 42 with genotype 3, and 8 with genotype 4 HCV isolates, respectively.

Source: Ref. [4].



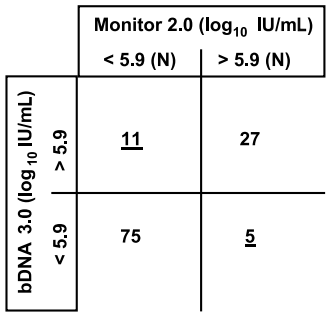


Fig. 2 (A) Scatterplot of $\log_{10}$ HCV RNA IU/mL values as determined by VERSANT HCV RNA 3.0 and Cobas Amplicor HCV Monitor 2.0 assays in 165 clinical samples. In the insert, the conversion equation and the correlation coefficient calculated by nonparametric regression analysis are given.[4] (B) Classification of test results obtained by both methods in sera of 118 patients chronically infected with HCV genotypes 1 and 4 according to the decision threshold of $\log_{10}$ 5.9 IU/mL (i.e., 800,000 IU/mL[14]). Numbers of discrepant results are indicated by underscore.

In contrast to the situation in HBV DNA viral load determinations, commercially available packages for HCV RNA quantitation have already been universally calibrated against an international WHO standard.[13] These attempts, however, did not completely lead to the expected widespread comparability of the results obtained with different methodologies. When testing 165 sera from patients infected with HCV in parallel with both HCV RNA bDNA 3.0 and the PCR-based Cobas Amplicor HCV Monitor™ 2.0 assay (Roche Diagnostics, Branchburg, NJ), we recorded a mean absolute difference between the results of $\log_{10}$ 0.23 (i.e., 1.7-fold) (Fig. 2A). Eleven percent of the paired results differed by even more than threefold,[4] i.e., a deviation that is generally regarded as clinically important in consecutive viral load determinations.[9] Such discrepancies may be particularly problematic in the clinical context if absolute HCV RNA concentrations are used for decision making. For instance, until recently a threshold value of 800,000 IU HCV RNA/mL was applied to tailor the initial duration of antiviral combination therapy in naïve patients chronically infected with HCV genotypes 1, 4, and 5.[14] Agreement between the HCV bDNA 3.0 and HCV Monitor assays in predicting viral loads either above or below 800,000 IU HCV RNA/mL (i.e., $\log_{10}$ 5.9) according to our results was only moderate, because about 14% of the samples were classified differently by both tests (Fig. 2B) and these misclassifications would have led to a wrong assignment of the initial duration of antiviral treatment in a considerable number of patients.[4] Germer and coworkers reported very similar observations,[15] indicating that HCV RNA concentrations close to any clinically defined threshold values should generally be interpreted with caution.

HIV-1 RNA Quantitation

HIV-1 RNA quantitation by bDNA signal amplification with the VERSANT HIV-1 RNA 3.0 assay was assessed in a large multicenter trial preceding U.S. product registration. In this evaluation, the test showed a specificity of 97.6% and a clinical sensitivity between 98.7% and 65.3%, depending on the HIV-1-infected patient's $CD4^+$ T-cell counts. As detection limit, 75 HIV-1 RNA copies/mL were established and the assay was linear up to 500,000 HIV-1 RNA copies/mL. Mean intra- and overall interassays imprecisions were 18.1% and 21.3%, respectively.[16] The test could quantify HIV-1 group M subtypes, but must not be used for detecting other subtypes of HIV-1 or HIV-2 strains.[17]

Commercial assays for quantitation of HIV-1 RNA in clinical samples lack standardization and so far have not been universally calibrated against the appropriate WHO reference preparation, which was available since 2001.[18] Consequently, quantitative values obtained with the third-generation bDNA assay were, on an average, 39% lower than the measurements recorded with the PCR-based Roche Cobas Amplicor HIV-1 Monitor (version 1.5) and the differences were consistent across the whole common reportable range of the two tests.[16] Despite these striking discrepancies, the treatment guidelines of the Department of Health and Human Services for HIV-infected adults and adolescents state that an HIV-1 RNA concentration of 55,000 copies/mL, as determined by either RT-PCR or bDNA, might represent a useful laboratory marker for the decision whether an asymptomatic patient with a $CD4^+$ T-cell count of greater than 350/mm^3 should be treated with antiretroviral agents or instead deferred from therapy.[19]

Other Pathogens

Besides its extensive use for viral load determinations, bDNA signal amplification has not yet gained widespread application in other fields of diagnostic clinical microbiology. Only a few prototype assays were reported for detection and quantitation of pathogens other than HBV, HCV, and HIV, including tests for GB virus C, cytomegalovirus (CMV), *Trypanosoma brucei* species, which cause the human sleeping sickness, and *Yersinia pestis*, the etiological agent of plague.[3,20] bDNA technology was also occasionally used to identify the mecA gene of methicillin-resistant *Staphylococcus aureus* isolates from clinical specimens. The obtained results suggested that the bDNA assay enabled mecA detection directly from blood culture bottles without the need for any subcultivation and was as sensitive and specific as the PCR-based comparative method.[21]

QUANTITATION OF mRNA BY bDNA SIGNAL AMPLIFICATION

bDNA technology during recent years has been increasingly adapted to the requirements of research laboratories and is now, for instance, a powerful tool for high-throughput mRNA quantitation from cell lysates or tissue homogenates. In this format, the assays are appropriate for a variety of research applications covering such different fields as regulation of gene expression, identification and validation of targets, secondary screening of biological agents, in vitro toxicology, metabolic and cell-signaling pathway studies, and cancer biology.[3,22] Although commercial kits for mRNA quantitation by bDNA signal amplification (QuantiGene™) are available from Genospectra (Fremont, CA), users, of course, still have to design a target probe set for the gene of interest. In this respect, they may rely on the help of the already mentioned ProbeDesigner software package, which allows for the prediction of nonspecific hybridization events, thereby reducing the overall assay background.[5]

bDNA SIGNAL AMPLIFICATION FOR IN SITU HYBRIDIZATION

bDNA signal amplification from a principal point of view offers a number of advantages for in situ hybridization (ISH) when compared to alternative PCR-based methods or catalyzed reporter deposition signal amplification: The methodology is not affected by polymerase inhibitors present in tissue specimens or endogenous biotin, intricate cell morphology is better preserved because no high-temperature incubations are necessary, and potential diffusion of amplification products away from the target site is not a significant concern with bDNA ISH, which therefore might provide a more accurate subcellular localization of nucleic acid sequences.[23]

bDNA ISH, e.g., could detect about one or two copies of human papillomavirus (HPV) DNA in cervical cancer cell lines and proved to be highly specific in discriminating cells infected with HPV type 16 from those with HPV type 18 DNA.[23] The same technique was subsequently applied to normal and HPV-infected cervical biopsy specimens and the obtained results led to the preliminary interpretation that bDNA ISH, as an adjunct to conventional histopathology, can perhaps improve future diagnostic accuracy at least in cases of HPV-mediated neoplastic disease.[24]

CONCLUSION

This article attempted to give a concise overview on the basic principles as well as the current clinical and research applications of bDNA technology. The widespread use of analytically reliable bDNA assays for viral load determinations during the past decade considerably increased our knowledge on the natural history and pathogenesis of HBV, HCV, and HIV infections; at present, quantitation of viral nucleic acids is an integral part of the clinical management of patients chronically infected with these pathogens. Notwithstanding its indisputable merits, bDNA technology still awaits the major breakthrough in other fields of diagnostic clinical microbiology and has just started to enter the wide area of possible research applications. At present, however, the future development and fate of bDNA methodology is difficult to predict; thus we will most probably only know in a few years which group of the various prophets is right: the ''bDNA supporters,'' who are envisioning further spread of the technology and are waiting for the creation of new applications by ongoing analytical refinement, or the ''bDNA skeptics,'' who believe that the technique has already reached its inherent limits and, consequently, will be replaced soon by newer and even more powerful approaches for nucleic acid quantitation.

ACKNOWLEDGMENTS

The author is grateful to Mrs. Sigrid Doehler (Bayer Diagnostics, Fernwald, Germany) for providing pdf files of some articles on bDNA signal amplification technology and to Mr. Sergei Viazov, D.Sc., Ph.D. (Essen

University Hospital, Essen, Germany) for critically reading the manuscript.

Brucella spp.

Vito G. DelVecchio
Cesar V. Mujer
Vital Probes, Inc., Mayfield, Pennsylvania, U.S.A.

INTRODUCTION

Brucellae are aerobic, gram-negative, nonmotile, facultative intracellular, non-spore-forming coccobacilli. The genus *Brucella* belongs to the α-2 subgroup of the class Proteobacteria and is composed of six currently recognized nomen species: *Brucella abortus*, *Brucella canis*, *Brucella melitensis*, *Brucella neotomae*, *Brucella ovis*, and *Brucella suis*. Several other strains have been isolated from marine mammals and have been grouped generically as *Brucella maris*.

Among the various nomen species, *B. abortus*, *B. melitensis*, and *B. suis* have been reported to cause human brucellosis, also called Malta fever, a chronic febrile illness characterized by undulating fever, arthritic pains, and some neurological disorders. Currently, there is no acceptable human vaccine, and treatment is via prolonged antibiotic therapy that usually lasts for a year. Human infection occurs by direct contact with tissues and fluids from infected animals, consumption of contaminated dairy products, and inhalation. Brucellosis is also a major zoonotic disease that causes abortion and sterility in wild and domesticated animals. The World Health Organization considers *B. melitensis* as the most important zoonotic agent because it is extremely infectious, partly because of its aerosolic nature. Because of its ability to cause a debilitating disease in humans, it is considered a potent biological warfare agent. It can also bring havoc to the economy when used as a weapon for agroterrorism.

BRUCELLA GENOMES

The *B. melitensis* strain 16M (Biovar 1, ATCC 23456) genome was the first to be sequenced, closed, and annotated from among the six *Brucella* nomen species.[1–4] This was followed by the genome of *B. suis* strain 1330 (Biovar 1).[5] The total genome size of *B. melitensis* is 3.30 Mb, similar to that of *B. suis* (3.31 Mb). The genome of *B. melitensis* is distributed over two circular chromosomes of 2.12 and 1.18 Mb, whereas that of *B. suis* is distributed at 2.11 and 1.20 Mb.[4,5] Their chromosome maps can be accessed at NCBI (http://www.ncbi.nlm.nih.gov/genomes/MICROBES/Complete.html).

Some general features of the *B. melitensis* and *B. suis* genomes are presented in Table 1. The *B. melitensis* genome encodes approximately 3197 ORFs whereas that of *B. suis* encodes 3388 ORFs. A GC content of 57% was noted for both species. In *B. melitensis*, the origins of replication are similar to those of other α-Proteobacteria. Housekeeping genes, including those involved in DNA replication, transcription, translation, core metabolism, and cell wall biosynthesis, are distributed on both chromosomes. Type I, II, and III secretion systems are absent, but genes encoding sec-dependent, sec-independent, and flagella-specific Type III, Type IV, and Type V secretion systems as well as adhesins, invasins, and hemolysins were identified.[4,5]

B. melitensis and *B. suis* genomes shared extensive similarity and gene synteny. Greater than 90% of their genes showed 98% to 100% identity at the nucleotide level. Those genes with less than 95% identity included mostly the hypothetical genes, the *UreE* urease component, the outer membrane proteins, membrane transporters, a putative invasin, and Shd-like adhesins. These genetic differences may significantly contribute to the differences in pathogenicity or host preference between the two organisms. A total of 7307 single nucleotide polymorphisms were noted between *B. melitensis* and *B. suis*. This interspecies frequency is lower than some of the intraspecies frequency reported in some other sequenced organisms.[5] Based on whole genome nucleotide alignments, 42 *B. suis* and 32 *B. melitensis* genes are completely absent from each other's genome. This difference may be due to insertion or deletion events that possibly took place during the course of the species evolution.[6,7] Overall, analysis of the *Brucella* genomes has not revealed any traditional virulence factors, toxin genes, or pathogenicity islands.[8] A study of the virulence mechanism of Brucellae is currently an active area of

research that may be deciphered by comparative proteomics analysis.

BRUCELLA PROTEOMES

Proteome refers to the entire set of proteins expressed by an organism at a specific time and under defined environmental conditions. Early studies of the proteomes of laboratory-grown *B. melitensis* strains B1115 and *B. ovis* were conducted by Teixeira-Gomes et al.[9,10] on silver-stained 2-DE gels. In these and other previous 2-DE studies, protein spots were identified by Edman sequencing and Western blotting (for a review, see Ref. [11]). An examination was also made of the proteomes of *B. melitensis* 16M and *B. abortus* grown under conditions of heat, acid, and oxidative stress. These early studies demonstrated that differentially expressed proteins were either induced or repressed under these conditions. Using traditional biochemical approaches, about 54 proteins were identified.[11]

The availability of a completely sequenced and annotated *B. melitensis* genome paved the way for a rapid global analysis of its proteome (Fig. 1).[12] Using whole-cell protein extracts of laboratory-grown *B. melitensis* 16M, a comprehensive proteome initiative was undertaken using a series of 2-D gel electrophoresis of narrow overlapping IPG strips from pH 3.5 to 11.0 and MALDI-TOF MS (for a review, see Ref. [13]). To date, more than 1000 nonredundant protein spots were detected and 557 proteins were identified representing 232 discrete ORFs. As shown in Fig. 2, the corresponding ORFs of the identified proteins are distributed evenly between each of the two circular *B. melitensis* chromosomes, indicating that both replicons are functionally active.

A global comparative proteome analysis of the virulent 16M and vaccine Rev1 strains of *B. melitensis* has been reported.[14] Significant differences in the expression levels of several proteins involved in various metabolic pathways especially those regulating iron acquisition, sugar binding, protein biosynthesis, and lipid degradation

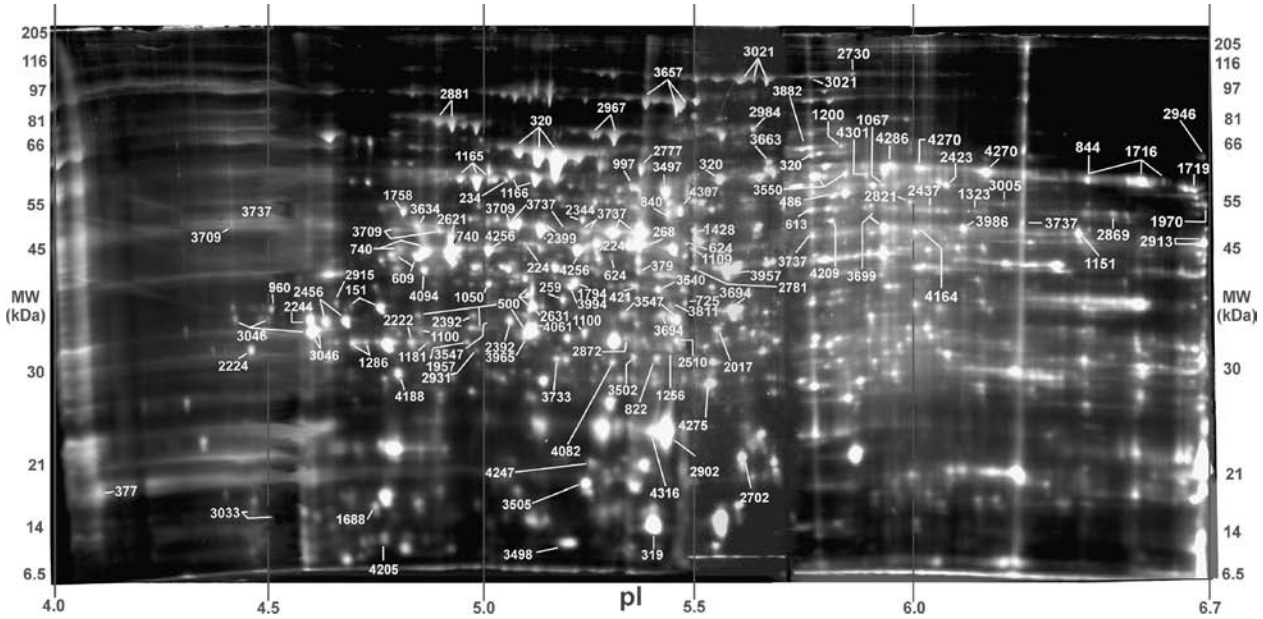

Fig. 1 Partial global proteome map of *B. melitensis* 16M. The map is a manually seamed, composite image of four narrow pH range 2-D gels, each containing 40–120 μg total protein extracted from chloroform-killed cultures of *B. melitensis* 16M. Gels were stained with SYPRO® Ruby for 12 hr before imaging under 470-nm light. (From Ref. [11].) (*View this art in color at www.dekker.com.*)

were noted. One major pathway associated with the survival of pathogens inside the host cell is that regulating iron metabolism. During infection, a macrophage reduces iron by producing chelating agents and actively exporting iron from the phagosome where the pathogen multiplies. In response, the pathogen synthesizes proteins designed to compete with the host for iron. One such protein is bacterioferritin whose accumulation is significantly greater in the vaccine strain Rev1 than in the virulent strain 16M. Likewise, Rev1 overexpressed an iron-regulated outer membrane protein and an iron (III)-binding periplasmic proteins which are normally derepressed during low iron availability. Such a misregulated system leads to unnecessary expenditure of energy and as a consequence Rev1 upregulated other energy-generating pathways, i.e., β-oxidation of fatty acids and protein synthesis to generate more reducing equivalents for the production of ATP. The significant accumulation of enoyl coenzyme A (CoA) hydratase and acyl-CoA dehydrogenase in Rev1 indicated the upregulation of fatty acid

metabolism. Both enzymes are involved in the synthesis of acetyl-CoA that consequently enters the TCA cycle. Further metabolic pathway analysis will unravel more phenotypic differences including virulence and host preference among the various nomen species of *Brucella*.

DIAGNOSIS

The diagnosis of human brucellosis is conventionally performed using serological and bacteriological tests. The Rose Bengal test,[15] the serum agglutination test, and the complement fixation test are the most accepted serological tests used worldwide. These tests are based on a reaction between *Brucella* cell antigen and antibodies produced in response to the infection. The accuracy of the Rose Bengal test is over 99%, but it can give false positive results with sera from patients infected with *Yersinia enterocolitica* or other cross-reactive organisms.[16] In contrast, the bacteriological diagnosis is based on the recovery of bacteria from the patient's blood. The biphasic method which uses both solid and liquid media in the same container has been recommended and is widely used.[17] Using this method, it may take from 3 to 35 days to determine whether the hemoculture being tested is positive.[18] The variation of bacterial growth in blood culture is due to a number of factors including the culture medium, the number of circulating bacteria, the time of blood collection, the volume of blood used for culture, the host's immune response system, and the intracellular characteristics of the bacteria.[19]

Molecular-based assays using PCR have been developed that can be used in detecting various nomen species of *Brucella*.[20–23] Compared to standard identification methods, PCR-based assays are fast, less expensive, highly accurate, and safe to perform. For instance, with real-time PCR specific for *B. abortus*, *B. melitensis*, and *B. suis*, the assay can be accomplished in less than 30 min.[24] This assay utilizes an upstream primer that is derived from the 3′ end of the genetic element *IS711*, whereas the downstream primers and probes are designed from signature sequences specific to a species or biovar. In addition to PCR-based assays, Western blot analysis of cytoplasmic proteins has the potential to differentiate past from subclinical infection.[25] Despite their advantages, molecular diagnostic tests have not been approved for clinical use by FDA.

CONCLUSION

The sequencing and complete annotation of the *Brucella* genomes have paved the way for a rapid and comprehensive characterization of the *Brucella* proteomes. By globally defining differentially regulated biochemical pathways, it is possible to identify factors that confer host preference, survival mechanisms inside host macrophages, and attenuation of virulence among *Brucella* species. Further, proteomics data may be used in the development of diagnostic assays, antimicrobials, and next generation of vaccines. This is important as there is no effective human vaccine and all available vaccines are pathogenic to humans. Future studies on the secretome and membrane proteins will also be most valuable in determining pathogenicity and host preference. The advances in genomics and proteomics have given rise to the development of powerful and highly specific diagnostic tools that may soon be used in conjunction with conventional methods for the rapid and accurate detection of *Brucella* infection in humans.

Brugada Syndrome

Robert Roberts
Ramon Brugada
Baylor College of Medicine, Houston, Texas, U.S.A.

INTRODUCTION

Since its initial description in the early 1990s, Brugada syndrome has attracted progressively more attention in the medical community. First, the disease takes the life of individuals in their 40s, during the most productive years. Second, the delineation of the disease coincided with a burst of activity in molecular biology and at the beginning of a golden age with the Human Genome. Third, once thought to be rare, the Brugada syndrome is now recognized to have a relatively high incidence, particularly in Southeast Asia. Thus, the past decade has witnessed a rapid growth in our understanding of the cellular and genetic basis of Brugada syndrome.

Basic research into the mechanisms underlying the Brugada syndrome is in its infancy and the next 10 years will provide a greater understanding of this lethal disease. What started as an electrocardiographic curiosity has become a great challenge for electrophysiologists, cardiologists, biophysicists, and molecular biologists.

CLINICAL FEATURES AND DIAGNOSIS

Brugada syndrome is characterized by a typical electrocardiographic pattern of ST segment elevation in the precordial leads, with or without right bundle branch block, malignant arrhythmias, and a structurally normal heart (Fig. 1).

It is certainly a challenge to risk stratify patients with Brugada syndrome. There have been many uncertainties which can only be clarified with further experience as more patients and families are being identified and followed for clinical outcome. Electrocardiographic criteria are used to try to risk stratify patients, but there is some disagreement on the criteria to be applied. Some of the conclusions are as follows. Symptomatic patients are at high risk. There is a consensus that symptomatic patients with documented ventricular fibrillation have close to a 50% chance of having another event within 5 years. If the patient experienced syncope, the recurrence rate is 20%.[1] Individuals with normal ECG at baseline and abnormal after antiarrhythmics have a good prognosis. This is the other side of the spectrum. Individuals that have the mutation but require an antiarrhythmic challenge to develop the abnormal electrocardiographic pattern probably also have a genetic background that is protecting them. A note of caution is required in this analysis; many of these are relatively young individuals, much younger than the symptomatic group. What will happen in the future remains unknown.[1] Individuals with an electrocardiographic pattern that normalizes are at the same risk as patients with a consistent ECG abnormality. If the substrate for arrhythmias depends on the transmural voltage gradient, one might postulate that patients would develop reentrant arrhythmias more often with the ST segment elevation. It is of course possible the ST segment elevation appears just moments before the episode of ventricular fibrillation. More data and patients will be required to assess the risk of transient vs. continuous ST segment elevation.

Those with a coved-type ECG are at higher risk than saddleback type. Actually, our group does not accept a diagnosis of Brugada syndrome without a coved-type ECG either before or after sodium blocker drug challenge. Again, this may correspond to the severity of the defect that throws off the balance of currents during the early phases of the action potential, as previously discussed. Our current understanding of basic mechanisms is that the substrate for VT/VF is unlikely to be present when only a saddleback type of ST segment elevation is manifest, but more likely in the presence of a coved type. Consistent with this hypothesis is the clinical observation that saddleback ST segment elevation usually progresses to a coved type before VT/VF is observed.

The use of potent sodium channel blockers to diagnose patients at risk for Brugada syndrome has raised some controversy. There is a wide variety of medications used to unmask the disease. False negative results have been reported with procainamide and flecainide.[2] False positive results have been reported with flecainide in patients with LQT3.[3] The value of the antiarrhythmic challenge will be able to be ascertained once more people are tested and genotyped for mutations.

GENOTYPE–PHENOTYPE CORRELATION

The myocardium is a heterogeneous milieu with multiple cellular subtypes having different functional and electrophysiological properties.[4] These electrophysiological distinctions are due to variations in the expression of ionic currents, especially between epicardium and endocardium. These differences contribute to the development of ST segment elevation and the substrate for reentrant arrhythmias. Experiments involving the arterially perfused right ventricular wedge preparation have shown the epicardial action potential notch is responsible for inscription of the electrocardiographic J wave and accentuation of the notch leads to amplification of the J wave, resulting in an apparent elevation of the ST segment.[5] This has been shown in pathophysiological states such as hypothermia, where an increase in the notch in the epicardium, but not the endocardium, causes an elevation of the J point and ST segment in the electrocardiogram. If the epicardial action potential repolarizes before that of the endocardium, the T wave will remain positive and the electrocardiogram will show a saddleback type of ST segment elevation. Further accentuation of the pathophysiological state will accentuate the notch and prolong the epicardial action potential so that it repolarizes after the endocardial response, thus leading to inversion of the T wave. The result is an electrocardiogram with a coved ST segment elevation and a negative T wave as observed in Brugada syndrome shown in Fig. 1. Progressive accentuation of the notch will eventually lead to loss of the action potential dome and marked abbreviation of the epicardial response.[6] The end result will be the creation of a transmural gradient between epicardium and endocardium, and thus the substrate for reentrant arrhythmias.[7] This is the mechanism believed to induce ventricular arrhythmias and sudden death.

Experimental models of the Brugada syndrome created by exposing right ventricular wedge preparations to a variety of pharmacological agents have highlighted the importance of I_{to}. The high expression of I_{to} during phase 1 of the action potential plays a pivotal role in the electrocardiographic pattern of the Brugada syndrome. It is the balance of currents active during phase 1 that determines the degree of ST segment elevation. The use of quinidine, a class IA antiarrhythmic with action to block I_{to}, among other currents, has been shown to be capable of restoring the action potential dome in epicardium, thus normalizing the ST segment elevation.[6] It is certainly a finding which could have clinical and therapeutic relevance. There is a group who advocate the use of this antiarrhythmic to treat Brugada syndrome[8] and there has been a case report in the literature of decreased ST elevation with the use of quinidine.[9]

Sodium channel blockers also increase the notch of the epicardial action potential and thus give rise to an ST segment elevation in the wedge preparation.[6] This has also proved useful in clinical practice as a form of diagnostic tool to unmask the electrocardiographic pattern in individuals suspected of having the Brugada syndrome. Sodium blockers such as ajmaline, procainamide, flecainide, and pilsicainide are now being used as diagnostic test to identify individuals with concealed Brugada syndrome.[10]

Two intriguing questions have arisen in recent years. One is why is this electrocardiographic pattern only present in the right precordial leads, and the second is why the Brugada phenotype is so much more prevalent in males vs. females of Southeast Asian origin. In the experimental myocardial, I_{to} is much more prominent in males than in females[11] and is much greater in the right ventricle than in the left ventricle of the heart.[12]

GENETICS

The first gene responsible for the disease was identified in 1998 by Chen and coworkers.[13] This gene, the α-subunit of the cardiac sodium channel gene, *SCN5A*, is

responsible for the phase 0 of the cardiac action potential. The identification of mutations in *SCN5A* causing the disease and the decrease in availability of sodium ions indicates that a shift in the ionic balance in favor of I_{to} during phase 1 of the action potential is the determinant of the disease.[7] To date, this is the only gene linked to Brugada syndrome. *SCN5A* has been identified in approximately 25% of the patients with Brugada syndrome, indicating there is at least another gene responsible for the disease. In 2002, a second locus on chromosome 3 was identified, although the gene responsible has not been identified.[14] Close to 60 different mutations in *SCN5A* have been reported to date and approximately half of them have been biophysically characterized. The common denominator in the analysis of the mutations is the decrease in Na current availability by two main mechanisms: lack of expression of the mutant channel, or acceleration of inactivation of the channel.[15] In the case of *T1620M* mutation, the alteration in the ionic currents worsened at higher temperatures.[16] This has clinical significance as several cases of ventricular fibrillation in patients with Brugada syndrome have been precipitated during febrile states.[17–19]

Brugada syndrome is inherited as an autosomal dominant disorder and usually the disease manifests itself in individuals at risk in their 40s. However, it has also been described as causing sudden infant death syndrome (SIDS).[20] In addition to Brugada syndrome, mutations of *SCN5A* can lead to a large spectrum of phenotypes, including long-QT syndrome (LQT3),[21] isolated progressive cardiac conduction defect,[22] idiopathic ventricular fibrillation,[13] and sudden unexplained nocturnal death syndrome (SUDS or SUNDS).[23] These are all considered allelic diseases, caused by mutations in the same gene. Electrocardiographic, clinical, and biophysical data have clarified the relationship between these diseases in part.

When comparing to LQT3, Brugada syndrome could be considered a mirror image. Biophysical data indicate that LQT3 mutations cause a delayed inactivation of the channel,[21] which is exactly the opposite to Brugada syndrome, where there is an accelerated inactivation.[16] The difference between the two diseases is, however, difficult to identify in some cases, and one family was described manifesting the phenotype of both Brugada and long-QT syndromes.[24] Likewise, the line between progressive conduction disease and Brugada syndrome is closer than ever after the publication of a paper with a family displaying both diseases.[25] Whether they represent variable phenotypic expression of the same disease is difficult to ascertain. All affected family members in this family, with Brugada syndrome or conduction disease, had a mutation that proved lethal to some of its members. This certainly raises important issues regarding therapy, prevention, and risk stratification.

Recent studies have shed some light on the distinctions or lack thereof between Brugada syndrome and sudden unexpected death syndrome (SUDS) in Southeast Asia. Sudden unexpected death syndrome is very prevalent in Southeast Asia. In countries such as Thailand, it is believed to affect up to 1% of the population, and it is the most common cause of death in young males, second only to car accidents.[26] The patients commonly die at night and the male-to-female ratio is on the order of 10:1. Electrocardiographically, the disease is identical to Brugada syndrome. It is also caused by mutations in *SCN5A* and biophysical data indicate a nonworking *SCN5A* or accelerated inactivation.[23] These characteristics are similar to those of the Brugada syndrome, indicating they are the same disease.

TREATMENT

The treatment of choice is an indwelling defibrillation. The question is who should receive it. The most controversial issue is the value of electrophysiological study as an indicator of prognosis. Studies from Priori et al.,[2] Kanda et al.,[27] and Eckardt et al.[28] have not found an association between inducibility and recurrence of events. Our data of close to 700 patients indicate that EP study inducibility is prognostic of risk. The use of electrophysiological data is probably not clinically necessary in the patient who has recovered from sudden cardiac death. These patients require a defibrillator. The controversy is how aggressive to be with asymptomatic patients. There is no doubt that asymptomatic patients are also at risk. Brugada syndrome generally affects individuals in their 40s, despite the fact that the genetic predisposition is present since birth. What determines the likelihood of a patient becoming symptomatic is at present unknown. Unfortunately, all symptomatic patients were previously asymptomatic for many years. Identifying which group will become symptomatic is a critically important preventative measure. Our group has shown that asymptomatic patients who are inducible have a 14 % chance of having an event. If they are noninducible they have less than a 2% of chance of having an event. We therefore advocate the implantation of a defibrillator in asymptomatic inducible patients. The remainder require close follow-up until evidence-based data provide further guidance for risk stratification.

GENETIC COUNSELING

When studying a monogenic disease such as Brugada syndrome, it must be understood that the presence of the mutation does not always mean the person will develop

the disease (varying penetrance). Brugada syndrome is inherited as an autosomal disorder which means the disease will be present in each generation and 50% of the offspring are expected to inherit the mutant gene and thus be at risk of developing the disease. Like most autosomal dominant disorders, penetrance is age dependent tending to increase with age. Several factors remain unknown as to why onset of the disease is so age dependent. Genes continuously interact with the environment and determine the phenotype, its variability, and its age of onset. The family should undergo ECG screening and genetic testing if possible. However, it is embedded in the general population that genetics determines everything, and they expect the worse from a positive diagnosis. Genetic counseling becomes, in this issue, the most important tool to put this family back to a normal lifestyle.

SCREENING FOR THE GENETIC DEFECT

Genetic screening in countries such as the United States is performed only as a research procedure. In Europe, genetic screening has been accepted in certain countries as a routine medical procedure. It is of note that only one gene, the cardiac sodium channel, has been identified and thus may only account for a small percentage of inherited Brugada syndrome. A second locus has been identified on chromosome 3 but the gene has not been isolated. We recommend sequencing the whole of the cDNA for cardiac sodium channel. This is necessary as over 60 mutations have already been identified in the sodium channel to be responsible for Brugada syndrome. It is recommended that all of the exons be amplified from genomic DNA. The sequencing primers are available online in GenBank.

CONCLUSION

The past decade has witnessed the identification of a new clinical entity responsible for sudden death in the young and the evolution of a strategy to diagnose, risk stratify, and treat patients with this syndrome. This has been possible thanks to the efforts of many centers around the world and to the collaboration of hundreds of physicians. This is still a very new disease, with a high social impact because it involves death of relatively young individuals. Through research and continued collaboration among the basic and clinical groups involved, we look forward to advances that will enable us to better identify those at risk and provide the means to treat them more effectively, so as to reduce the burden of this disease on the affected families.

Burkholderia pseudomallei

Sumalee Tungpradabkul
Mahidol University, Bangkok, Thailand

INTRODUCTION

Burkholderia pseudomallei is a causative agent of melioidosis, an infectious disease being recognized increasingly as an important cause of morbidity and mortality in many regions of the world. The organism is a free-living environmental saprophyte bacterium that is limited in its distribution to tropical, subtropical, and in endemic areas especially in the tropical regions of Southeast Asia and in the northern parts of Australia. The increase of worldwide travel and spreading of *B. pseudomallei* to humans and animals results in the potential for melioidosis to be found around the world. The organism is commonly found in water and soil and is usually transmitted to humans through skin abrasion or by respiratory route.[2] Infection by this organism exhibits interesting clinical features including its ability to cause severe disease, resulting in highly fatal septicemia. The incubation period can be days to many years after infection. This disease affects all age groups in both sexes[3] and could be also found in healthy person or in immunodeficient conditions such as diabetes mellitus.[4] Because this disease may be acute or chronic and can be symptomatically confused with other disease and septicemia caused by other gram-negative bacteria,[2] the most reliable and simple diagnosis is bacterial culture using selective medium. The disadvantage of using bacterial culture is that it is time consuming and the result obtained is often too late to be useful. Moreover, the method is limited to identify noncultivated bacteria and to distinguish the closely related species such as *Burkholderia cepacia*, *Burkholderia mallei*, and *Burkholderia thailandensis*, a nonvirulent species, as well. In this article, the development of diagnosis methods including the advanced knowledge of genomic and proteomic study will be therefore discussed.

BACTERIOLOGICAL CLASSIFICATION

Burkholderia, formerly called *Pseudomonas* in homology group II, was transferred to a new genus (*Burkholderia*) including *B. cepacia*, *B. pseudomallei*, *B. mallei*, and *Burkholderia pickettei* in 1992 by Yabuuchi et al.[5] using 16S rRNA sequence, DNA–DNA homology values, cellular lipid and fatty acid composition, and phenotypic character. Recently, a new species, *B. thailandensis*, is also classified in the *Burkholderia* genus.[6]

B. pseudomallei is gram-negative rod, nonacid-fast, non-spore-forming, and has bipolar flagella when stained with Sudan black. The organism is a causative agent of melioidosis. For a recent review, see Ref. [1].

B. cepacia, which is placed within the genus *Burkholderia*, has emerged as an increasingly important opportunistic pathogen, particularly in relation to patients suffering from cystic fibrosis.[7] There are several distinct biochemical characters to separate *B. cepacia* from *B. pseudomallei*. However, there are some evidences indicating the similarities of these two species such as the same fatty acid pattern and the same pH optimum for their phosphatase activity.[5] Diagnostic bacteriology concerning *B. pseudomallei* and *B. cepacia* is attracting much attention in melioidosis areas.

B. mallei is a nonmotile, gram-negative rod-shaped bacterium that stains irregularly with methylene blue.[8] In contrast to *B. pseudomallei*, growth of *B. mallei* is more slowly on nutrient agar. Like other *Burkholderia* genus, *B. mallei* is an obligate aerobe. The colonial appearance of *B. mallei* overlaps in appearance with 24-hr *B. pseudomallei* colonies and it is difficult to distinguish them. *B. mallei*, a causative agent of glanders disease, is a seriously infectious disease in equine.[8] Human glanders is rare but can be found primarily in veterinarians, horse and donkey caretakers, abattoir workers, and laboratory workers.[9] *B. mallei* and *B. pseudomallei* are very similar with respect to their nutritional, biochemical, and genetic properties, and in addition, glanders bears a striking resemblance to melioidosis both clinically and pathologically. However, they are epidemiologically dissimilar.

B. thailandensis is a new species which is found in soil isolates (environmental isolates) from the northeastern Thailand. This species was classified in the *Burkholderia* genus in 1998 by Brett et al.[6] There are some evidences which support the significant genotypic dissimilarities exhibited between this organism and the true *B. pseudomallei* strains. Although this organism is almost identical to *B. pseudomallei* in terms of morphology and antigenicity, some differences could be demonstrated. The significant differences in the sequences of 16S rRNA

DOI: 10.1081/E-EDGP 120025615

gene,[10] the exoenzyme production,[10] the flagellin gene,[11] and the hamsters virulence are seen when compared between these two species.

GENOME STRUCTURE

Recently, the complete three genomic sequences of the genus *Burkholderia* have been determined. All are virulent species—*B. cepacia*, *B. pseudomallei*, and *B. mallei*. The *B. cepacia* (the former name) or *Burkholderia cenocepacia* genome consisted of three chromosomes of 3.87, 3.22, and 0.88 Mb with a total size of 8.1 Mb. The G+C content of this genome is 66.9%. The genome of *B. pseudomallei* strain K96243 is 7.24 Mb, with a G+C content of 68.06% consisting of two chromosomes of 4.07 and 3.17 Mb.[12] These genome data have been produced by the *B. cenocepacia* and *B. pseudomallei* Sequencing Group at the Sanger Institute and can be obtained from ftp://ftp.sanger.ac.uk/Projects (accessed November 2003). In *B. pseudomallei* genome, there are approximately 7000 open reading frames, with 60% code for proteins of unknown function. There are no plasmids. The *B. mallei* strain ATCC23344 has a smaller genome of about 5.9 Mb and 5000 open reading frames.[13] The *B. mallei* genome data can be obtained from the Institute for Genomic Research (TIGR) Web site at http://www.tigr.org (accessed November 2003). The main differences between *B. pseudomallei* and *B. mallei* are in the cell envelope genes, which are more in *B. pseudomallei*, and in the energy metabolism genes as well. *B. pseudomallei* also has very few insertion sequences (IS) compared with *B. mallei*. This is consistent with *B. pseudomallei*, the ancestral organism of *B. mallei*, which has become an obligate pathogen.

To date, the proteomic profiles of *B. pseudomallei*, both extracellular and intracellular proteomes, are under investigation. However, many genes with coding regions have been studied and the sequences are available in the public databases.

IDENTIFICATION AND DIAGNOSIS

Bacteriological Examination

Isolation and identification of *B. pseudomallei* by cultivation remains the method of choice for definitive diagnosis of melioidosis. It is relatively simple and economical to perform. It needs neither elaborate nor expensive equipment but requires experienced personnel, particularly in the interpretation of the results. Its main drawback is that it takes at least 3–4 days to obtain the results, and by that time, it may be too late for successful management, as a high percentage of patients admitted for acute septicemia die within 24–48 hr of admission. Recently, an automatic BacT/Alert® nonradiolabeled blood culture system can be used to overcome this problem. Culture of *B. pseudomallei* was detected to be positive approximately 62% within 24 hr and 90% within 48 hr.[14] Although the use of a sensitive automated system has considerably cut down the incubation time normally required for the less sensitive semiautomatic or manual systems, its remaining drawbacks are the running cost and its availability only in large hospitals.

Some clinical specimens, such as throat swab and sputum, are generally heavily contaminated by other organisms. The use of selective media, a modified Ashdown medium containing additional chemicals such as colistin on MacConkey's agar or crystal violet, glycerol, neutral red, and gentamicin on trypticase soy agar, has been devised for isolation of *B. pseudomallei* from clinical specimens.[15] Availability of a costly API 20NE test panel has considerably simplified the identification of *B. pseudomallei*. However, the API test has been reported to misidentify for *Chromobacterium violacium* and other bacteria.[16]

However, four species—*B. pseudomallei*, *B. mallei*, *B. cepacia*, and *B. thailandensis*—are similar in many biochemical properties. To differentiate *B. pseudomallei* from *B. mallei*, motility assay is the method used to distinguish these organisms because *B. mallei* is nonmotile as a result of a lack of flagella. To distinguish *B. pseudomallei* from *B. cepacia*, the Minitek disc system was developed in 1992 as a tool for the differentiation.[17] In case of *B. thailandensis*, the ability to assimilate L-arabinose by *B. thailandensis* is used to differentiate this organism from *B. pseudomallei*.[18] At present, other specific methods based on immunology and DNA technology have been developed to use in identification and diagnostic detection of *B. pseudomallei*.

Immunological Diagnosis

Rapid and specific immunological diagnosis is used to overcome the problem of time-consuming bacteriological examinations. However, regardless of the detection of antibodies or antigens, with the immunological assays, one needs highly specific reagents. Several immunological assays have been developed and used for the detection of either *B. pseudomallei* antibodies or antigens (for review, see Ref. [19]).

Antibody detection

The first method is agglutination, which is simple but gives low sensitivity in detecting antibody to *B. pseudomallei*. In 1970, two methods, the complement fixation test (CF)

and the indirect hemagglutination test (IHA), were developed. An IHA test is still being widely used in many endemic areas of infection. One of the main drawbacks of these two assays that limit their value in clinical situations is the presence of background antibody in some healthy individuals in the endemic area. This is largely attributable to unrecognized subclinical infection in these individuals. In 1981, Ashdown had developed indirect fluorescent antibody staining (IFA) by applying immunofluorescence to detect the antibody in human serum after infection. The IgM antibody could be detected rapidly by fluorescence electroscopy. This method has been very useful for screening of melioidosis. The disadvantages of the method are the expensive microscopy and the need for skilled persons to interpret the results. Enzyme-linked immunosorbent assay (ELISA) has sensitivity, specificity, stable inexpensive reagents, and simple equipment, which is appropriate for use in determination of antibody present in melioidosis patients in developing country. This method has been performed to detect antibody to crude antigen, exotoxin, and endotoxin. Other detection methods such as gold blot have also been developed to detect IgM and IgG antibodies. However, the method has not been evaluated for their clinical usefulness in a large-scale field trial. More recently, recombinant antigens specific for *B. pseudomallei* have been produced and appeared to be highly specific and useful for the diagnosis of melioidosis.

Antigen detection

This approach is more logical and is superior to antibody detection because it indicates active disease. Many immunological methods have been developed for the detection of *B. pseudomallei* antigen, including the detection of soluble secreted product in blood and urine, and the detection of whole organisms in pus, wound, sputum, and throat swabs. The first method was undertaken by Ismail et al. in 1987, when they developed a monoclonal antibody-based assay for the quantitation of exotoxin. This assay could detect toxin in the range of 16 ng/mL of culture supernatant fluid. Similarly, in 1990, Wongratanacheewin et al. have developed a polyclonal antibody-based avidin–biotin ELISA which could detect *B. pseudomallei* antigens in the culture filtrate at a concentration as low as 4 ng/mL. However, both methods have never been evaluated in real clinical situations. More recently, a highly sensitive assay was developed for the detection of antigen, most likely the LPS at a concentration of 12.2 ng/mL, in the urine of patients with systemic and localized infection. When applied to clinical specimens, a sensitivity of 81% and a specificity of 96% have been achieved. The assay is, however, more complicated and more costly to perform and thus may not be very practical for routine use in smaller health centers with a limited health budget. Recently, another antigen-detecting assay based on the use of monoclonal antibody reactive against 200-kDa antigen secreted by *B. pseudomallei* was developed. This sandwich ELISA detection was shown to be highly reliable giving 75% sensitivity and 95% specificity. Other assay systems have been developed and evaluated including latex agglutination and immunofluorescence. The former is not sensitive enough for routine use and needs prior concentration, whereas the latter requires a fluorescent microscope that is not readily available in most laboratories in the endemic area.

Molecular Diagnosis

Because in a medical microbiological laboratory, pathogenic microorganisms particularly need to be identified under killed conditions, molecular diagnosis in different clinical specimens has been successfully used for the diagnosis of a large number of infectious diseases of man and animals and, more recently, evaluated for its reliability in melioidosis. In detection of melioidosis, the hybridization technique does not have sufficient sensitivity[20] and therefore in more recent years, the PCR approach has been more commonly performed with satisfactory results (for review, see Ref. [21]). Different sets of specific primers have been evaluated including the regions in the 23S rRNA, 16S rRNA, a junction between 16S and 23S rRNA, ribosomal protein subunit 21 (rpsU), and specific sequences designed from a specific DNA region. Using these specific primers, as few as a single bacterium present in the clinical specimens such as blood samples[21] or spleen tissue samples[22] can be successfully amplified in laboratory scale and detected with sensitivity approach to 100%. However, none of these has been subjected to critical evaluation in the real clinical situation. Because low numbers of bacteria in samples are suspected to be one of the causes of the low sensitivity of PCR, the amount of bacteria in blood of around half of septicemic melioidosis patients is beyond detection. Adding steps for concentrating the bacteria from blood could definitely improve the sensitivity.[21]

Molecular diagnosis method for discriminating among the three virulent species, *B. pseudomallei*, *B. cepacia*, and *B. mallei*, is more interesting. PCR-RFLP of the flagellin gene sequence has been applied for identification of *B. pseudomallei* and *B. cepacia* from the clinical isolates.[23] Surprisingly, the molecular system based on the flagellin gene cannot be applied for differentiation of *B. pseudomallei* and *B. mallei*,[24] although *B. mallei* is a nonmotile species. The PCR-based differentiation of the 23S rDNA sequence between *B. pseudomallei* and *B. mallei* has been reported using a species-specific primer

in which one nucleotide is substituted for a *B. mallei* template. Recently, PCR-RFLP based on a specific DNA fragment has been developed to differentiate *B. pseudomallei* and *B. mallei*.[25] Although these methods have never been evaluated in real clinical situations, these could be applied for epidemiological study and medical microbiological laboratory in identifying under kill conditions or noncultivation pathogenic bacteria as well. More recently, the PCR based on specific flagellin gene primers can be applied to epidemiological identification of *B. pseudomallei* and *B. thailandensis* and the mixed population of these two species as well.[26] The difference between the 16S rRNA gene sequences of *B. pseudomallei* and that of *B. thailandensis* is only 1%, and it is therefore not discriminative enough to distinguish the two species. The groEL gene sequence is better for distinguishing between *B. thailandensis* and *B. pseudomallei*, and the GroEL amino acid and groEL nucleotide sequences of this single gene locus may potentially be useful for a two-tier hierarchical identification of medically important *Burkholderia* at the genus and species levels.[27]

CONCLUSION

Melioidosis undoubtedly qualifies as an emerging infection because there is no doubt that it has been recognized more frequently during the past two decades, both within established endemic areas and elsewhere. This is probably largely because of greater familiarity with the organism and the disease it causes and of improvements in laboratory knowledge and facilities. Our current understanding of the molecular structure in the genome level of *B. pseudomallei* and other related species such as *B. cepacia* and *B. mallei* has also increased a possible way for rapid diagnosis. However, the culture method remains the method of choice, not only because of its reliability, but also because of its simplicity and cost. Its only drawback is that it takes up a great deal of time before a definitive diagnosis can be made. To help speed up the time needed for bacterial identification, a combination of the culture method with anyone of the immunological and molecular diagnostic methods discussed in this article could be used and results evaluated.

ACKNOWLEDGMENTS

The study was a part of Melioidosis project supported by the Thailand Research Fund, the Institutional Strengthening program under funding of the National Science and Technology Department Agency, Thailand, the fund from the Graduate Institution, and the fund for promoting the Junior Scientist, Mahidol University. The author would like to thank Prof. Dr. Rachanee Udomsangpetch for critically reading this manuscript.

Butyrylcholinesterase Gene Polymorphism

Weidong Liu
Toshikazu Hada
Hyogo College of Medicine, Nishinomiya, Hyogo, Japan

INTRODUCTION

Human butyrylcholinesterase (BChE: EC 3.1.1.8; OMIM 177400), also called serum cholinesterase and pseudocholinesterase, is one of the enzymes routinely measured for liver function in serum. Butyrylcholinesterase is a plasma esterase that hydrolyzes acetylcholine, other choline esters, and choline ester-containing drugs such as succinylcholine. Except for agricultural chemical poisoning and hepatic dysfunction, low serum cholinesterase is usually caused by mutations in the BChE gene. To identify inherited abnormalities, both biochemical and genetic methods are used. Phenotypic and genetic polymorphism exist in the BChE gene in different ethnic groups; some of the polymorphism has been related to drug metabolism and disease occurrence. Here the detection and clinical implications of phenotypic and genetic polymorphism are described.

PHENOTYPIC POLYMORPHISM

Serum BChE activity is determined by using benzoylcholine chloride as a substrate. Phenotypes were determined by the inhibition of cholinesterase activity by 10 μmol/L dibucaine or by 50 μmol/L sodium fluoride. Established normal inhibitory values were $\geqq 77\%$ for dibucaine number (DN) and $\geqq 55\%$ for fluoride number (FN).[1] Three main BChE phenotypes have been defined: 1) the U form with normal DN and FN; 2) the A (atypical) form, less inhibited by dibucaine than the U phenotype; and 3) the F form with lower dibucaine and fluoride inhibition. They are also called ''qualitative variants.'' The quantitative variants such as the S- (silent form), H-, J-, and K-variants are the diminished numbers of effective circulating molecules and are present in approximate concentrations of 0%, 10%, 30%, and 70% of normal, respectively.[1,2]

Human BChE protein also shows a complex molecular polymorphism. Numerous forms of BChE protein can be detected by gel electrophoresis. Four main forms, named C1, C2, C3, and C4 according to their electrophoretic mobility on starch gel, have been identified. C1, C3, and C4 are monomer, dimer, and tetramer forms, respectively. The C2 component is a BChE monomer–albumin conjugate.[3] The C5 variant is considered a polymorphism in different ethnic groups and may be related to hypercholinesterasemia. Other components often observed depend on storage, partial proteolysis, and/or electrophoresis conditions.[3] Familial hypercholinesterasemia was reported with C_5 (+) or (−) band.[4,5]

GENETIC POLYMORPHISM

The human BChE gene is located on chromosome 3q26. The genomic region for BChE spans about 70 kb and has four exons and three large introns.[6] Polymerase chain reaction-single strand conformation polymorphism (PCR-SSCP), PCR-restriction fragment length polymorphism (PCR-RFLP), and competitive oligo-priming-PCR (COP-PCR) were used to detect the common variants of the BChE gene.[7,8] For rare mutations, sequencing the PCR products is necessary. Usually, a DNA sample is extracted from peripheral blood, and exons 2, 3, and 4, which encode the mature protein of the BChE gene (Genbank Accession Number: J02879), are individually amplified by the PCR method. A total of 35 cycles of amplification are performed, each round consisting of a denaturation step at 94C for 1 min, an annealing step at 55C for 1 min, and an extension step at 72C for 1.5 min. After the sizes and homogeneity of the PCR products are confirmed by agarose gels stained with ethidium bromide, direct sequencing is performed using a dye terminator cycle sequencing core kit and a DNA sequencer.[9,10] The primers used for PCR and sequence are listed in Table 1.

Two genetic polymorphisms in the noncoding region of BChE were found early in 1990. At nucleotide −116, the frequency of G is 0.92 and that of A is 0.08. At nucleotide 1914, the frequency of A is 0.74 and that of G is 0.26.[11] These frequencies are considered to have no effect on BChE activity. At least 49 mutations have been reported that are associated with low serum BChE activity, including 15 truncating and 34 nontruncating mutations (Fig. 1). The genetic mutation related to the atypical phenotype is D70G. Two fluoride-resistant phenotypes

Primers come from Refs. [9] and [10]. Nt: nucleotide.

are F-1 for T243M and F-2 for G390V. K-, J-, and H-variants are A539T, E497V, and V142M, respectively. Other than the truncating mutations, some of the non-truncating mutations such as P100S and D170E, some compound heterozygous mutations (e.g., D70G linked to A539T), and multiple mutations (Q119X, L330I, and A539T) are attributed to silent variants (S form). Heterotypic mutations (D70G and D70H, 943–944insA, and T315S) have also been reported in the BChE gene.[1,2,7,9,12] When multiple point mutations occur simultaneously in a BChE molecule, one mutation may magnify or counteract the effect of another mutation. Therefore the phenotype of BChE cannot exactly reflect the genotype.[2,9]

The frequency of the silent BChE phenotype (S form) is estimated to be ~1/100,000 in the majority of the populations investigated, but it is present in ~1–2% in Eskimos and Vysyas from Andhra Pradesh.[12] In unselected populations in Caucasian-origin Italians, the atypical variant allele frequency is 0.009 and the K variant is 0.128, similar to some previously published data for different ethnic groups. The paper also reported that low

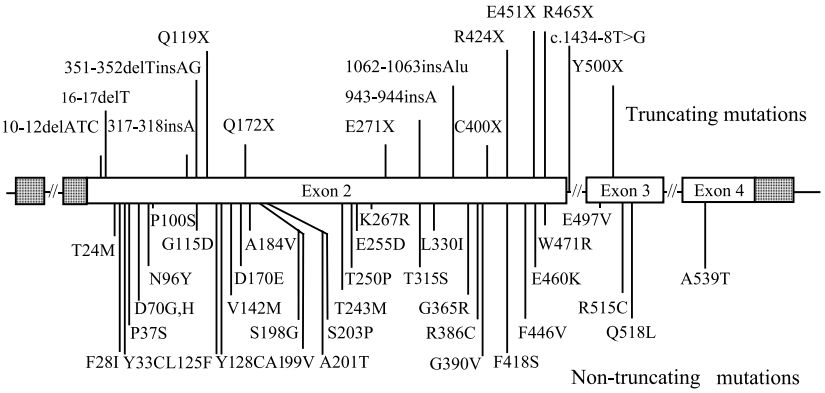

Fig. 1 Mutations found in the serum cholinesterase gene. (Mutations F28I, N96Y, 317–318insA, R386C, R424X, and E460K come from Ref. [7]. All of the others come from Ref. [2].)

serum cholinesterase is 2.2% and low FN or DN/FN is 1.1% in these peoples.[1] These values show that polymorphism is very common in normal populations.

Distinct ethnic differences in genetic mutations of the human BChE gene have been reported. The P100S, L330I, G365R, and R515C were only found in Japanese, whereas A (G70D), F-1 (T243M), F-2 (G390V), J (E490V), and H (V142M) variants existed mostly in European, American, and Australian populations.[1,2,7–13]

K-variant polymorphism has a similar high frequency (>0.1) in Americans, Chinese, Italian, Australian, and Japanese.[1,2,8] However, the K-variant was not found in Georgian and Ashkenazi Jews.[14] The K-variant is associated with Alzheimer's disease in Europeans,[6] but not in Asians such as Chinese and Japanese.[13,15] The K-variant might be a protective factor, presumably because of its reduced enzymatic activity, and the wild-type allele of BChE could be a risk factor for Alzheimer's disease.[6] Indeed, some effective therapeutic agents such as donepezil and tacrine currently used to treat Alzheimer's disease are cholinesterase inhibitors.[6]

No mutation has been found in the BChE gene in patients with hypercholinesterasemia. Some patients with hypocholinesterasemia have had no mutations found in the BChE gene. It is suggested that some other protein has affected BChE activity in the serum.

Patients with inherited a-, hypo-, or hypercholinesterasemia generally have no signs or symptoms and can lead a healthy life. Gene diagnosis is used to distinguish between hypocholinesterasemia caused by the genetic factor or liver disease. If a muscle relaxant such as succinylcholine or mivacurium is injected in patients with low serum cholinesterase, BChE activity greater than 30% of normal is necessary to metabolize the drug safely.[1] If prolonged apnea has been caused by administration of succinylcholine or mivacurium, an injection of fresh plasma or refined BChE should be used immediately. Butyrylcholinesterase may also be used as a medicine to treat poisoning caused by cocaine or organophosphorus pesticides.[16,17]

CONCLUSION

The genetic polymorphism of the BChE gene is very common in the normal population. It can be detected by PCR-SSCP, PCR-RFLP, COP-PCR, or by directly sequencing the PCR product. The phenotype of BChE cannot exactly reflect the genotype. Genetic methods can be used to distinguish inherited hypocholinesterasemia from acquired. Distinct ethnic differences exist in the BChE gene. Muscle-relaxant drugs should be used carefully with patients having low serum cholinesterase. Research on the polymorphism of the BChE gene may be useful in clarifying the mechanism and treatment of some nerve diseases.

CADASIL

Marie Magdeleine Ruchoux
Parc EuraSanté, Lille, France

Michel Franck
Ecole Nationale Vétérinaire de Lyon, Marcy l'Etoile, France

INTRODUCTION

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an inherited syndrome that leads to dementia. The key features of the disorder are migraine, recurrent subcortical events, mood disorders, and dementia in association with diffuse leukoaraiosis on neuroimaging. The CADASIL or *Notch3* gene encodes a transmembrane (TM) receptor exclusively expressed in vascular smooth muscle cells (VSMCs) in adult human tissues. The brain pathology is typical of subcortical vascular dementia with a diffuse leukoencephalopathy and numerous small deep infarcts. This is underlaid by a systemic angiopathy characterized by prominent VSMC alterations in humans as well as in Notch3 transgenic mice. So far, mechanisms of such VSMC destruction are not elucidated and further analysis of the *Notch3* pathway and of a more adapted animal model will provide insights into the CADASIL VSMC physiology. The next and most important step is to find preventive treatments for this dramatic condition.

CLINICAL DESCRIPTION

Four main symptoms are observed in CADASIL: migraines with aura, ischemic attacks, mood disturbances, and cognitive decline or dementia. The clinical presentation is highly variable between and within families. The age of onset varies greatly, depending on the criterion used for the onset of the disease.[1–3] Migraine attacks may begin even before age 10 years, but more commonly during the second and third decades. The most constant finding is a history of ischemic events, transient or completed, which are present in 87% of symptomatic individuals. They are often recurrent over years, leading to gait difficulties, pseudobulbar palsy, and incontinence. All subjects older than age 66 years have developed ischemic signs and all deceased subjects had suffered from strokes.[3] Mood disturbances such as severe depression of the melancholic type are present in more than 20% of cases. Rare manic episodes and psychotic disorders were found in families with a common phenotype.[3] The second most frequent feature is the development of cognitive deficits (59% of symptomatic cases), which displays a slowly progressive course with additional stepwise deterioration similar to sporadic Binswanger's disease. It happens between the ages of 40 and 70 years, with about 80% of the CADASIL patients aged over 65 years being demented. Dementia is invariably of the subcortical vascular type (SVD), with apragmatism, apathy, and memory impairments, whereas the patients perform relatively well in the routine Mini Mental Status Examination (MMSE). Epileptic seizures occur in about 6–10% of the patients. Routine laboratory examinations are usually noncontributory.

The differential diagnosis of CADASIL is broad. Before their final diagnosis, many of the patients are diagnosed as having multiple sclerosis, cerebral vasculitis, Binswanger's disease, leukoencephalopathy of indeterminate cause, or Alzheimer's disease.[1–5]

NEUROIMAGING

The two key neuroimaging features in CADASIL are multiple focal lacunar infarcts and diffuse white matter (WM) T2-weighted (T2w) hyperintensities observed with magnetic resonance imaging (MRI) (Fig. 1A and B) corresponding to the diffuse rarefaction of WM or leukoaraiosis on computed tomography (CT) scanning.[3] MRI is an essential tool for the CADASIL genetic study because neuroimaging penetrance of CADASIL is complete or almost complete between the ages of 30 and 40 years.[4] Changes highly suggestive of CADASIL diagnosis were already detected in asymptomatic mutation carriers, even in an 18-year-old CADASIL subject.[3] Areas of high T2w and fluid attenuated inversion recovery (FLAIR) signal intensity within the anterior temporal and paramedian superior frontal WM are useful radiological signs that help to differentiate CADASIL from subcortical arteriosclerotic encephalopathy.[4] Conversely, the absence of periventricular hyperintensities in practice excludes the diagnosis of CADASIL.[4]

(E and F) GOMs within VSMC infoldings (E, ×27,800; F, ×12,930).

PATHOLOGY

Pathological findings on autopsy of CADASIL patients include multiple small, deep infarcts in WM, deep gray matter in the brainstem, and a diffuse myelin loss in the hemispheric WM (Fig. 1C). The cortex, cerebellum, and other tissues seem well preserved. Histological sections show a widespread angiopathy first described in small- and medium-sized brain arteries.[3] Finally, lesions occur throughout the systemic blood vasculature including capillaries and veins.[5]

This angiopathy is characterized by a slight to marked thickening of the wall depending on the localization, destruction of VSMCs, and wall accumulation of eosinophilic smudgy material, which is periodic acid Schiff-positive (PAS^+) but negative in Congo red staining, ruling out the diagnosis of amyloid angiopathy.[3,5,6] The ultrastructural CADASIL hallmark is a granular osmiophilic material (GOM) without filament-like profiles[5,6] surrounding VSMCs and often lodging within VSMC infoldings (Fig. 1D–F). So far, the GOM nature is not known. An important breakthrough in understanding CADASIL vascular wall changes is the finding that the Notch3 protein expression is restricted to VSMCs[7] and that its extracellular domain (NECD) accumulates within CADASIL patients' vessel walls, in close vicinity to GOMs and can be visualized immunohistochemically.[7] Given the uncertain specificity and sensitivity of this technique,[8] GOMs observed in skin biopsies continue to remain a diagnostic tool.[3,5,6] Moreover, it appears to be detectable early, before age 20 years in skin vessels.[3] Nevertheless, we did not find

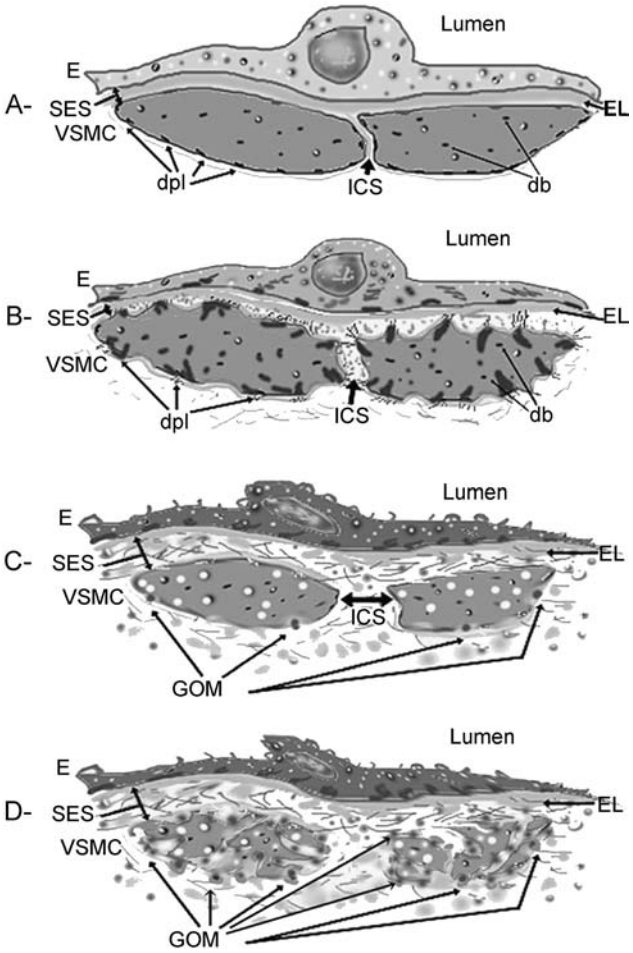

Fig. 2 Schematic representation of vascular changes in CADASIL patients and transgenic mice. (A) Normal vessel wall. (B) First modifications observed within the vessel wall of young CADASIL patients (8 years old) and of young mice before 10 months. (C and D) Evolution of VSMC alterations with a dramatic separation of the different vessel wall cells and the presence of GOM (arrow) observed on and after 20 years in humans and 14 months in transgenic mice. GOM in very young patients (8 years old), whereas VSMC alterations were already present, suggesting that VSMCs are the target of Notch3 mutations. In a study of 50 CADASIL cases, Brulin et al.[9] confirmed that skin VSMC alterations begin early; since age of 20 years, VSMCs are already isolated, irregular-shaped, and surrounded with an increased extracellular matrix, which seems to just replace the VSMC destruction (Figs. 1D and 2B and C). VSMC destructions increase with the patient's age. Finally, vessel wall VSMCs are barely recognizable at 60 years (Fig. 2D) Interestingly, no real stenosis (lumen diameter decreasing) is found compared with 20 younger controls even though vessel walls are thickened. These findings are also observed in brain tissues from five CADASIL cases.[9]

GENETICS

Genetic linkage analysis and DNA[10] sequencing have shown that CADASIL is caused by mutations in the human *Notch3* gene at locus chromosome 19p13.[11]

Notch3 belongs to the family of highly conserved Notch/LIN-12 receptors, which includes four members in vertebrates.[12] This gene has 33 exons and encodes for a TM receptor that is a component of an intercellular signaling pathway essential for controlling cell fate during development in a wide range of organisms, including insects, nematodes, and mammals.[13] The Notch3 molecule is synthesized as a 2321-amino acid precursor containing all typical Notch motifs, namely, an extracellular region exhibiting a signal sequence and an extracellular domain (NECD) with 34-tandem epidermal growth factor (EGF)-like repeats followed by three Notch/LIN-12 repeats, a TM segment, and an intracellular domain (NICD) containing six cdc10/ankyrin repeats flanked by two nuclear localization signals (Fig. 3).[12,13] During maturation and activation, Notch3 undergoes three proteolytic cleavages (Fig. 3). The first cleavage (S_1) occurs in the Golgi apparatus where a furine-like convertase cleaves Notch between its NCID and its NECD. After the reappearance of these two domains, they bind to each other to generate a heterodimeric receptor. At

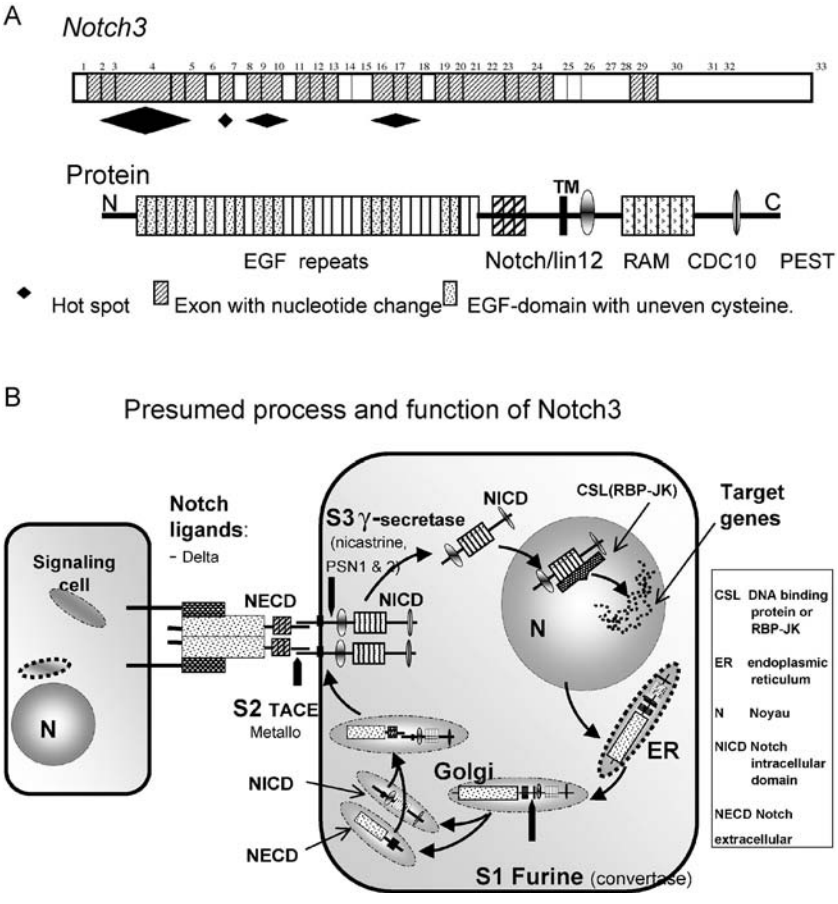

Fig. 3 (A) Preferential location of mutations on *Notch3* EGF repeats involved in CADASIL Notch3 protein. (B) Schematic representation of the three cleavages (S_1, S_2, and S_3) that occur during Notch3 maturation.

the cell surface, the receptor interacts with ligands, Jagged-1 or Delta-1, which are TM proteins expressed to juxtaposed cells.[12] Ligand interaction leads to a second cleavage (S_2) of the receptor. A metalloprotease ADAM-17, also called TNFα-converting enzyme (TACE), cleaves the NECD, precisely 12 amino acids outside of the plasma membrane. This cleavage releases the NECD to the extracellular space. The third cleavage is the result of the γ-secretase complex formed by nicastrine, preseniline1, and preseniline2. This last cleavage releases the NCID, which translocates to the nucleus, where it regulates transcription associated with a DNA-binding protein CSL (RBP-Jk) (Fig. 3).[12]

Molecular screening of all 33 coding exons within a large panel of CADASIL patients revealed that most of the mutations are missense mutations;[11] other mutations including splice site mutations and deletions, which have been identified in a few patients, lead to small in-frame deletions.[14] All the mutations are located within the EGF-like repeats of the NECD, with a strong clustering within exons 3 and 4, which encode the first five EGF repeats (Fig. 3).[15] CADASIL mutations are highly stereotyped, leading to an odd number of cysteine residues within an EGF-like repeat.[15]

GENOTYPE–PHENOTYPE CORRELATION

No correlations are found between a mutation and a clinical phenotype because a family unique presentation such as migraine or stroke is also found with several other mutations.[2,3] Additionally, we did not notice neither different clinical presentations nor different skin vessel wall lesions in CADASIL patients with mutations located either in the first or very last exons. Interestingly, a homozygous patient followed in Finland was indistinguishable when compared with an age-matched heterozygous patient with the same R133C Notch3 mutation. The double dose of gene defect does not appear to aggravate the symptoms, which indicates that either mutated Notch3 receptors retain some of their function, or other molecules can compensate for the loss.[16]

MANAGEMENT AND GENETIC COUNSELING

The broad variety of CADASIL symptoms in affected families often leads to its underdiagnosis and misdiagnosis. A truly negative family history by no means excludes this diagnosis because a patient with a de novo Notch3 mutation has been reported.[17] Consequently, patients presenting with neurological deficits, leukoaraiosis, and a positive family history will benefit from a mutation analysis of hotspot 3–4–5–11EGF-encoding exons. In case of negative result, a skin biopsy is performed for ultrastructural and immunohistochemical studies. A positive result leads to a mutation analysis of all EGF-encoding exons and then to a mutation screening of remaining *Notch3*.

ANIMAL MODEL

Similarities were found between *Drosophila*-lethal Abruptex and human CADASIL because they are precisely analogous at the molecular level and both are genetically dominant. This model was proposed to provide more general insights into the VSMC biology because its mutations also lead to an odd number of NECD cysteine.[18] Recently, transgenic mice in which the SM22α promoter drove the expression of the full-length human Notch3 with the Arg90Cys mutation (one CADASIL archetypal mutation) were generated.[19] These A90C-Tg mice showed GOM deposits, NECD accumulation, and evidence of VSMC degeneration strikingly similar to those observed in CADASIL patients. Vessel changes were systemic but more prominent in the tail arteries. Time course analysis of vessel changes revealed that VSMC damages were present before NECD and GOM accumulation occurred (Fig. 2B and C), and that the first ultrastructural findings were the disruption of normal VSMC anchorages to adjacent extracellular matrix and cells (Fig. 2B). Unfortunately, these A90C-Tg mice showed no evidence of brain damage; nevertheless, they modeled the early stage of the human disease before onset of clinical symptoms. One knows the difficulty in predicting the accuracy with which animals will model a corresponding human disease. The mouse with its short life expectancy and its brain anatomy is actually far from humans. SVD model requires animals with brain macroscopically similar to that of humans. In the future, these facts must be taken into account in studying diseases similar to those of humans.

PATHOGENESIS

In the absence of stenosis and occlusions in CADASIL vasculature, hemodynamic troubles need to be explained in the light of typical vessel changes. The extensive destruction of VSMCs and pericytes suggests that hypotonicity may play a more important role in the pathogenesis of cerebral ischemia than vascular occlusion. Several studies, employing different specialized imaging techniques, have indicated a reduced baseline cerebral blood flow and a reduced cerebrovascular reactivity in CADASIL patients and in asymptomatic mutation carriers.[20–22] Moreover, diffusion tensor MRI and proton

MR spectroscopy studies indicate that cerebral tissue damage is much more widespread than is evident on conventional MRI.[21,22] It correlates with previous pathological observations, showing a diffuse angiopathy as severe in WM as in the cortex[5,6] but with different consequences depending on the vascular density.[5,6] Interestingly, the dependence of endothelial permeability on the presence of pericytes was recently demonstrated.[23] Pericyte alteration and destruction observed in CADASIL probably result in a decrease in permeability because VSMCs and pericytes secrete vascular endothelial growth factor (VEGF), a growth factor that is also the most potent permeability factor.[24] Therefore, leukoaraiosis could be the result of both oligemia and decreased permeability. The latter could explain why the only tissues affected are those depending on the blood–brain barrier because all the exchanges rely on a perfectly working capillary bed.

Now, the utmost question is: On the molecular and cellular levels, what sequence of events leads from Notch3 mutation to the characteristic VSMC alterations? Recent data suggest that trafficking and localizing, rather than signaling, of Notch3 are affected: cultured human embryonic kidney cell lines expressing mutant *Notch3*^{R142C} showed a higher propensity to form intracellular aggregates.[13] On the opposite, the link between this cleavage product and the VSMC destruction is not explained.

CONCLUSION

So far, over 500 families have been identified worldwide in many different ethnic groups.[3] With the awareness of the hereditary aspects of CADASIL and Notch3 mutation analysis, special care and management of CADASIL patients are improving and genetic counseling is being provided to patients and their families. In the absence of preventive therapeutics, the combined efforts of research groups are focused on finding an animal model presenting brain parenchyma damage comparable to that of humans. This could be the key to unveiling the sequence of events leading from mutant gene to VSMC destruction and, in the future, could function as a model for therapeutic testing.

In the SVD field, the identification of CADASIL as a hereditary systemic vascular disease represents a paradigm for research, and the significance of the findings goes well beyond the condition itself because new disease identifications are likely to be in progress.

Calicivirus

C. Anthony Hart
A. D. Radford
University of Liverpool, Liverpool, U.K.

INTRODUCTION

The human caliciviruses have recently been subdivided into the *Norovirus* and the *Sapovirus* genera. Norwalk agent was the first human viral enteropathogen to be described. It was designated the cause of ''Winter vomiting disease'' and named after Norwalk, Ohio, USA, in 1972. They do not have a classic calicivirus morphology on electron microscopy and were also referred to as small round structured viruses (SRSV). The sapoviruses are named after a virus found in Sapporo, Japan, in 1982. They have the classical cup-shaped depressions (calyx is Greek for a cup) in their surface when viewed by negative stain electron microscopy. The noroviruses are an important cause of vomiting with or without diarrhea and are responsible for large outbreaks of disease in the community, in hospitals, or on cruise liners. After rotavirus they are the most important etiological agents of gastroenteritis. The sapoviruses cause mild diarrheal disease predominantly in children.

THE VIRUSES

The family Caliciviridae is a group of small (27–40 nm) unenveloped round viruses with a linear, positive strand, unsegmented RNA genome.[1] The family includes vesiviruses that infect cats (feline calicivirus) and pigs (vesicular exanthema of swine), the lagoviruses of hares and rabbits (rabbit hemorrhagic disease), and the human caliciviruses (genera: *Norovirus* and *Sapovirus*). Hepatitis E virus has been removed from the family Caliciviridae and is currently of ''unclassified status.''[2]

Noroviruses (prototype strains Hu/NLV/Norwalk virus/8FIIa/1968/95) are 38 nm in diameter by electron cryomicroscopy (Table 1). By negative stain electron microscopy they are 27–32 nm in diameter with a feathered edge (Fig. 1). The capsid is made from a single major capsid protein that can self-assemble in the absence of viral RNA to form viruslike particles (VLP). Most of our information on virus morphology comes from VLPs. The capsid comprises 90 dimers of the capsid protein which form particles with T-3 icosahedral symmetry. There are two major capsid domains: the shell (S) and protruding (P) arm. The P-domains form archlike structures that give the virus its feathery outline. The S-domain forms a β-barrel and is at the N-terminus. The P-domain is the carboxy half of the protein and shows sequence variability. It is divided into the P1 [amino acids (αα) 226–278 and αα 406–520] and the P2 (αα 279–405) subdomains. The P2 subdomain shows the highest sequence variability. The P1 subdomain forms the sides of the archlike structure and the P2 subdomain is at the top of the arch. P2 is a major antigenic site and is involved in receptor binding.

It has thus far proved impossible to maintain noroviruses (or sapoviruses) in artificial culture so knowledge of the genome is derived from analysis of cDNA copies of virus genome extracted from human stool samples and by comparison with the caliciviruses that are easier to grow [feline calicivirus (FCV) and vesicular exanthema of swine virus (VESV)] in culture. The norovirus genome is a positive sense polyadenylated single-stranded RNA of around 7.6 kb. It is organized as three open reading frames (ORF). The first ORF at the 5′ end encodes a large nonstructural polyprotein of predicted mass 193.5 kDa or 1738 (αα). This contains motifs with similarity to the helicase, serine protease, and RNA-dependent RNA polymerase of picornaviruses, and is thought to be post-translationally cleaved by proteolysis to the individual enzymes. ORF2 encodes a protein of 533 αα, which is the capsid protein, and can self-assemble to form VLPs when expressed using a baculovirus vector in insect cells.[3] At the 3′ end ORF3 encodes a small (212 αα) basic protein, which is a minor structural protein.[4]

The sapoviruses (prototype strain Hu/SLV/Sapporovirus/1982/JR) are of similar size to noroviruses but have a much more distinct morphology. They have 32 cup-shaped depressions at each of the fivefold and threefold axes. These lead to their characteristic ''Star of David'' appearance (Fig. 2) on negative stain electron microscopy. The genome of sapovirus Manchester is slightly shorter than that of noroviruses at 7.4 kb, and it is arranged differently. ORF1 encodes both the nonstructural proteins and the capsid protein, which is found in-frame at the end of the nonstructural ORF.[5] ORF2 encodes a basic protein

Table 1 Norovirus genogroups

Genogroup	Viruses and hosts
I	*Humans*: GI-1 (Norwalk), GI-2 (Southampton), GI-3 (Desert Storm), GI-4 (New Orleans, Chiba), CI-5 (Apalachicola Bay, Musgrove), GI-6 (Hesse)
II	*Humans*: GII-1 (Hawaii, Wortley), GII-2 (Melksham), GII-3 (Toronto), GII-4 (Bristol), GII-5 (Hillingdon, White River), GII-6 (Seacroft, Florida), GII-7 (Leeds, Gwynedd), GII-3 (Idaho Falls), GII-n (Erfurt). *Pigs*: SW/NLV/SW43/1992/JP
III	*Cattle*: GIII-1 (Jena)
IV	*Humans*: GIV-1 (Fort Lauderdale, Alphatron)
V	*Mice*: GV-1 (murine norovirus)

similar to that of ORF3 of noroviruses. There is another potential ORF within the capsid gene that might encode a further basic protein of unknown function.

VIRAL VARIABILITY

Both genomic and antigenic analyses have shown that the noroviruses are highly variable. They are divided into five major genogroups within which are clustered a number of genotypes on the basis of sequence variations in polymerase and capsid genes. Most human infections are due to genotypes I and II with genogroup II being responsible for the majority (73%) of outbreaks of disease.[6] Genotype IV viruses have also been detected in humans, but their role in disease is unclear. Genogroup II noroviruses have recently been detected in pigs,[7] but so far genogroup III viruses are restricted to cattle, and the recently described genogroup V norovirus was found in a mouse.[8] However, the genome is constantly mutating and within each genogroup and genotype variants can be found. There is even evidence for mutation of a genogroup II norovirus from a heart transplant patient with chronic diarrhea lasting over 2 years.[9] The mutations tend to accumulate in the P2 region of the capsid protein, which is a major target for the immune response. There are fewer studies of sapovirus variability. Studies based on part of the RNA polymerase (278–286 nucleotides) and capsid genes have divided sapoviruses into five genogroups. As with the noroviruses there are a number of genotypes within the genogroups and increasing evidence of great variability.[10]

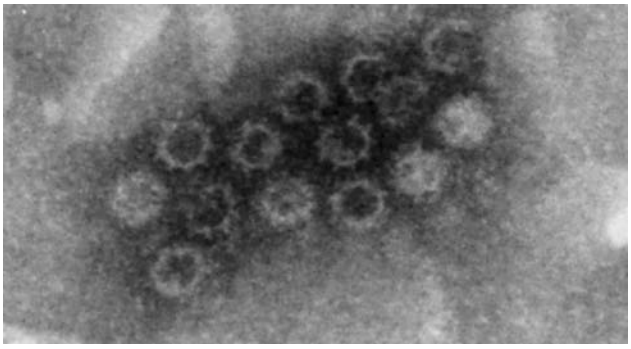

Fig. 1 Negative stain electron micrograph of noroviruses showing their ''feathery edge.''

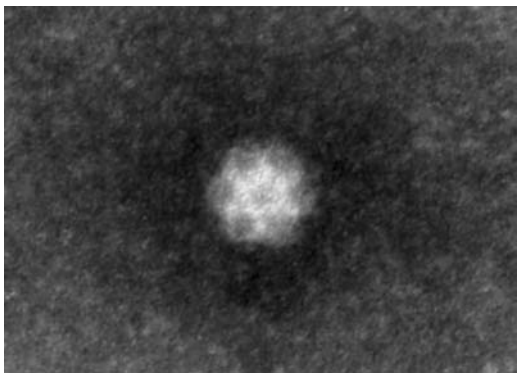

Fig. 2 Negative stain electronmicrograph of a sapovirus demonstrating cup-shaped depressions and the classic ''Star of David'' appearance.

REPLICATION, PATHOGENESIS, AND IMMUNITY

Neither human noroviruses nor sapoviruses have been cultured in cell lines or intestinal organ culture so little is known of their replication in vivo or in vitro.

Both viruses are excreted in feces and vomitus, and infection is acquired by ingestion or even inhalation of aerosolized vomit. The incubation period ranges from 10 to 51 hr with a mean of 24 hr in volunteers.[11] The site of infection in the gastrointestinal tract is unknown but from the short incubation period it is likely to include the jejunum.[12] The receptor(s) for noroviruses appear to be the ABH histo-blood group antigens and heparan sulfate

proteoglycans.[13] How human caliciviruses cause disease expression is not known. Although it was previously thought that virus shedding was short-lived, there is increasing evidence for virus excretion before onset of disease and for several weeks after clinical recovery.[11,14,15] Immunity to human caliciviruses is poorly understood. In challenge experiments, six volunteers who developed gastroenteritis after ingesting Norwalk virus developed disease when challenged again with the same virus 27–42 months later, despite a brisk antibody response.[11] There does, however, appear to be a correlation between antisapovirus antibodies and immunity to infection.

EPIDEMIOLOGY

The human caliciviruses have a worldwide distribution being detected in every country they have been sought.[11] In a community-based study in Holland 20% of cases of gastroenteritis were due to noroviruses and 6% to sapoviruses.[15] Noroviruses were detected in all age groups whereas sapoviruses were found only in children with 19% of cases being found in those under 6 months.[15] Seroprevalence studies in developed countries indicate that antibodies to noroviruses are acquired gradually in childhood, and by adulthood 50% are seropositive.[11] In contrast, in some developing countries norovirus seropositivity reaches 100% by 4 years of age.[11] Virtually all adults have antibody to sapoviruses and in Kenya most children are seropositive by 2 years of age.[11] Sapovirus infections appear to be endemic particularly in infants and, in temperate countries, predominate in the cooler winter months often before the rotavirus season. In contrast, noroviruses, while also able to cause sporadic disease, are frequently associated with explosive outbreaks of disease being responsible for up to 80% of outbreaks. These can be community-wide but cause particular problems in health-care institutions such as hospitals and nursing homes. Outbreaks on holiday cruise ships attract great publicity.[16] Finally, food- and waterborne outbreaks occur frequently. Shellfish such as oysters and mussels, which are filter feeders and concentrate noroviruses discharged into the sea in human excreta, are particularly associated with outbreaks. However, other foodstuffs including raspberries and delicatessen food contaminated at source or during preparation also precipitate outbreaks.[14,17] There is recent evidence for a global epidemic of infection with a single GII-4 norovirus which was detected in 55% of unrelated outbreaks in the United States and in seven countries on five continents.[18] Its emergence was related to an increase in the prevalence of norovirus gastroenteritis.

THE DISEASE

In general, norovirus infection is associated with sudden onset of nausea and vomiting that is severe, projectile, and frequent. However, a significant proportion of patients report diarrhea, abdominal cramps, headache, myalgia, and pyrexia.[11,15,16] In the elderly, however, disease can be severe and cause death. In a study of diarrheal disease in the United Kingdom there were 43 deaths in 38 outbreaks in hospitals or elderly care facilities,[19] and in the United States norovirus is estimated to account for 7% of fatalities due to foodborne disease.[20] Disease manifestation persists for a median of 5 days with diarrhea persisting for a median of 4 days. The median duration of illness decreased with age.[15] Chronic diarrhea can occur in the immunocompromised.[9] Sapovirus gastroenteritis is more often associated with diarrhea than vomiting; however, nausea and vomiting precede diarrhea in a proportion of cases. Disease persists for a median of 6 days.

DIAGNOSIS

This can be by visualization of the virus by electron microscopy, detection of antigens, detection of genome by RT-PCR, or detection of specific antibody. Electron microscopy is how the viruses were first detected; however, the sensitivity of the test is low. Feces must contain at least 10^6 virus particles per milliliter. The virus is small and detection requires an experienced electron microscopist. Finally, the quantity of virus excreted drops rapidly below detectable levels after onset of disease. Antigen detection has used immune adherence hemagglutination, radioimmunoassay, and enzyme immunoassay (EIA) formats.[1] Enzyme immunoassays for antigen detection are now available commercially. However, they are neither highly specific nor sensitive at detecting all genogroups of noroviruses.[21] There are no commercially available antigen capture EIAs for sapoviruses. Genome detection by reverse transcription polymerase chain reaction (RT-PCR) is the most sensitive and specific method available for detection of human caliciviruses.[1,22,23] However, selection of the correct primers is of major importance. Even relatively well-conserved regions of the genome such as the helicase or polymerase regions have nucleotide identities as low as 36% between genera and genotypes.[1] However, broadly reactive primer sets targeting the RNA polymerase of circulating noro- and sapoviruses have been designed which perform well[22] but may cross-react with the polymerase of other viruses.[24] It may therefore be necessary to screen for the two genera separately. A highly sensitive broadly based quantitative RT-PCR has recently been

Table 2 Examples of primers used for the detection of human calicivirus from feces

devised for noroviruses.[23] Some primer sets used to detect the human caliciviruses are shown in Table 2. It is likely that new primer sets will be required as our understanding of the range and variability of human caliciviruses expands. Antibody detection is used only for epidemiological purposes and numerous different antigens are needed.

TREATMENT AND PREVENTION

There is no specific treatment nor method of prevention of infection. Viruslike particles stimulate specific immune responses and are currently being tested for efficacy in vaccine.[11,15,27] In the face of outbreaks the only methods of prevention are isolation of cases and use of disinfectants.

CONCLUSION

Noroviruses are the most frequent causes of outbreaks of gastroenteritis. They are genetically and antigenically highly diverse and are able to mutate in a human host. Their major disease manifestation is vomiting. Sapoviruses tend to cause mild diarrhea predominantly in children.

Cyril Carroll
National University of Ireland, Galway, Ireland

INTRODUCTION

Campylobacter spp. are the most common cause of bacterial foodborne illness worldwide. Despite this, they are poorly understood in terms of growth, survival, and pathogenesis. The recent publication of the genome sequence for *Campylobacter jejuni* NCTC11168 presents an opportunity to advance our knowledge of this organism, its detection, its mechanisms of survival, and its pathogenesis. Therefore, the application of genomics and proteomics may answer important questions about *Campylobacter* spp. and contribute to the development of effective control procedures that will reduce the incidence of *Campylobacter*-related illness.

THE GENUS *CAMPYLOBACTER*

Members of the genus *Campylobacter* are gram-negative, nonspore-forming, motile-curved, or S-shaped spiral cells (0.5–0.8 μm long and 0.2–0.5 μm wide) during logarithmic growth. In stationary phase cultures or on exposure to air or adverse conditions, the cell morphology changes to coccoid, even in the absence of de novo protein synthesis. Although there are 16 members of the genus identified to date, those associated with human disease are *C. jejuni*, *Campylobacter coli*, *Campylobacter lari*, and *Campylobacter upsaliensis*, and it is these species that will be primarily considered. Optimum growth occurs in a microaerobic environment of 5% oxygen, 10% carbon dioxide, and 85% nitrogen. Iron is an essential nutrient, but intracellular iron homeostasis must be maintained, because iron in combination with oxygen leads to the generation of toxic reactive oxygen species.[1] *Campylobacter* species may grow over a wide spectrum of temperatures ranging from 25°C to 42°C.[2] With regard to survival in a hostile environment, *Campylobacter* spp. can enter a viable but nonculturable (VNC) state; recovery from that state is variable and may be due to strain differences.[3]

PATHOGENESIS

Campylobacteriosis is the leading cause of foodborne illness worldwide. The clinical manifestations of the disease are very diverse, ranging from mild, noninflammatory watery diarrhea to more severe inflammatory diarrhea with abdominal cramps. The incubation time can be 1–7 days, and although severe illness can last more than a week, the disease is generally self-limiting and complications are rare. Antibiotics may be used in such clinical circumstances as high fever, bloody stools, prolonged illness with symptoms lasting more than a week, pregnancy, infection with human immunodeficiency virus (HIV), and other immunocompromised states, although they are not generally required. Erythromycin is the drug of choice, and resistance to it remains relatively low following decades of use.[4] It is estimated that about 1 in 1000 cases of campylobacteriosis results in the neurological disorder Guillain–Barré syndrome.[5] Another related neurological disorder, Miller–Fisher syndrome, is also associated with *C. jejuni*.

Campylobacter spp. colonize the gastrointestinal tract of animals that act as a vehicle of transmission. In the human host, they colonize the ileum and colon, with colonization being facilitated by both the spiral shape (which helps cells to corkscrew their way through the mucous) of the cell and bacterial motility. The mechanisms by which *Campylobacter* spp. cause disease are poorly understood, but involve toxin production and/or damaging of the host epithelial cells by invasion, or inflammatory response. *Campylobacter* toxins play a significant role in pathogenesis and, recently, cytolethal distending toxins (CDTs) of *C. jejuni* have been shown to be of particular significance.[6] CDTs have a mode of action different from other toxins (e.g., enterotoxin), which is not fully understood. The most important virulence factor appears to be the flagellum. Chemotaxis toward mucin, adherence, iron metabolism, invasion, and intracellular survival are other important virulence factors. Given the large number of genes probably involved in virulence, effective regulation of virulence is essential.

DOI: 10.1081/E-EDGP 120020829

The most important virulence regulators appear to be the ferric uptake regulator, two-component regulatory systems, and *fla* gene regulation.[7]

EPIDEMIOLOGY AND TYPING

Although the origin of a particular *Campylobacter* infection is rarely traced, transmission probably occurs via fecal contamination. Other sources of *Campylobacter* infection include unpasteurized milk, water, and pet contact. The infective dose is low, being about 800 cells ingested.

Campylobacter species represent a taxonomically heterogeneous group and many typing methods have been used to study the epidemiology of *Campylobacter* infections. These include biotyping, serotyping, phage typing, auxotyping, ribotyping, multilocus enzyme electrophoresis, amplified fragment length polymorphism (AFLP), and pulse field gel electrophoresis (PFGE). Biotyping campylobacters is of limited value as strains have relatively fastidious growth requirements and only a few biochemical tests give adequate discrimination. Two serotyping methods are most often used: the Penner scheme and the Lior scheme. These serotyping methods are primarily used by a few reference laboratories because of the time and expenses involved in maintaining good-quality antisera.

DNA-based typing methods have advantages over phenotypic-based methods in that they are faster, more discriminatory, and widely available.[8] Each method has advantages and disadvantages, but for its speed and simplicity, typing of the flagellin gene (*fla* typing) has been widely used. The primers A1 (5′-GGA TTT CGT ATT AAC ACA AAT GGT GC-3′; forward) and A2 (5′-CTG TAG TAA TCT TAA AAC ATT TTG; reverse), followed by digestion with *Dde*I,[9] are the most widely used methods. This has been used in efforts toward interlaboratory standardization.[10] PFGE, based on standardized protocols, has also been used for subtyping *C. jejuni* strains in PulseNet laboratories and is, at present, considered the gel standard genotyping method.[11]

The *Campylobacter* genome contains highly variable ''plastic'' regions, which gives some strains the ability to disguise themselves and avoid the host immune system. This plasticity can distort the results of genotyping methods for *Campylobacter* spp.

ISOLATION AND DETECTION

There are many culture-based methods for the isolation and detection of *Campylobacter* spp. These include basal media such as Colombia, Brucella, and *Campylobacter* Blood-Free Selective Medium. The addition of antibiotic supplements (such as Bolton, Skirrow, or Preston) as selective agents and blood or charcoal (to quench toxic compounds or to prevent accumulation of photochemically generated oxygen derivatives) is necessary to improve isolation. Other media such as *Campylobacter* cefoperazone deoxycholate selective agar (CCDA) contain the antifungal agent amphotericin B and the broad-spectrum antibiotic cefoperazone, which inhibits both yeast and fungi. The medium and incubation temperature used can influence the genotype of *Campylobacter* spp. detected,[12] rate of survival (Murphy et al., unpublished data), oxygen tolerance,[13] and percentage isolation.[14] Using culture-based methods, presumptive results can be obtained in 2–3 days, whereas definitive results can take 3–5 days.

The enrichment of samples, combined with a direct method of detection, is frequently used to enumerate *Campylobacter* spp., especially where cell numbers are low.[15] The use of a resuscitation incubation period at 37°C facilitates the recovery of injured cells. The incubation temperature of 42°C, which is used routinely for the isolation of thermotolerant *Campylobacter* spp., can inhibit many nonthermotolerant species associated with gastroenteritis.

Genetic-based methods of detection offer an alternative to culture-based methods. These methods are sensitive, specific, rapid, and less cumbersome than traditional culture-based methods. An extensive range of polymerase chain reaction (PCR) assays, based on different target genes and primers, has been described for the detection and identification of *Campylobacter* spp. Of 26 primer pairs tested, the combination of OT1559 (5′-CTGCTTAACA-CAAGTTGAGTAGG) and 18-1 (5′-TTCTGACGGTAC-CTAAGGAA), targeting the 16S rRNA gene, was found to be most selective. This primer pair was then used in a multicenter international collaborative trial, testing 10 target and 8 nontarget strains. The results showed 93.7% sensitivity and 100% specificity.[16] With multinational disease outbreaks occurring, the move toward standardization of methods used for isolation and epidemiology is essential.

There is no simple method for the identification of *Campylobacter* to subspecies level. Discrimination between *C. jejuni* and *C. coli* can be achieved by using a combination of PCR amplification with a DNA probe hybridization step to detect and discriminate subspecies[17] by PFGE or multiplex PCR.

SURVIVAL

Most foodborne pathogens are robust organisms capable of surviving the stressful environment outside the host. Various mechanisms have evolved to enable survival of oxidative stress, starvation, heat, cold, and so on.

Campylobacter spp. lack many of these important survival mechanisms.[3] In particular, they lack the typical stationary-phase response mediated by rpoS.[18] In a farm environment, *C. jejuni* can be isolated from animals, milk, slurry, farm vehicles, water, and so on. They can also be isolated during food processing and from various food samples. This implies that, although they are apparently sensitive, they must be capable of surviving environmental stress by as yet unidentified mechanisms. The VNC state is one such possible mechanism, but two others have been recently reported. These are the production of an extracellular protein that confers stress resistance[19] and the observation of an adaptive tolerance response.[20] The indications are that *Campylobacter* spp. are quite robust in their ability to survive outside the host; otherwise, they would not be the principal cause of foodborne illness worldwide.

GENOMICS AND PROTEOMICS

The amount of DNA sequence data available and the methods used to exploit it have grown exponentially in recent years. The aim of this work is to understand how the various components of an organism interact to function properly, not just to catalogue a list of genes and how they function. Genomics describes the study of the genetic makeup of an organism, whereas proteomics is the study of the protein composition of the cell. There are more proteins in an organism than there are genes because transcriptional control, posttranslational modification, and so on can lead to multiple products form the one gene—hence the need to study the interrelationship between genomics and proteomics, which is termed functional genomics.

The recent publication of the genome sequence of *C. jejuni* NCTC11168 has shown that it has a circular chromosome of 1.6 Mbp, a G+C content of 36%, and a predicted 1654 proteins.[21,22] One of the most notable features of the genome sequence was the presence of hypervariable sequences associated with genes encoding biosynthesis/modification of surface structures, or linked to hypothetical genes. Whole genome comparison of different *C. jejuni* isolates has quantified this degree of genetic heterogeneity among different strains. Pearson et al.[23] have shown that 16.3% of the genes are absent or divergent in one or more of the 18 strains tested. Despite this, the genome sequence contains virtually no transposons, phage remnants, or insertion elements, and few repeat sequences, raising the question as to the source of the heterogeneity. The sequencing of a second strain of *C. jejuni*, which should be available in 2004, and the availability of the genome sequence of *C. coli*, *C. lari*, and *C. upsaliensis*, which are in progress,[24] should give a better understanding of genetic heterogeneity in *Campylobacter* spp.

There has been an upsurge in research capitalizing on the availability of the genome sequence. DNA microarrays are being used for genome analysis, gene expression, identification, and typing (called genomotyping). Large biotechnology companies are using DNA-based microarrays to develop new drugs. This can avoid large-scale, expensive mode-of-action studies. Gene expression studies (transcriptomics) have tended to predominate functional genomics. Although this does have the advantage of showing what genes are turned on and when, it has the disadvantage that it gives no information on the expression of these genes as functional proteins. Two-dimensional (2-D) gel electrophoresis is the best method to study protein expression. However, protein concentrations less than 1 ng cannot be routinely measured; certain proteins (e.g., hydrophobic membrane-bound proteins) are not suitable for separation by 2-D gels, and differences in abundance of proteins cannot be accounted for by this method. Until further development of new technologies, gene expression studies, in association with 2-D gel electrophoresis, will be necessary to yield maximum information. New technologies, such as polysome-bound mRNA profiling, will bridge the gap between genomics and proteomics, as it will give information on every level of regulation between transcription and translation. However, it cannot be used to study posttranslational modification.[25]

Although the ''genomic'' understanding of *Campylobacter* spp. has been advanced recently, research on proteomics has lagged behind. Very little information relating to protein expression by *Campylobacter* has been published. We have studied the proteomics of *C. jejuni* during induction of an adaptive tolerance response to acid and aerobic conditions. Under conditions of induction, 11 proteins were upregulated, 21 were downregulated, and 60 ''new'' proteins were identified. These ''new'' proteins could be due to upregulation of low-abundance proteins not detected in uninduced samples. Identification of these proteins by matrix-assisted laser desorption initiation time of flight (MALDI-TOF) analysis showed the induction of global regulatory systems, such as two-component regulators, methylation proteins, and heat shock proteins. The generation of mutants and the complementation of these mutants with the expressed gene on a plasmid are necessary to show functional relationships in survival and pathogenesis.

CONCLUSION

Advances in the genomics of *Campylobacter* spp. have resulted from the publication of the genome sequence.

Whole genome-based DNA microarrays are being used for the detection, isolation, and typing of *Campylobacter* spp. When developed further, these methods will revolutionize the epidemiology of *Campylobacter* spp. Gene expression studies, in association with protein expression studies, should begin to provide the type of information that will result in a better understanding of *Campylobacter* pathogenesis and virulence, and the mechanisms by which they cause disease, although development of new technologies will be necessary to bridge the gap between genomics and proteomics. Although advancing the scientific understanding of *Campylobacter* spp. will undoubtedly result from this research, the application of this information to achieving a reduction in the occurrence of *Campylobacter*-related illness is essential.

Cancer Chemotherapy—Overview on the Clinical Impact of Polymorphisms in Metabolizing Enzymes

C

Ikuo Sekine
Nagahiro Saijo
National Cancer Center Hospital, Chuo-ku, Tokyo, Japan

INTRODUCTION

Cancer chemotherapy has progressed greatly over the past five decades, providing not only temporary control of the metastatic disease that develops in 60% to 70% of cancer patients during their lifetime, but also curative therapeutic interventions for patients with some types of locally advanced solid tumors and hematologic malignancies. Cancer chemotherapy is distinct from other general drug therapies because of the following characteristics: 1) advanced cancer remains a life-threatening disease in many cases; 2) the therapeutic index, the ratio of the dosage required to produce toxicity and an antitumor effect, is narrow; 3) patients are treated with or close to the maximum tolerated dosage, with toxicity levels so severe that treatment-related death occurs in about 1% of patients who receive chemotherapy; 4) chemotherapy drugs are administered intermittently, usually on a weekly or monthly basis; 5) the delay between the administration of anticancer agents and their clinical effects is a matter of days to weeks; and 6) two to four anticancer agents are often administered as combination chemotherapy for many tumors, with drug–drug interaction, significantly affecting the pharmacokinetics of each agent in some cases. Until recently, the therapeutic dosage of anticancer agents was determined empirically in Phase I trials, without any consideration of interindividual variability in drug pharmacology. The plasma drug concentration, however, can vary greatly between individuals of the same weight and with the same drug dosage, leading to lethal toxicity or no antitumor effects. Genetic polymorphisms in drug metabolizing enzymes are therefore of utmost importance for achieving a favorable outcome from drug therapy.

TYPES OF ENZYMES

Dihydropyrimidine Dehydrogenase

Dihydropyrimidine dehydrogenase (DPD; EC 1.3.1.2), the first and rate-limiting enzyme in the three-step catabolic pathway of the endogenous pyrimidine bases uracil and thymine, also catalyzes the reduction of 5-fluorouracil (5-FU) to dihydrofluorouracil. The human DPD enzyme is a homodimer of a 111-kDa subunit with 1025 amino acids residues containing FMN, NADPH, and flavin adenine nucleotide (FAD) binding sites; the enzyme is encoded by a single gene (DPYD gene) with 23 exons mapped to chromosome 1p22.[1,2]

Familial DPD deficiency was first described in 1984 in pediatric patients exhibiting thymine–uraciluria with a variety of neurologic symptoms. Of the more than 20 DPYD allelic alterations, the most common variant in patients with DPD deficiency is the homozygous deletion of exon 14 that is caused by a G to A point mutation at the splice donor site (DPYD*2A variant). This variant is detected in 24% to 52% of patients with DPD deficiency.[2,3] Screening for the presence of this variant in the general population revealed that it was found in 1.2% or less of individuals from various ethnic backgrounds.[2,3] Dihydropyrimidine dehydrogenase activity is also regulated at the levels of transcription and translation. Expression of the DPYD gene and DPD activity in the liver and colonic tissues varies markedly. Dihydropyrimidine dehydrogenase activity in peripheral blood mononuclear cells from the general population and from unselected cancer patients varies widely among individuals, with a significantly low enzyme activity found in 3–6% of these populations.[1,2]

As severe toxicity with neurologic symptoms associated with the administration of 5-FU in a patient with familial pyrimidiuria was first described in 1985, several patients with DPD deficiency have developed severe 5-FU-induced toxicity. However, pretreatment analyses of DPD activity in human peripheral blood mononuclear cells showed a weak or no correlation with 5-FU clearance and failed to predict a risk of toxicity in patients receiving 5-FU.[2] A genotyping test for DPYD mutations explained the reduction in DPD activity in only a limited number of patients. The sensitivity of the test for identifying patients at high risk for severe 5-FU toxicity was also low. Thus, no single test has been validated as a tool for individualizing the dosage of 5-FU.[2]

Methylenetetrahydrofolate Reductase

Methylenetetrahydrofolate reductase (MTHFR; EC 1.5.1.20) catalyzes the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, which donates a methyl group to homocysteine to produce methionine. This enzyme has a central regulatory role in the metabolism of folate and methionine, both important factors in DNA synthesis, repair, and methylation.[4] The molecular weight of this enzyme is 77 kDa, and the enzyme is encoded by a gene with 11 exons located on chromosome 1p36.3.

Severe MTHFR deficiency was first described in 1972 in a 15-year-old boy who exhibited mental retardation, progressive neurologic deterioration, and homocystinuria. Of the 33 polymorphisms identified in the MTHFR gene, the most common was a C to T transition at nucleotide 677 (C677T), corresponding to an alanine to valine change at codon 222. Homozygosity for this mutation results in an enzyme activity level that is equal to 30% of the wild-type enzyme activity level found in vitro and is found in 10–16% of both Caucasian and Asian populations. Heterozygosity, resulting in 60% of the enzyme activity level found in vitro, is found in up to 40% of the population.[4,5] This variant is associated with an increased risk for various common cancers, probably as a result of the insufficient methylation of genomic DNA.[6]

An association between the MTHFR C677T polymorphism and severe methotrexate (MTX) toxicity has been reported in patients with breast cancer receiving cyclophosphamide, MTX, and 5-FU; patients with chronic myelogenous leukemia following hematopoietic cell transplantation; patients with acute leukemia undergoing maintenance chemotherapy; patients with ovarian cancer treated with carboplatin and MTX; and patients with rheumatoid arthritis receiving MTX.[7] As MTHFR does not metabolize MTX directly and is not the primary target of this agent, an imbalance in folate pools and a reduced ability to recycle folate have been proposed as important mechanisms in the development of MTX toxicity.[5]

Cytochrome P450

The cytochrome P450 enzymes are a superfamily of heme proteins that carry out the oxidative, peroxidative, and reductive metabolism of many structurally unrelated compounds, including endogenous steroids, fatty acids, and bile acids, as well as xenobiotics such as environmental pollutants. They are also responsible for the metabolic activation and/or inactivation of many drugs, including anticancer agents.[1,8]

CYP1A2 accounts for nearly 15% of the cytochrome P450 found in the human liver and metabolizes more than 20 drugs including caffeine, theophylline, imipramine, clozapine, and propranolol. Dacarbazine requires oxidative *N*-demethylation by CYP1A2 for its activation to exhibit a DNA-alkylating action.[1] Reported interindividual variations in CYP1A2 expression range from 15- to 60-fold in a number of ethnic and geographically distinct populations. The human CYP1A2 gene, consisting of seven exons, is located on chromosome 15. Among the 14 known variant alleles of CYP1A2, CYP1A2*1C and CYP1A2*1K lead to a reduction in enzyme activity, but their clinical significance in dacarbazine metabolism and toxicity is unknown.

CYP2C8 catalyzes the formation of 6-alpha-hydroxypaclitaxel, one of the major paclitaxel metabolites in human plasma and bile. The CYP2C8 gene is one of four CYP2C gene family members located on chromosome 10q24. Six variant alleles have been reported, and CYP2C8*3 is associated with a low enzymatic activity and a reduction in the metabolism of paclitaxel.[9]

CYP3A4 accounts for as much as 60% of the cytochrome P450 enzymes in the human liver and is responsible for the oxidative metabolism of an estimated 50% to 60% of all clinically used drugs, including anticancer agents such as teniposide, etoposide, cyclophosphamide, ifosfamide, vindesine, vinblastine, vincristine, vinorelbine, paclitaxel, docetaxel, and irinotecan.[1] The CYP3A4 gene has been mapped to 7q22.1, and 24 variant alleles have been reported. A more than 10-fold interindividual variation in the clearance of CYP3A4 substrate drugs is seen in vivo, but structural mutations in the CYP3A4 gene do not seem to be a major factor in this functional variation.[10] In contrast, the expression levels of CYP3A4 in the human liver vary up to 60-fold in the general population. CYP3A4 expression is known to be induced by various therapeutic agents, including glucocorticoids, rifampicin, barbiturates, and other xenobiotics. Recently, nuclear receptors, such as the constitutive androstane receptor (CAR) and pregnane X receptor (PXR), have been reported to mediate such inductions and may play an important role in the large variation in CYP3A4 expression.[11]

CYP3A4 is involved in the metabolic pathways of many anticancer agents, and it may be possible to predict the pharmacokinetics and toxicity of an anticancer agent by its effect on CYP3A4 activity, as shown in an excellent correlation between docetaxel clearance and pretreatment CYP3A4 activity measured by excreted 6-beta-hydroxycortisol.[12] In addition, the inhibition or induction of CYP3A4 activity by a drug may lead to an alteration in the pharmacokinetics and toxicity profile of an anticancer agent. The sequence of cisplatin followed

by paclitaxel administered in a 24-hr infusion induced a 33% reduction in the clearance rate of paclitaxel and a more profound neutropenia than the reverse drug sequence in a Phase I study.[13] This finding can be explained by the reduction in CYP3A4 activity produced by cisplatin, although the mechanisms responsible for this sequence-dependent drug–drug interaction are not entirely understood. Enhanced vincristine toxicity was observed in two patients with acute lymphoblastic leukaemia who concomitantly received itraconazole, which inhibits CYP3A4 activity.[14] The CYP3A4-inducing antiepileptic agents carbamazepine, phenytoin, and phenobarbital decreased the steady-state paclitaxel concentration and toxicity in patients with glioblastoma multiforme, leading to a 42% higher maximum tolerated paclitaxel dosage in patients who received the antiepileptic agent, compared to that in patients who did not receive any of these agents.[15] These antiepileptic agents also increased the systemic clearance of vincristine by 63% in patients with brain tumors, compared with a control group.[16]

Thiopurine *S*-Methyltransferase

Thiopurine *S*-methyltransferase (TPMT; E.C. 2.1.1.67) is a cytosolic enzyme that catalyzes the *S*-methylation of aromatic and heterocyclic sulfhydryl compounds.[1] The natural substrates for TPMT remain unknown, but this enzyme is involved in the intracellular inactivation of 6-mercaptopurine, 6-thioguanine, and azathioprine. The TPMT gene consists of 10 exons located on chromosome 6p22.3. Thiopurine *S*-methyltransferase activity in erythrocyte lysates is well correlated with the level of TPMT activity in the liver and kidney. An inverse correlation between TPMT activity and the accumulation of 6-mercaptopurine metabolites in erythrocytes has been established. Patients with TPMT deficiency are at a high risk of potentially fatal hematopoietic toxicity after receiving a standard dosage of 6-mercaptopurine, and the mercaptopurine dosage should therefore be reduced by 10- to 15-fold.[17]

Thiopurine *S*-methyltransferase activity is inherited as an autosomal codominant trait. Population studies in Caucasians have shown a trimodal distribution of TPMT activity, with about 90% of subjects having high activity, 10% of subjects having intermediate activity, and 0.3% having no activity. Of the 10 mutant alleles resulting in a low TPMT activity, TPMT*2, TPMT*3A, and TPMT*3C account for 80–95% of the intermediate or low enzyme activity cases. The frequencies and patterns of these alleles exhibit ethnic variations. TPMT*3A is the most prevalent mutant allele among Caucasians, whereas TPMT*3C is the most common mutant allele among Asians.[17] A variable number tandem repeat (VNTR) polymorphism within the TPMT promoter has also been reported. The VNTR length varied from three to nine repeats, and an inverse relationship existed between the sum of the repeat units on the two alleles and the level of erythrocyte TPMT activity, although the effects of this relationship were quantitatively small.[17]

Uridine Diphosphate Glucuronosyltransferase

Uridine diphosphate glucuronosyltransferases (UGTs; E.C.2.4.1.17) are a family of enzymes in the endoplasmic reticulum that catalyze the conjugation of hydrophobic endogenous and xenobiotic compounds into hydrophilic glucuronides with UDP-glucuronic acid.[18] The human UGT family is divided into two major classes, UGT1 and UGT2, based on an amino acid sequence comparison. At least 15 human UGT cDNAs have been identified to date. Of these, eight are classified as UGT1 isoforms (UGT1A1, 1A3, 1A4, 1A6, 1A7, 1A8, 1A9, and 1A10) encoded by the UGT1A genes located on chromosome 2q37, and seven are classified as UGT2 isoforms (UGT2A1, 2B4, 2B7, 2B10, 2B11, 2B15, and 2B17) encoded by the UGT2 genes located at chromosomes 4q13 and 4q28.

The UGT 1A1 isoform glucuronidates bilirubin and SN-38, an active metabolite of irinotecan. An absence or reduction in UGT1A1 function leads to three inherited forms of disorders in humans: Crigler–Najjar syndrome type I, Crigler–Najjar syndrome type II, and Gilbert's syndrome. All of these disorders are the results of either mutant UGT1A1 alleles or mutations in the UGT1A1 promoter sequences.[18] The insertion of TA bases in the repetitive TATA-box upstream of the UGT1A1, the TA[6] allele (UGT1A1*28), causes a reduction in the expression of the gene when compared with the wild-type TA[5] allele. UGT1A1*28 is a relatively common polymorphism, and heterozygosity for the mutated allele and homozygosity for the mutated alleles are found in 55% and 11%, respectively, of the European population and in 28% and 2%, respectively, of the Asian population.[1] Heterozygosity and homozygosity for UGT1A1*28 are both significant risk factors for severe irinotecan toxicity. Other UGT1A1 variant alleles, UGT1A1*6 and UGT1A1*7, are not associated with irinotecan toxicity.[19]

Two other UGT isoforms, UGT 1A7 and UGT 1A9, also glucuronidate SN-38, in vivo, but their clinical significance with regard to irinotecan toxicity is unknown.

Glutathione *S*-Transferase

Glutathione *S*-transferase (GST; EC.2.5.1.18) catalyzes the glutathione conjugation reaction in detoxification pathways for a wide variety of electrophilic compounds including anticancer agents to make them more water-soluble, less toxic, conjugates.[1] The human cytosolic GST enzymes, classified into six families, α, μ, ω, π, θ, and ζ, comprise heterodimers or homodimers of subunits. Orally administered busulfan, a bifunctional alkylating agent, is eliminated by conjugation with glutathione in the intestinal mucosa, and the large interpatient variation in busulfan clearance is associated with the activity of GSTs, especially the α-isoform. In addition, alteration of GSTs in tumor cells is considered to be associated with their resistant phenotypes against anticancer agents through direct detoxification and inhibition of the MAP kinase pathway. The expression of GST-π in non-small cell lung cancer tissue was significantly related to clinical response to cisplatin-based chemotherapy in small case series studies.[20]

CONCLUSION

Individual variations in responses to anticancer agents can be partly explained by genetic polymorphisms in their metabolizing enzymes. Genotype–phenotype correlations, however, are still poorly understood because epigenetic influences on gene expression make it difficult to estimate the exact effects of genetic conditions on the activities of metabolizing enzymes. To enable customized and individualized cancer chemotherapies in which the most favorable dosage and drug combination are administered, further studies should focus on parameters that are closely correlated with the pharmacokinetics and pharmacodynamics of an agent and on well-designed clinical trials to evaluate their clinical usefulness.

INTRODUCTION

Chemotherapy is still one of the main treatment options for the therapy of various malignancies. Anticancer drugs have to be metabolized by several enzymes and can also be degraded by specific enzymes. As activities of these enzymes may vary from patient to patient and may significantly influence the treatment outcome, understanding of the effects of increased or decreased drug-metabolizing enzyme activities help in the design of the optimal chemotherapeutic regimen. More recently, these treatment attempts may even be designed for every patient based on their genetic pattern. Considering the narrow therapeutic range of many anticancer compounds, precise dosing of such drugs is mandatory. The determination of genetic conditions, i.e., polymorphisms of specific genes encoding enzymes, might help to predict the effects of selected anticancer drugs. Thus ineffective administration of chemotherapeutic drugs or even the occurrence of severe toxic side effects could be avoided.

In this article, we focus on three enzymes that play a major role for effective treatment with 5-fluorouracil (5-FU), 6-mercaptopurine (6-MP), or irinotecan. The enzymes involved in the development of severe toxicity associated with these drugs are dihydropyrimidine dehydrogenase (DPD), thiopurine *S*-methyltransferase (TPMT), and UDP-glucuronosyltranferase 1A1 (UGT1A1). The genes encoding for these enzymes can be examined prior to chemotherapy using molecular methods for genetic testing and thus possible side effects can be predicted.

DIHYDROPYRIMIDINE DEHYDROGENASE

The chemotherapeutic compound 5-Fluorouracil (5-FU) is a widely used drug for the treatment of various types of cancer, such as colon or breast tumors. Optimal combinations with other chemotherapeutic compounds have been developed because of its limited efficacy when used alone. More recently, prodrugs of 5-FU were invented that can be administered orally. In particular, for patients suffering from advanced colon or breast cancer, oral administration can significantly improve the quality of life.

The therapeutic effects of 5-FU are caused by the inhibition of RNA and DNA synthesis. 5-FU is metabolized to 5-fluorouridine and further phospholylated to 5-fluorouridinetriphosphate, which replaces uridine 5′-triphosphate (UTP) in RNA. On the other hand, 5-FU can be converted to 5-fluorodeoyxyuridine and further to the respective 5′-triphosphate, which causes the inhibition of DNA synthesis. The monophosphate of 5-fluorodeoxyurdine (5-FdUMP) itself is an inhibitor of the enzyme thymidylate synthase, which is responsible for the conversion of dUMP to dTMP.

The degradation of 5-FU is metabolized by the enzyme dihydropyrimidine dehydrogenase (DPD), which generates dihydro-5FU (5-FUH_2), an inactive metabolite of 5-FU. The metabolic pathway is depicted in Fig. 1.

Therefore, patients with increased activity of DPD might require higher 5-FU doses to achieve antitumor activity. Decreased activity of this enzyme, however, might cause higher 5-FU levels with the risk of life-threatening toxicities.[1] DPD deficiency might have been the cause of severe neutropenia in patients after 5-FU administration.[2–4] Even lethal toxic effects were reported in DPD-deficient patients. Because of the very narrow therapeutic range of 5-FU, knowledge of the activities of these metabolizing enzymes might yield essential information for individual dosing. Thus ineffective doses or life-threatening toxicities at doses in the regular range may be avoided. Significant reduction of DPD activity resulting in severe 5-FU toxicity can even be caused by the inactivation of one allele of the DPD gene. Various mutations of the DPD gene (DPYD),

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020979

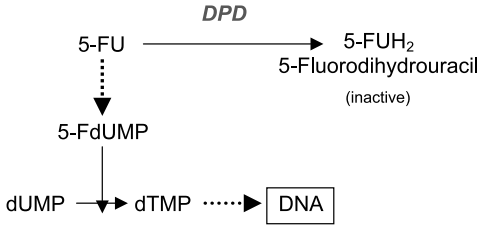

Fig. 1 The metabolic pathway of DPD action. (*View this art in color at www.dekker.com.*)

which are associated with reduced enzyme activity and increased risk of toxicity, were identified.[5,6] For instance, a mutation for DPYD*9A was identified in patients suffering from toxic 5-FU side effects. However, DPYD mutations do not always result in reduced enzyme activity (biochemical phenotype). There are patients who have inherited DPD deficiency and are at high risk for 5-FU toxicity, but many others inherit variant alleles without clear association between genotype and 5-FU toxicity. However, van Kuilenburg and coworkers[6] described the correlation of the rather frequent (1.8% heterozygotes in the normal population) mutation (IVS14+1G<A) of the DPYD, which might also be associated with 5-FU toxicity. They even described the lethal outcome of 5-FU treatment in a patient who was homozygous for this mutation. So far, various DPYD allelic variants are known. In some cases, these genetic variants correlate with altered DPD activity; in other cases, this connection remains to be further elucidated. However, some of the DPD gene mutations such as DPYD*2A and DPYD*9A are considered to be of clinical relevance. This renders DPYD as a potential candidate for pharmacogenetic profiling prior to chemotherapy with 5-FU, and thus adverse drug effects might be avoided. To be considered beneficial for all patients, a closer correlation between genotype and phenotype needs to be established, and then all relevant genetic alterations, i.e., single nucleotide polymorphisms (SNPs) have to be tested prior to therapy. This could lead to the development of personalized therapy for every patient with maximum effect and minimum toxicity.

C

THIOPURINE *S*-METHYLTRANSFERASE

Childhood acute lymphoblastic leukemia (ALL) is the most common childhood malignancy and can be cured in most cases via chemotherapy. ALL is treated by a combination of various drugs; however, 6-mercaptopurine (6-MP) is one of the drugs required to maintain remission. It is mandatory to adjust 6-MP dosage according to the toxicity of 6-MP, which is mainly caused by the accumulation of the active metabolite 6-thioguanine triphosphate (6-TGTP) via the metabolite 6-thioinosine-monophosphate (6-TIMP; metabolic pathway shown in Fig. 2). 6-MP is an antimetabolite, which has to be activated to its triphosphate in order to be incorporated into DNA. On the other hand, 6-MP, but also 6-TIMP, can be inactivated by the enzyme TPMT to their inactive methylated metabolites 6-methylmecaptopurine (6-MMP) or 6-methylthioinosinemonophosphate (6-MTIMP). Thus decreased TPMT activity may lead to accumulation of the active 6-MP metabolite, and increased activity may lead to ineffective drug concentrations. Another drug which is methylated by TPMT is 6-thioguanine (6-TG), and indirectly the compound azathioprine, which is a prodrug of 6-MP. 6-TG is also being used as cytotoxic agent, and azathioprine is used as an immunosuppressant to treat rheumatic diseases. In all cases, elevated or depressed TPMT activity can cause ineffective accumulation of drug metabolites or toxic side effects, respectively. This can even include fatal myelosuppression after a standard dose of a thiopurine drug. Various other cases of TPMT-deficient patients showing severe side effects after 6-MP treatment are known. Therefore, the determination of polymorphisms of the TPMT gene prior to therapy might help to identify patients at risk of developing toxic side effects from 6-MP therapy. Genetic diversity (e.g., 238G>C, 460G>A, 719A>G) causes enhanced proteolysis of TPMT proteins and correlates

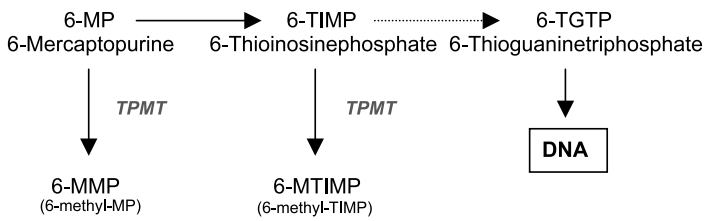

Fig. 2 The metabolic pathway of TPMT action. (*View this art in color at www.dekker.com.*)

with decreased TPMT enzyme activity and increased risk of treatment.[7] However, adverse drug reactions, such as hepatic toxicity, cannot be linked to TPMT polymorphisms and activity. Some TPMT variant alleles, which are associated with low enzyme activity, are known.[8–12] In Caucasians (55–70%), however, TPMT*3A is the most common variant allele attributed to low TPMT activity.[13] TPMT*3C is more common among Asians compared to Caucasians, where this variant is quite rare (<1%). The wild-type TPMT gene is associated with higher TPMT activity, and heterozygosity or homozygosity for one variant allele show significantly reduced enzyme activity.[14–16] It has to be considered that molecular testing, which has to be performed prior to therapy, might vary from one ethnic group to another, and still be unable to provide 100% safety. Some still unknown mutations might also be responsible for decreased TPMT activity.[17] Thus TPMT phenotyping is being performed in various establishments. The enzyme activity of erythrocytes correlates well with the activity of bone marrow cells and might therefore be measured prior to therapy. However, significant variability of enzyme activities in wild-type patients are known and cannot yet be clearly linked to genetic patterns. Even in TPMT heterozygotes, an increased risk of thiopurine hematopoietic toxicity was observed by Relling et al.[18] Individual dosing of 6-MP might help to successfully treat ALL, and therefore the aim is to find all genetic variants that are linked to altered TPMT activity. In such a way, genotyping might help to determine the individual dose needed for effective cancer chemotherapy.

UDP-GLUCURONOSYLTRANFERASE 1A1

UDP-glucoronosyltransferases are enzymes responsible for detoxification and elimination of various metabolites and drugs. These enzymes also catalyze the inactivation of irinotecan (CPT-11), an analog of the alkaloid camptothecin. CPT-11 is clinically used for the treatment of refractory and advanced colorectal cancers. Dose-limiting toxicities are diarrhea and pancytopenia. CPT-11 is metabolized to its active product, SN-38, by the enzyme carboxylesterase 2. As depicted in Fig. 3, UGT1A1 is responsible for the inactivation of SN-38, the most relevant metabolite of CPT-11, to the glucuronide of SN-38. CPT-11 can also be directly inactivated by formation of the inactive oxidation product, aminopenthan carboxylic acid (APC). Responsible for this step are cytochromes *P*450 3A4 and 3A5, as shown in Fig. 3. However, the formation of the SN-38 glucuronide is the most important inactivation pathway of CPT-11. This step is catalyzed by UGT1A1, an enzyme that is also responsible for bilirubin conjugation. The formation of glucuronide is the limiting step for renal clearance, which provides the solubility in water. Therefore, decreased UGT1A1 might not only cause hyperbilirubinaemia (unconjugated bilirubin), but also the accumulation of SN-38 and the toxic side effects of CPT-11 treatment. A condition based on a genetic defect of the UGT1A1 gene is known as Gilbert's syndrome, which is associated with increased bilirubin concentrations and occasionally severe CPT-11 toxicity, as previously described by Wasserman et al.[19] The genetic defect associated with Gilbert's syndrome is a TA insertion in the promotor region of the gene;[20] the variant allele is named UGT1A1*28.[21] Another mutation of the gene, which is mainly found among Asians is a G211A mutation (UGT1A1*6).[22] In Asian populations, Gilbert's syndrome is a result of missense mutations (either homozygous or heterozygous) in the coding sequence. Another important regulatory element of UGT1A1 is the phenobarbital-responsive enhancer module (PBREM), which might contain variants affecting inducible gene expression. Innocenti et al.[23] recently showed that the haplotype structure of promoter is probably different between Caucasians and African-Americans. The mutations result in reduced enzyme activity and the likelihood of toxic side effects of CPT-11 treatment.

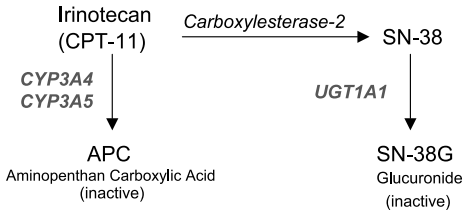

Fig. 3 The metabolic pathway of UGT1A1 action. (*View this art in color at www.dekker.com.*)

CONCLUSION

Chemotherapy remains an important option for the treatment of various malignancies. Drugs have to be activated and inactivated by various enzymes. We have described three enzymes (DPD, TPMT, and UGT1A1) responsible for the degradation of 5-FU, thiopurines, and CPT-11—all of which are widely used anticancer agents. As the activities of these enzymes might vary from patient to patient, standard doses could either cause

severe toxicities or be ineffective. Therefore, the future goal should be to individualize dosing according to the genetic pattern of the patient reflected in different enzymatic activities. Molecular testing prior to therapy for identifying factors which predict the treatment outcome and supports individualized therapy are needed. One approach is to determine the variants of the genes coding for the above mentioned enzymes. These genetic polymorphisms should be associated with altered enzyme activities. Thus doses could be predicted for every single patient. As described, a number of genetic variations and mutations are known for the enzymes. Some of them translate into altered enzyme activities. However, because of the huge number of mutations—not always linked to a different phenotype—and because of the genetic differences between ethnic groups, until now it has not been possible to draw final conclusions, which are advantageous for all patients. Nevertheless, for the described enzymes, genetic testing may provide additional information and help to predict the individual dosage for many patients. We hope that, as a result of intensive research in this field, ''personalized therapy'' with drugs having a narrow therapeutic window, such as anticancer compounds, might be possible in the near future.

Candida spp.

Philip Lewis White
Sam Hibbitts
University of Wales College of Medicine, Cardiff, U.K.

INTRODUCTION

With the number of immunocompromised patients at risk for fungal infections on the rise and with yeasts representing the most common fungal isolates from human patients, concerns over infections caused by the genus *Candida* continue to expand. In 1999, *Candida* species were reported as the fourth most frequent cause of nosocomial blood-borne infection within the critically ill population, and with this population ever increasing, it seems reasonable to predict a mounting number of deep-seated candidal infections.[1] However, improved awareness/diagnosis of the disease, combined with the development of novel detection techniques, may have produced a deceptive increase in the incidence of candidosis.

Candidal infections can target almost every tissue in the human body, with superficial infections being the most common and with invasive infections providing the greatest concerns for clinicians. The genus *Candida* contains approximately 200 species, but few species are considered as opportunistic pathogens, although it is probably only a matter of time until further species would have been considered as causative agents for a case of superficial or deep-seated candidosis.

TYPE OF PATHOGEN

Candida species are primarily saprophytic eukaryotic organisms and only occasional opportunistic pathogens. Many species exhibit a bitrophic existence, spending much of their life as common commensals of the gastrointestinal (GI) tract and mucous membranes of humans only to become pathogenic because of debilitation of the host. Indeed, the most significant source of *Candida* causing candidosis is endogenous.[2]

Despite the main cause of invasive candidosis (IC; *Candida albicans*) being considered as an obligatory animal saprophyte,[2]*Candida* species, including *C. albicans*, are frequently isolated from nonanimal environments. Indeed, *Candida* is an important cause of nosocomial bloodstream infections, with 97% of candidemias attributed to *C. albicans*, *Candida glabrata*, *Candida parapsilosis*, *Candida tropicalis*, and *Candida krusei*.[3]

RANGE OF INFECTIONS

Superficial Candidosis

For an informative review of superficial candidosis including the symptoms, predisposing factors, and treatment for oral, genital, cutaneous, and chronic mucotaneous candidosis, and candidosis of the nail, then refer to the comprehensive book by Odds.[2] The following text represents a summary of some of the information available.

Oral Candidosis

Oral candidosis (OC) is one of the most frequent human fungal infections. Commonly affecting the young, the aged, and the immunosuppressed, it has various clinical forms [pseudomembranous candidosis (oral thrush), atrophic candidosis, hyperplastic candidosis, and angular cheilitis]. Its diagnosis can be complicated by a lack of culture or symptoms; however, because *Candida* species are regular human commensals (30–50% of the normal population),[4] then an oral culture of *Candida* does not confirm a case of OC and only histological evidence can validate an infection.

C. albicans is the most prevalent cause of OC (60–80% of yeasts isolated from the mouth), with at least eight other species documented as causative agents of OC and with non-*C. albicans* emerging as relatively common causes of OC.[4] Furthermore, novel species of *Candida* (*Candida dubliniensis*)[5] have been, and will continue to be, isolated over time. The treatment regime is usually topical; however, oral fluconazole has proven successful with acquired immunodeficiency syndrome (AIDS) patients, although monitoring for fluconazole-resistant strains is essential.

Genital Candidosis

Candida species are common organisms of the female genital tract, which are isolated from 20% of normal women.[4] *C. albicans* is the most common cause of vaginal candidosis (VC) (up to 89% of infections),[6] although *C. glabrata* is emerging as an important pathogen that could become resistant to fluconazole treatment.[7]

DOI: 10.1081/E-EDGP 120020830

Affecting 75% of women during their lifetime,[4] VC is a common problem. As the prevalence of *Candida* detected by culture is the same in women with or without symptoms, meaningful diagnosis is difficult and both culture and clinical symptoms should be evaluated to define the condition.[2]

VC can be a severe source of irritation and discomfort to the patient, but the condition can have more serious consequences. Infection with VC has been considered as a risk factor for human immunodeficiency virus (HIV) infection[8] and gynecological surgery performed on patients with VC has led to systemic candidal infections.[2] VC has also been transmitted congenitally from mother to child,[2] with some research indicating that treatment for VC during pregnancy actually reduced the opportunity for premature births.[9]

Penile candidosis is far less common than vaginal infection, although it can be a result of sexual transmission. It is usually an uncomplicated infection that responds to topical antifungal therapy.

Invasive Candidosis

IC (deep-seated candidosis) is a worldwide disease that targets the immunocompromised population, with *Candida* species able to infect virtually every deep organ. Localized systemic candidosis is the term given to an infection of an individual organ, whereas disseminated candidosis (*Candida* septicemia, candidemia) involves the infection of several organs where the disease has been propagated by the bloodstream. This classification is not rigid and the diagnosis of systemic candidosis in one organ may be the initial sign of disseminated candidosis observed earlier at that particular site.[2]

The population at risk for IC will generally be immunocompromised, usually as a result of treatment for cancer, organ transplantation, HIV, or intensive care unit (ICU) treatment. However, surgery, antibiotic use, a central venous line, prematurity, parenteral nutrition, damage to the GI mucosal membrane, and neutropenia have been indicated as predisposing factors to infection.[10] Furthermore, several of these risk factors may be combined in certain case scenarios.[10]

C. albicans is the most common cause of IC, although the contribution of non-*C. albicans* species causing IC is rising. There are distinct geographical and patient group distributions to the species causing non-*C. albicans* infections,[11] and recent publications have highlighted the diagnosis of polycandidal IC, which could be significant when initiating the correct antifungal therapy.[12]

With high mortality rates associated with IC (up to 40%), early diagnosis and treatment of IC are essential. However, the diagnosis of IC can be problematical, with up to 50% of patients with autopsy-proven IC having multiple negative blood cultures.[13] The British Society for Medical Mycology has produced a review article highlighting the problems and proposing standards that should be met to provide optimal surveillance and diagnostic programs for invasive fungal infections.[13]

Treatment for IC involves the use of a systemic antifungal agent, such as fluconazole or amphotericin B, with or without flucytosine, plus the removal of central venous catheters. Fluconazole should not be used with *C. krusei* or *C. glabrata* infections. Recent developments in antifungal therapy have seen the emergence of a new triazole ''voriconazole'' and a novel group of drugs, the echinocandins, of which ''caspofungin'' is the first licensed drug. Both of these have given promising results in treating IC, with the added benefit of being effective against *Aspergillus* infections.

MOLECULAR CHARACTERIZATION

The Stanford Genome Technology Center has recently sequenced the entire diploid genome of *C. albicans*. Covering 1.6×10^7 bp, with eight pairs of chromosomes and containing over 9000 genes encoding proteins of at least 100 amino acids, it is larger and shares only 60% gene homology with the genome of *Saccharomyces cerevisiae*—the organism often used to predict antifungal targets in *C. albicans*.[14,15] Compared to *S. cerevisiae*, *C. albicans* has more genes that are specific to it—a factor that could account for its pathogenicity and ability to colonize various environments.[16]

Within the genome, 567 genes have been designated as essential for survival, with an estimated 1400 genes required for growth.[15] The genome contains several large gene families encoding proteases, lipases, and cell wall proteins, and, together with genes distinct to *C. albicans*, are considered good targets for antifungal agents.[14] Furthermore, different strains of *C. albicans* have varying numbers of rDNA units, with some strains possessing over 200 copies,[17] making it an ideal target for molecular-based identification methods.

MOLECULAR TESTING

With an increasing number of cases of IC but lack of a sensitive detection method, it has become essential to develop techniques that overcome traditional limitations. Molecular methods detecting nonculturable/nonviable cells or circulating free fungal DNA have been developed, which may provide an alternative to culture-based

techniques. Owing to these culture limitations, most diagnostic molecular mycology techniques have focused on detecting IC, with little work performed on detecting superficial candidosis.[18,19] Although it is likely that the methods used to detect IC could detect a case of VC or OC, it is uncertain whether the result gained would provide any additional information, at extra expense, over culture. This is not the case for IC, where the samples tested should be from a sterile site and are unlikely to be culture-positive. With this in mind, the rest of the review will follow the current trend and concentrate on molecular testing for IC.

The field of diagnostic molecular mycology has, to a certain degree, been led by the Tubingen group, which has published methods using traditional molecular techniques,[20] polymerase chain reaction enzyme-linked immunosorbent assay (PCR-ELISA) methods,[21] and real-time PCR methods[22] for detecting *Candida* but has also highlighted some of the limitations of molecular mycology in a diagnostic scenario.[23] However, many groups have now published alternative methods that provide equally sensitive and specific methods for different amplification platforms, or to meet different requirements (Table 1).

Before performing any amplification procedure, it is essential to obtain high-quality nucleic acid. With the current increased interest in diagnostic molecular mycology, numerous protocols for extracting fungal nucleic acids from various sample types have been published. The recommended specimen is ethylenediaminetetraacetic acid (EDTA) whole blood. Permitting the detection of free circulating candidal nucleic acids plus the extraction of nucleic acids from phagocytosed and circulating cells (lost in serum samples), it may generate higher fungal nucleic acid yields.

All whole blood fungal nucleic acid extractions have one thing in common—their laborious nature. All should have effective red cell and white cell lysis; mechanical, chemical, or enzymatic disruption of the fungal cell wall; lysis of the fungal cell membrane to release the nucleic acids; and then purification of the nucleic acids. In 1997, Loeffler et al.[24] published a combined heat–alkali–enzymatic extraction procedure that is widely used. Combining ''in-house'' steps with the commercial Qiagen Tissue kit, it achieved good sensitivity and could be performed within the working day. Originally, the method used the enzyme Zymolase to form spheroplasts; however, Zymolase can be contaminated with DNA from *S. cerevisiae*,[23] which would be problematical when performing PCR with pan-fungal/yeast primers/probes. To overcome this problem, recombinant lyticase has been extensively employed, although this increases the cost of the assay.

Recently, a semiautomated method using some ''in-house'' steps to lyse blood cells, mechanical disruption of the fungal cells by bead beating and automated nucleic acid release, and purification by the Roche MagnaPure has been presented.[25] It also achieves high sensitivity and reduces the hands-on time by approximately half, but does require the purchase of an expensive piece of equipment.

On obtaining high-quality nucleic acids, various molecular methods can be performed to test for the presence of candidal DNA (Table 1). More traditional molecular techniques for detecting candidal DNA have been highlighted previously.[26] Despite having good sensitivity and specificity, their major disadvantage is the need for postamplification handling, which increases the turnaround time and possibility of contamination.

With the development of many real-time nucleic acid amplification systems, many research works have focused on developing assays to detect invasive fungal infections. The detection of *C. albicans* DNA using the Roche Light-Cycler™ and hybridization (fluorescence resonance energy transfer, FRET) probes has given high sensitivities (5 cfu/mL whole blood) and specificities,[22] but the system was specific for *C. albicans* only and did not detect other pathogenic *Candida* species. More recent research overcame this problem by designing a single probe that could detect—but not differentiate—seven pathogenic *Candida* species to the same sensitivity.[26] Originally, the assay used the less familiar (first-generation) Biogene Light-Cycler™, but by slight modifications to the probe sequence and by changing the fluorescent labeling, the assay can now be used on the Roche Light-Cycler as a hydrolysis (TaqMan) probe system (Table 1).

Because of the limited number of detection channels on Light-Cyclers to date, multiplexing of PCRs has not been an option. However, by using the TaqMan PCR system, it is possible to detect and differentiate *C. albicans*, *Candida kefyr*, and *C. glabrata* in one reaction and *C. parapsilosis*, *C. tropicalis*, and *C. krusei* in a second multiplexed reaction.[27] The method provides a specific alternative to culture-based identification for clinical isolates and, although not stated in the publication, has good sensitivity (10^1 cfu) when extracting from whole blood (M. Guiver, personal communication).

A good alternative to PCR is isothermal amplification of RNA by Nucleic Acid Sequence-Based Amplification (NASBA).[28] Using avian myeloblastosis virus reverse transcriptase (AMV-RT), RNAse H, and T7 RNA, polymerase amplification occurs at 41°C, removing the need for a separate RT step or for PCR machines. Detection can be achieved by enhanced chemiluminescence (end point) or by molecular beacon (real time), and, like other molecular assays, NASBA has high sensitivity and specificity, but because of the ubiquitous nature of RNases, there may

Table 1 Recently published molecular methods used to detect *Candida* species

Method	Target	Primer sequences	Probe sequence/enzyme	PCR conditions
PCR/Southern blotting[20]	*C. albicans* 18S rRNA gene[a]	5′-ATT GGA GGG CAA GTC TGG TG-3′; 5′-CCG ATC CCT AGT CGG CAT AG-3′ (concentration 2 μM)	TCT GGG TAG CCA TTT ATG GCG AAC CAG GAC (concentration 30 pM)	50 μL reaction; 0.5 mM dNTPs, 1.0 mM $MgCl_2$, 1.5 U *Taq* polymerase; 35 cycles: 94°C/30 sec, 62°C/1 min, 72°C/2 min; 1 cycle: 72°C/5 min; blotting: alkali blotting to a nylon filter; antidigoxigenin–alkaline phosphatase labeling

TaqMan PCR[27]	*C. albicans* ITS2 region[c]	5′-GGG TTT GCT TGA AAG ACG GTA-3′; 5′-TTG AAG ATA TAC GTG GTG GAC GTT A-3′ (concentration 0.2 μM)	5′-(FAM) ACC TAA GCC ATT GTC AAA GCG ATC CCG (TAMRA)-3′ (concentration 0.1 μM)	25 μL reaction; 12.5 μL of TaqMan PCR Master Mix; 50°C/2 min, 95°C/10 min; 45 cycles: 95°C/15 sec, 60°C/1 min
Hydrolysis probe/ Light-Cycler PCR[26][d]	*Candida* species 18S rRNA gene	5′-CTC GTA GTT GAA CCT TGG-3′ 5′-GCC TGC TTT GAA CAC TCT-3′ (concentration 0.75 μM)	5′-(FAM) ATC TTT TTG ATG CGT ACT GGA CCC TG (TAMRA)-3′ (concentration 0.4 μM)	20 μL reaction; 1× Roche Faststart LC hybridization reaction mix (containing *Taq* polymerase, dNTPS), with 4 mM $MgCl_2$; 1 cycle: 95°C/15 min, up to 60 cycles: 95°C/15 sec, 62°C/30 sec
NASBA RNA detection[28]	*C. albicans*, *C. parapsilosis*, *C. tropicalis* 18S rRNA gene[e]	5′-ATG TCT AAG TAT AAG CAA TTT A-3′; 5′-*AAT TCT AAT ACG ACT CAC TAT AGG GAG AGA* CAT GCG ATT CGA AAA GTT A-3′[f] (concentration 0.27 μM)	5′-(Biotin) ATC CCG ACT GTT TGG AAG GGA TGT-3′	20 μL reaction (for buffer mix, see original article); incubate buffer mix at 65°C/5 min, 41°C/4 min, and then add enzyme mix (see original article); incubate at 41°C/90 min; NASBA products are detected by incubating with capture probe-coated magnetic beads

[a]By using different probes, *C. glabrata*, *C. krusei*, *C. parapsilosis*, and *C. tropicalis* can be detected.
[b]A melt program can be included. If the Faststart LC hybridization reaction mix is used, then an initial denaturation of 95°C/10 min should be included.
[c]By using different primers and probes, *C. glabrata*, *C. kefyr*, *C. krusei*, *C. parapsilosis*, and *C. tropicalis* can be detected. Multiplexing is also possible.
[d]Species detected by the probe: *C. albicans*, *C. dubliniensis*, *C. glabrata*, *C. kefyr*, *C. krusei, C. parapsilosis*, and *C. tropicalis*. The system was originally developed for use on the Biogene Light-Cycler using a Cy5-labeled probe. By modifying the probe sequence and labeling, it can now be used on the Roche system. The conditions above are for the Roche system.
[e]By using different probes, *C. glabrata*, *C. krusei*, *Candida lusitaniae*, and *C. tropicalis* can be detected.
[f]Bases in italics represent the T7 promoter sequence.

be problems with target degradation, leading to false-negative results.

Interest in the epidemiology of fungal infections has grown concurrently with the interest in molecular diagnostics. However, the DNA fingerprinting of *Candida* is a field that should be addressed in detail, with the current review of Soll[29] being a good place to start.

CONCLUSION

With the limitations of culture techniques for detecting IC being well publicized, it is only a matter of time before nonculture techniques become routine. However, with molecular techniques still to be evaluated on a large scale and with the existence of other nonculture methods (e.g., ELISA), then the correct plan of action is still not clear and is far from being decided. Furthermore, with the existence of resistant *Candida* strains that would be identified if cultured, then traditional methods may still have benefits despite recent publications targeting resistant *Candida* species.[30]

Capillary Electrochromatography

Vladislav Kahle
Institute of Analytical Chemistry, Academy of Sciences of the Czech Republic, Brno, Czech Republic

INTRODUCTION

Capillary electrochromatography (CEC) is a quickly developing high-performance analytical separation method based on a combination of principles of liquid chromatography (LC) and capillary electrophoresis (CE). In CEC, the driving force dragging the mobile phase through the separation column is electroosmotic flow (EOF), which is induced by applied electric field. The method enables the separation of neutral analytes with selectivity typical of LC, whereas the charged analytes' migration velocity, high separation efficiency, and simplicity of instrumentation correspond to CE. Important progress was made in the column technology, allowing a burst of applications, particularly in pharmaceutical chemistry and biochemistry. In spite all of this, CEC at the present time is not considered a mature technique. Intensive development and associated lack of specialized instrumentation characterize the current situation. Nevertheless, it is obvious that CEC is a promising analytical tool in many important application areas.

BASIC CONCEPTS OF CEC

History

The roots of CEC can be traced back to several decades (e.g., Ref. [1]), but only the experiment of Jorgenson and Lukacs[2] demonstrated the real separation power of the new emerging analytical method. After that, Knox and Grant[3,4] used very small silica particles to gain extremely high separation efficiencies, and a steep growth of interest documented by an exponential increase in the number of articles began, giving a cumulative number of some 1300, to date. All this information is considered in several discussed general reviews[1,5–14] and monographs.[15–17]

EOF

In CEC, the EOF is harnessed to propel the mobile phase through the column unlike the pressure-driven flow in LC. EOF results from electrophoretic movement of the diffuse part of the electric double layer and its magnitude, measured as linear velocity u_{eo} by a neutral marker, are given by the Helmholtz–Smoluchowski equation:

$$u_{eo} = (\varepsilon_o \varepsilon \zeta E)/\eta$$

where ε_o is the permittivity of vacuum, ε is the dielectric constant of the mobile phase, ζ is zeta potential, E is electric field strength, and η is viscosity. In comparison with the pressure-driven parabolic flow in LC, the EOF is less dependent on the pore diameter and its flow profile is flatter, which both lead to a decrease of peak broadening and to a higher separation efficiency of CEC. Because the whole column operates as an electroosmotic pump, smaller sorbent particles and longer columns could be used in comparison with LC, which also facilitates a higher efficiency. The direction of EOF is from anode to cathode in the negatively charged silica-based packing. EOF of the opposite direction is also possible in packings with a positively charged surface (e.g., in polymeric monoliths containing quaternary ammonium groups).

Separation Mechanisms

Two basic mechanisms influence the migration velocity of analytes:[15,18] a partition between solid and liquid phases as in LC in the case of neutral analytes (characterized by capacity factor k) and electrophoretic migration as in CE for charged analytes (characterized by effective mobility $\mu_{eph,eff}$). Other separation mechanisms (e.g., ion exchange, size exclusion, chiral recognition, and molecular imprinting) can also participate.[14]

Figure 1 can be used to compare some separation characteristics of LC, CE, and the hybrid of both CEC: 1) the expected higher separation efficiency of CEC in comparison with LC is clearly visible in Fig. 1; 2) the higher selectivity of CEC compared with CE—originating from the broad range of partition coefficients, on one hand, and relatively small difference in solutes mobilities, on the other hand—is also obvious from Fig. 1; 3) in CEC, the separation window is wider ($-1<k<\infty$) than in LC ($0<k<\infty$) because of the increased velocity of charged solutes comigrating with EOF; and 4) the combination of two orthogonal separation mechanisms, viz. partition and

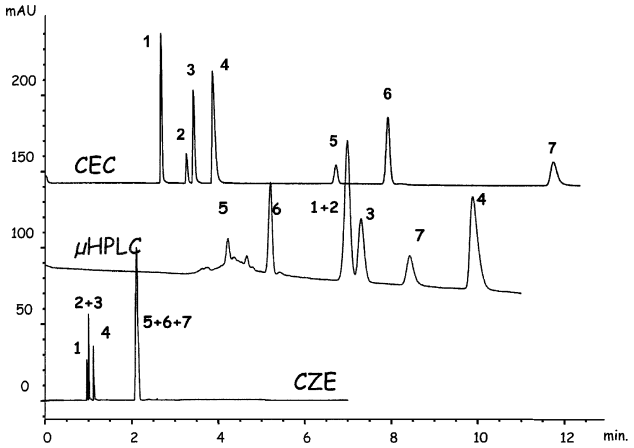

Fig. 1 Comparison of separation of drug mix by capillary electrochromatography (CEC), microliquid chromatography (μLC), and CE. Column (CEC and μLC): Spherisorb ODS-I, 3 μm, 250 (335) × 0.1 mm, (CE) uncoated fused silica capillary 250 (335) × 0.075 mm. Eluent: ACN 25 mM phosphate, 0.2% hexylamine, pH 2.5 (80:20), voltage (CEC and CE): 25 kV, pressure (μLC): 200 bar, temperature: 20°C. Peaks: 1=procaine, 2=timolol, 3=ambroxol, 4=metoclopramide, 5=thiourea, 6=naproxene, 7=antipyrine. (From Ref. [19].)

migration, gives rise to a much larger potential to manipulate selectivity.

Column Technology

A typical CEC column[1,5,6,10,20] is a fused silica capillary (50–100 μm ID, 200–500 mm long), filled either by particulate or monolithic[21] stationary phase. The small column internal diameter is dictated by the necessity of heat dissipation. Open-tube CEC columns (10–25 μm ID) were also used, but these suffer from smaller detection sensitivity. The basic problem of particle packed column is frit, which is unavoidable to keep the tiny sorbent particles (1.5–10 μm in diameter) in the original position. The ultimate solution here is the use of silica or organopolymeric monolithic columns.[17]

CEC INSTRUMENTATION

The setup of an electrochromatograph is, at least in principle, simple (Fig. 2). Identically as in LC and CE instruments, it comprises three basic parts: injector, separation column, and detector. The high-voltage power supply serves the mobile-phase propulsion through the column by EOF, instead of the pump used in LC. Mostly, either commercial electrophoreographs or laboratory-made devices are used,[22] still substituting specialized CEC instrumentation. Sometimes, a slightly more complicated setup incorporating hydraulic pressure capabilities is employed. The pressure can be applied the same either on both ends of the CEC column maintaining the bubble suppression, or on the injection side only. The latter method is called pressure-assisted CEC and forms a connecting link to pressure-driven LC.

For the injection, the dip of the end of the CEC column into the sample vial and subsequent electrokinetic sample sucking is frequently used (Fig. 2, position A), which is very simple but could bring about a decrease of repeatability. To overcome this problem, another sample injection method exploiting a sample and mobile-phase flow splitter was developed.[10,22]

Because of the predominantly chromatographic character of CEC separation, the mobile-phase gradient elution is important to attain higher peak capacity and shorter separation time, especially for complex samples

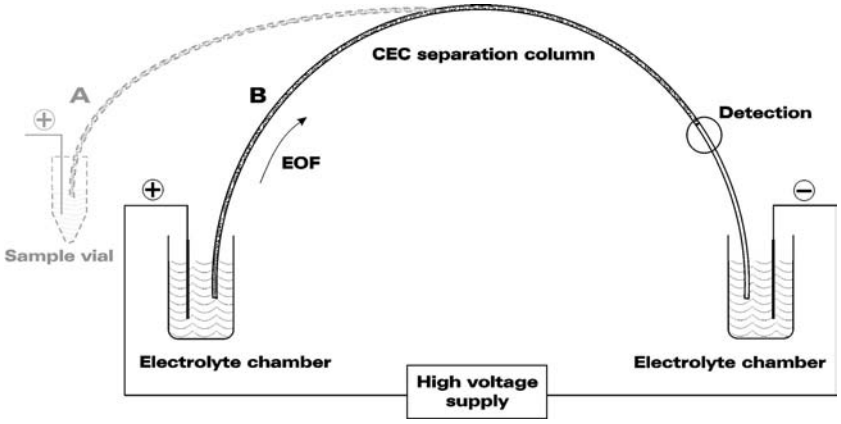

Fig. 2 Schema of electrochromatograph. (A) Electrokinetic sample injection. (B) CEC separation.

containing analytes of a wide polarity range. An array of gradient elution methods based on various principles was suggested.[7,10–12,22]

The methods, serving for detection of separated analytes, are in CEC essentially the same as in CE.[1,6–8,22] The on-column ultraviolet (UV) photometry is most often used but suffers from a decreased sensitivity because of the short optical path length. Methods increasing the path length (e.g., Z cell) are sometimes used, but increased peak dispersion and the resulting loss of efficiency are to be expected. The basic problem of the otherwise extremely sensitive (laser-induced) fluorometry is a lack of native fluorophores. Then the derivatization by reactive fluorescence tags comes into consideration,[22,23] bringing the benefit of a high-sensitivity detection of otherwise poorly detectable analytes. The instrumentally complex but highly specific and informationally rich method is the coupling of CEC to mass spectrometry,[17,22] which is especially important for proteomic studies.[24]

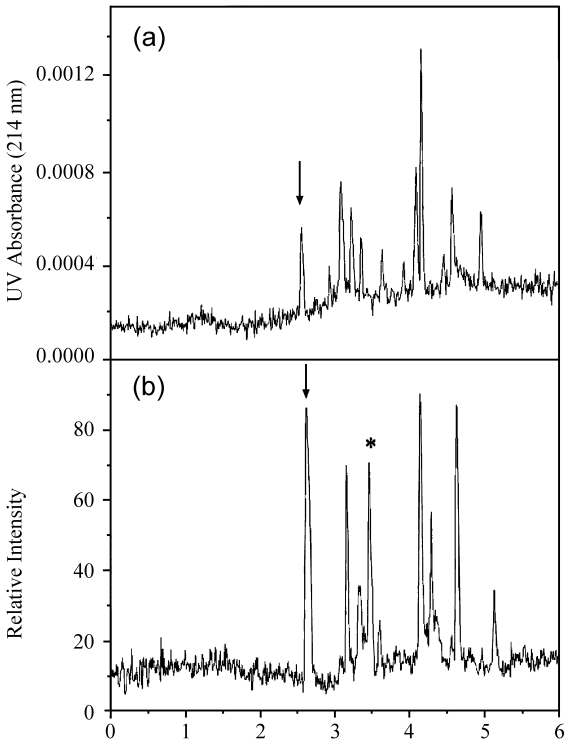

Fig. 3 UV trace (a) and TIC (b) of gradient CEC separation of a tryptic horse heart myoglobin digest. Conditions: 0–35% acetonitrile gradient in 6 min; column length, 40 cm (for UV detection, 35 cm to UV detector); separation voltage, −14 kV; injection, −2000 V × 5 sec; UV detection at 214 nm; MS detection speed, 8 Hz. (From Ref. [28], with permission from the American Chemical Society.)

APPLICATIONS

Originally, the CEC was developed for the separation of neutral analytes to extend the possibilities of CE, and a typical application in these early days was analysis of polynuclear aromatic hydrocarbons. Since then, the application range of CEC has increased dramatically and, nowadays, it covers analyses typical of LC but also of CE. Various previously mentioned separation modes were applied. Organic molecules of a wide range of functionalities; molecular weight; neutral, acidic, or basic origin; achiral or chiral origin; and synthesized or natural origin were successfully separated. Hundreds of application articles appeared in the literature and most of them were collected in several reviews.[1,7–9,11,25,26] The application of CEC in the pharmaceutical industry was critically reviewed.[27] From a proteomic point of view, the separation of peptides and proteins is of great importance (Fig. 3).

CONCLUSION

CEC is a modern and rapidly developing analytical separation method, often designated as a hybrid of electrophoresis and chromatography. The reasons for the growing popularity of CEC are high separation efficiency, simplicity of instrumentation, low operating costs resulting from miniaturization, low sample consumption, and expectations of selectivity tuning in the case of charged analytes. It is supposed that its importance will grow in connection with the solution of actual challenges, which are column technology, lack of specialized instrumentation, and better understanding of separation mechanisms, to name the most significant.

Capillary Electrophoresis

Ronald J. A. Trent
Melody Caramins
Bing Yu
Royal Prince Alfred Hospital, Camperdown, Australia

INTRODUCTION

The range of DNA changes detected in diagnostic genomics include 1) single-base changes that include normal variations (DNA polymorphisms such as SNPs) and DNA mutations, 2) deletions that can be small (the ΔF508 three-base-pair deletion in cystic fibrosis) or very large (some examples of α° thalassemia), 3) rearrangements, e.g., the flip-tip on the X chromosome leading to hemophilia A, 4) sizing of simple tandem repeats such as microsatellites or expansions in triplet repeats found in a number of neurological disorders, and 5) epigenetic effects such as DNA methylation associated with gene silencing.

To detect these changes in DNA, four broad classes of DNA tests are used. These tests are based on 1) sizing, 2) hybridization, 3) sequencing, and 4) quantitation. For most DNA diagnostic assays, efficient and reproducible separation of DNA fragments and accurate sizing are key requirements. Traditionally, this has been undertaken by slab gel electrophoresis using polyacrylamide or agarose. These electrophoretic techniques are slow, and the accuracy is limited if visual inspection is used for sizing. As well as being time consuming, the traditional electrophoretic approaches are less amenable to automation.

Capillary electrophoresis is now replacing slab gel electrophoresis because it is faster, more sensitive and reproducible, and allows greater flexibility in the design of diagnostic DNA assays. The modern DNA laboratory will utilize capillary electrophoresis in conjunction with robotics to ensure that diagnostic DNA tests are efficiently and accurately undertaken.

PRINCIPLES OF CAPILLARY ELECTROPHORESIS

Capillary electrophoresis has proven to be a versatile technique for analyzing a wide range of analytes. Variations include 1) open tubular or capillary zone electrophoresis (CZE), 2) capillary gel electrophoresis (CGE), 3) micellar electrokinetic chromatography, 4) capillary isoelectric focusing, 5) capillary isotacophoresis, and 6) capillary electrochromatography (CEC).[1–3] For the purpose of this overview, CGE will be described to illustrate its utility in DNA analysis with a brief comment on other analytes. Capillary zone electrophoresis is used for the analysis of a wide range of charged simple organic molecules, inorganic ions, peptides, and proteins. Capillary gel electrophoresis is the method of choice for sizing and sequence analysis in the DNA diagnostic laboratory.

A simplified diagrammatic representation of CGE is given in Fig. 1. A constraint with the traditional slab gel electrophoresis is the heat generated by the applied voltage, which is limited to 5–40 V/cm. In contrast, a capillary is more effective in dissipating heat, thereby allowing higher voltages (up to 300 V/cm). This leads to shorter running times and sharper bands. The migration of an analyte is influenced by size, charge, and unique to CGE, is the electroosmotic flow (EOF). Only picogram amounts need to be loaded as the detection system can use a laser–CCD camera system. Software will allow the appropriate loading and running conditions to be selected and is also used for analysis and interpretation of the results.

THE CAPILLARY

Capillaries can be made of fused silica, glass, or Teflon. The most popular is fused silica, which is externally coated with polyimide to give it greater strength and flexibility. The polyimide layer is usually removed at the detector end to enable online detection. Capillary lengths range from 10 to 100 cm, and internal diameters vary from 20 to 100 μm. These narrow bores improve heat dissipation due to a higher surface area to volume ratio.

Manufacturers recommend that capillaries are changed after a defined number of injections in diagnostic work. In our laboratory, the capillaries are replaced after 200 injections. Multichannel CGE, such as that used in the ABI Prism 3700 DNA Analyzer®, allows simultaneous

The sample is loaded automatically and the end products are detected through a laser–CCD system (▣). Software allows the injection and electrophoresis conditions to be selected, and fragments to be characterized based on their size and color. (*View this art in color at www.dekker.com.*)

analysis of information from 96 capillaries, thereby facilitating high-throughput DNA analysis.

SAMPLE LOADING

Capillary gel electrophoresis requires smaller amounts of sample compared to slab gels (nanoliters compared to microliters) to avoid excessive band broadening.[4] Loading is automated, and injection volume can be controlled and standardized by varying the force and time. Samples can be loaded in a number of ways including hydrodynamic or electrokinetic injections. For hydrodynamic loading, the capillary is subjected to a pressure difference between its extremities. The pressure difference can result from gravity, application of pressure inside the sample vial, or aspiration of the sample through the capillary tube. Hydrodynamic injection produces more reproducible sample loading. For electrokinetic injection, the capillary tip is dipped into the sample for a fixed time and a potential is applied. Electrokinetic injection results in the best flow profiles but can give a biased sample because more mobile ions can be preferentially introduced.[4]

SAMPLE MIGRATION

The mobility of sample ions under the influence of applied voltage is dependent on their charge/mass ratio. Therefore, when separating a sample, smaller, more highly charged ions will be detected first, followed by larger, lesser-charged ions. Application of voltage across a capillary filled with electrolyte causes a bulk EOF of solution along the capillary.[2] This results from a characteristic of fused silica capillaries in which the inner wall becomes covered with acidic silanol groups. The degree of EOF is dependent on the pH. At a pH below 4, the ionization is small, and so the EOF flow rate is not significant. Silanol groups become fully ionized at pH>9, which produces a strong EOF. To maintain electrical neutrality, cations build near the surface. Under the influence of an applied voltage, these cations, and the water molecules dissolving them, migrate toward the cathode, resulting in a net solution flow along the capillary. At pH of 7 or more, the EOF is strong enough to sweep anions to the cathode regardless of their charge, thereby allowing separation and analysis of analytes with mixtures of size and charge.[2]

If EOF is undesirable for analysis, it can be reduced or eliminated by coating the internal surface of the capillary or adding surfactants and/or buffer additives to the separation buffer.[4] Reducing or eliminating the EOF leads to a more efficient and reproducible separation of DNA fragments. Without the effect of EOF, the order in which DNA fragments migrate in gels with CGE is dependent on their molecular size, with smaller fragments having a shorter migration time (like slab gel electrophoresis).[3]

POLYMER GEL MATRIX

Capillary gel electrophoresis can be used for separation of small DNA fragments such as nucleotides or small oligonucleotides (10–150 bases in size).[3] For larger

DNA fragments, electrophoresis must be undertaken with a separation matrix such as agarose, polyacrylamide, or a liquid polymer to act as a molecular sieve. For CGE, there are two types of gel matrices in use: relatively high viscosity cross-linked (i.e., chemical) or low viscosity non-cross-linked (i.e., physical). The latter are more flexible, and hence widely used because of the following properties: 1) they can operate at more extreme temperatures, and 2) they are easily replaced by rinsing the capillary, thus minimizing contamination and enhancing convenience. With both types of gel matrices, capillaries that are modified by coating agents can be used to eliminate the EOF.[4]

Commercially produced polymers are available. Liquid polymers made in-house are cheaper but formulation is more likely to vary between batches thereby affecting reproducibility and sensitivity. Although costly, commercial polymers are produced to specific standards and consistent quality, which are important considerations in the DNA diagnostic laboratory.

Products such as glycerol, mannitol, urea, and formamide can be added to the sieving media for different purposes. For example, 5% glycerol can be used to preserve secondary structures when SSCP analysis is performed. Formamide is used to keep double-stranded DNA denatured when DNA fragment analysis is required.

DETECTION SYSTEMS

Ultraviolet (UV)–visible based detection is used on many CGE applications. This type of system is applicable to a wide range of analytes, and is sensitive enough for many applications. However, the detection limit with UV is limited because of the small internal diameter of the capillary. For example, with this mode of detection, a DNA fragment of approximately 200 bp would need to have a concentration of about 0.5 μg/mL.[3] Therefore, detection systems based on laser-induced fluorescence are preferred if lower detection limits are needed.

Laser-induced fluorescence is also attractive because it allows the detection of multiple parameters in the same tube; that is, multiplexing and DNA sequencing become possible. DNA primers can be labeled with different fluorophores. On passing through the detection window in the capillary, the fluorescein-labeled polymerase chain reaction (PCR) products are excited by the laser and emit fluorescence with various emission spectra depending on the dye. The emitted fluorescence is detected by a CCD camera and the information is relayed to the computer, where data collection software processes it and displays the information as a graph of fluorescence color and intensity against size. Multicolor fluorescence detection also allows the use of in-lane size standards, thereby increasing accuracy and reproducibility when unknown samples are being sized.

DNA MUTATION DETECTION

Capillary gel electrophoresis is ideal for detecting DNA fragment sizes that include small or large deletions, insertions, allele-specific amplification fragments, and oligonucleotide ligation or primer extension products. For example, a common mutation in the genetic disorder cystic fibrosis is ΔF508 mutation. This involves a 3-bp deletion in the *CFTR* gene. To detect this deletion by CGE, we label the forward primer with FAM, a fluorophore that emits a blue light spectrum on laser excitation. After PCR amplification, the product is separated on CGE. The mutant, shorter allele emits a blue fluorescence at 91 bp, compared with the normal allele that produces a peak of blue fluorescence at 94 bp. The two peaks are easily distinguishable. As well as separating wild type and mutant alleles on the basis of size, it is possible to distinguish point mutations on the basis of color. This is illustrated by SNP analysis (Fig. 2a).

For DNA sequencing, the four terminating dideoxynucleotides are each labeled with different flurophores. Each time a ddNTP is incorporated into the extending product, it results in termination of product extension, with the terminal nucleotide identified by its fluorescent label. The final product is composed of a heterogeneous population with different-sized products that can be distinguished by their various spectral emissions. With the fluorescent labeling, the entire reaction can be run in the same capillary; that is, multiplexing is possible, which was also illustrated in the earlier SNP example.

GENOTYPING

Applications for genotyping are extensive, ranging from linkage mapping for research or diagnostic purposes to forensic or paternity testing, microbiological typing, and veterinary or agricultural trait mapping.[5–7] Electrophoretic conditions with high precision are essential in many of these applications. For 2-bp microsatellites, standard deviations of ±0.3 nucleotide are required to ensure with 99.7% probability that the tested alleles are identical or different.[8] This level of precision is achievable with CGE.

Capillary gel electrophoresis can be problematic when it is used to determine the absolute size of a DNA fragment. This is illustrated by DNA triplet repeat expansions, such as those in Huntington disease.[9]

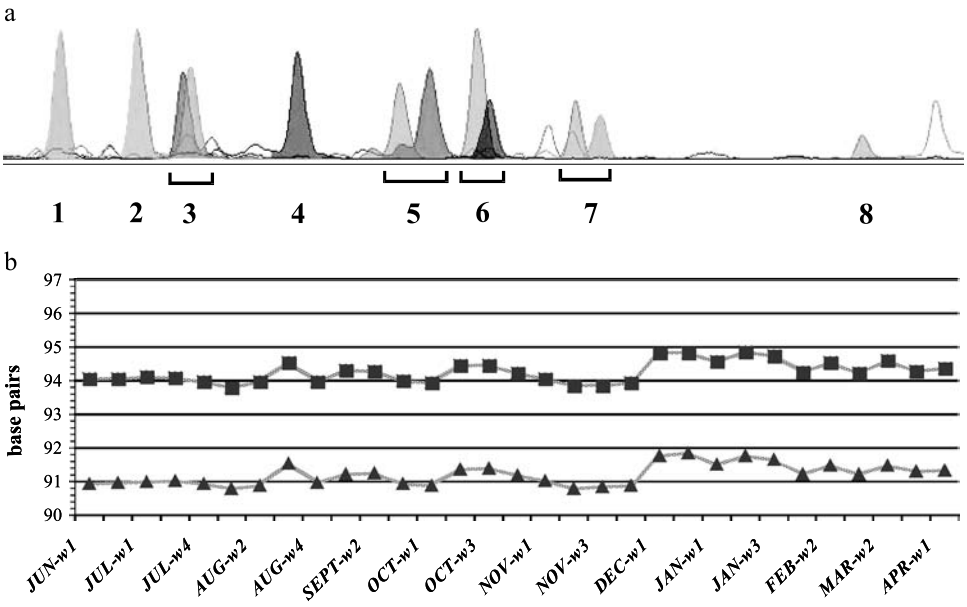

Fig. 2 (a) Detecting eight SNPs in the 5′UTR and intron 2 of the *MT3* gene. The various alleles are numbered 1–8 and demonstrate the utility of CGE in multiplexing and distinguishing various fragments on the basis of size and/or color. SNPs #3 and #6 illustrate how comigrating alleles for each SNP are distinguishable by primers labelled with two different fluorochromes. SNPs #4 and #6 are distinguishable by their migratory distance. (b) QA graph for normal and mutant (ΔF508) fragments for cystic fibrosis. It can be seen that over a period of 10 months, there has been little drift outside the acceptable limit of 1 bp for the mutant (91 bp) and normal (94 bp) fragments. (*View this art in color at www.dekker.com.*)

Although the resolving power of CGE can distinguish variations in DNA fragments as small as 1 bp, the sizing of a DNA fragment can be a potential source of error. With the Huntington disease example, we observed that the sizes of triplet repeats determined through CGE were always one to two repeats (3–6 bp) less than the gold standard obtained by the ^{32}P slab gel technique.[10] This discrepancy is unacceptable in the above triplet repeat scenario for which an accurate measure of the repeat number is essential because the cutoff for predicting the development of disease occurs exactly at 40 repeats.

Sizing in CGE depends on the algorithm that converts mobility data for an unknown peak into size information based on size vs. mobility results from the size standards.[11] Incorrect size calls can come from poor resolution of two or more peaks, and of particular relevance to CGE, the aberrant mobility of unknown peaks. Incomplete denaturation leading to sequence-specific secondary structures is a recognized cause of aberrant mobility and can be avoided by optimizing the denaturing conditions in CGE.[11] Another way around this potential problem is to normalize the automated size measurements to known fragment sizes. We take the latter approach in Huntington disease by incorporating a CAG allelic ladder with known CAG fragment sizes as an additional sizing standard, thereby allowing exact sizing of the triplet repeat.[12]

QUALITY ASSURANCE

Technology based on CGE facilitates QA activities. In the laboratory, regular monitoring of graphs representing the known PCR product sizes for the various assays are kept for these purposes (Fig. 2b). A drift of more than 1 bp in the case of cystic fibrosis testing for the ΔF508 mutation is unacceptable, requiring the controls to be rerun, and requiring a review of all reagents. A persisting drift could indicate the possibility of hardware or software problems.

OTHER APPLICATIONS

Although we have focused on the genomic uses of CGE, the technology is universally applicable to the separation of a wide range of analytes including peptides, proteins, carbohydrates, drugs for clinical or forensic applications, as well as applications in biotechnology and environmental analysis.[13–15]

The review by Thormann[13] compares capillary electrophoresis to current analytical approaches in licit and illicit drug assays including high-performance liquid chromatography (HPLC), gas chromatography, and high-throughput automated immunoassays and photometric assays. It concludes that capillary electrophoresis has yet

Table 1 Some examples of capillary electrophoresis platforms

Manufacturer	Instrument	Web site
Applied Biosystems	Options from a single capillary to combinations of 4, 16, 48, and 96 capillaries. The most recent platform (3730) incorporates a new detection technology as well as allowing active control of running temperature from 18°C to 70°C. The option to control the running temperature provides an additional variable for DNA mutation testing, e.g., a technique such as SSCP	http://www.appliedbiosystems.com/
Beckman Coulter	P/ACGE-MDQ is a single-capillary system designed for general uses for protein, organic compounds, and nucleic acid analyses. CGEQ 8000 is an eight-capillary system	http://www.beckmancoulter.com/
SpectruMedix	96-channel capillary system capable of handling six different sample trays and up to 30-color capacity	http://www.scientificassociates.8m.com/

to realize its full potential, and is more likely to complement the existing technologies than replace them. However, the reproducibility coupled with the potential to perform drug measurements in nanoliter volumes of body fluids is an attractive option in a clinical chemistry, pharmacology, or forensic laboratory setting.

CONCLUSION

Capillary gel electrophoresis has revolutionized the work flow in the DNA diagnostic laboratory. It provides opportunities for increasing the level of automation at all steps from sample receipt to the generation of a computer-based result. As well as its inherent high sensitivity, the robustness and excellent reproducibility of this technology are critical parameters in an environment requiring accuracy and ongoing QA. Improved efficiency and faster turnaround times come from the multiplexing potential available from the use of fluoroscein-labeled primers or capillary arrays. From the health and environmental perspective, the avoidance of potentially hazardous reagents such as acrylamide and ethidium bromide used in conventional DNA slab gel electrophoresis is an additional benefit of CGE. Hardware and CGE reagent costs are high, but this is offset by the saving in time and human resources. There are a number of platforms now available, and increasing competition will ensure that costs continue to fall (Table 1). A wider range of instrumentation options is described in Ref. [16].

This overview started with a description of six types of capillary electrophoresis. However, there is considerable potential for innovation with this technology. As the Human Genome Project expands the opportunities in proteomics, combinations of capillary electrophoresis with techniques such as mass spectrometry will identify novel ways in which to analyze proteins and peptides.[14] Developments in nanotechnology coupled with capillary electrophoresis (microchip capillary electrophoresis) will mean faster analysis times, decreased costs and waste, and portability that would open up options for point-of-care DNA diagnostic testing.[17]

Cardiomyopathy, Dilated (Familial)

Dagmar I. Keller
Gisèle Bonne
INSERM U582, Paris, France

INTRODUCTION

Dilated cardiomyopathy (DCM) is a cardiac disorder characterized by dilatation of the left ventricle (LV) or both ventricles, with impaired systolic function. Familial DCM (FDCM) accounts for 25% of DCM. The clinical course of DCM/FDCM is determined by heart failure and arrhythmia with high morbidity and mortality despite progress in disease management. FDCM is inherited autosomal-dominant, autosomal-recessive, or X-linked. Mutations in at least 19 genes have been identified, indicating wide genetic heterogeneity and resulting in pure FDCM or distinct phenotypes of FDCM with other cardiac, muscle, or specific pathologies. Diseased proteins are localized in different cellular compartments. Because of wide phenotype and genotype heterogeneity, precise phenotype–genotype correlations are not available yet and predictors for clinical outcome are still largely undetermined.

CLINICAL DESCRIPTION

DCM is defined by the World Health Organization (WHO) as myocardial disorder ''characterized by dilatation and impaired contractility of the left ventricle or both left and right ventricles. It may be idiopathic, familial/genetic, viral and/or immune, alcoholic/toxic, or associated with recognized cardiovascular disease in which the degree of myocardial dysfunction is not explained by the abnormal loading conditions or the extent of ischemic damage. The histological findings are frequently nonspecific. The usual presentation of the disease is heart failure, which is often progressive. Arrhythmias, thromboembolism, and sudden death are common and may occur at any stage.''[1]

The prevalence of DCM in the general population is 40–50 cases per 100,000. Almost 50% of DCM cases are idiopathic, with an incidence of five to eight cases per 100,000 per year.[2] At least 25% of DCM cases are familial,[3] inherited most frequently autosomal-dominant, besides autosomal-recessive and X-linked forms. FDCM is clinically heterogeneous with distinct phenotype groups arising from various inheritance patterns.[4] FDCM can be pure or combined with other cardiac diseases, in particular conduction system defects, skeletal myopathies, and sensorineuronal deafness, or in the context of inherited multisystem diseases. In fatal infantile forms of FDCM, mitochondrial DNA mutations have been found.

Besides family history, no clinical parameter can distinguish familial from nonfamilial DCM.[5] Both forms are diagnosed by transthoracic echocardiography for assessment of LV structure, dimension, systolic/diastolic function, and heart valve morphology/function. Hallmark findings are marked dilatation of the LV cavity with normal wall thickness and globally reduced systolic function. Regional wall abnormalities do not exclude FDCM/DCM. Electrocardiogram (ECG) and ambulant ECG monitoring reveal conduction system defects such as atrioventricular conduction blocks, sinus node dysfunction, and atrial and ventricular tachyarrhythmias.

FDCM/DCM is a leading cause of heart failure and arrhythmia. Symptoms of congestive heart failure are dyspnea on exertion, decreased exercise tolerance, orthopnea, paroxysmal nocturnal dyspnea, fatigue, edema, and abdominal distension. Chest pain results from limited coronary vessel reserve. Ventricular arrhythmia leads to palpitations, syncope, and sudden cardiac death (SCD). Severe LV dilatation and dysfunction result in thromboembolic complications.

Despite progress in therapy, 5-year mortality is high (between 15% and 50%). SCD accounts for 30% of deaths and occurs irrespective of LV systolic function.

DIFFERENTIAL DIAGNOSIS

FDCM is distinguished from other specific cardiac diseases and systemic processes resulting in secondary ventricular dilatation and dysfunction:[1] eccentric hypertensive cardiomyopathy, ischemic cardiomyopathy, decompensated valvular heart disease, alcoholic cardiomyopathy, and myocarditis. Less common are cardiomyopathies resulting from amyloidosis, sarcoidosis, hemochromatosis and other metabolic disorders, and peripartum cardiomyopathy. Doxorubicin can cause toxic cardiomyopathy.

DOI: 10.1081/E-EDGP 120025788

MANAGEMENT

Pharmacological therapy is the standard approach in heart failure treatment.[6,7] Angiotensin-converting enzyme (ACE) inhibitors reduce preload and afterload, and wall stress. ACE inhibitors reduce mortality, hospitalization rate, and progression of heart failure, and are indicated for all patients with systolic LV dysfunction. Angiotensin II receptor antagonists have equal effects on symptoms but without the bradykinin-related side effects of ACE inhibitors. Reduction in mortality has been shown for these drugs. The major advancement in heart failure therapy is the use of low-dose β-adrenergic blockers. The effect of β-blockade on mortality is additional to the effect of ACE inhibitors, and benefit is independent of the severity of heart failure. Digitalis is a positive inotropic agent and provides symptomatic benefit without effect on mortality. Diuretics are indicated in symptoms of volume overload despite the use of ACE inhibitors and digitalis. Spironolactone is a potassium-sparing diuretic agent and has been shown to reduce mortality. First-generation calcium channel antagonists are contraindicated in standard treatment guidelines in heart failure because they reduce survival rate and exacerbate symptoms.

Anticoagulants or antiplatelet agents are recommended in LV ejection fraction less than 30%. Atrial fibrillation requires chronic anticoagulation.

Cardiac resynchronization with biventricular pacing improves symptoms in advanced heart failure. Patients with impaired systolic function and at high risk for SCD benefit from biventricular pacing properties of an implantable cardioverter defibrillator (ICD). Implantable cardioverter defibrillator implantation is recommended in *LMNA* mutation carriers. Higher-degree atrioventricular conduction defect requires pacemaker therapy. Benefits of LV assist devices are tempered by a high complication rate. Heart transplantation in end-stage disease improves survival and quality of life. Monitored physical conditioning with general education improves exercise capacity and quality of life.

MOLECULAR GENETICS

Familial DCM is genetically heterogeneous because various inheritance patterns are involved, and many chromosomal loci and disease genes have been identified by genetic studies in affected families (Table 1).

Autosomal-Dominant FDCM

Fifteen loci and 12 genes, encoding proteins of different cellular compartments, have been identified to be involved in autosomal-dominant FDCM with pure DCM. δ-Sarcoglycan, encoded by *SGCD*, is one of the four (α, β, δ, and γ) proteins forming the sarcoglycan complex—a component of the glycoprotein transmembrane complex (DCG) in the plasma membrane. *DES* and *VCL* encode cytoskeletal proteins, desmin, an intermediate filament, and metavinculin, respectively. *PLN* encodes phospholamban in the sarcoplasmic reticulum, a major substrate for cAMP-dependent protein kinase in cardiac muscles. It is an inhibitor of cardiac muscle sarcoplasmic reticulum Ca^{2+}-ATPase. Mutations have been identified in sarcomeric proteins: actin encoded by *ACTC*, cardiac troponin T encoded by *TNNT2*, cardiac myosin-binding protein C encoded by *MYBPC3*, β-myosin heavy chain encoded by *MYH7*, α-tropomyosin encoded by *TPM1*, and titin encoded by *TTN*. Telethonin/TCap is encoded by *TCAP* and is a substrate of titin. TCap interacts and colocalizes with the muscle limb protein (MLP), which is a Z-disc protein encoded by *CSPR3*. Recently, MLP mutations have been identified in DCM families.[8]

Four disease loci have been related to autosomal-dominant FDCM with a conduction defect. The only gene identified is *LMNA* encoding lamins A and C, components of the nuclear envelope, produced by alternative splicing.[9] *LMNA* mutations have been found in FDCM associated with atrial fibrillation[10] and in FDCM with LV apical aneurysm.[11] For autosomal-dominant FDCM with skeletal myopathy and conduction defect, the only identified disease gene is again *LMNA*. Mutations are associated with autosomal-dominant Emery–Dreifuss muscular dystrophy (AD-EDMD)[12] and limb girdle muscular dystrophy type 1B (LGMD1B), and were recently described in a myopathy specifically affecting the quadriceps muscle.[13]

Autosomal-Recessive FDCM

Autosomal-recessive FDCM is rare and cosegregates with skeletal myopathies. Mutations in four genes have been identified. A homozygous *LMNA* mutation was identified in autosomal-recessive Emery–Dreifuss muscular dystrophy (AR-EDMD).[14] *SGCB* encodes β-sarcoglycan, a component of the sarcoglycan complex linking the extracellular matrix to the dystrophin. Mutations in *FKRP* were identified in two allelic disorders: a form of limb girdle muscular dystrophy (LGMD2I) and a form of congenital muscular dystrophy (MDC1C). *FKRP* encodes the fukutin-related protein, a newly identified protein implicated in glycosylation of α-dystroglycan, another component of the DCG complex.[15,16] Mutations in *DSP*, encoding desmoplakin, a protein of the desmosome complex, cause DCM associated with wooly hair and keratoderma.

Table 1 DCM genes and phenotypes

Inheritance	Chromosome	Gene (OMIM number)	Protein	Phenotype
AD	1q32	*TNNT2* (191045)	Cardiac troponin T	Pure DCM

AD, autosomal dominant; C, cardiac; M, muscular; O, other; AR, autosomal recessive; XL, X-linked; DCM, dilated cardiomyopathy; CD, conduction defect; EDMD, Emery–Dreifuss muscular dystrophy; LGMD, limb girdle muscular dystrophy; MDC, congenital muscular dystrophy; DMD, Duchenne-type muscular dystrophy; BMD, Becker-type muscular dystrophy.
Number in parentheses represents an accession number in Online Mendelian Inheritance in Men (OMIM) (http://www.ncbi.nlm.nih.gov).

X-linked FDCM

X-linked FDCM leading to pure DCM is associated with mutations in the cytoskeletal protein dystrophin, encoded by *DYS*. Mutations were identified in Duchenne and Becker-type muscular dystrophy, in which DCM is a constant feature. Mutations in tafazzin, a protein of unknown function encoded by *TAZ*, result in early-onset DCM with lethality in infants and Barth syndrome. Emerin, an integral protein of the inner nuclear membrane binding to lamin A/C, is encoded by *EMD* and is associated with X-linked Emery–Dreifuss muscular dystrophy (XL–EDMD).

GENETIC TESTING

Mutations in disease genes can be detected after gene amplification by polymerase chain reaction (PCR), followed by a mutation screening technique (single-strand

conformation polymorphism, denaturing high-performance liquid chromatography, or others) and finally by sequencing. These techniques are highly specific, if different conditions are analyzed and if the PCR primers largely surround the exons and important intronic sites. The sensitivity depends on several factors, particularly one cannot exclude the implication of another as-yet identified gene and/or that PCR primers may hide a point mutation.

MOLECULAR MECHANISMS

Mutations in *LMNA* produce up to eight different disorders, now called laminopathies, and it is not clear how they do so. To date, 35 *LMNA* mutations have been identified in autosomal-dominant FDCM with conduction disease without associated skeletal symptoms: 23 missense and 6 nonsense mutations, and 6 insertions/deletions with frameshift leading to truncated proteins. These mutations are located all along the gene, with 31 being common to both lamins A and C, 1 being specific for lamin C, and 3 being specific for lamin A. More than 101 *LMNA* mutations have been identified in families with autosomal-dominant skeletal myopathies (EDMD or LGMD1B), in which DCM-conduction defect is a constant feature at an adult age. These mutations are located all along the gene. Thus there is no specific ''DCM-restricted domain'' in lamin A/C.

Mutations in sarcomeric genes can cause both FDCM and familial hypertrophic cardiomyopathy (FHC). Sarcomeric gene mutations in the two distinct clinical entities can result in energetic compromise and alterations in myofibrillar calcium sensitivity, suggesting a unifying pathophysiological mechanism in both FDCM and FHC.

Mutations in cytoskeletal proteins leading to FDCM are thought to produce reduced force transmission from the sarcomere to the extracellular matrix (for review, see Ref. [17]).

Mechanisms by which FDCM is associated with skeletal symptoms still need to be elucidated. A possible key role might be attributed to modifier genes, which influence phenotype expressivity. Environmental factors may contribute to phenotypical variability.

GENOTYPE–PHENOTYPE CORRELATION

Genotype–phenotype correlations are not yet determined for the majority of disease genes because of the wide phenotype and genotype heterogeneity and the lack of informational data obtained from families carrying the same FDCM gene mutation. Data about natural disease history are available for *LMNA* mutations.[18] Compared to noncarriers, FDCM patients with *LMNA* mutations had significantly poorer cumulative survival with more severe and progressive DCM.

GENETIC COUNSELING

Genetic counseling is preliminary and under development. Limitations are wide genetic heterogeneity and lack of genotype–phenotype correlation. Screening of first-degree relatives focuses on history, physical examination, and clinical tests. If a disease mutation is known in a family, genetic testing can be used for evaluation of relatives at risk for developing FDCM. Noncarriers might be reassured that they will not develop FDCM in the context of a specific mutation. The complex genotypical and phenotypical variability underlines the necessity for further extensive genotype–phenotype correlation studies on large families.

CONCLUSION

FDCM shows a wide genotype heterogeneity with various inheritance patterns and a large number of involved genes. The major goals are to identify all genes implicated in FDCM, to study large informative families, to correlate genotypes and phenotypes, and to identify patients at high risk for SCD. Experimental approaches using animal models will help in elucidating pathophysiological mechanisms involved in disease development.

Cardiomyopathy, Hypertrophic (Familial)

C

Dagmar I. Keller
Lucie Carrier
INSERM U582, Paris, France

INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is a myocardial disease characterized by left and/or right ventricular hypertrophy and dysfunction. HCM shows wide phenotypical heterogeneity with regard to age of onset, degree and distribution of hypertrophy, and type and severity of clinical manifestations. The familial form of HCM (familial hypertrophic cardiomyopathy, or FHC) is genetically heterogeneous. The typical form is caused by mutations in 12 different genes encoding proteins of the contractile apparatus. The variability of the phenotype depends not only on the major gene mutation, but on the complexity of the genetic status and modifier genes. Molecular genetic studies have given insights into the pathogenesis of FHC and have elucidated ''poison peptide'' and ''haploinsufficieny'' as molecular mechanisms. A common underlying mechanism could be energy depletion with a key role in hypertrophy development.

CLINICAL DESCRIPTION

HCM is a primary myocardial disease defined by the World Health Organization (WHO) as ''left and/or right ventricular hypertrophy, which is usually asymmetric and involves the interventricular septum.''[1] Histological features include myocyte hypertrophy and disarray, and increased interstitial fibrosis.

The diagnosis of HCM is made by clinical examination, electrocardiogram, and transthoracic echocardiography for the detection of unexplained left ventricular hypertrophy (LVH) greater than 13 mm in the absence of another cardiac or systemic disease. LVH is typically asymmetric with a diffuse or segmental (subaortic, midventricular, or apical) pattern and is usually associated with a hyperdynamic left ventricle (LV).[2] The differentiation of HCM from physiologically mild LVH, such as in athletic hearts, is crucial. Distinction in a nonobstructive or obstructive form of HCM is based on the presence or absence of a systolic outflow tract gradient under resting and/or provoking conditions. Symptoms in HCM are complex.[3] Exertional dyspnea, typical or atypical angina, and loss or impairment of consciousness are produced by multiple mechanisms. LV outflow tract obstruction depends on both the LV contractility state and loading condition. Mitral insufficiency from distortion of the mitral valve apparatus can be severe and can contribute to symptoms of heart failure. Diastolic dysfunction is a hallmark finding in HCM and can lead to diastolic heart failure. Myocardial ischemia results from a misbalance of oxygen demand/supply in the hypertrophied myocardium even in the absence of coronary artery disease. Sustained ventricular tachycardias and ventricular fibrillation can lead to syncope and sudden cardiac death (SCD); embolic complications of atrial fibrillation may increase morbidity.

The clinical course of FHC does not follow a unique pattern. The age of onset varies widely between 15 and 60 years, depending on the genetic background. SCD is often the first manifestation in young individuals and competitive athletes. Patients can exhibit no or only mild symptoms over the long term, or the disease can progress to systolic dysfunction and heart failure.

DIFFERENTIAL DIAGNOSIS

All other causes of LVH have to be excluded as longstanding, insufficiently treated or untreated hypertension and aortic stenosis. The distinction of LVH as physiological adaptation in athletes is mandatory. Systemic disease with infiltrative heart processes can cause an HCM-like phenotype: amyloidosis, Noonan's syndrome, multiple lentigines syndrome, Friedreich's ataxia, mitochondrial cytopathies, and hemochromatosis.[4]

MANAGEMENT

Therapeutical Approaches for HCM Are Symptom-Oriented

β-Blockers act as negative inotropic drugs and are used as first-line drugs in patients with or without LV obstruction, and are the preferred treatment in symptomatic HCM patients with an LV outflow tract gradient only by exertion.[5] Verapamil, a calcium antagonist with negative

DOI: 10.1081/E-EDGP 120025787

inotropic properties, is used in both obstructive and nonobstructive forms in patients without severely disabling symptoms. Disopyramide, a class IA antiarrhythmic drug with negative inotropic effects, is reserved for patients with outflow tract obstruction not responding to β-blocker and verapamil. End-stage HCM requires adapted therapy including angiotensin-converting enzyme (ACE) inhibitors or angiotensinogen II receptor blockers, diuretics, spironolactone, and digitalis.

Septal myectomy can abolish the gradient caused by severe outflow tract obstruction. Alcohol septal ablation initiates controlled septal myocardial infarction to reduce the gradient. Dual-chamber pacing allows substantial reduction of the gradient and more aggressive medical treatment. Patients at high risk for SCD with important outflow tract gradient benefit from biventricular pacing properties of an implantable cardioverter defibrillator.

Risk stratification for SCD in HCM patients is currently based on available clinical data, but does not yet allow to precisely identify all patients at high risk.[6]

MOLECULAR GENETICS

In about 60% of cases, HCM is inherited as autosomal-dominant FHC. The prevalence is 1/500 in the common adult population. In the typical form of FHC, mutations in 12 different disease genes encoding proteins of the sarcomere have been identified (Table 1 and Fig. 1). Four genes encode the thick filaments: *MYH7* for β-myosin heavy chain (β-MyHC) and *MYH6* for α-myosin heavy chain (α-MyHC), *MYL3* for essential myosin light chain (MLC-1), and *MYL2* for regulatory myosin light chain (MLC-2); five genes encode the thin filaments: *ACTC* for α-cardiac actin (α-cAct), *TNNT2*, *TNNI3*, and *TNNC1* for the cardiac troponins T, I, and C (cTnT, cTnI, and cTnC), and *TPM1* for α-tropomyosin (α-TM). *MYBPC3* encodes the cardiac myosin-binding protein C (cMyBP-C), *TTN* encodes titin, and *CRP3* encodes the muscle LIM protein (MLP), which is a Z-disc protein stabilizing the contractile apparatus. Recently, a mutation in the promoter region of the phospholamban gene (*PLN*) has been reported.[8] Patients presenting FHC associated with the Wolff–Parkinson–White syndrome plus ventricular preexcitation exhibited mutations in *PRKAG2*, encoding the γ_2-regulatory subunit of AMP-activated protein kinase (AMPK), a metabolic protein.

Today, about 200 mutations in all these disease genes are known (http://www.angis.org.au/Databases/Heart/heartbreak.html). Eighty percent of the genotyped families present a mutation in *MYH7* and *MYBPC3*;[9] at least these two genes should be systematically screened for mutations in routine diagnostics.

GENETIC TESTING

Mutations in disease genes can be detected after gene amplification by polymerase chain reaction (PCR), followed by a mutation screening technique (single-strand conformation polymorphism, denaturing high-performance liquid chromatography, or others) and, finally, by sequencing. These techniques are highly specific if different conditions are analyzed and if the PCR primers largely surround the exons and important intronic sites. Sensitivity depends on several factors; particularly, one cannot exclude the implication of another as-yet identified gene and/or that PCR primers may hide a point mutation.

Table 1 FHC genes, loci, and proteins

Gene	Locus	Protein
MYH7	14q11.2–q12	β-myosin heavy chain (β-MyHC)
MYH6	14q11.2–q12	α-myosin heavy chain (α-MyHC)
MYL3	3p21.2–p21.2	Ventricular essential myosin light chain (MLC-1s/v)
MYL2	12q23–q24.3	Ventricular regulatory myosin light chain (MLC-2s/v)
ACTC	15q14	α-cardiac actin (α-cAct)
TNNT2	1q32	Cardiac troponin T (cTnT)
TNNI3	19p13.4	Cardiac troponin I (cTnI)
TNNC1	3p21.3	Cardiac troponin C (cTnC)
TPM1	15q22.1	α-tropomyosin (α-TM)
MYBPC3	11p11.2	Cardiac myosin-binding protein C (cMyBP-C)
TTN	2q24.3	Titin
CRP3	11p15.1	Muscle LIM protein (MLP)
PRKAG2	7q36	AMP-activated protein kinase (AMPK)
PLN	6q22.1	Phospholamban

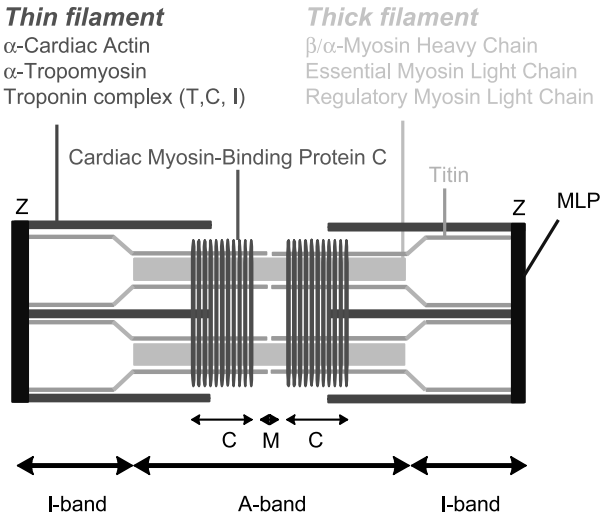

Fig. 1 Localization of FHC disease proteins in the sarcomere. (Adapted from Ref. [7].) (*View this art in color at www.dekker.com.*)

MOLECULAR MECHANISMS

Genetically modified models of FHC elucidate the involved molecular mechanisms. Ex vivo analysis in cellular models was used to analyze the impact of exogenous mutants on sarcomeric structure and contractility. Histopathology or molecular consequences of mutations at mRNA or protein levels were assessed on human cardiac or skeletal muscle biopsies. In vitro analysis of purified mutant proteins has given insights into mechanical and enzymatic alterations of specific molecules. In vivo studies in animal models allow several measurements.

Most of the FHC gene mutations are missense mutations. The mutated proteins are stable and incorporated into the sarcomere after gene transfer in various cellular models (for review, see Ref. [10]) and present in human skeletal biopsies carrying a heterozygous mutation in the *β-MyHC* or *α-TM* genes.[11,12] Mutated proteins act as poison polypeptide and lead to FHC by a dominant negative effect on sarcomere structure and/or function.

Most of the *MYBPC3* mutations result in a frameshift and may produce a C-terminal truncated protein, which is faintly accumulated in fetal rat cardiomyocytes,[13] even after infection of neonatal rat cardiomyocytes with adenovirus, in which they are degraded by the proteasome.[14] Truncated protein was not detected in myocardial tissue of patients carrying a frameshift *MYBPC3* mutation.[15–17] Altogether, these data strongly suggested that frameshift mutations act as ''null allele'' leading to haploinsufficiency. To further elucidate this hypothesis, we developed cMyBP-C null mice by gene targeting.[18] The heterozygous cMyBP-C-deficient mice, carrying only one functional allele, displayed asymmetric septal hypertrophy with myocardial disarray at 10–11 months of age. Therefore, these mice represent the first model with the major feature of human FHC, which is usually asymmetric hypertrophy predominantly affecting the interventricular septum.

The underlying pathophysiological mechanism by which missense and frameshift mutations cause LVH remains to be determined. The conventional concept of decreased contractility caused by mutant sarcomeric proteins, resulting in neuroendocrinal and mechanoreceptor responses and compensatory hypertrophy, has been inconsistent with experimental and clinical data (for review, see Ref. [19]). Energy metabolism may play a key role as trigger for the development of HCM,[20] which is supported by HCM-like phenotypes caused by mutations in metabolic proteins. Patients with a *MYH7*, *MYBPC3*, or *TNNT2* mutation exhibit impaired energy metabolism irrespective of the LVH degree.[21] We proposed that the link between mutation and energy depletion might be a disproportional alteration of mechanical and enzymatic properties of mutant sarcomeric proteins, which can result in inefficient ATP utilization.[22]

GENOTYPE–PHENOTYPE CORRELATION

The FHC phenotype shows wide interfamilial and intrafamilial heterogeneity depending on the major gene mutation, the complexity of the genotype, and the influence of modifier genes and environmental factors. Phenotypes resulting from *MYH7* mutations are usually associated with early LVH onset. Particular *MYH7* mutations are associated with high SCD risk: Arg403Gln, Arg719Trp, Arg453Cys, and Arg723Gly. The Gly256Glu, Val606Met, or Leu908Val *MYH7* mutations have a good prognosis in regard to arrhythmic events.[23] Mutations in *MYBPC3* correlate with mild hypertrophy in young patients, late onset of symptoms, and good prognosis before the age of 40 years.[24] Minimal LVH is found in *TNNT2* mutations, but can be associated with high SCD risk.[25] Studies of *MYBPC3* and *TNNT2* mutations have shown incomplete penetrance and disease expression in adult patients, often associated with minimal or absent LVH.

Five percent of families present individuals with a complex genetic status as homozygotes, double heterozygotes, or compound heterozygotes.[9] Compound and double heterozygotes for mutations in *MYBPC3* and *MYH7* develop a higher degree of LVH compared with single heterozygotes. Homozygotes for a mutation in

MYBPC3 or *MYH7* exhibit SCD at young age, atrial arrhythmias, and congestive heart failure.[9]

Genetic studies have revealed the presence of clinically healthy individuals carrying mutant alleles, which is associated in first-degree relatives with a typical phenotype of the disease.[26,27] This variable expressivity could reflect the existence of modifier genes or polymorphisms, which could modulate the phenotypical disease expression. Components of the renin–angiotensin–aldosterone system have been analyzed in patients with FHC (for review, see Ref. [28]).

GENETIC COUNSELING

The complexity of the wide phenotypical heterogeneity in the context of a complex genotype necessitates a multidisciplinary and multistep approach. Good clinical practice presumes interactive work between cardiologists, geneticists, and psychological support.[29] Genetic counseling is used for a general disease information and specifically for prenatal counseling and/or diagnostics if one parent is affected and predictive diagnosis in phenotypical healthy family members. Genetic testing of first-degree family members and relatives should be encouraged. If mutation analysis is not possible, repetitive clinical examination for HCM diagnosis is recommended.

CONCLUSION

FHC is an inherited cardiac disorder associated with a wide phenotype and genotype heterogeneity. Careful phenotype characterization and genetic studies are important in critical decision making in regard to optimal patient management. Further genotype–phenotype correlation studies and analysis of clinical data may, in the future, allow to identify FHC individuals at high risk for SCD.

INTRODUCTION

Until recently, molecular genetic testing was confined to specialist laboratories with substantial expertise in this area, but such tests are now increasingly being carried out in routine clinical laboratories. The development of systems to ensure the quality of testing procedures and methods has lagged behind the extremely rapid growth in the application of DNA-based testing in medicine. Concerns over the accuracy of genetic test results are given added importance because individuals are usually only tested once in their lifetime, and the consequences of an incorrect result may be far-reaching. Public perception currently holds that genetic tests are highly accurate and represent ''state of the art'' technology. These factors combine to make total quality in molecular genetic testing a matter of primary importance, if a loss of public confidence is not to result.

A broad range of products and services benefit from the development of technical standards aimed at raising levels, of safety, reliability, interchangeability efficiency and other aspects of quality. National standards institutes work together under the International Standards Organisation (*www.iso.ch*) to develop International Standards and within Europe these are developed as European Norms (ENs). These standards refer to the use of appropriate Reference Materials (RMs) to validate test equipment or testing methods as an important part of any analytical testing system. Currently, no CRMs are available for molecular genetic testing. The IVD Directive of the EC (98/79/EC) requires, amongst other things, in vitro diagnostic medical device (IVD) manufacturers to assure the traceability of values assigned to their calibrators and control materials through available reference measurement procedures and/or available reference materials of a higher order (e.g., established International Standards.)

Thus, the demand for reference materials for genetic testing is driven by a combination of regulatory requirements and the desire of testing laboratories to be assured that their results are correct. This entry explores some of the issues which must be considered when designing RMs for molecular genetic testing and describes current research and development efforts in this area.

OVERVIEW

Reference Measurement Systems and Traceability Chain

In order to harmonize, standardize, and improve the quality of genetic diagnostic services the establishment of reference measurement systems is of pivotal importance. Diagnostic measurements must be accurate, precise, specific, comparable among laboratories, and traceable to the available reference measurement procedures and available reference materials of a higher order. Manufacturers are obliged to demonstrate traceablitity to a CRM according to the IVD directive 98/79/EC. Certified reference materials are reference materials qualified with a certificate stating assigned values and uncertainties (i.e., expected variability in the values), intended use, information about the matrix (the form of the material), and commutability. The three elements of reference measurement systems (RMS) are internationally accepted agreed reference measurement procedures (RMP), CRM, and reference laboratories.

The standard EN ISO 17511:2003 refers to the RMS, and it requires for measurement of quantities in biological samples: definition of the analyte with regard to the intended use of the measurement results, RMP for the selected quantity in samples, and suitable reference materials for the selected quantity, e.g., primary calibrators and secondary matrix-based calibrators that are commutable (i.e., the range of assays in which the CRM will perform correctly).

Traceability is defined[1] as a property of the result of a measurement, or the value of a standard, whereby it can be

DOI: 10.1081/E-EDGP 120020931

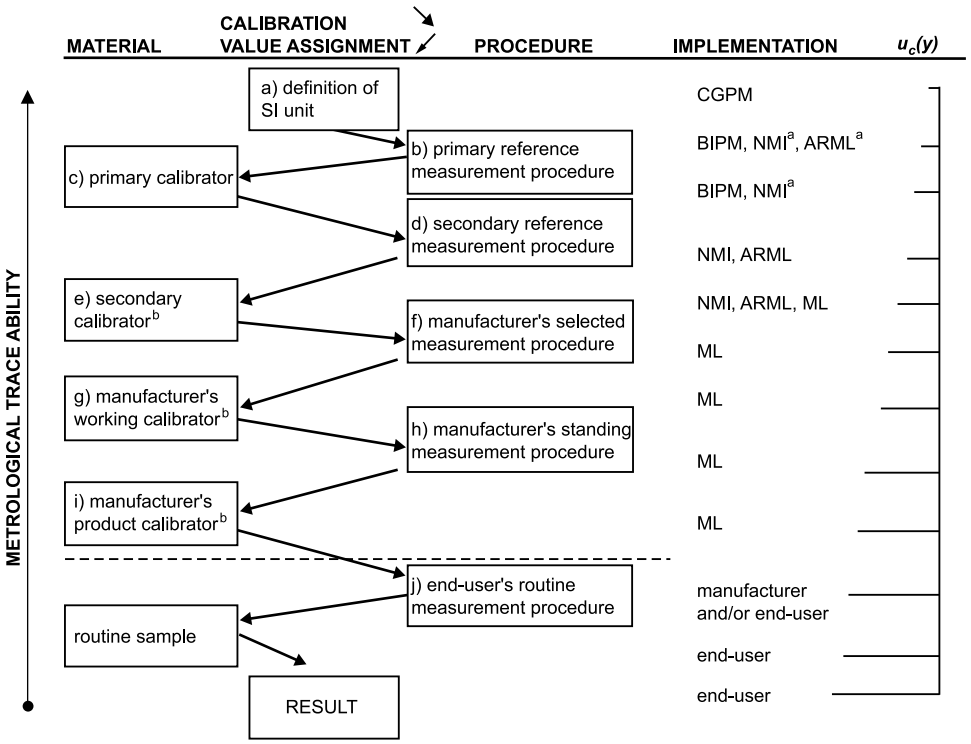

Fig. 1 Calibration hierarchy according to one scheme given in EN ISO 17511.

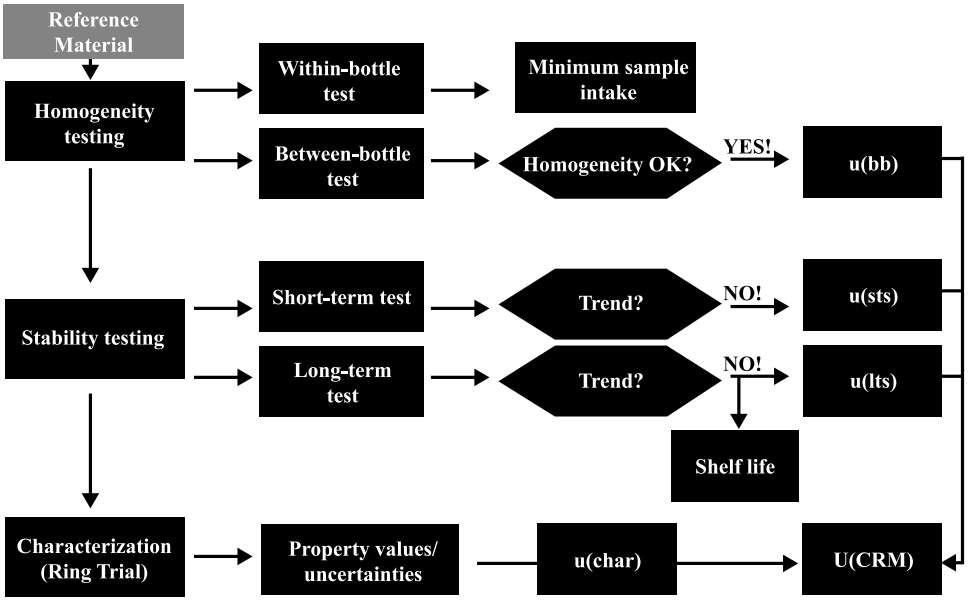

Fig. 2 Typical certification campaign scheme.

related to stated references, usually national or international standards, through an unbroken chain of comparisons (Fig. 1) all having stated uncertainties. The certification of a CRM is an integrated process of a correct preparation, homogeneity, and stability demonstration, and accurate and traceable characterization that leads to a certified value together with its total uncertainty as shown in Fig. 2.

In fact the Guide to Expressing Uncertainty in Measurement (GUM), revision of ISO Guide-35,[2] defines that all components of uncertainty of ''the sample on the desk of the user'' should be properly accounted for. The uncertainty of a CRM is calculated as the sum of the different uncertainties coming from different measurements. The role of CRMS is to facilitate measurements that are traceable, reliable, and comparable, and in which users can have confidence. Commutable CRMs (i.e., CRMs that will perform correctly in a wide variety of assays) are necessary to cover the broad scope of methodological approaches used.

DEVELOPMENT OF REFERENCE MATERIALS

Overview

Genetic testing involves the determination of whether a particular DNA sequence is present or absent in a patient's sample. In some cases, tests are designed to determine the presence or absence of known mutations (mutation testing), whereas in other cases the sample is screened for any deviation from the normal DNA sequence (mutation scanning).

There exist a large number of approaches for both mutation testing and mutation scanning. The situation is further complicated by the existence of many different types of genetic mutation (point mutations, deletions large and small, gene rearrangements, duplications, triplet repeat expansions), each of which may require different testing or scanning technologies. There is no ''gold standard'' testing or scanning method which will detect all possible mutation types. Although many genetics tests are qualitative in nature (presence or absence of a DNA sequence), some are quantitative. These involve either the measurement of the number of copies of a gene or part of a gene (to test for duplications or deletions) or the measurement of the number of copies of the repeated sequence in short repeated stretches of DNA which may be located adjacent to or within genes. Preparation of certified reference materials for molecular genetic testing had until recently not been attempted, and there are as yet no CRMs available in this field. Currently, molecular genetics tests are validated using reference materials which are often derived from research laboratories. These materials are deemed to be valid on the basis that an expert laboratory has determined that the material contains (or does not contain) a particular mutation. The materials are usually distributed on an informed peer-to-peer basis in response to personal requests made to the expert laboratory. There are few instances of organized distribution of genetic reference materials which have been validated in a methodical way by more than one laboratory. One exception involves the materials distributed for the purposes of external quality assurance (EQA) schemes. These materials are routinely validated by two laboratories before distribution, and the consensus result obtained by scheme participants provides further validation. However, the amount of such materials remaining in participating laboratories after completion of EQA schemes is usually small, perhaps only sufficient for a few assays. For quantitative tests, this may be sufficient to calibrate in-house materials which can then be used as reference samples and run with each batch of tests. Qualitative tests, however, require positive and negative control material which can be run with each batch of test samples. It is not unusual for a laboratory to test many hundreds of samples without ever encountering a positive result.

Thus a continuing supply of reference material which is certified to give a positive result is required for each test. The material left over from EQA schemes cannot fill this requirement. Furthermore, many laboratories are beyond the reach of the EQA schemes which are currently in place and have no access to these materials. These laboratories are likely to be the ones most in need of external validation of their tests through the use of appropriate reference materials. The fact that many laboratories fail to provide correct mutation detection in the ongoing European EQAs[3] further stresses the need for the availability of *certified* RMs.

The IVD Directive

The EU Directive on in vitro Diagnostic Medical Devices (98/79/EC), which came fully into force in Member States in December 2003, requires that all in vitro diagnostic devices carry the CE mark. The Directive explicitly covers materials transferred between laboratories as described above. Paragraph (9): ''Whereas, although internationally certified reference materials and materials used for external quality assessment schemes are not covered by this Directive, calibrators and control materials needed by the user to establish or verify performances of devices are in vitro diagnostic medical devices.'' Manufacturers of kits for genetic tests also have to obtain CE marking for their products under this Directive. For this, they are obliged to assure the traceability of values ''through available reference material

procedures and/or available reference materials of a higher order'' (Annex 1, Section 3). The expected rapid rise in the number of such kits on the market, and the increasing proportion likely to be designed for direct use by the public, adds urgency to the requirement for the availability of CRMs for genetic testing.

Validation Methodologies

In the absence of any ''gold standard'' method for genetic testing, reference materials must be certified by a consensus approach. The range of approaches used for each RM will be determined by the nature of the genetic change contained in the RM. For example, large triplet repeat expansions (fragile X syndrome, myotonic dystrophy) are not amenable to standard polymerase chain reaction (PCR) amplification and must be analyzed by Southern blotting or by a modified PCR method, whereas single-base substitutions are not readily detected by Southern blot, but can be ascertained by a wide range of other methods. In each case, the widest range of methods compatible with the particular RM should be used, with particular emphasis placed on using methods which are as independent of each other as possible, such as denaturing gradient gel electrophoresis, or sequencing using different protocols and hardware. This will be important, not only to assure that the characteristic assigned to the RM (presence/absence of a mutation) is correct, but also to ensure that the RM will be useful in calibrating or validating as wide a range of test methodologies as possible. Wherever possible, the methodology employed to verify the RM should include direct determination of the DNA sequence, using multiple replicates in different centers.

Types of Reference Material

Besides the testing methodology employed, the other major variable to be considered in designing a RM is the type of material which should be used. One can envisage many types of material as potentially suitable (Table 1), such as cultured cell lines, genetically engineered cell lines, genomic DNA (gDNA), recombinant (cloned) DNA fragments (rDNA), PCR amplified DNA, synthetic DNA (sDNA), and dried blood spots.

The parameters to be considered in selecting a reference material are as follows.

1. *How similar is the reference material to the material usually received for testing?*

   Most laboratories receive samples of biological material taken directly from patients for testing. This may be blood, mouthwash, chorionic villi, or indeed any tissue containing nucleated cells. DNA is extracted from these samples in the testing laboratory, by one of a large variety of methods. Laboratories have in general optimized their testing procedures to work reliably on DNA prepared by their selected protocol. Some testing protocols require DNA to be prepared by embedding whole cells in agarose blocks. It is impractical to prepare a RM using a patient's sample directly, as sufficient material would not be available for a useful batch. As CRM producers guarantee, certify, and monitor stability of the CRMs, these materials must be produced, stored, and delivered in a stable defined format, which is different to a native patient sample. Thus the practical material most similar to the usual samples will be cultured cells or immortalized cell lines. As most testing requires purification of genomic DNA as a first step, purified genomic DNA must be the next most suitable material in terms of similarity to the usual test material. However, both of these types of material have certain drawbacks (Table 1). No matter how the DNA for an RM is prepared, it will be different from the DNA routinely tested in most testing laboratories in terms of purity from contaminants, salt concentration, average fragment size, and many other parameters, and this may interfere with the proper functioning of tests in some laboratories. The most one can expect from a RM based on purified DNA is that the DNA is of the highest purity required for the range of assays in

Table 1 Choosing a reference material formulation/presentation

Type	Similar to usual samples	Versatile	Stable	Economical to produce	Storage cost	Ethical issues
Cell line	+++	+++	−	+	−	+
Genomic DNA	++	++	+*	++	++	+
Recombinant DNA	+	++	++	+++	++	++
PCR product	+	++	++	+++	++	++
Synthetic DNA	−	−	++	++	++	+++

+++, excellent; ++, very favorable; +, moderate; −, less favorable.
*If freeze-dried, rating becomes ++.

which it is to be used and that all of its physical and chemical properties are fully documented.

2. *How versatile is the material? i.e., is it technically suitable for use in all the possible testing methodologies?*

   As indicated above, a wide range of molecular genetic techniques can be used to test for the same mutation. Some forms of RM will be suitable for a wider range of tests than others. In essence, the more like total genomic DNA a RM is the more versatile it will be, so this parameter is linked to the previous one. Reference materials based on short DNA fragments, whether cloned, produced by PCR, or chemically synthesized will not be useful RMs for tests which involve Southern blotting or other long-range techniques, but they may be excellent RMs for short-range techniques. The testing methodologies employed are tailored to the type of mutation under study: short-range techniques for point mutations and long-range techniques for large triplet repeat expansions and major gene rearrangements. Thus the optimal type of RM will depend on what type of mutation the RM is designed for. When RMs for highly multiplexed tests are required, only artificial RMs will normally be possible, as natural sources will only contain at most two mutations.

3. *How stable is the material likely to be?*

   As a batch of RMs must have a reasonable shelf life to be useful (5 years is a sensible target), the stability of the proposed RM is of central importance. Experience of maintaining DNA banks in diagnostic and research centers tells us that purified DNA is one of the more stable biomolecules, and may survive intact in solution at 4°C or even room temperature for many years, as long as it is stored in a suitable solution and at high concentration. Freeze-dried DNA may be stable at room temperature.

   Intact cells are likely to be the least stable of all the forms of RM, as they need to be preserved at at least −70°C and preferably in liquid nitrogen to ensure their integrity. The other RM types, all consisting of purified DNA, may have similar stability characteristics, but this will need to be determined experimentally. The very large fragments in purified genomic DNA are more likely to be affected by physical shearing on storage in liquid, or on freezing and thawing, than the shorter fragments in PCR products or recombinant DNA. Dried blood in spots appears to be reasonably stable over several years at room temperature.

4. *How expensive or economical is it to produce large batches of the material?*

   In order to meet the requirements of a certified reference material, the material must be capable of being prepared in large batches suitable for many hundreds or even thousands of tests. This is possible for all of the RM types mentioned above, but is likely to be much more economical in the cases of PCR products and cloned DNA fragments. A 20 μL PCR reaction, diluted one million-fold for use as an RM, yields 20 liters of the product.

5. *How expensive or economical is it to store and to transport the material?*

   With RMs for molecular genetic testing, we are dealing with very small quantities of material in each aliquot, so bulk is not a problem to be considered. The parameters contributing to the cost of storage and transport are stability (discussed above) and hazard. Storage and transport costs will of course rise sharply with decreasing stability because of the requirement for refrigeration/freezing. Hazards associated with biological materials include pathogens which may be harbored by cell lines but most potential contaminants are unlikely to be present in purified DNA.

6. *Are there ethical or ownership issues associated with the material?*

   It is clear that apart from synthetic DNA, which is the least suitable material from other points of view, all types of RM are derived directly or indirectly from a human source. Full ethical approval must be obtained from donors of material for the establishment of cell lines, or the use of blood or other samples in RM development. Concerns may remain, however, that consent may be later withdrawn or challenged, or that testing of the RM for mutations other than the one specified in the certification process might constitute an invasion of the donor's genetic privacy. Furthermore, materials derived from human sources may be the subject of ownership claims when used for commercial purposes. Thus the further removed from a human source an RM is the less likelihood there is that such problems may arise. Cloned DNA fragments are removed from their genomic context, but their derivation must be documented under Genetically Modified Organism (GMO) regulations. Polymerase chain reaction products must be derived from a genomic DNA sample, which is traceable to an individual.

   The approach must then be to minimize the potential consent and ownership problems by obtaining appropriate informed consent and releases for each human source. Other legal issues concern transportation of RMs over boundaries. Often, a human- or biological-source-derived material is deemed to be potentially hazardous, which may hinder distribution of RMs in international initiatives.

Some types of reference material and their suitability under the headings discussed are summarized in Table 1.

Ongoing Initiatives to Develop Reference Materials

Several initiatives are ongoing to produce RMs for genetic testing in Europe and North America. In Europe, the CRMGEN project, funded by the European Union's Fifth Framework for Research, is developing reference materials in the form of cell lines, genomic DNA, PCR products, and plasmids for a range of common genetic tests (www.crmgen.org). Based on the expertise gained in the project, guidelines for the future production and validation of RMs will also be developed and published. The European Commission's Institute for Reference Materials and Measurements (IRMM) is collaborating with the International Federation of Clinical Chemistry (IFCC) to produce plasmid-based RMs for prothrombin variants. In the United Kingdom, the National Institute for Biological Standards and Control (NIBSC) is working on a number of gDNA RMs for Factor V Leiden testing based on cell lines.

In the United States, the Centers for Disease Control and Prevention are coordinating efforts to source, produce, and validate new reference materials for genetic testing[4] which are ongoing both in academic centers and in the private sector.[5]

INTRODUCTION

The reference standard essential for all molecular biology is direct nucleotide sequencing. This ''Gold'' standard is used for studies ranging from gene mutation screening in human disease to the sequencing of an entire genome. Sequencing protocols had been developed that used either chemicals or dideoxy nucleotides, although the former became less popular because of the use of toxic chemicals. If direct nucleotide sequencing was less expensive then there would not be the need for mutation screening techniques.

MUTATION DETECTION

Because of the cost of the direct sequencing techniques described above,[1,2] many mutation detection procedures have been developed. The most important criteria for an efficient mutation screening technique is the detection of new mutations within a gene. Several methods have been developed to screen for sequence changes in either cellular RNA or genomic DNA, including denaturing gradient gel electrophoresis (DGGE),[3] chemical cleavage of mismatch (CCM),[4] single-stranded conformation polymorphism (SSCP),[5] heteroduplex analysis (HA),[6] conformation sensitive gel electrophoresis (CSGE),[7] and denaturing high-performance liquid chromatography (DHPLC).[8] These methods detect all sequence changes such as nonsense, frameshift, splice site, and missense mutations as well as polymorphisms, whereas the protein truncation test (PTT)[9] screens specifically for truncating mutations. The detection efficiency of these different methods varies significantly depending on the size of the template screened. Single-stranded conformation polymorphism has been one of the most popular screening procedures used over the last decade because of its simplicity along with a sensitivity of >95% for fragments of approximately 150 bp. However, this sensitivity decreases to <5% for fragments of around 600 bp.[10] Conformation sensitive gel electrophoresis is also technically simple and has a sensitivity of 90–100 % for fragments of up to 450 bp.[11] Denaturing gradient gel electrophoresis requires much optimization for each fragment screened, but will yield a sensitivity of ~99% for fragments of up to 500 bp.[12] Chemical cleavage of mismatch has a sensitivity of between 95% and 100% for fragments >1.5 kb in size[13] and is perfect for screening larger fragments while still achieving a high sensitivity of detection.

CHEMICAL CLEAVAGE OF MISMATCH

Early studies demonstrated that mismatched bases became chemically reactive. Mismatched guanine and thymine react with the compound carbodiimide,[14] and mismatched cytosine reacts with hydroxylamine (NH_2OH). Mismatched thymine also reacts with osmium tetroxide (OsO_4),[4] potassium permanganate/tetramethylammonium chloride ($KMNO_4$/TMAC),[15] and potassium permanganate/tetraethylammonium chloride ($KMNO_4$/TEAC).[16] These chemical reactions were exploited in the development of the mismatch detection techniques, chemical cleavage of mismatch,[4] and the carbodiimide method.[14] Chemical cleavage of mismatch or chemical mismatch cleavage (CMC) was developed for use in the detection of single-base mismatches in cloned DNA, and with the advent of PCR, was employed to the screening of genomic DNA and mRNA.[4] Chemical cleavage of mismatch is based upon the detection of base mismatches in double-stranded DNA hybrids called heteroduplexes. These heteroduplexes are generated by mixing probe (wild type) and target (patient) DNA. When the sequence is different in the target compared to the probe, which can be caused by mutation or polymorphism, the usual Watson–Crick base pairing is disrupted. These free bases can then be chemically modified whereby they become substrates for piperidine cleavage of the DNA strand at or adjacent to the mismatch. Probe and/or target DNA can be fluorescently or radioactively labeled with the subsequent detection of cleavage products using either an automated fluorescent analyzer or autoradiography in conjunction

with denaturing polyacrylamide gel electrophoresis (Fig. 1).

Practical Considerations

PCR template

Chemical cleavage of mismatch gene-screening protocols can be designed using either patient genomic DNA as the template for PCR or mRNA isolated from specific tissues such as muscle or skin, or ectopic mRNA from peripheral blood lymphocytes. However, when total RNA is used as the template, a nested PCR protocol will probably be required to obtain enough DNA for the CCM procedure.

Labeling of fragment

The original CCM studies used DNA probes that had been radioactively end-labeled.[4] This technique was thought to detect nearly 100% of single-base substitutions,[17] but was considered dangerous because of the use of radioactivity along with toxic chemicals such as osmium tetroxide. However, the introduction of fluorescent-based technology has greatly improved the safety aspect of the procedure. Fluorescent CCM (FCCM), or fluorescence-assisted mismatch analysis (FAMA), has been developed whereby DNA can now be either internally labeled using fluorescently labeled dUTPs,[13] or end-labeled using fluorescently labeled primers,[18] although both procedures will achieve the same sensitivity of detection. Subsequent cleavage product analysis yields precise information on the position of the sequence change from either end of where the mismatch is positioned. A product of 850 bp may yield products of 700 and 150 bp, although the scientist will not know whether the mutation is 150 bp from the 5′ end of the fragment or 150 bp from the 3′ end. This can be overcome by using a protocol that utilizes different fluorescent labels on the 5′ and 3′ primers. To obtain 100% sensitivity of mismatch detection it will be necessary for both probe and target to be labeled. Some reports have demonstrated that a number of thymine–guanine mismatches are resistant to modification by osmium tetroxide.[17] However, the complementary DNA strand heteroduplex will consist of an adenine–cytosine mismatch that can be modified by hydroxylamine.

Heteroduplex formation

The correct formation of the probe/target heteroduplex is essential for chemical modification, although this can be inhibited by the sequence context and/or size of the fragment being studied. Autosomal dominantly inherited disorders will demonstrate a mutation on one chromosome and thus the patients DNA will be heterozygous and can naturally form a heteroduplex. However, autosomal recessively inherited disorders may demonstrate homozygosity and will not form a heteroduplex. Here, or where the mode of inheritance is not known, the patient DNA should be mixed with control DNA. Heteroduplex formation is performed by the denaturation of the double-stranded DNA followed by controlled cooling to permit annealing of the target and probe DNA strands.

Chemical modification

The majority of studies to date have used a combined hydroxylamine/osmium tetroxide protocol. However,

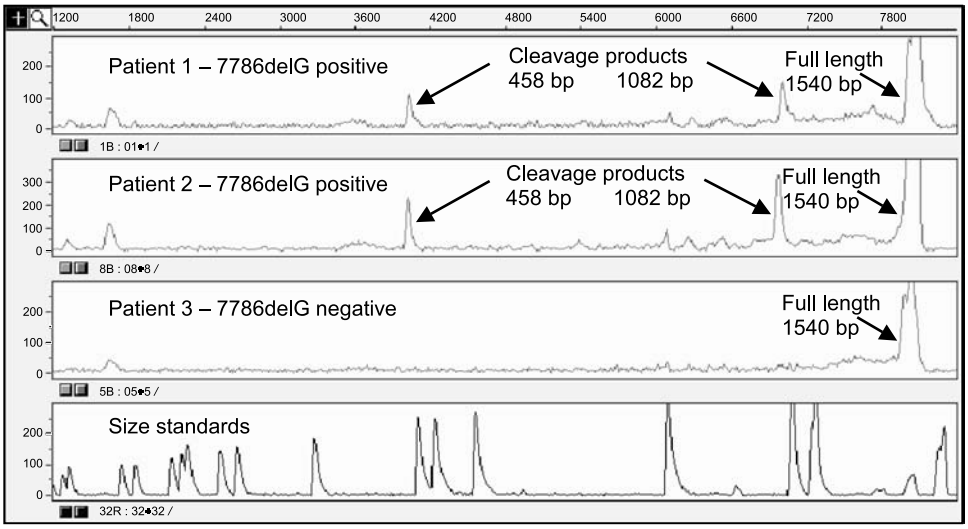

Fig. 2 FCCM analysis of the common British *COL7A1* mutation 7786delG. FCCM of fragment 19 (exons 103–108) for two patients heterozygous for the mutation 7786delG (lanes 1–2) and a negative control (lane 3). Lane 4 contains the size standards. Cleavage peaks (458 + 1082 bp) in lanes 1 and 2 are absent for the negative control. The uncleaved peak is 1540 bp.

because of the toxic nature of osmium tetroxide, work has been undertaken to validate a safer replacement. Potassium permanganate/tetraethylamine chloride[16,19,20] is now preferred because in addition to resolving the safety concerns of osmium tetroxide it can also overcome the lack of reactivity of some thymine–guanine mismatches.[17] Recently, a combination single-tube protocol has been developed, termed Single-Tube Chemical Cleavage of Mismatch Method, that permits the chemical modification of heteroduplexes by potassium permanganate/tetraethylamine chloride and hydroxylamine without the need for intermediate purification steps.[19]

Solid-phase technology

The original CCM protocol[4] required many lengthy ethanol precipitation stages that limited the quantity of work performed each day. However, the development of an ultrarapid protocol that made use of biotinylated PCR primers, in conjunction with streptavidin-coated paramagnetic beads, yielded a solid-phase CCM protocol. Exploitation of the affinity of biotin for streptavidin along with microtitre plate technology permits easy and effective purification of the cleavage products, thereby allowing high throughput screening to be performed.[13] Very recently, the solid-phase CCM protocol has seen further development whereby the DNA is immobilized on solid silica supports. This version of solid-phase CCM is fast and sensitive for detection of sequence changes.[21]

Detection protocols

Depending on the labeling protocol used, cleavage products can be detected using standard denaturing polyacrylamide gel electrophoresis (PAGE) apparatus and detected using standard X-ray film, or on a fluorescent DNA fragment analyzer utilizing PAGE or, more recently, capillary electrophoresis.

CLINICAL APPLICATIONS

Chemical cleavage of mismatch has been applied to the screening of many diseases including hemophilia A (*factor VIII*),[22] Fabry disease (α-*galactosidase A*),[23] hereditary breast and ovarian cancer (*BRCA1*),[24] Fanconi anaemia (*FANCC*),[25] dystrophic epidermolysis bullosa (*COL7A1*)[26] (Fig. 2), and ataxia telangiectasia (*ATM*).[27]

CONCLUSION

Since its development over 15 years ago, CCM has been shown to be a very efficient method for the detection of sequence changes in DNA and RNA. Although it is technically more involved than other gene-screening techniques such as SSCP, HA, or CSGE, and can include the use of toxic chemicals, it is ideally suited to screening relatively large fragments in excess of 1.5 kb

and will accurately pinpoint the position of the sequence change. To date, apart from direct nucleotide sequencing, FCCM remains the fastest, most accurate, and sensitive fluorescent mutation screening technique available, and these high standards will only improve in the future with the optimization of fluorescent and solid-phase technologies.

INTRODUCTION

Chlamydia pneumoniae causes usually mild infections of the respiratory tract in humans. It has further been associated with diverse chronic inflammatory diseases such as atherosclerosis and asthma. *Chlamydia pneumoniae* is a member of the order Chlamydiales which contains a couple of other human pathogens and animal pathogens. A common feature of all chlamydiae is a unique biphasic, strictly intracellular life cycle. Metabolically inactive elementary bodies (EBs) infect the cells, then they transform into reticulate bodies which multiply inside special inclusions. Because of this developmental cycle, chlamydiae are difficult to culture, posing special challenges to diagnosis and research. Research on these bacteria is further complicated by the lack of gene transformation systems.

DESCRIPTION OF THE GENUS

Taxonomy

C. pneumoniae belongs to the genus *Chlamydia*, which also contains the species *Chlamydia trachomatis*, *Chlamydia psittaci*, and *Chlamydia pecorum*. Due to the detection of new *Chlamydia*-like organisms and genetic analysis, in 1999 a new taxonomy was proposed which divides the common chlamydiae into the two families, *Chlamydophila* (including *C. pneumoniae*) and *Chlamydia*, and adds two more families containing the newly detected chlamydia-like organisms (Table 1).[1] This proposal, however, is still controversial, leading to the concomitant usage of old and new taxonomies in current publications.[1,2]

Life Cycle

A common feature of all chlamydiae is the unique biphasic, strictly intracellular life cycle. The cycle starts with the attachment of small ($\sim$0.3 μm), metabolically inactive EBs to the host cell. After internalization, these transform into reticulate bodies (RBs; $\sim$1 μm) which multiply by binary fission inside an inclusion. In the case of *C. pneumoniae*, these RBs begin to reorganize to EBs after 2 days, until finally the inclusion and cell rupture thereby releasing new EBs (Fig. 1).

In vitro a third state, the so-called persistent or aberrant state, can be induced by IFN-γ, antibiotics, or depletion of nutrients.[3] When the inducing stimulus is removed these forms can reenter the normal developmental cycle.

Macromolecular Composition

Chlamydiae have a bilayered cell membrane similar to other Gram-negative bacteria. The cell membrane contains species-specific antigens such as the major outer membrane protein (MOMP), as well as common antigens such as lipopolysaccharide (LPS).[4] Major outer membrane protein is the most prominent membrane protein making up about 60% of the surface proteins. Variable domains of this protein allow the division of *C. trachomatis* but not *C. pneumoniae*, into different serovars. In the genome of *C. pneumoniae* open reading frames of 21 putative polymorphic membrane proteins (Pmp) have been found.[5] For some, presence on the surface of chlamydiae and immunogenicity could be demonstrated.[4,6]

All chlamydiae share the same LPS structure[7] with a comparably low number of acylic groups, which is probably responsible for the low endotoxic activity. Lipopolysaccharide is used as a group complementation fixation antigen and recombinant ELISA–antigen for chlamydial serodiagnosis. Heat shock proteins, such as the genus-specific heat shock protein 60 (HSP60), are additional important immunogenic antigens although they are scarcely expressed on the surface. Also of interest is a Type III secretion apparatus that is expressed on the surface of reticulate bodies as well as EBs.[5]

Genome

The genomes of four *C. pneumoniae* strains (CWL029, AR39, J138, TW183) have been sequenced and published.[5,8–10] Additionally, the genomes of three *C. trachomatis* strains (trachoma serovar D: D/UW-3Cx; serovar L2 L2/434/Bu; Nigg-MoPn, proposed *Chlamydia muridarum*), one *C. psittaci* (GPIC, proposed *Chlamydia caviae*)[2–4] and one parachlamydial strain[1] are available and more genomes are soon to be published.

With slightly more than 1 million base pairs (1.23 million for *C. pneumoniae*) chlamydiae possess one of the smallest genomes in the bacterial world.[8,10] The different chlamydial genomes have a homology of about 80% and there are very few genetic differences within the species of *C. pneumoniae*.

Chlamydiae were previously considered to be ATP-parasites but interestingly possess putative proteins for the synthesis of ATP.[5] The presence of two genes encoding (ADP)ATP-translocases, however, make it likely that chlamydiae additionally import host cell ATP.[11]

In some strains of *C. pneumoniae*, and also *C. psittaci*, different bacteriophages have been demonstrated.[8]

Additional contemporary information about the chlamydial genomes can be accessed on the Internet: http://www.ncbi.nlm.nih.gov/genomes/MICROBES/Complete.html, http://www.tigr.org/tdb/, http://chlamydia-www.berkeley.edu:4231/.

CLINICAL SIGNIFICANCE

Respiratory Tract Infections

C. pneumoniae is endemic worldwide and is responsible for an estimated 10–20% of community acquired pneumoniae. The first contact with *C. pneumoniae* usually occurs at a young age leading to a seroprevalence of 50% to 60% by the age of 30, which slowly rises with age.

Infection is transmitted via respiratory secretions. After a variable incubation period of up to 4 weeks the disease begins with growing hoarseness and aching throat, mild cough, and fever and does later develop into an atypical pneumonia.[12,13] In rare cases infection may also present as sinusitis or otitis media or lead to the aggravation of asthma.[14] In immunocompetent individuals the infection is usually self-limiting, but may be complicated by superinfections. In immunocompromised persons infection may take a more severe course. Reinfections do occur but are generally milder than primary infections.[13]

C. pneumoniae and Atherosclerosis

Since the first report of a link between *C. pneumoniae* and coronary heart disease (CHD) in 1988,[15] the chlamydia-arteriosclerosis theory has been challenged by a vast number of epidemiological and experimental studies, resulting, however, in contradictory outcomes. Recent meta-analysis of serological studies did not confirm the early reports of a serologic correlation.[16,17] But direct investigation of arteries by PCR and immunohistochemistry revealed that 25% to 50% of atherosclerotic vessels contain chlamydiae compared to only 2% of healthy vessels.[17,18] There is, however, considerable variation among different studies and only poor correlation between the different detection methods.[17]

In vitro, chlamydiae were able to infect all cells relevant in the development of arteriosclerosis, including macrophages, endothelial cells, and smooth muscle cells.[19] *Chlamydiae* further promoted the expression of proatherogenic receptors, second messengers, and enzymes in cell culture experiments.[19]

While early studies addressing antibiotic intervention of arteriosclerosis seemed to show a positive effect, this result has not been confirmed in recent studies.[20]

Animal experiments with mice and rabbits have also produced conflicting results concerning the development

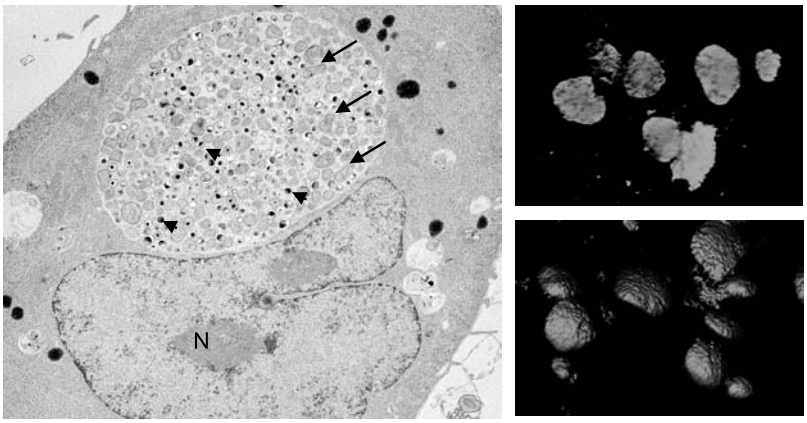

Fig. 1 *C. pneumoniae* in HeLa cells 72 hr post infection. The transmission electron microscopic image shows an inclusion containing reticulate bodies which are still dividing (long arrows) and already developed elementary bodies (short arrows) as well as intermediate forms (N=nucleus of the cell). The right pictures represent 3-D images of an immunofluorescent staining with a FITC-labeled antibody targeting chlamydial LPS (green) and a fluorescence in situ hybridization with a Cy-3-labeled DNA-probe targeting specific sequences on the chlamydial ribosomal RNA (red), respectively. Some inclusions are already rupturing and their infectious content is spreading ready to infect new host cells. (Photos courtesy of Poppert and Horn.) (*View this art in color at www.dekker.com.*)

of arteriosclerosis after infection with *C. pneumoniae*.[21,22] Although the enthusiasm regarding the detection of a bacterial cause of atherosclerosis has been dampened by the contradictory results, the debate is still ongoing.

C. pneumoniae and Other Chronic Diseases

A considerable number of papers report on a link between *C. pneumoniae* and chronic diseases such as multiple sclerosis,[23] lung cancer,[24] chronic fatigue syndrome, morbus Alzheimer, and various others. However, these reports mainly rely on rather small studies and are, as those for arteriosclerosis, hampered by the lack of standardized and validated detection methods.

PATHOGENETIC MECHANISMS

The various chlamydial infections show an analogous pattern of pathology.[25] Initially, polymorphonuclear leukocytes infiltrate the locus of infection followed by lymphocytes, macrophages, and plasma cells. A strong Th1 response seems to be of major importance for the clearance of infection.

Recurrence of infection frequently occurs. This may be explained by the survival of chlamydiae inside the protected cell, possibly in the aforementioned so-called persistent state. Another possibly important factor is the ability of chlamydiae to suppress apoptosis.[26]

DIAGNOSIS

Laboratory diagnosis of *C. pneumoniae* infections can be performed by culture, serology, and nucleic acid amplification tests.[27] In tissues, chlamydiae can additionally be targeted by immunohistochemistry and in situ hybridization techniques.

The most frequently used approach for the diagnosis of *C. pneumoniae* infections is serology. Although, often, it can only retrospectively demonstrate a significant rise in antibody titers. In primary infection, specific IgM is detectable from 2 to 3 weeks until 2 to 6 months after infection. IgG antibodies may not appear until 2 months after infection. In reinfection, complement fixation as well as IgM antibodies often remain negative while the IgG titer may rise to 1:512 or more as soon as 1 week after infection.[28,29] There are yet no validated serologic markers for persistent or chronic infection, but IgA antibodies in combination with high titers of IgG antibodies may be indicative.[29]

The most used and recommended serologic test is the microimmunofluorescence test (MIF), which uses purified formalinized EBs from *C. pneumoniae*, *C. trachomatis*, and *C. psittaci* that are fixed on glass slides in distinct, small spots. It can therefore simultaneously determine species-specific antibodies to the three chlamydiae.[29] The chlamydial complement fixation test, based on the common lipopolysacharide antigen (LPS), may react more promptly, but has a low sensitivity for reinfection. It does not distinguish between various species of chlamydiae and is therefore generally not recommended.[27] The same

is valid for whole inclusion fluorescence tests that are not species-specific either and not yet sufficiently validated to be recommended.[27] Enzyme immunoassays (EIA) offer a more automated and standardized workflow. Evaluations of these tests are currently underway.[27]

Culture of *C. pneumoniae* is hampered by great technical effort and limited sensitivity. Therefore it is not used routinely, but remains essential for the determination of resistance and the characterization of strains for research purposes. Cultured chlamydiae can be identified by PCR[30] or by species-specific antibodies (Fig. 1). We have recently developed a probe set for differentiation of chlamydiae by fluorescent in situ hybridization (FISH) that can be implemented for this purpose and may also be used for the detection of chlamydiae in clinical samples (Fig. 1).[31]

A variety of DNA amplification methods has been described using different formats (nested,[32] nonnested, real-time LightCycler PCR,[33] and enzyme time-released touch down PCR.[34]) and targeting different gene sequences including the ompA gene, 16SrRNA gene, omcB, and the Pst I fragment.[17] These methods are increasingly used to detect *C. pneumoniae* in respiratory specimens as well as in tissues; however, standardization of these methods is urgently required to avoid discrepant results.[27]

Immunohistochemistry (IHC) is used for the detection of *C. pneumoniae* in tissues for research issues such as the association of chlamydiae with arteriosclerosis.[27] Contrary to PCR and culture, this technique allows for the preservation of the tissue structure and localization of the antigen. Results, however, have to be interpreted carefully as artifacts and positive stainings are difficult to distinguish.[27]

An additional technique preserving the histology of the tissue is in situ hybridization with labeled DNA probes.[27,31] This technique is hampered by similar problems as seen in IHC.

THERAPY

The recommendations for antibiotic treatment of *C. pneumoniae* infections are based on in vitro studies, animal experiments, case reports, and experiences with the treatment of other chlamydial infections. Therapeutic regimens for *C. pneumoniae* include doxycycline, erythromycin, or clarithromycin for 2–3 weeks or a 5-day course of azithromycin. For recurrent infection a second course with a different antibiotic is recommended. There are singular publications of development of resistance in *C. trachomatis*, but resistance in *C. pneumoniae* has never been reported. However, antibiotic testing is not standardized and valid studies comparing various therapeutic regimens do not exist.

CONCLUSION

Diagnosis of *C. pneumoniae* is still unsatisfactory. Internationally standardized and validated assays especially for nucleic amplification and antibody detection are warranted. The first steps in this direction have been taken for example with the formulation of recommendations from the Centers of Disease Control (United States).[27] The standardization of diagnosis may eventually allow determining the contribution of *C. pneumoniae* in chronic inflammatory disease more precisely.

The known sequences of the chlamydial genomes were already the base for many elucidating studies and will be the base for further research.[8–11] Methods for the genetic transformation of chlamydiae are not in sight, but transcriptional analysis will further contribute to elucidate mechanisms of chlamydial infection by identifying the involved genes and their interplay. The microarray techniques are increasingly implemented for transcriptional profiling of global gene regulation and more results are soon going to be published.[35] Functional research on chlamydial proteins will also base on the expression of chlamydial proteins in transformable organisms such as *Escherichia coli*. Two-dimensional (2-D) gel electrophoresis is a promising technique for the analysis of protein expression in chlamydiae and some of the abovementioned data have already been derived from 2-D gel electrophoresis partly in genomic–proteomic approaches[3,4,6] (more contemporary information about chlamydiae and proteomics is available at http://www.gram.au.dk). In addition to enhancing the functional understanding of chlamydiae, proteomics might help to identify proteins for diagnostic purposes and even targets for the development of a vaccine.

Chlamydia trachomatis

Hsi Liu
Centers for Disease Control and Prevention, Atlanta, Georgia, U.S.A.

INTRODUCTION

Chlamydiae are gram-negative intracellular bacteria which contribute to a wide range of acute and chronic diseases. Four species are included in the genus *Chlamydia*: *C. trachomatis*, *C. pneumoniae*, *C. psittaci*, *and C. pecorum*. *Chlamydia psittaci* and *C. pecorum* are animal pathogens with humans becoming infected only as a result of exposure to infected animals. In contrast, *C. trachomatis* and *C. pneumoniae* infections appear to be restricted to humans, with *C. pneumoniae* having recently emerged as a significant cause of respiratory tract disease, with no obvious animal host.

BIOLOGY OF THE ORGANISMS

Chlamydiae are obligate intracellular bacteria of limited metabolic capability, characterized by a dimorphic growth cycle. The infectious form is called the elementary body (EB) and is a condensed sporelike spheroid. The EB is metabolically inactive, consisting of a tightly compacted chromosome or nucleoid, and an outer membrane of covalently linked lipopolysaccharides. When it encounters host cells, the EB is taken in by receptor-mediated endocytosis. It has been suggested that a trimolecular mechanism is used to bridge a host receptor with a chlamydial receptor by glycosaminoglycan.[1] The mannose receptor has also been suggested to have a role in the EB's entry into the cell.[2] The engulfed EB is enclosed in an endosome which does not fuse with a lysosome.

Several hours after entering the cell, the EB converts to a metabolically active form called the reticulate body (RB) that undergoes binary fission, forming microscopically visible inclusions containing hundreds of organisms within 24 hr. In a further 24–48 hr, the reticulate bodies condense to transform into infectious EBs that are liberated as a result of cell lysis. Polysaccharide components may form within the inclusions after 48 to 60 hr of development, depending on the chlamydial species. *Chlamydia trachomatis* can be distinguished from *C. psittaci* and *C. pneumoniae* as a result of this polysaccharide material, which stains brown with iodine. *Chlamydia psittaci* and *C. pecorum* essentially cause infections of animals, with humans becoming infected as a result of exposure to infected secretions of those animals. In contrast, *C. pneumoniae* has recently emerged as a significant cause of respiratory tract disease in humans, with no obvious animal host.

The human pathogen *C. trachomatis* has been further subdivided into 15 serovars (A–K and L1–L3), based on the monoclonal antibodies that identify epitopes located in the major outer membrane protein (MOMP). *Chlamydia trachomatis* can also be classified into two biovars, based on the diseases it causes. Serovars A, B, Ba, and C have been associated with the eye disease trachoma, and serovars D, E, F, G, H, I, J, and K with genitourinary tract infections. Both diseases have worldwide distribution. Together, they are termed the trachoma biovar. The L1, L2, and L3 serovars are associated with the more invasive sexually transmitted disease (STD) lymphogranuloma venereum (LGV), which is prevalent in sub-Saharan Africa, South America, and Southeast Asia (the LGV biovar).

TRACHOMA

Trachoma remains the most common cause of preventable blindness in the world. It is found in communities with poor hygiene or sanitation facilities and inadequate access to potable water. The infection is endemic in many tropical and subtropical areas, especially countries in northern and southern Africa, the Middle East, and on the Indian subcontinent. It is transmitted by direct contact or by flies, which act as mechanical vectors. Trachoma presents as conjunctivitis of both the palpebral and bulbar conjunctivae, followed by the formation of lymphoid follicles; the sequelae, entropion, and trichiasis arise as a result of conjunctival scarring, causing corneal damage. Repeated infection and associated bacterial superinfection can result in visual impairment and blindness. The conjunctival epithelium of infected children is the most important reservoir of infection in the affected communities. High chlamydial loads occur in very young children and have been directly correlated with severity of inflammatory changes.[3]

Diagnosis

Trachoma is frequently diagnosed based on its clinical presentations. In the laboratory, Giemsa staining of

DOI: 10.1081/E-EDGP 120024081

conjunctival scrapings can identify cytoplasmic inclusions within conjunctival epithelial cells, and organisms can be detected by tissue culture method or by nucleic acid amplification tests (NAAT) such as PCR.[3,4]

Treatment and Control

Recent studies have shown that a single dose of azithromycin is as effective as a long course of topical tetracycline (42 doses over a 6-week period) in treating trachoma, and the effect of treatment lasts for 1 year.[3,4] However, only small differences in effectiveness have been found between mass treatment programs and programs treating active cases only.[5] WHO has set a goal of eliminating trachoma by 2020, using the SAFE program.[6,7] ''SAFE'' stands for *surgery* to correct lid deformities, *antibiotics* to treat active disease, *face-washing*, and *environmental controls* to reduce transmission.

GENITOURINARY CHLAMYDIAL INFECTION

Chlamydia trachomatis infection of the genitourinary tract is the most common bacterial STD in both the United States (>4 million new cases per year) and worldwide (>50 million new cases per year). Many infected individuals of either sex are asymptomatic; but symptomatic urethritis is common in men, whereas women may present with a mucopurulent cervicitis and acute salpingitis. The most serious complication of infection in men is epididymitis. Without treatment, more than 40% of infected women may develop pelvic inflammatory disease, which may lead to tubal infertility or increased risk of ectopic pregnancy. Pregnant women may transmit their infection to their babies as they pass through the infected endocervix at the time of delivery. The baby may develop a mild, neonatal conjunctivitis and/or afebrile pneumonia. Infection stimulates host inflammatory and immune responses, but the immunity is of short duration and reinfection occurs frequently.

Diagnostic Tests

A definitive diagnosis of chlamydial genital infection can be established solely on the basis of laboratory testing. In the past, the standard laboratory test for *C. trachomatis* genital infections was isolation of the causative organisms in cell culture. By definition, this test is 100% specific but it lacks sensitivity when compared to the newer NAATs. Several commercial tests are currently available (Table 1), and new tests are being developed every year.[8–11] The Roche Amplicor and Cobas Amplicor CT/NG tests use polymerase chain reaction;[12] the Becton-Dickinson B-D-ProbeTec test uses strand displacement amplification;[13] and the GenProbe Aptima test uses transcription-mediated amplification. All three tests amplify the cryptic plasmid which is found in >99% of the clinical isolates.[14] Unfortunately, the Abbott LCx test, which employs the ligase chain reaction, is no longer commercially available. The NAATs are extremely sensitive and can be applied to noninvasive specimens such as first-catch urine and self-administered vaginal swabs. However, NAATS detect dead as well as living organisms and may give false-positive results, particularly in low-prevalence settings, and they are relatively expensive. Liquid Pap smear medium for CT/NG collection has also been used with acceptable results.[15] As with all testing, each laboratory must establish an ongoing quality-assurance program to validate the test results.[16] Two nonamplified nucleic acid probe tests are commercially available which can diagnose both *C. trachomatis* and *Neisseria gonorrhoeae* simultaneously, but cannot differentiate between the two, requiring additional tests for verification. The GenProbe PACE 2 test uses a DNA probe that is specific for the rRNA. The Digene Hybrid Capture II test uses an RNA probe that is specific for the DNA of *C. trachomatis* and targets both the genomic DNA and cryptic plasmid.[17] The commercial DNA probe tests, direct immunofluorescence tests, and antigen-capture ELISA tests are all used in peripheral laboratories, but lack sensitivity when compared to NAATs. Serological tests are of little value in the diagnosis of *C. trachomatis* infections caused by serovars A–K except in the case of detection of specific IgM responses in babies presenting with neonatal pneumonia where high titers of antibody may be detected when using an indirect immunofluorescence test.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV) is caused by *C. trachomatis* serovars L1, L2, or L3. The LGV organisms are more invasive than those that cause other sexually transmitted infections and may spread systematically via the lymphatics.

Diagnosis

Lymphogranuloma venereum is usually diagnosed on the basis of clinical symptoms, signs, and exclusion of other relevant diseases, especially chancroid and syphilis. Serology (with detection of high titers of broadly cross-reactive antichlamydial antibody), isolation of *C. trachomatis* from the site of infection, and application of molecular tests can all assist in the diagnosis; but all tests for LGV are subject to the same constraints as tests for

Table 1 Comparison of Chlamydia tests

Commercial name	Company	Advantages	Disadvantages
Amplification tests			
Amplicor CT test	Roche	• Cryptic plasmid as target and MOMP was used as alternate target • Endocervical swab • Male urethra • Male and female urine	
Cobas Amplicor GC/CT	Roche	• Automated test	• Requires special instrument
Ligase Chain Reaction (Lcx; LCR)	Abbot	• FDA approved since 1995 • PCR+ligase • Automatic test • Less contamination problem • Cryptic plasmid as target and MOMP is used as alternate target • Used by 13.5% of laboratories	• Discontinued
Hybridization tests			
ProbeTecET	Becton-Dickson	• FDA approved since 1999 • Detects both GC and CT • Strand displacement amplification • Fast throughput • Endocervical swap • Male urethra • Male and female urine	• Report variations from site to site
Gen-Probe Amplified CT	Gen-Probe	• Transcription Mediated Amplification (TMA) of rRNA • Use 16s RNA as alternate target • Male and female urine • Male and female swab	• Labor-intensive
Gen-Probe PACE 2C	Gen-Probe	• A screening test • Has several versions • Competitive probe version uses labeled probe • Low cost • Used by 41% of laboratories (Pace 2C); used by 21.5% of laboratories (Pace 2)	• May be less sensitive than NAATS • Cannot be used in urine
Digene Hybrid Capture II (HCII)	Digene	• Antibody capture of DNA • Signal amplification test • Detect both GC and CT	• Does not differentiate CG/CT • Less sensitive
Gen-Probe Hybridization Assay	Gen-Probe	• rRNA hybridize to CT and CG • Specimens do not need to be refrigerated and last for 7 days	

genitourinary infection. Lymphogranuloma venereum infection is usually confirmed after isolating the organism and sequencing the MOMP gene, a time-consuming process. A combined PCR and restriction fragment length polymorphism (RFLP) test has been used to diagnose and differentiate LGV from trachoma biovars.[18] Currently, the only specific test which can rapidly differentiate LGV from the trachoma biovar is a multiplexed real-time PCR developed at the Centers for Disease Control and Prevention. This test is based on a gene deletion of the polymorphic membrane protein H (*pmpH*) gene in the trachoma biovar, which differentiates it from the LGV biovar.

GENOMICS AND MOLECULAR TYPING

The Chlamydia genome is composed of a chromosome of approximately 1.04 million base pairs and a plasmid of 7493 base pairs.[19] The trachoma and LGV biovars have high gene sequence homology and usually only single

base-pair mutations are found between the two. Several genes show heterogeneity that is important.

The major outer membrane protein (MOMP) gene exhibits extensive sequence variation within the serovars. The differences are mainly clustered in four regions (VD1 through 4), which form the basis of serovar differentiation, using sequencing methods and antibody typing.[20,21] The finding that the tryptophan synthase gene becomes inactivated in the ocular infection could prove to be useful in differentiating ocular chlamydial isolates from those normally causing genital tract disease.[22] The finding of polymorphism in the *pmpH* gene has enabled us to differentiate the trachoma from the LGV biovars.[23]

CONCLUSION

Our understanding of the biology of *C. trachomatis* has progressed tremendously, leading to development of better diagnostic methods. While clinicians should understand each type of test and its limitations, in general molecular tests such as NAATs are likely to continue to replace traditional tests in the future.[24]

Chromogenic In Situ Hybridization (CISH)

Bae-Li Hsi
National Health Research Institutes, Taiwan, Republic of China

INTRODUCTION

In situ hybridization (ISH) on routine formalin-fixed paraffin-embedded (FFPE) tissues faces several technical challenges. It has not always been easy to consistently obtain satisfactory ISH results on FFPE tissue sections. The major obstacle is the permeability of the section to the probes and detection reagents. The method that gave the most consistent results in our hand uses microwave to heat slides in an EDTA buffer to a temperature close to boiling for 15 min. The step is similar to the heat-induced antigen-retrieval step that has been popular in the immunohistochemistry laboratories. The sections were then digested by pepsin (Zymed Laboratories, South San Francisco, CA) or proteinase K (DAKO Co., Carpinteria, CA). For the ease of use and consistency of results, we recommend the use of commercially available, ready-to-use digestion agents. The amount of time required for the digestion varies according to the type of tissues and method of fixation; consistency is essential so that the result can be easily reproduced.

There are several difficulties of using traditional fluorescent in situ hybridization (FISH) on FFPE sections. The autofluorescence of formalin-fixed tissues often obscures the real fluorescence signals. Tissue morphology is difficult to appreciate under dark-field microscopy at high magnification. Moreover, FISH slides cannot be stored or archived for longer periods of time. We demonstrated here the use of chromogenic in situ hybridization (CISH) for the study of genomic alteration in cancer on FFPE sections. The technique allows ISH data to be interpreted using conventional bright-field microscope.

The detail protocols for two experiments were shown. Although commercial kits are available for both experiments, more detail information was given; thus readers can use it as model to develop protocols for their own experiments. The first experiment uses two-color CISH to examine the translocation of *MYC* gene on chromosome 8 in Burkitt lymphoma. The second example demonstrates combined IHC and CISH for HER2 protein expression and gene amplification in breast cancer.

PROBE DEVELOPMENT

With the completion of human genome program and the easy accessibility of human genome information, ISH probes can now be easily selected and prepared. The essential information is provided in the following protocol. More detailed protocols can be obtained from standard molecular biology texts or technical manuals of commercial suppliers.

Bacterial artificial chromosomes (BACs) were selected from the genome browser (http://genome.ucsc.edu/cgi-bin/hgGateway) and ordered from CHORI (http://www.chori.org) or Research Genetics (http://www.resgen.com). Usually, two closely positioned BACs of 200 to 300 kb were used together as one probe. Thus, the final labeled probe covers about 400- to 600-kb genomic DNA. DNA of human insert from the BACs was prepared using standard protocol.[1] The probes were labeled by random priming with biotin or digoxigenin using a commercial labeling kit (Invitrogen, Co., Carlsbad, CA; Roche Applied Science, Indianapolis, IN). The labeled probes were purified using MicroSpin S-200 HR column (Amersham Biosciences, Piscataway, NJ), and the quantity and quality of labeled DNA were evaluated by gel electrophoresis or spectrophotometry (usually 5 μg from one labeling reaction). Cot-1 DNA (Invitrogen) was added to the labeled probe (10 times the quantity of labeled probe, e.g., 50 μg of Cot-1 for 5 μg of labeled probe). This anneals with, and blocks, the nonspecific repeating sequences, such as *alu* or LINE sequences.

The probes used for the two examples were prepared before the completion of the human genome program. The selection of probe was slightly different from the method described above. The probes for MYC translocation were YAC probes. The human DNA inserts in the YAC were isolated by pulsed-field gel electrophoresis. For the HER2 probe, the two BACs were selected by ''BLAST'' HER2 gene sequence in the National Center for Biotechnology Information (NCBI) database. The nonspecific repeating sequences were removed in the commercial version of the probe.[3] Thus, no blocking DNA, such as Cot-1 DNA, was added to the probe. All probes are available from Zymed Laboratories.

MYC TRANSLOCATION IN BURKITT LYMPHOMA

The translocation of *c-MYC* gene on 8q24 is a hallmark of Burkitt lymphoma. Two yeast artificial chromosomes

DOI: 10.1081/E-EDGP 120020724

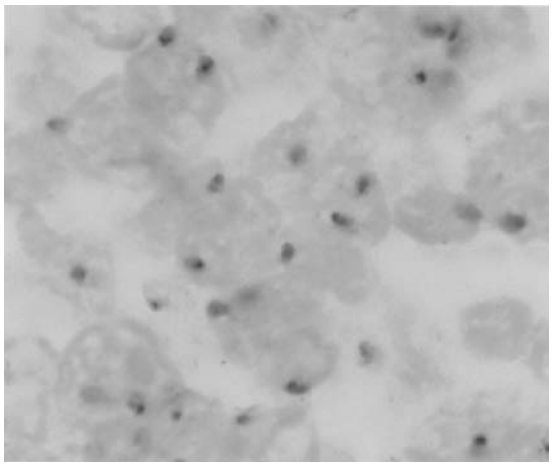

Fig. 1 CISH of MYC on a sample with normal chromosome 8. Majority of red and brown signals are adjacent to each other. The red and brown signals could be clearly differentiated. (*View this art in color at www.dekker.com.*)

(YACs) on the centromeric side of *c-MYC* gene and two YACs on the telomeric side of *c-MYC* gene were selected. The centromeric probe was labeled with digoxigenin and the telomeric probe was labeled with biotin. On the normal chromosome, the two probes were close together. On the abnormal chromosome, the signals of the two probes were apart.

Four-micrometer sections were cut from FFPE tissues and placed on Superfrost Plus slides (Fisher Scientific). The slides were dried in an oven at 37°C overnight. After dewaxing and dehydration, the slides were placed in a preheated pretreatment solution (100 mM Tris–base, 50 mM EDTA, pH 7) in a microwave oven (GE Appliances, model JE1390GA 001) at 199°F for 15 min. After pretreatment, the slides were rinsed with PBS and digested with Digest-All 3 (Zymed) at 37°C for 2 min. The slides were rinsed in PBS and postfixed in 10% buffered formalin for 1 min, dehydrated in graded ethanol, and air dried.

Ten microliters (50 ng) of MYC probe (Zymed) was added over the section and covered with a coverslip. The edges of the coverslip were sealed with rubber cement. The slides were placed in HYBrite slide warmer (Vysis) at 94°C for 3 min and incubated in a humidified chamber at 37°C overnight. The stringency wash was carried out in 0.5× SSC at 72°C for 5 min. For detection, the sections were preblocked with CAS-Block (Zymed) for 10 min and incubated with enzyme conjugate containing alkaline phosphatase (AP)-labeled antidigoxigenin (Roche Applied Science) and horseradish peroxidase (HRP)-labeled streptavidin (Zymed) at 1:500 dilution in antibody diluent (10% normal goat serum in CAS-Block) for 60 min. After washing in PBS/T (0.025% Tween-20 in PBS), the color for HRP was developed using DAB (Zymed) and the color for AP was developed with Fast Red (Zymed) according to the manufacturer's instruction. The slides were counterstained with hematoxylin and mounted in Glycergel (DAKO).

CISH allowed the morphology of the tissue sections to be easily examined. The area of tumor cells could be identified at low magnification; chromosome ISH results on these tumor cells were then examined using 100× objective. The microscope must be of sufficiently high quality to allow the brown color of DAB and red color of Fast Red be clearly differentiated (Figs. 1 and 2) at high magnification.

In the ideal condition, signals on a tissue section that do not have chromosome translocation at 8q24 should all be shown as adjacent red/brown signals. However, often, only part of each nucleus was present on the section. If the sectioning cut through chromosome 8 at area close to 8q24, then individual red or brown signal may be observed on normal tissue samples. In a 4-μm-thick section of normal lymph node, up to 5% of the signals may be shown as single red or single brown signal.

Because of sectioning effect, many nuclei will have incomplete signal profiles. The traditional way of reading FISH results is to look for a nucleus containing all four of the expected red and brown signals. However, a simpler approach is to identify regions predominantly composed of neoplastic cells, then simply record the total number of red, brown, and red/brown signals in that region. The tumor with the translocation should have about 1/3 of all

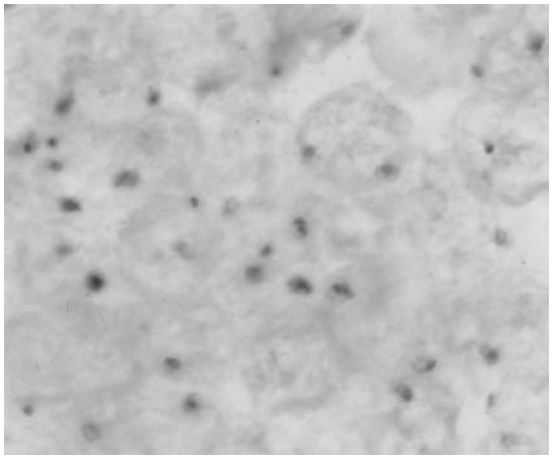

Fig. 2 CISH of MYC on a sample with 8q24 translocation. The image shows individual red, individual brown, and red/brown adjacent signals. (*View this art in color at www.dekker.com.*)

the signals shown as red/brown, 1/3 as red only, and 1/3 brown only.

Using this method of recording data for translocation study, the counting from five samples that did not have 8q24 translocation showed that around 90% of signals were red/brown and about 5% were either individual red or individual brown. The counting from five samples that had 8q24 translocation showed that around 40% of signals were red/brown and around 30% were either individual red or individual brown.

COMBINED IHC AND CISH OF HER2 IN BREAST CANCER

The protocol described here allows immunohistochemistry (IHC) and chromogenic in situ hybridization (CISH) to be combined, such that genetic alternation and protein expression were evaluated using an ordinary light microscope. This technique can have many uses. It can be used, as in this experiment, to evaluate the genetic modification of the gene and the resulting alternation of gene expression;[4] or IHC can be used simply as marker to differentiate different cell type.

The FFEP sections were prepared and pretreated with pretreatment solution as previously described. For immunohistochemistry, the sections were preblocked with CAS-Block for 10 min, then incubated with rabbit antibody to HER2 (Zymed) for 30 min. After washing in PBS/T, the slides were incubated with AP-labeled goat antirabbit IgG (Zymed) at 1:100 dilution in antibody diluent for 30 min and washed with PBS/T. Then, the color of AP was developed with Vector-blue (Vector). The sections were then digested with Digest-All 3 and in situ hybridization was carried out according to the protocol described in the previous section using digoxigenin-labeled HER2 probe (Zymed). For detection, the slides were first incubated with CAS-Block for 10 min, and then incubated with FITC–antidigoxigenin (Roche Applied Science) at 1:500 dilution in antibody diluent for 60 min. After washing in PBS/T, the slides were further incubated with HRP–anti-FITC (Zymed) for 60 min and washed in PBS/T. Then, the color of HRP was developed with DAB (Zymed). The slides were counterstained with hematoxylin and mounted in Glycerogel (DAKO).

The IHC results and CISH of highly amplified *HER2* gene can be viewed at 10× objective. The tumor cells with cluster of amplified *HER2* gene usually are also strongly positive for the HER2 IHC (Fig. 3). The normal cells are negative of HER2 IHC and the nuclei contain only one or two CISH signals for the *HER2* gene. Using conventional bright-field microscopy, the nonamplified HER2 signal could be observed with 40× objective. However, because of the reflective nature of DAB, the signal can be observed at 10× using phase-contrast microscopy.

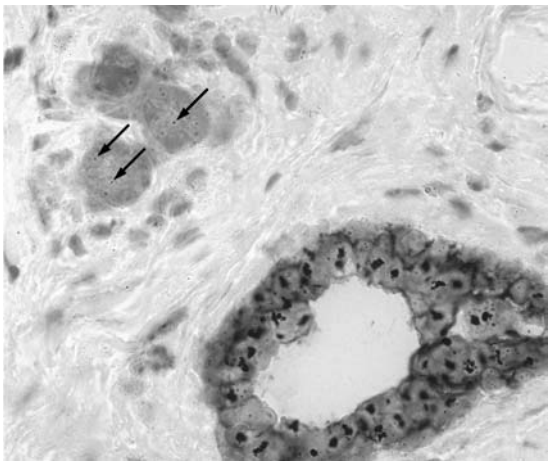

Fig. 3 HER2 IHC/CISH in 4-μm-thick paraffin section of breast carcinoma open biopsy. Tumor cells with clusters of highly amplified *HER2* gene and strong IHC staining can be seen. The arrows point to normal HER2 signals in cells of a normal breast epithelium, which is negative for IHC staining. (*View this art in color at www.dekker.com.*)

CONCLUSION

We demonstrate here the technique of CISH on FFPE tissue sections. It has many advantages over traditional FISH. However, CISH also offer much more limited option than FISH in image analysis. The FISH signals can be computer enhanced, quantified, and analyzed. Computer-assisted analysis also allows multiple probes labeled with several different colors of fluorochrome to be used. Furthermore, the experimental procedure for FISH using directly labeled probe is less time consuming than CISH. However, in routine pathology, the convenience of CISH often outweighs its shortcoming. The most important advantage is that the morphology of tissue can be clearly visualized. They can then be compared with sections stained with other traditional methods, e.g., H+E and IHC, using conventional bright-field microscopy. The slides can also be archived as easily as other routinely prepared slides.

The combination of IHC with CISH, such as in the HER2 example, allows the confirmation of IHC results by ISH. Often, the CISH result was much more quantitative and less variable than the IHC data. More

importantly, it allows the potential of examining gene modification and the consequence of protein expression on tissue section.

Chronic Myelogenous Leukemia—Molecular Diagnosis and Monitoring

Jo-Anne Vergilio

Adam Bagg
Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania, U.S.A.

INTRODUCTION

Chronic myelogenous leukemia (CML) is a myeloproliferative disorder with a well-known molecular pathogenesis, the understanding of which has resulted in the recent exciting development and application of targeted molecular therapy. Molecular techniques play an integral and well-established role in the diagnosis and monitoring of CML, with the latter detection of minimal residual disease being pertinent to both a determination of therapeutic response and efficacy, as well as in the detection of early relapse.

CLINICAL DESCRIPTION

Chronic myelogenous leukemia originates from the transformation of a hematopoietic stem cell with resultant expanding myelopoiesis that, when untreated, characteristically evolves through three phases: a chronic phase manifested by myeloid hyperplasia with circulating granulocytes in all stages of maturation; an accelerated phase of shorter duration during which myeloid elements begin to lose the ability to differentiate; and inevitably, a blast phase of acute leukemia that is usually of myeloid (70%), but can be of lymphoid, phenotype.

Although some patients are asymptomatic with coincidental detection of a leukocytosis on routine medical evaluation, the chronic phase of disease typically has an insidious onset with symptoms related to hypermetabolism, including fatigue, anorexia, weight loss, and night sweats. Massive splenomegaly is common. With disease progression, patients typically develop worsening anemia and thrombocytopenia. Without treatment, the median survival of CML is 4–5 years from diagnosis.

GENOTYPE–PHENOTYPE CORRELATION

The reciprocal t(9;22)(q34;q11) translocation is probably the initial transforming event in the development of CML. This translocation yields a shortened chromosome 22 that is the Philadelphia (Ph) chromosome. With the translocation, two distinct genes are fused: 1) *BCR* that encodes a cytoplasmic protein of uncertain function with oligomerization, serine threonine kinase, and GTPase-activating domains; and 2) *ABL* that encodes a nonreceptor tyrosine kinase normally localized to the nucleus.[1] The resultant chimeric gene and fusion transcript yield a protein with constitutively heightened tyrosine kinase activity that is relocated from the nucleus to the cytoplasm and phosphorylates a variety of cellular substrates with consequent proliferative, growth factor independent, antiapoptotic, and defective adhesive properties in the transformed cells.

The subsequent occurrence of specific cytogenetic and molecular genetic events, in addition to t(9;22), heralds disease progression prior to hematological and/or clinical manifestations. The acquisition of +Ph, isochromosome 17q, and +8 commonly indicates an impending blast crisis while molecular abnormalities associated with disease progression include overexpression of *BCR–ABL*, upregulation of the *EVI1* gene, mutations in tumor suppressor genes *P16*, *P53*, *CDKN2A*, and *RB1*, and aberrant DNA methylation of the translocated *ABL* allele.[2,3] Deletion of the derivative chromosome 9 is an independent poor prognosticator that predicts rapid progression to blast crisis with shortened survival.[4]

PREVALENCE

Chronic myelogenous leukemia comprises ~20% of all leukemias, with a worldwide incidence of 1–1.5 cases per 100,000 population per year. The median age at diagnosis is 50 years, although pediatric cases have also been reported.

DIFFERENTIAL DIAGNOSIS

An important entity in the differential diagnosis of CML is a leukemoid reaction that is nonneoplastic in origin,

DOI: 10.1081/E-EDGP 120030780

arising secondary to other causes, including infection. Other myeloproliferative/myelodysplastic disorders, such as atypical chronic myelogenous leukemia and chronic myelomonocytic leukemia, must also be distinguished from CML given their similar clinical presentations; however, both lack the *BCR–ABL* translocation.

MANAGEMENT

Allogeneic stem cell transplantation (ASCT) is the only proven curative therapy for CML with cure rates of ~70–80% in young (age <40 years) chronic-phase patients who have HLA-matched donors and undergo transplantation within 1 year of diagnosis.[5] However, the associated morbidity and mortality of ASCT is significant; furthermore, most (~65%) patients do not have a suitably matched donor while older patients are often suboptimal candidates for transplantation.

An appreciation and comparison of other treatment options requires an understanding of what constitutes an efficacious therapeutic response; this is gauged using three basic parameters: hematological, cytogenetic, and molecular. Hematological remission is achieved when the blood counts and spleen size have normalized. Cytogenetic response is quantified and graded based upon the percentage of residual Ph+ cells. Traditionally, cytogenetic response serves as the ''gold standard'' for analysis, providing an important predictor of patient survival. Once conventional hematological and cytogenetic remission has been achieved, monitoring then relies upon minimal residual disease assessment using more sensitive molecular techniques to detect the *BCR–ABL* fusion transcript. With successful ASCT, both hematological and cytogenetic remission are achieved and the *BCR–ABL* transcript is no longer detectable.

In patients who are not suitable candidates for ASCT, alternative therapies include interferon-alpha[6] and, more recently, imatinib mesylate (or Gleevec, STI571). Molecular targeted drug therapy with imatinib, a synthetic tyrosine kinase inhibitor, has shown activity in all phases of CML with substantial responses in newly diagnosed patients in chronic phase.[7–10] In an on-going randomized Phase III trial (IRIS), the observed rate of complete cytogenetic remission in newly diagnosed CML patients was 76% with imatinib vs. 15% with interferon plus Ara-C (median follow-up 18 months).[8] Although long-term outcome data are not yet available, imatinib has emerged as the therapy of choice for initial, although still noncurative, treatment of CML as the *BCR–ABL* fusion transcript persists at low levels. One major obstacle to treatment has been the development of therapeutic resistance, particularly in individuals with advanced disease. Mechanisms of resistance include 1) amplification of the *BCR–ABL* chimeric gene at the genomic or transcript level, and 2) point mutations in the kinase domain of *BCR–ABL* (altering its responsiveness to imatinib).[11]

MOLECULAR GENETICS

The t(9;22) translocation can result from several different breakpoints in the *BCR* and *ABL* genes, each with different chimeric fusion proteins that confer somewhat specific clinicopathological features and indicate that this translocation is not pathognomonic of CML (Fig. 1A and B). These breakpoints, indistinguishable by traditional karyotyping, can only be differentiated using molecular techniques. In each, most of *ABL* is juxtaposed to variable 5′ portions of *BCR*. Whereas the breakpoint involving *ABL* is relatively conserved, usually arising in the intron before exon 2 (a2), the breakpoints involving *BCR* are more variable. Breakpoints arising in the major breakpoint cluster region (*M-bcr*) are by far the most common in CML. They occur after either exon 13 (e13 or b2) or exon 14 (e14 or b3), encode a p210 fusion protein, and are present in the vast majority (~99%) of patients with CML.

MOLECULAR GENETIC TESTING

Two broad scenarios necessitate molecular testing in CML: diagnosis and subsequent therapeutic monitoring.

Diagnosis

Whereas cytogenetics identifies the presence of the t(9;22) translocation as well as other chromosomal abnormalities, documentation of the t(9;22) is successful in only ~95% of cases of CML. In one-half of the remaining patients with a normal karyotype, the *BCR–ABL* fusion is only detectable at the molecular level, due to a submicroscopic genetic fusion. In those patients with a normal karyotype, who have the clinical and hematological profile of CML, molecular testing serves a primary role in identifying such patients. In the remaining patients negative for both the Philadelphia chromosome and the *BCR–ABL* fusion, alternative diagnoses must be considered.

Qualitative RT-PCR

Methodologically, qualitative RT-PCR can be performed with a simple, nested, or multiplex approach. Nested

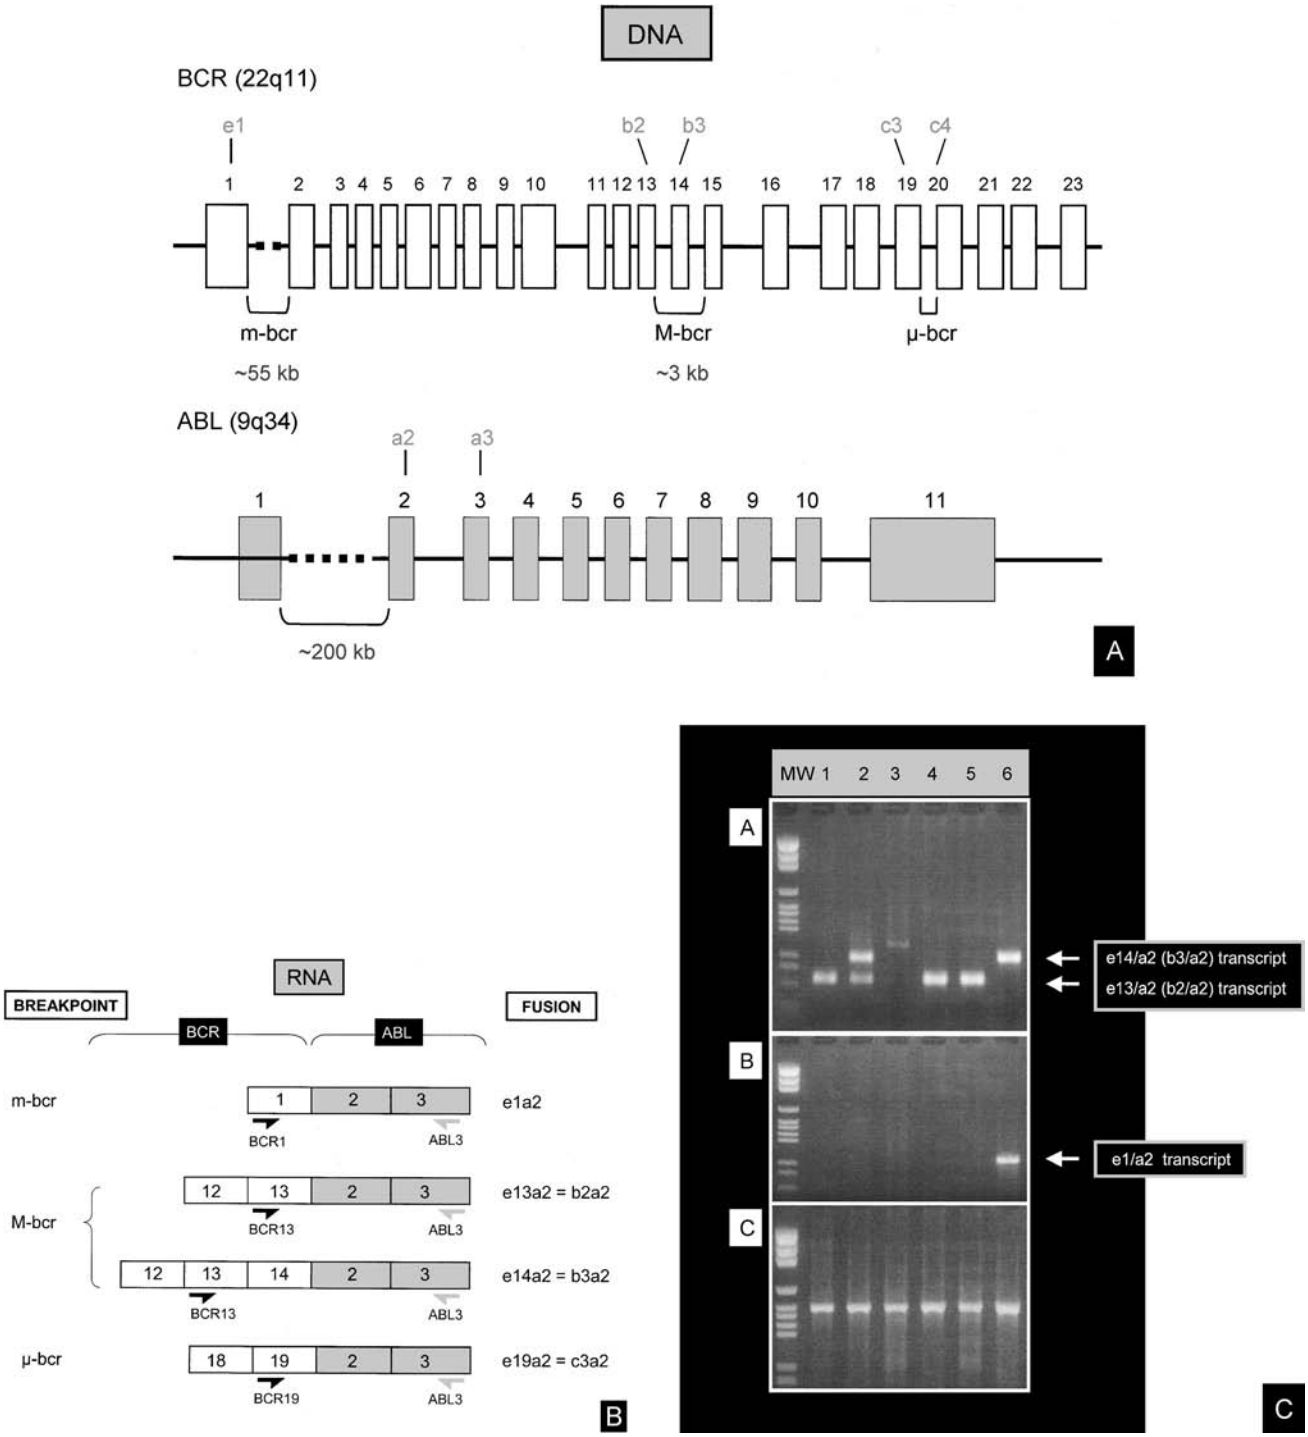

Fig. 1 Schematic representation of (A) the *BCR* and *ABL* genes demonstrating the primary breakpoint cluster regions (bcr) and (B) the RNA/cDNA structure of the most common chimeric transcripts and the primers used for their RT-PCR amplification. The μ-bcr occurs in the uncommon chronic neutrophilic leukemia and is not routinely evaluated. (C) Conventional qualitative RT-PCR for detection of the most common *BCR–ABL* fusion transcripts using gel electrophoresis. Upper panel (A): *BCR* exon 13 (b2) and *ABL* exon 2 (a2) primers. Middle panel (B): *BCR* exon 1 (e1) and *ABL* exon 2 (a2) primers. Lower panel (C): β2-microglobulin primers. Lanes: (1) intron 13 breakpoint, (2) intron 14 breakpoint with alternative splicing to *BCR* exon 13, (3) ? novel breakpoint, ? nonspecific band, (4) intron 13 breakpoint, (5) intron 13 breakpoint, (6) intron 14 breakpoint with alternative splicing to *BCR* exon 1. See text for details.

approaches are to be avoided for routine laboratory practice given the significant risk of contamination and false positivity. With nonnested, simplex RT-PCR, one assay is performed using a single pair of primers. Primers for *BCR* exon 13 (b2) and *ABL* exon 2 (a2) identify both the e13a2 (b2a2) and e14a2 (b3a2) fusion transcripts that differ in size by 75 bp (Fig. 1C, lanes 1 and 6, upper panel). Use of this primer set allows for the molecular detection of CML in nearly all cases (~99%); however, in rare instances, variant breakpoints may occur, yielding a false-negative result or alternatively sized RT-PCR product. The incorporation of an *ABL* exon 3 (a3) primer, in place of an a2 primer, permits the routine detection of rare *ABL* intron 3 breakpoints and has been recommended by some for routine evaluation.[12]

Multiple fusion transcripts may be detectable with a single *BCR* intron 14 breakpoint due to alternative splicing of the primary transcript that yields either an accompanying e13a2 (Fig. 1C, lane 2, upper panel) or an e1a2 (Fig. 1C, lane 6, upper and mid panels) transcript. Identification of the e1a2 transcript requires a separate BCR primer targeting BCR exon 1 (e1) (Fig. 1C, mid-panel, lane 6), and although not essential to the diagnosis of CML, some studies suggest its presence to be a poor prognosticator associated with metamorphosis.[3]

Interpretation

A negative RT-PCR result renders CML extremely unlikely, but does not definitively exclude the diagnosis given the rare variant breakpoints alluded to above. Similarly, a positive RT-PCR result does not definitively invoke a diagnosis of CML, given that *BCR–ABL* fusion transcripts have been identified in the blood of as many as two-thirds of healthy individuals using an extremely sensitive nested RT-PCR technique.[13] However, whereas the majority of CML patients express either the e13a2 or the e14a2 chimeric transcripts, healthy individuals express primarily the e1a2 type. Furthermore, the extreme level of sensitivity achieved ($\sim 10^{-8}$) with this nested technique is neither required nor recommended for diagnostic clinical testing, and thus misdiagnosis should not be an issue.

Monitoring

An understanding of laboratory monitoring is predicated on an appreciation of therapeutic goals and options. The goal of therapy is to eliminate disease; however, if eradication of the neoplastic clone cannot be achieved then therapeutic intent relies on tumor control with an attempt to forestall disease progression.

Molecular monitoring with qualitative RT-PCR originated in the posttransplantation setting. Here it serves two distinct functions: first to document remission and then to monitor for disease relapse. In the latter, molecular monitoring permits early disease detection (prior to hematological or cytogenetic manifestations), when the tumor burden is low and presumably more amenable to treatment. At molecular relapse, therapeutic options include the withdrawal of immunosuppressive agents and/or the administration of donor lymphocyte infusions (DLI) with an improved response when implemented prior to overt hematological relapse.

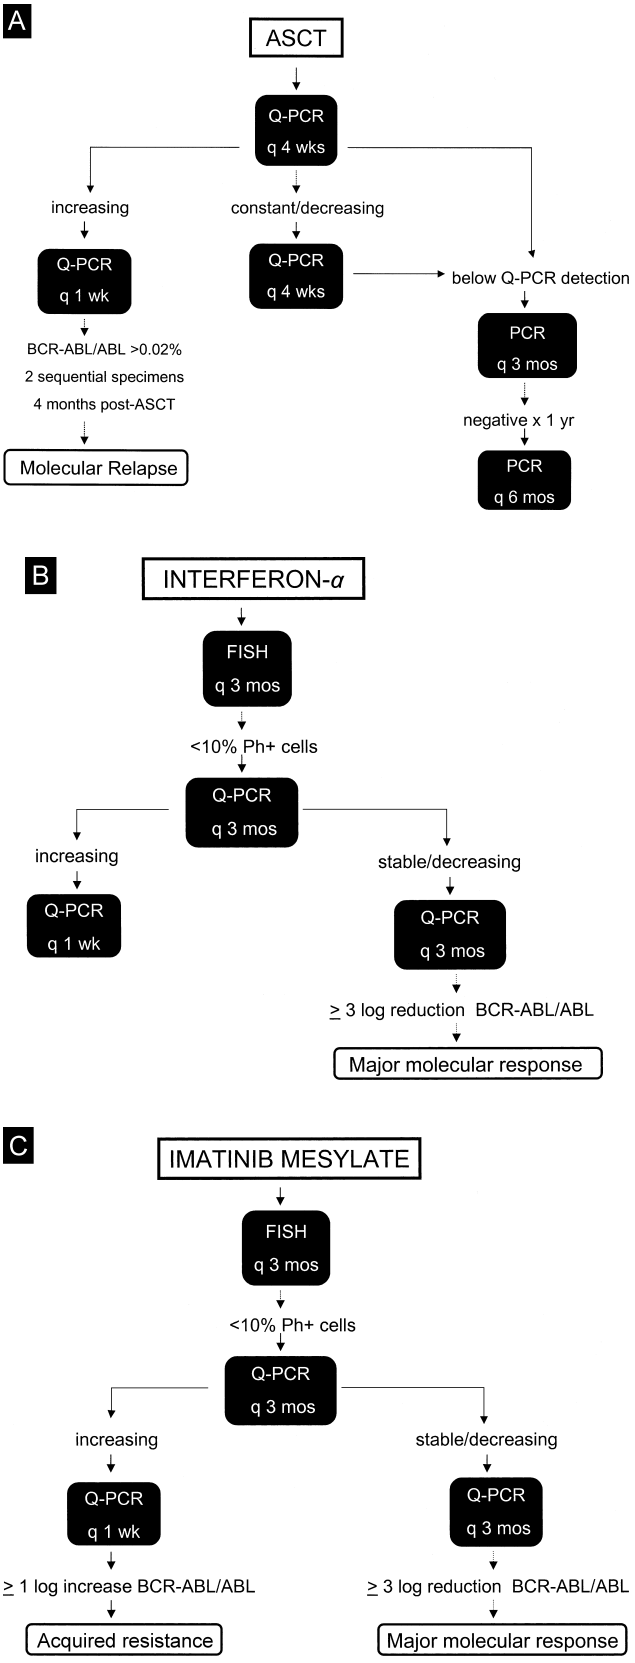
Therapeutic context dictates the ramifications of any test result. In the setting of ASCT, the interval post-transplant, the type of transplant (i.e., unrelated vs. allogeneic-related matched), and the presence or absence of T-cell depletion may all impact the prognostic relevance of qualitative test results. Most patients are qualitatively RT-PCR positive in the first 6 months following ASCT and such results are thus of little consequence. Six to 12 months after ASCT, however, positive qualitative results are highly predictive of subsequent relapse.[14,15] Here RT-PCR positivity precedes cytogenetic and hematological relapse by several months.

Although qualitative RT-PCR has been the mainstay of minimal residual disease assessment, a single positive qualitative result is, in isolation, of little clinical predictive value.[16] In contrast, quantitative RT-PCR shows broad relevance to posttherapeutic monitoring whether after transplantation or other therapeutic modalities. Logically, low or falling transcript levels correlate with successful treatment or continued remission, and elevated or rising transcript levels predict relapse. Consequently, quantitative RT-PCR has emerged as the preferred modality for posttherapeutic monitoring.

Quantitative RT-PCR

Real-time RT-PCR affords sensitive, rapid, and reproducible quantification of mRNA/cDNA transcripts. Although sensitivities are somewhat less than with conventional or nested RT-PCR, the dynamic range of fluorescent detection is much broader, spanning five to six orders of magnitude, with a lower limit of detection of $<0.01\%$ (10^{-4}).[12] Most importantly, real-time RT-PCR permits the serial precision required in clinical diagnostic applications.

Various fluorescent detection systems have been used to quantify *BCR–ABL*. The major chemistries employed are the use of Taqman™ or FRET probes. For both of these, RNA or cDNA standards of known concentration



are used to generate a standard curve [log (copy number) vs. threshold cycle (C_T)], from which the unknown sample quantity is determined and then normalized against an internal reference (ideally *ABL*). The final result is usually reported as a percentage ratio (e.g., *BCR–ABL/ABL*).

Interpretation

The establishment of specific criteria to define molecular response, remission, and relapse has been difficult in light of the on-going evolution, and increasing sophistication, of quantitative technology, without universal technical standardization. Nevertheless, pertinent information can be ascertained.

With respect to monitoring postransplantation, several quantitative indicators emerge. Thus, a modified definition of molecular relapse has been proposed as rising or persistently high levels of *BCR–ABL*, delineated as a *BCR–ABL/ABL* ratio of >0.02% ($\sim 10^{-4}$), in two sequential specimens procured more than 4 months after ASCT.[17]

Although imatinib has shown encouraging results in the treatment of CML, the long-term correlates of clinical outcome remain to be defined. Nonetheless, recent studies suggest that quantitative RT-PCR values correlate with established cytogenetic response criteria and are associated with a differential short-term outcome.[18] In the IRIS study, a ''major molecular response (MMR)'' is defined as a $\geq$3 log reduction in *BCR–ABL/BCR* levels compared to median pretreatment levels. Here, MMR was achieved in 39% of newly diagnosed CML patients after 12 months of imatinib as compared to only 2% of patients on interferon plus Ara-C.[10] Patients with this degree of molecular response to imatinib had a negligible risk of disease progression in the short-term.

One additional advantage of kinetic monitoring with imatinib is that it allows for the early recognition of therapeutic resistance. In this scenario, patients with a suboptimal therapeutic response may undergo screening for causative point mutations (e.g., using allele-specific

Fig. 2 Algorithms for the frequency of therapeutic monitoring in CML: (A) after allogeneic stem cell transplantation (ASCT), (B) with interferon-α, and (C) with imatinib mesylate therapy. [FISH, fluorescence in situ hybridization; mos, months; Ph, Philadelphia chromosome; PCR, qualitative reverse transcription polymerase chain reaction; Q-PCR, quantitative reverse transcription polymerase chain reaction; wk(s), week(s)].

oligonucleotide PCR), the identification of which could prompt implementation of alternative treatment strategies. Preliminary work with microarrays has identified differential gene expression profiles between patients with imatinib sensitivity and resistance.[19] In the future, this technology may predict therapeutic response and thus dictate front-line therapy.

Regardless of the therapeutic strategy, large prospective studies that correlate quantitative RT-PCR data with long-term clinical outcome are keenly anticipated. These investigations will direct the formulation of new guidelines to assist with the future therapeutic monitoring and clinical interpretation of these tests. Until then, a number of algorithms have been proposed for posttherapeutic monitoring (Fig. 2).[20,21] One final caveat in molecular RT-PCR analysis, whether qualitative or quantitative in methodology, is that it cannot assess the clonal evolution of disease. For this assessment, cytogenetic karyotypic analysis is required and must be performed every 6 months throughout the monitoring process regardless of the therapeutic modality employed. The emergence of cytogenetically abnormal (but Ph-negative) clones with the use of imatinib further underscores the need for periodic conventional cytogenetic analysis.[22]

CONCLUSION

The evolution in our understanding of CML has led to the molecular dissection of this disease with the implementation of successful targeted therapy. The molecular laboratory plays a vital role in the diagnosis as well as therapeutic evaluation and monitoring of CML patients. In the future, this may extend beyond merely measuring *BCR–ABL*, as new insights are developed from microarray studies.

Clarithromycin Resistance Associated Gene Mutations

C

Sabine Pereyre

INTRODUCTION

Resistance to macrolides may occur via different mechanisms. Among them mutations in the 23S rRNA have been recently described. It concerns different bacteria of clinical relevance but most importantly *Helicobacter pylori*, a bacterium for which several detection methods have been proposed. In this review, we will present briefly the basis for the resistance mechanism and the recent development in the field of *H. pylori* diagnosis.

RESISTANCE INDUCED BY RIBOSOMAL MUTATIONS

Macrolide antibiotics inhibit protein synthesis through their interactions with the 50S subunit of the bacterial ribosome by binding near the entrance of the peptide passage channel. The interactions have mainly been mapped by chemical footprinting experiments and X-ray crystallography[1] to the peptidyl transferase region within domain V of 23S rRNA. Positions A2058 and A2059 (*Escherichia coli* numbering) appeared to be essential for macrolide binding. Interaction with domain II of 23S rRNA has also been suggested,[2] but they have no direct interaction with ribosomal proteins.[1]

Three main mechanisms of resistance have been reported: drug inactivation, active efflux, and modification of the target sites by methylation or mutations.[3,4] Resistance conferred by ribosomal mutations was first observed in the single rRNA (*rrn*) operon of yeast mitochondria then obtained in *E. coli*.[3] Reports are now common both in Gram-positive and Gram-negative clinical pathogens (Table 1). This mechanism is responsible for clarithromycin resistance in the vast majority of strains of *Mycobacterium* spp. and *H. pylori*.[3] Similar mutations have also been reported in *Treponema pallidum*, *Propionibacterium* spp., and *Mycoplasma* spp.. Generally, pathogenic species that develop macrolide resistance through rRNA mutations possess only one or two *rrn* operons, such as in the case of *H.pylori* (two operons), *M. avium*, and *M. pneumoniae* (one operon).[3] Resistance in bacteria with multiple *rrn* operons is generally conferred by Erm methylation or active efflux. However, there are recent reports of macrolide resistance in laboratory and clinical strains of *Streptococcus pneumoniae* and *Staphylococcus aureus* which harbor four and six *rrn* operons, respectively.[5,6] Susceptibility of erythromycin decreases as the number of the mutated copies increases,[7] and high-level erythromycin resistance can be achieved only when at least half of the copies are mutated.

The consequence of point mutation in the domain V of 23S rRNA is a decrease of the affinity of the macrolide for its ribosomal target. An absence of binding of radiolabeled erythromycin to ribosomes isolated from *H. pylori* or *M. hominis* resistant strains suggested that the mutations lead to a conformational change in the ribosome at the macrolide binding site.[8,9]

The resistance phenotype conferred by alterations in the 23S rRNA target varies according to the substituted base. There have been a plethora of strains identified with mutation A2058G or A2059G/C (*E. coli* numbering) that confers macrolides, lincosamides, and streptogramin B (MLS_B), and macrolides and lincosamides (ML) resistance, respectively.[3] The A2058G substitution is the most frequent in clinical isolates and leads to the highest minimal inhibitory concentrations (MICs). Substitutions A2058C and A2058U are less common (Table 1). Mutations at positions 2057 and 2611 have also been reported. They destabilize the base pairing G2057-C2611 in the single-strand structure of the central loop but have generally a weak impact on the MICs of macrolides.[3] Mutations at position 2062 were described in mycoplasma laboratory isolates and in *S. pneumoniae* clinical strains,[10,11] and were associated with resistance to 16-membered macrolides and streptogramin combinations. Mutations at positions 2609, 2610, and 2613 have been associated with macrolide resistance in laboratory mutants but have never been reported in clinical isolate. Moreover, a T-to-C transition at position 2717 (*H. pylori* numbering) in domain VI of 23S rRNA conferred a low-level clarithromycin resistance in *H. pylori* clinical isolates.[12] Resistance by ribosomal mutations in domain

[a]*E. coli* numbering.
[b]L, laboratory strain; C, clinical strain.
[c]+L4, +L22, associated alterations in ribosomal proteins L4 or L22.
[d]The phenotypes conferred to the different type of macrolide antibiotics are given when these were specified in the original articles. The lack of a notation does not imply sensitivity but indicates that no specific phenotype was reported. M, macrolides; M14, M15, M16, 14-, 15- 16-membered macrolides; L, lincosamides; S_B, streptogramin B; S_A–S_B, streptogramin combination; K, ketolides; ery, erythromycin; clr, clarithromycin; azi, azithromycin; cli, clindamycin; Q–D, quinupristin–dalfopristin; tel, telithromycin; ND, nondetermined.

II of 23S rRNA has been rarely described in laboratory strains of *E. coli* and *S. pneumoniae*.[3,13] An increase of the ketolide telithromycin MIC was described. Recently, mutations in ribosomal proteins L4 and L22 were associated with resistance to macrolides and related antibiotics in laboratory or clinical isolates of *S. aureus*,[14] *M. pneumoniae*,[11] or *Streptococcus* species including *S. pneumoniae*.[5] The mutations are clustered in conserved sequences of L4 and L22 proteins, regions that mediate the binding to 23S rRNA or contribute to the formation of the tunnel wall. As crystallographic studies showed no direct interaction between ribosomal proteins and macrolides,[1] resistance presumably results from an indirect conformational change in the tunnel region that forms a major portion of the macrolide binding site.

METHODS FOR DETECTION IN *HELICOBACTER PYLORI*

Developments in this field are due to the following:

1. The clinical importance of this bacterium which is not only responsible for peptic ulcer disease but also gastric malignancies. *H. pylori* infection has been recognized by the International Agency on Research on Cancer as a type 1 carcinogen and is indeed the first infection to be involved in cancer in humans. Another cancer, gastric MALT lymphoma, can also be cured by eradicating the bacterium.
2. The key role of clarithromycin in eradication treatment: clarithromycin has low MICs, good diffusion, and limited influence of low pH. Nevertheless, clarithromycin resistance may occur and jeopardize the treatment success. The eradication rate of the main treatment combination (clarithromycin and amoxicillin plus a proton pump inhibitor bd for 7 days) decreases from 88% to 18% if the strain is resistant. The prevalence of the resistant strains in adults varies from less than 5% in Northern Europe to more than 15% in Southern Europe. It is even higher (20–25%) among children. The main risk factor for *H. pylori* resistance to clarithromycin is consumption of this drug, essentially for respiratory tract infections.[15]

As resistance is caused by a limited number of point mutations, it was possible to develop methods for their detection. The three major point mutations are A2143G (70%), A2142G (12%), and A2142C (3%) corresponding to A2059G, A2058G, and A2058C respectively in *E. coli*

numbering. However, this last percentage is underestimated because in most of the studies, the A2142C mutation was not sought.[15]

PCR-Based Methods

These mutations can obviously be detected by sequencing, but many other PCR-based techniques have been developed (Table 2). The most widely used is PCR-RFLP with *Bsa*I and *Bbs*I.[8,16] A third enzyme (*Bce*A1) allowing the detection of the A2142C mutation has recently been proposed.[17] However, these techniques have drawbacks, most are time consuming and are subject to the risk of PCR contaminations.

The main progress has been the application of real-time PCR and the fluorescence resonance energy transfer (FRET) chemistry. The first attempt concerning *H. pylori* was made on strains and was published in 1999.[18] Since then, it has been extended to both the detection of the bacterium and its resistance to clarithromycin, directly in gastric biopsies.[19–22] In our study,[21] we only tested sensitivity as biopsies were obtained from patients who had failed a first eradication therapy and were all *H. pylori* positive. Indeed, in only one case out of 200 (99.5% sensitivity) did we not obtain amplification products. The results of FRET–melting curve analysis (MCA) were compared to those of two phenotypical methods of susceptibility testing performed on the corresponding strains obtained by culture: Etest and agar dilution. The results of the two phenotypical methods agreed in 195 cases (98%), and among them the FRET–MCA was concordant in 188 (96.4%). Using agar dilution as the gold standard, sensitivity and specificity of FRET–MCA were 98.4% and 94.1%, respectively. The mutations identified by FRET–MCA were also compared to those obtained by PCR-RFLP performed on a subset of biopsy specimens and a good agreement was found. In only three cases (1.5%) did we find a clarithromycin-resistant phenotype and a wild-type genotype only, suggesting either that mutations in the 23S rDNA were not detected by this method, or that other mechanisms not related to mutations may be involved.

Table 2 Molecular methods for *Helicobacter pylori* testing of clarithromycin resistance

Based on amplification of 23S rRNA gene
– Sequencing
– RFLP (restriction fragment length polymorphism)
– OLA (oligonucleotide ligation assay)
– DEIA (DNA enzyme immunoassay)
– PHFA (preferential homoduplex formation assay)
– INNO-LiPA (line probe assay)
– Mismatch PCR
– DG-DGGE (double gradient-denaturing gradient gel electrophoresis)
– FRET–MCA (fluorescence resonance energy transfer–melting curve analysis)
Based on hybridization
– FISH assay (fluorescence in situ hybridization assay)

Matsumura et al. using a similar biprobe assay reported a perfect sensitivity and specificity (100%) for *H. pylori* detection on 186 biopsies and also a perfect correlation with the PCR-RFLP results in 151 cases. However, few cultures were performed in this study and the A2142C mutation was not reported.[20]

The assay described by Lascols et al. is different for *H. pylori* detection as they used an LC-Red 640 primer as the sensor probe. Sensitivity and specificity of their assay tested on 196 biopsies, in comparison to histology and culture, were 97% and 94.6%, respectively. Regarding clarithromycin resistance determined for 59 of 66 *H. pylori* positive biopsies, the sensitivity and specificity were 91% and 100%, respectively.[22]

In contrast to the previous studies using a biprobe assay, Gibson et al.[18] and Chisholm et al.[19] used a monoprobe assay with SYBR green 1 as the quencher which transfers its energy to a probe labeled with Cy5. For *H. pylori* detection, Chisholm et al. reported a sensitivity of 85% and a specificity of 98% on 121 biopsies tested, 17 being *H. pylori* positive. Sensitivity and specificity for the detection of clarithromycin resistance seem inferior, and few resistant cases were tested.

The FRET–MCA also has the potential of detecting mixed infections, essentially wild type and a resistant mutant, which may not be seen by using phenotypical methods. Indeed, mixed infections represented 21% of the total and three genotypes were even detected in one case. A genotype can be detected when it represents at least 10% of the DNA mixture.

The other advantages of this assay are:

- Obtaining a very quick result (2 hr) with limited manpower which can be compared to the week's delay in obtaining phenotypical results
- Avoiding any handling post-PCR which is an important source of contamination in laboratories
- Avoiding the demanding transport conditions necessary to perform culture and susceptibility testing. Shipment by mail at ambient temperature is convenient.

The limitation of the assay described above[21] is the difficulty in separating the A2143G and A2142G mutations. The melting curves for the two genotypes differ only by 1°C (Fig. 1), which does not allow a reliable distinction in routine testing. Despite the fact that the A2142G mutation is usually associated with higher MICs

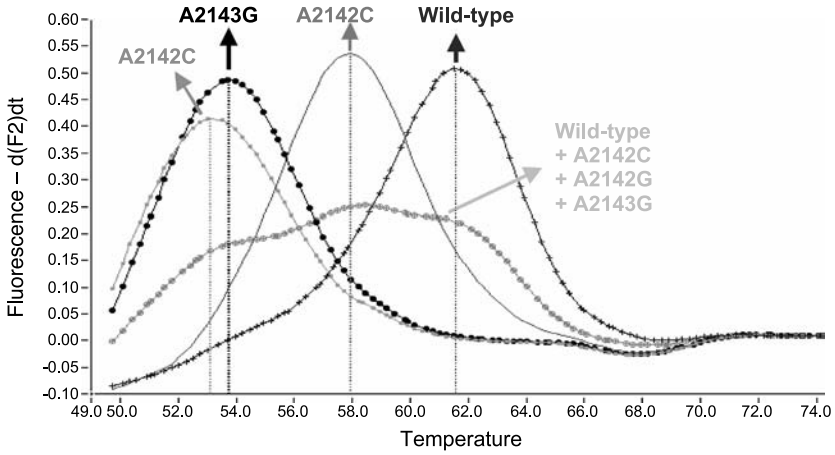

Fig. 1 Melting curve analysis of the 267-bp fragment of the 23S rRNA gene obtained with the LightCycler® assay for the wild-type and mutant strains with the A2142G, A2143G, and A2142C mutations. The melting curve corresponding to a mixture containing equal proportions of wild-type, A2142G, and A2142C is also shown, and three melting peaks with the corresponding T_m can be observed. Values on the *y* axis represent the ratio of the first negative derivative of the change in fluorescence (dF) with the variation in temperature. (*View this art in color at www.dekker.com.*)

than the A2143G mutation, there does not seem to be any clinical relevance as both mutations are highly associated with treatment failure.

The limitation of all FRET–MCA tests is the availability of a special thermocycler which is costly. The first available model used in most of the published experiments is the LightCycler™ (Roche Diagnostics), but several other apparatuses are now coming out on the market and the cost is decreasing. Such thermocyclers can also be used for numerous applications other than the detection of single nucleotide polymorphisms using a biprobe.

An interesting application currently being developed is the detection of *H. pylori* and its possible clarithromycin resistance in stool samples which has the tremendous advantage of being a noninvasive test. The problem of inhibition of Taq polymerase by stool compounds such as vegetal polysaccharides has now been almost solved by using special DNA extraction kits (Qiagen).

Non-PCR-Based Method

The possibility of detecting clarithromycin resistance without performing PCR also exists, by fluorescence in situ hybridization (FISH). This method has been applied to the detection of *H. pylori* and its clarithromycin resistance by Trebesius et al.[23] It consists of an rRNA-based whole cell in situ hybridization using a set of fluorescent labeled oligonucleotide probes. Labeling of intact single bacteria is monitored by fluorescence microscopy. This method allows the detection of *H. pylori* with a 16S rRNA probe labeled with the fluorochrome Cy3 (red) and of resistant mutants with a 23S rRNA probe labeled with fluorescein (green) simultaneously. This method proved to be sensitive and specific when compared to standard methods of culture and susceptibility testing. No discrepant result was noted for 45 cases. In another study, there were 11 discrepant results among 69 cases. These cases corresponded indeed to mixed infections with susceptible and resistant strains. This method has the advantage of being independent of a nucleic acid preparation, it is not prone to inhibition like PCR and is quick. It also allows visualization of the bacteria including coccoidal forms and can be performed on paraffin embedded biopsy samples. A limitation could be the observer-dependent result and sometimes difficulty in reading. It has not been compared yet to the FRET–MCA protocol.

These new methods which provide a result within a few hours are very important for clinical practice because they have the potential to change the management of *H. pylori* infection; indeed, to administer, as a first line therapy, a regimen without clarithromycin in case of clarithromycin resistance instead of an empirical treatment in areas with high levels of this resistance and then to improve the eradication rate.

METHODS OF DETECTION IN THERMOPHILIC *CAMPYLOBACTER* SPP.

Resistance of thermophilic *Campylobacter* spp. to macrolides is not yet a major problem in clinical isolates (<5%), but a trend toward an increase has been noted.

The mechanism also concerns a point mutation in the 23S rDNA essentially in the 2075 position (equivalent to *H. pylori* 2143 and *Escherichia coli* 2059 coordinate), A2075G. The A2074C mutation is seldom found.

We have developed a FRET–MCA similar to the assay described for *H. pylori* but only to be used for detection of the point mutation on isolates.[24] The same probes can be used with different primers.

This assay was applied to 141 thermophilic *Campylobacter* strains (49 macrolide susceptible and 92 resistant). Sensitivity and specificity were 100%; 95% of the cases corresponded to an A2075G mutation.

NEW METHOD OF DETECTION IN GRAM-POSITIVE COCCI

A denaturing high-performance liquid chromatography (DHPLC) technique was recently evaluated in streptococci and staphylococci.[25] This rapid screening method allows automated detection of single base substitution as well as small insertions or deletions employing a combination of temperature-dependant denaturation of DNA and ion pair chromatography. In this method, after PCR amplification of regions of interest in 23S rRNA, L4, or L22 genes, wild-type and mutant PCR products are mixed in an equimolar ratio, heated to denature each strand, and then allowed to reanneal until they form a mixed population of homoduplexes plus heteroduplexes containing the mismatched bases. Under conditions of partial denaturation temperature, the heteroduplexes elute from the column earlier than the homoduplexes because of their reduced melting temperature. Denaturing high-performance liquid chromatography data analysis is then based on a qualitative comparison of peak number and/or shape of a single peak between the sample and reference chromatograms. A good sensitivity was obtained in *S. aureus* mutants as one mutated *rrl* copy mixed with five wild-type copies was detected.

CONCLUSION

The discovery of macrolide (clarithromycin) resistance associated gene mutations has been an important step in the understanding of resistance in many pathogens. At this stage, it also has a practical application for *H. pylori* given its clinical importance and low number of point mutations allowing an easy detection. More progress is expected in the future for bacterial species with mutations at various sites.

Clostridium botulinum

Miia Lindström
Mari Nevas
Hannu Korkeala
University of Helsinki, Helsinki, Finland

INTRODUCTION

Clostridium botulinum is a bacterium that is widely spread in the environment and in raw foods. *C. botulinum* strains produce lethal neurotoxins during their logarithmic growth. The toxin, when ingested or formed in vivo in humans and animals, causes botulism, a neuroparalytic disease that may lead to death unless treated. The diagnosis of botulism is based on the detection of neurotoxin and *C. botulinum* organisms in a patient. Conventional diagnostic methods for the detection of *C. botulinum* and its toxins are poorly developed. However, the use of molecular tools such as polymerase chain reaction (PCR) methods has greatly facilitated the diagnosis of *C. botulinum* during the last decade.

C. BOTULINUM

Classification and the Microbial Ecology of *C. botulinum*

C. botulinum is an anaerobic gram-positive rod-shaped bacterium that forms heat-resistant spores.[1] The taxonomic denominator is the production of botulinum neurotoxin (BoNT). Based on the serological properties of the BoNT they produce, *C. botulinum* strains are divided into types A–F, with types A, B, E, and F being human pathogens, and types C and D being animal pathogens. Based on their metabolic properties, *C. botulinum* strains are divided into groups I–III.[2] Groups I and II include strains that are pathogenic to humans, whereas group III includes strains causing botulism in animals. Various characteristics of the organisms belonging to different groups are presented in Table 1.

Prevalence of *C. botulinum*

C. botulinum is widely spread in the environment, with group I organisms predominating in the temperate regions of the world, and group II organisms prevailing in aquatic environments in the Northern hemisphere. *C. botulinum* types A, B, and E are more frequently found in the environment than type F. As a consequence of a high prevalence of spores in the environment, raw foods may contain *C. botulinum* spores. Proteolytic types A and B have been frequently detected in fruits, vegetables, and meat, whereas nonproteolytic types B and, E in particular, are frequently present in fish.[3–5]

HUMAN BOTULISM

Human botulism develops as a consequence of BoNT entering the blood circulation and blocking neurotransmitter release in peripheral nerve endings. The clinical manifestation of botulism includes a descending flaccid paralysis with dysphagia, dry mouth, double vision, difficulties in swallowing, dilated pupils, dizziness, and muscle weakness. These are accompanied by paralysis of the more peripheral parts of the body, and, finally, by respiratory muscle paralysis, which may lead to death. In addition, nonspecific symptoms related to different forms of botulism may precede the actual paralysis.

Classical Food-Borne Botulism

The classical food-borne botulism is an intoxication due to the ingestion of BoNT. Thus the first indications of illness before the paralytic condition are gastrointestinal in nature, mainly nausea, vomiting, and abdominal cramps. The typical incubation period is 18–72 hr. The most common differential diagnoses include Guillain–Barré syndrome, chemical intoxication, stroke, or staphylococcal food poisoning.[6] The estimated case fatality rate of food-borne botulism outbreaks worldwide is 20%. During the last decades, a worldwide average of 450 outbreaks of food-borne botulism with 930 cases has been reported annually.[7] More than half of the cases (52%) were because of BoNT type B, whereas 34% and 12% were because of types A and E, respectively. Only on rare occasions is type F toxin associated with human botulism. Countries with a high incidence of botulism include China, Poland, the former Soviet Union, Germany, Italy, Spain, the United States, France, and Yugoslavia. The vehicle foods include most frequently mishandled

Table 1 Some characteristics of *C. botulinum* strains and botulinum neurotoxin

Feature	*C. botulinum* group I	*C. botulinum* group II	*C. botulinum* group III
Type of neurotoxin produced	A, B, F	B, E, F	C_1, D
Metabolism	Proteolytic	Nonproteolytic	Nonproteolytic/weakly proteolytic
Optimal growth temperature (°C)	35–40	18–30	37–40
Minimum growth temperature (°C)	10	3–3.3	10
Growth-limiting pH	4.3–4.6	5.0	5.1–5.6
Growth-limiting a_w	0.94	0.97	0.98
Heat resistance of spores	$D_{112°C}$ 1.2 min	$D_{85°C}$ 0.3–98 min	$D_{104°C}$ 0.02–0.9 min
Location of neurotoxin gene	Chromosome	Chromosome	Bacteriophage
Species sensitive to neurotoxin	Human (A, B, F), cattle and horse (B)	Human (B, E, F), cattle and horse (B), birds (E)	Cattle and sheep (C, D), horse, mule, and birds (C)

home-prepared foods, but occasionally commercial products are involved.

Infant Botulism

Infant botulism is an infection that may follow the in vivo outgrowth and toxigenesis from *C. botulinum* spores.[8] Infant botulism affects small children under 1 year of age, and is typically because of group I *C. botulinum*. Prolonged constipation, followed by distinctive flaccid paralysis that is manifested by impaired feeding, facial muscle paralysis, and general weakness, is typical. The symptoms of infant botulism may vary from a self-limiting constipation to unexpected death of a child, in which case it is occasionally misdiagnosed as sudden infant death syndrome.[8,9] The case fatality rate is less than 2%.[10] The only foodstuff associated with infant botulism is honey, which may carry a high number of *C. botulinum* spores.[3,11] Dust and other environmental materials seem to be important sources of spores.[8,9]

Other Forms of Botulism

Wound botulism is mainly found among injecting drug abusers using contaminated needles or impure heroin.[12] Wound botulism is an infection that develops when *C. botulinum* spores germinate and grow in profound wounds or abscesses. The clinical picture is similar to food-borne botulism, with the absence of gastrointestinal signs. The median incubation period is 7 days. The estimated case fatality rate is 15%.[7]

The adult form of infectious botulism is rare and resembles infant botulism in its pathogenesis and clinical status.[13] People with altered intestinal flora because of abdominal surgery, prolonged antimicrobial treatment, or gastrointestinal wounds and abscesses may be affected. Because a patient history of ingestion of toxic foods has typically not been found, the diagnosis of classical food-borne intoxication may be excluded.

Inhalation botulism may result from aerosolization of BoNT, and a few human cases have been reported.[14] Iatrogenic botulism with local or generalized weakness is rare and has been reported to develop as a consequence of therapeutic injection of BoNT.[15]

Management of Botulism

Preventive measures against food-borne botulism include proper handling, effective heat processing,[16] and continuous cold storage of foods. The treatment of all forms of botulism basically involves the use of a therapeutic trivalent antitoxin and intensive symptomatic treatment, particularly respiratory support.[17] In wound botulism, the treatment additionally consists of surgical debridement and antibiotic therapy.

DIAGNOSTICS OF BOTULISM AND *C. BOTULINUM*

The diagnosis of botulism is primarily based on the history of eating suspected foods, as well as detecting BoNT in patients and in suspected food samples.[10] The detection of *C. botulinum* cells in clinical and food specimens strongly supports the diagnosis. Electroneuromyography may be used to distinguish botulism from similar neurological diseases.[10]

Conventional Culture Techniques

The culture method for the detection and isolation of *C. botulinum* includes broth culturing in anaerobic media,

such as tryptone–peptone–glucose–yeast extract medium or cooked meat medium, and subsequent culturing on plating media. Typical colonies on egg yolk agar plates show a positive lipase reaction, and a weak β-hemolysis is seen on blood agar. Proper selective media allowing the growth of all strains of *C. botulinum* are not available. Commercial biochemical reaction series have been developed for the identification of anaerobic bacteria, but these tests have been shown to be unreliable in the diagnosis of *C. botulinum*.[16]

Toxin Detection

The only standard method for the detection of BoNT is the mouse bioassay. Two mice are injected intraperitoneally with a sample elution, and, in the case of a positive sample, the mice die with symptoms typical of botulism. The toxin type is determined by seroneutralization of the toxic samples with specific antitoxins. The immunoassay formats reported for the detection of BoNT include radioimmunoassay (RIA), gel diffusion assay, and passive hemagglutination assay (PHA). However, many of these assays provide poor sensitivity or specificity, which decreases the diagnostic value of the methods. An exception is enzyme-linked immunosorbent assay (ELISA), which may reach sensitivity similar to the mouse bioassay. A recently published ELISA format has been validated in the United States.[18] Another method with sensitivity and specificity similar to the mouse assay is the endopeptidase assay, which is based on the specific zinc endopeptidase activity of BoNTs in nerve terminals.[19] Synthetic peptides resembling the soluble *N*-ethylmaleimide-sensitive fusion protein attachment receptor (SNARE) complex proteins involved with neurotransmitter release in peripheral nerve endings serve as substrates for the toxin.

Molecular Detection of *C. botulinum*

PCR and DNA probes provide a sensitive tool for the detection of *C. botulinum*. The greatest sensitivities of PCR protocols for *C. botulinum* in various sample materials vary from 2.5 pg of DNA[20] to 0.1 cfu (or spore)/g food[21] and 10 cfu/g feces.[21,22] A multiplex PCR assay that enables the simultaneous detection of all human pathogenic serotypes A, B, E, and F has provided a marked improvement in the PCR detection of *C. botulinum*.[21] Nested PCR involves several subsequent amplifications and provides an increased sensitivity in the detection of *C. botulinum*, for example, in feces.[22] The disadvantage of PCR detection directly from a sample is the possible detection of dead cells because of intact DNA after cell lysis. This problem is overcome by combining enrichment procedures with PCR.[4] Alternatively, reverse transcription polymerase chain reaction (RT-PCR) may be used to distinguish viable and dead bacterial cells.[23] Quantification may be obtained by combining PCR with the most probable number culture technique,[4] or by real-time PCR.[24]

Molecular Characterization of *C. botulinum*

Molecular characterization of *C. botulinum* may be used to study the genetic diversity of the organism,[4,5] and in tracing the causative agents of botulism outbreaks.[9,25] Pulsed field gel electrophoresis (PFGE) provides excellent discriminatory power and reproducibility, whereas the PCR-based method (randomly amplified polymorphic DNA assay, or RAPD) is less reproducible but can be quickly performed. The application of rRNA gene restriction pattern analysis (ribotyping) has been used to identify bacterial species yielding distinct patterns for groups I and II *C. botulinum*.[4]

The entire genome sequence of *C. botulinum* type A strain ATCC 3502 has been established,[26] which enables the development of DNA microarrays containing the whole genome of the organism. The arrays are anticipated to provide more efficient tools for the genomic analysis of *C. botulinum*.

CONCLUSION

A rapid and reliable diagnosis of botulism is a prerequisite for successful therapy. The only standard method for the detection of BoNT is the mouse bioassay, which leads to ethical concern because of the use of laboratory animals. The lack of appropriate selective growth media renders the culture methods laborious, and nontoxigenic *C. botulinum*-resembling cultures may cause false-positive signals. The molecular detection of *C. botulinum* involves the detection of the *bont* gene, indicating the presence of the organism—but not its toxin—in a sample. Molecular characterization of *C. botulinum* may be applied in tracing the causative agents of botulism outbreaks.

To facilitate the diagnostics of botulism, more advanced methods for toxin detection and isolation of *C. botulinum*, in particular, are required.

Clostridium difficile

Michel G. Bergeron
Maurice Boissinot
Universite Laval, Sainte-Foy, Quebec, Canada

INTRODUCTION

Widespread use of broad-spectrum antibiotics triggered the emergence of *Clostridium difficile* as an important bacterial pathogen associated with diarrhea and colitis in hospitalized patients. This toxigenic bacterium causes significant morbidity and mortality, and imposes a pronounced economic burden on the health system. Appropriate treatment requires efficient diagnosis, and several techniques have been developed to detect toxins produced by this microbe. However, immunodetection techniques often lack sensitivity, whereas cytotoxicity assays can only be performed in laboratories equipped with tissue culture facilities. Newer and faster methods based on rapid detection of genes encoding the toxins are providing promising simpler approaches.

DISCOVERY AND IMPACT OF *C. DIFFICILE*

C. difficile is an anaerobic, spore-forming, gram-positive rod. This bacterial species owes its name to the difficult circumstances of its first isolation in 1935 from the intestinal flora of healthy neonates.[1] In the laboratory conditions of those days, its slow growth and requirement for culture under anaerobic atmosphere posed some difficulties now essentially resolved by modern techniques developed for the cultivation of anaerobes. Colonization most likely occurs by fecal–oral transmission, and ingested spores of *C. difficile* can survive the passage through gastric acid and germinate into the colon. In the preantibiotic era, pseudomembranous colitis was a rare complication of intraabdominal surgery.[2] However, this life-threatening condition became more frequent with the increased use of antibiotics and, in 1978, *C. difficile* was identified as the etiologic agent of pseudomembranous colitis.[3] This bacterium is now recognized as the cause of approximately 20% of all cases of antibiotic-associated diarrhea. *C. difficile*-associated disease can produce symptoms ranging from mild nuisance diarrhea to fulminant colitis.[2] It has been calculated that patients acquiring this disease during their hospitalization stay >50% longer than the adjusted length of stay for a typical patient whose course was not complicated by *C. difficile* diarrhea.[4] This increases cost by $3669 per infected patient. These authors estimated that the annual cost for treating *C. difficile* diarrhea in the United States exceeds $1.1 billion for hospital care only. Morbidity and mortality associated with *C. difficile* diarrhea are high and reflect the generally poor health of patients at higher risk of acquiring this infection.

PATHOPHYSIOLOGY AND GENOMICS OF VIRULENCE DETERMINANTS

C. difficile's main virulence determinants are two exotoxins: toxins A and B. In animal models, toxin A was shown to be an enterotoxin inducing both diarrhea and inflammation. By contrast, in tissue culture, toxin B was much more cytotoxic than toxin A and was designated as cytotoxin. The genes for toxin A (*tcdA*) and toxin B (*tcdB*) are highly homologous, and the carboxy-terminal regions of both toxins encode a glucosyltransferase specific for the host small GTP-binding proteins of the Rho family. Glucosylation of these small GTP-binding proteins leads to a disorganization of the cytoskeleton and provokes cell death. The toxins also trigger inflammatory response and fluid secretion. Epithelial damages such as necrosis and ulceration can eventually lead to the formation of the characteristic pseudomembranes observed in pseudomembranous colitis.[5] The level of humoral response against *C. difficile* toxins appears to confer a certain amount of protection to the host, which may explain why certain individuals remain asymptomatic carriers of toxigenic strains, others only develop mild diarrhea, and some suffer from severe colitis.[6]

Sequence analysis revealed that both toxin genes are part of a multigene operon located within a 19.6-kb pathogenicity locus (PaLoc) inserted into the chromosome of *C. difficile*. PaLoc genes are conserved in toxigenic strains and are systematically absent from nontoxigenic strains.[7] Restriction enzyme mapping analysis of the PaLoc revealed variant *C. difficile* strains, which differ in length and restriction sites from the reference strain. Twenty groups of such variants have been described and

DOI: 10.1081/E-EDGP 120020834

defined as toxinotypes I–XX.[8] Although *tcdB* restriction sites are more variable than those of *tcdA*, deletions and insertions are more frequently observed in *tcdA*. In fact, some toxinotypes are associated with a toxin A-negative, toxin B-positive phenotype. These strains, which were first isolated from asymptomatic children, are now increasingly recovered from patients presenting symptoms ranging from diarrhea to pseudomembranous colitis.[9] Therefore the presence of toxin A is not required to cause the disease, and toxin B, by itself, can induce significant damage to human intestines.[10]

EPIDEMIOLOGY AND PREVENTION

Toxigenic *C. difficile* is carried asymptomatically in about 25–80% of infants and in 20% of hospitalized patients, but only in less than 3% of the adult population of developed countries.[11,12] *C. difficile*-associated disease is primarily a nosocomial infection causing 300,000 to 3 million cases of diarrhea and colitis in U.S. hospitals each year.[5] This pathogen is also responsible for community-acquired diarrhea but at a much lower rate. Epidemiological factors influencing this low incidence in the general population are not fully understood, but the number may be underestimated.[2] Risk factors often associated with *C. difficile*-associated diarrhea include old age, length and number of hospital stay, and invasive medical procedures. However, the most important factor appears to be the use of antibiotics. The normal bowel flora possess a certain ability to resist colonization by pathogenic microbes. Alteration of this barrier by antibiotics presumably predisposes to invasion by *C. difficile* and subsequent toxin production. Although virtually all antibiotic molecules have been associated with *C. difficile* infections, the broad-spectrum antibiotics clindamycin, penicillin, and cephalosporin have been the most frequently implicated. In fact, a recent critical review of the 1978–2001 literature describing the association of antibiotics with nosocomial *C. difficile*-associated diarrhea concluded that most studies were flawed due to incorrect control groups, inadequate sample sizes, and imprecise analysis of confounding factors.[13] In their opinion, only two studies were of sufficient quality to reasonably establish a causal relationship between particular antibiotic molecules and *C. difficile*-associated diarrhea, and these molecules were indeed the three listed above. However, this does not exclude other antibiotics from predisposing to the disease.[14] In some institutions, policies limiting the prescription of certain antibiotics appeared to decrease the rate of *C. difficile* colitis and diarrhea in hospitalized patients.[12] However, decision to restrict the use of some therapeutic molecules has to be weighted against the clinical benefits of using such antimicrobial agents.

Patients contribute to disseminate *C. difficile* toxigenic strains in hospital settings where endemic and epidemic situations may occur. To prevent cross-contamination of patients with *C. difficile*, contact precautions must be implemented until diarrhea stops. However, *C. difficile* spores can survive for months in hospital environments, and patients can be contaminated via contact with care personnel or contaminated objects. Moreover, spores can resist several commercial detergents commonly used to clean surfaces in healthcare institutions. Chlorine-based disinfectants appear to be a better choice and may contribute to reduce the incidence of *C. difficile* infections.[15] However, to limit *C. difficile*-associated diarrhea in hospitals, measures must include a combination of rational use of antibiotics and better infection control.[16]

CLINICAL FEATURES AND TREATMENT

C. difficile infection has been shown to cause a wide spectrum of intestinal symptoms including mild to severe diarrhea, chronic diarrhea, colitis, pseudomembranous colitis, and toxic megacolon.[2] Although *C. difficile* is occasionally isolated in extraintestinal pathologies, these cases are infrequent and usually involve a polymicrobial infection. Typically, *C. difficile*-associated diarrhea appears within 1–2 weeks following the administration of an antibiotic. Watery stools may contain mucus and sometimes blood. Patients may present fever, abdominal cramps, and leukocytosis. However, even severe cases may present no diarrhea or just loose stools. Radiographic evidence of distended colon can indicate toxic megacolon. Prolonged or severe disease can be complicated by dehydration problems, bowel perforation, and death. Diagnosis is based on history of recent or ongoing antibiotherapy, appearance of diarrhea or other symptom of colitis, and demonstration of infection by toxigenic *C. difficile*.

Treatment should begin by discontinuing the incriminated antibiotic whenever possible. However, this measure alone will resolve diarrhea in only one fifth of patients. Therefore, in cases with severe diseases or other comorbid conditions, anti-*C. difficile* antibiotics such as metronidazole and vancomycin are the first two drugs of choice for specific *C. difficile* therapy. Treatment of asymptomatic carriers is not recommended because antibiotics may prolong excretion of the bacteria.[12] On discontinuation of anti-*C. difficile* antibiotherapy, approximately 20% of patients experience recurrence of the infection. This situation can be explained by relapses

caused by incomplete eradication of the bacteria due to the persistence of spores in the digestive tract. However, between 32% and 75% of patients suffering from recurrences are, in fact, reinfected by a new strain acquired from the environment.[17]

LABORATORY DIAGNOSTIC APPROACHES

Because many hospitalized patients are asymptomatic carriers, testing patients for *C. difficile* infection is only recommended if diarrheal stools are present.[12] Laboratory diagnosis is performed by detection of toxigenic *C. difficile* by culture, immunodetection of toxin, or cytotoxicity assay.[18]

Stool cultures on selective cycloserine–cefoxitin–fructose agar can yield to *C. difficile* isolation in 2–3 days. Unfortunately, culture is not specific for toxin-producing strains and is seldom used for clinical diagnosis.[5] However, isolated strains provide reliable bacteriological information for epidemiological purposes.

Cytotoxicity assay, which detects cytopathic effects of toxin B on mammalian cells, is the most sensitive and specific test available. It is considered the gold standard test to identify *C. difficile* toxins directly from the stools of infected patients. A filter-sterilized fecal suspension is added into a mammalian cell culture and monitored for the appearance of cytopathic effects caused by disruption of the cytoskeleton. In parallel, a control fecal filtrate supplemented with a specific antiserum neutralizing for clostridial cytotoxin is used to demonstrate the specificity of cytopathic changes. The drawback of this assay is that it is relatively slow (24–48 hr) and requires tissue culture expertise and facilities. Some authors suggest that performing cytotoxin assay directly on stools, as well as by culture followed by detection test for toxin produced in vitro, might improve the detection of patients harboring toxigenic strains.[18]

Enzyme immunoassays (EIAs) for toxin detection are now widely available from several manufacturers. These tests are rapid and simple to perform directly from stool samples. Most assays use monoclonal antibodies against toxin A. However, because some clinical isolates have been shown to produce only toxin B and still cause the disease, more recent EIAs combine the detection of both toxins A and B. However, none of the EIAs is as sensitive as the cytotoxicity assay.[19] This is why in the event that EIA testing is negative and diarrhea persists, it is recommended to repeat EIA testing on a second sample and even a third sample from patients suspected of infection by toxigenic *C. difficile*.[5]

Several sensitive and specific molecular diagnostic methods based on detection of toxin genes directly from feces have been proposed.[20–24] However, most of these tests targeted either only the gene for toxin A, or the gene for toxin B. Therefore strains belonging to toxinotypes altered or even deleted in the primer regions could be missed. In all cases, these assays where developed in classical PCR formats requiring time-consuming and contamination-generating post-PCR manipulations to identify the amplification products. For clinical laboratories, the potential risks of false-positive reactions due to carryover of previously amplified genetic materials render PCR assays relying on agarose gel electrophoresis impractical for analysis of amplicons. In addition, the PCR-inhibitory substances inherently present in feces specimens suppose an efficient sample preparation procedure to remove these inhibitors without having to sacrifice the sensitivity of the assay. Most of these procedures add complex technical steps that are time-consuming. One exception is the cleverly designed immunomagnetic preparation procedure of Wolfhagen et al.[24] However, it had not been tested on many specimens.

Recently, our team published the first real-time PCR assay for the detection of toxigenic *C. difficile* in feces.[25] This test targets both toxin genes and is a closed-tube assay. This means that amplification and detection of nucleic acids are performed in the same tube, therefore minimizing human intervention and reducing risk of contaminating laboratory surfaces with amplified material. The closed-tube assay format is a major improvement, which will permit a more general acceptance of PCR testing in clinical settings. Our test uses a rapid and simple sample preparation protocol requiring hands-on technician time of around 15 min, which is similar to EIA assays used for *C. difficile*. Target sequences for primers and probes were chosen by identifying conserved regions within *tcdA* and *tcdB* gene sequences available in GenBank. The *tcdA* and *tcdB* amplicons are 158 and 101 bp, respectively. The two molecular beacon probes were labeled with different fluorophores, hence allowing multiplex PCR and simultaneous detection of the two toxin genes. The use of two target genes increases assay robustness by maximizing the likelihood of detecting at least one toxin gene if the other presents variations in the primers or probe region. The 45-cycle PCR reaction took 45 min and the fluorescent signal was acquired in real time at each cycle on a Smart Cycler (Cepheid, CA) apparatus. Total time to response was less than 1 hr from reception of samples into the laboratory. The detection limit was 5×10^4 CFU/g of stool. When compared to cytotoxicity testing, the real-time PCR assay demonstrated a specificity and a positive predictive value of 100%, a sensitivity of 97%, and a negative predictive value of 96%. Further

validation of the test in a broader clinical trial is, of course, required. However, such specific, sensitive, and especially rapid identification and detection of toxigenic *C. difficile* may improve the management of patients and facilitate a more rational use of antibiotics.

CONCLUSION

Many difficulties still encountered with *C. difficile* infections are linked to the availability of rapid and simple diagnostic assays. The prevention of *C. difficile* infections is much more complex than just restricting the use of some antibiotic molecules. Almost all classes of antibiotics have been implicated in triggering *C. difficile* diarrhea. Therefore only rational use of all antibiotics for all infections can have optimal impact, and this could only be achieved when clinical microbiology laboratories would have novel molecular diagnostic assays able to provide detection and identification of microbial pathogens within 1 hr from reception of samples.[26,27] Moreover, *C. difficile* toxin infections emerge due to complex interactions between the complicated ''normal bowel microflora,'' host response and general health status, environmental factors varying from hospital to hospital, and the genetic potential of *C. difficile*. It is surprising to realize how little we know about the ecology of the different bacterial species living within our own gut. With the aging population in developed countries and the increasing number of immunosuppressed patients, we are likely to face more opportunistic pathogens such as toxigenic *C. difficile*. Rapid (<1 hr) DNA-based tests used to detect these pathogens should become a very important tool of prevention because they will guide physicians and infection control nurses to respond in an efficient manner to nosocomial infections. The economic impact of such rapid response should be tremendous.

INTRODUCTION

Clostridium perfringens, a gram-positive, spore-forming rod, is an important cause of histotoxic and enteric disease in humans and other animals. Although ubiquitously distributed in soils throughout the world, *C. perfringens* is also found as part of the normal animal intestinal flora. Like all pathogenic clostridia, *C. perfringens* is renowned for toxin production with an arsenal of over 15 different toxins. The presence of genes encoding the four ''major lethal'' toxins (α-toxin, β-toxin, ε-toxin, and ι-toxin) is used to classify *C. perfringens* isolates into one of the five types (A–E) (Table 1). Type A strains are largely responsible for human gas gangrene and other histotoxic infections, whereas type C strains secrete β-toxin and can cause enteritis nectroticans in undernourished individuals. Although not used in the typing scheme, the *C. perfringens* enterotoxin (CPE) is responsible for *C. perfringens* type A food poisoning, as well as nonfood-borne gastrointestinal (GI) illness. This chapter describes the current status of *C. perfringens* genomics, as well as molecular methods (where available) for diagnosing human infections caused by this bacterium.

C. PERFRINGENS: GENOMIC INSIGHTS

Genome Projects

Early physical maps indicated that the *C. perfringens* genome size varies between isolates (3–3.7 Mb).[1] These studies also mapped the location of chromosomal virulence factors (such as α-toxin and perfringolysin O), the key two-component regulator VirR/VirS, as well as some metabolic and sporulation-related genes.[2] Those physical mapping results have recently been confirmed by genome sequencing projects with two type A *C. perfringens* (strain 13 and ATCC 13124).[3,4]

As typical of clostridial species, the strain 13 genome was found to be AT-rich (71% overall AT content).[4] No high GC content chromosomal regions were detected, suggesting the absence of chromosomal pathogenicity islands.[4] Many sporulation and germination genes with homologues in *Bacillus subtilis* were identified; however, over 80 genes mediating these two processes in *B. subtilis* are absent from strain 13.[4] Genomic analysis of strain 13 identified some potential new virulence factors and putative two-component regulatory systems that could be important for pathogenesis.[4] DNA microarrays and proteomic platforms based on strain 13 have been developed, and their use is now contributing to our understanding of regulatory and metabolic pathways.[5]

Extrachromosomal Virulence Factors

Many *C. perfringens* virulence factors, including toxins such as CPE, β-toxin, ε-toxin, ι-toxin, and β2-toxin, as well as urease, can be encoded by genes located on large (~100 kb) virulence plasmids.[6,7] Interestingly, at least one toxin gene, *cpe*, can reside on either the chromosome or large plasmids (further discussion below).[7] Some virulence genes colocalize to the same plasmid, including the urease and *cpe* genes in various *C. perfringens* types, as do defective *cpe* and ι-toxin genes in type E isolates.[7,8] To date, only one virulence plasmid (pCP13 carrying the gene encoding β2-toxin) has been sequenced.[4] The best studied *C. perfringens* virulence plasmids (other than pCP13) are those carrying *cpe* sequences in types A (discussed below) and E strains.[8,9]

The absence of chromosomal clonality in isolates possessing any of the plasmid-borne toxin genes suggests that these plasmids (or their toxin genes) are mobile. The *cpe* plasmid was recently shown to transfer between *C. perfringens* isolates via conjugation, confirming horizontal transfer for that toxin gene.[10] One insertion element, IS*1151*, has been linked to multiple toxin genes, suggesting that this element may also contribute to toxin gene mobility.[7,9]

Polymerase Chain Reaction-Based Toxin Typing of *C. perfringens*

A rapid multiplex polymerase chain reaction (PCR) assay has been developed for determining the toxin type (A–E)

DOI: 10.1081/E-EDGP 120021465

Table 1 *C. perfringens* toxin types

Toxin type	Toxin α	Toxin β[b]	Toxin ε[b]	Toxin ι[b]	Genotypes	Diseases[a] Human	Diseases[a] Veterinary
A	+	−	−	−	*plc*	Gangrene	Diarrhea (dogs, pigs, etc.)
					plc, cpe[b]	GI disease (food poisoning,[c] antibiotic-associated diarrhea,[d] sporadic diarrhea[d])	Necrotic enteritis (fowl)
					plc, cpb2[b]		
					plc, cpb2, cpe		
B	+	+	+	−	*plc, cpb, etx*		Dysentery (lambs)
					plc, cpb, etx, cpb2		Enterotoxemia (sheep)
C	+	+	−	−	*plc, cpb*	Enteritis necroticans	Necrotic enteritis (piglets, foals, etc.)
					plc, cpb, cpb2		Enterotoxemia (sheep)
					plc, cpb, cpb2, cpe		
					plc, cpb, cpe		
D	+	−	+	−	*plc, etx*		Enterotoxemia (goats, sheep, etc.)
					plc, etx, cpb2		
					plc, etx, cpe, cpb2		
					plc, etx, cpe		
E	+	−	−	+	*plc, iap/ibp, cpe*[e], *cpb2*		Enterotoxemia (calves, rabbits, etc)

plc=alpha toxin; *cpe*=*C. perfringens* enterotoxin; *cpb2*=*C. perfringens* beta2 toxin; *cpb*=*C. perfringens* beta toxin.
etx=*epsilon* toxin; *iap* and *ibp*=*iota* toxin A and B fragments, respectively.
[a]Diseases listed are inclusive of the toxinotype and are not shown linked to specific genotypes.
[b]Genes encoding these toxins are located on large virulence plasmids (*cpe* can be found on either the chromosome or on a plasmid).
[c]Linked to *cpe*-chromosomal isolates.
[d]Linked to *cpe*-plasmid isolates.
[e]Silent *cpe* gene.

of *C. perfringens.* This PCR assay has largely replaced the demanding classical *C. perfringens* typing procedure, which depended on antibody neutralization of toxins in *C. perfringens* culture supernatants. The most recent version of the multiplex PCR typing assay amplifies different size products from the genes encoding CPE, as well as α-toxin, β-toxin, ε-toxin, β2-toxin, and ι-toxin (Fig. 1).[11] This method is effective using either purified DNA or colony lysates as template. However, care must be taken in using this multiplex PCR for diagnosis, as amplification of a toxin gene does not necessarily correlate with expression of that toxin.[8]

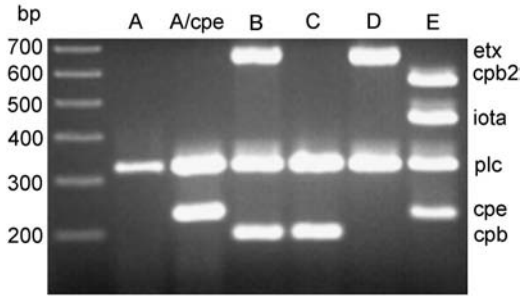

Fig. 1 Multiplex PCR toxinotyping assay for determining the toxin genotype of *C. perfringens* isolates. Representative toxinotypes are located at the top of the gel and the toxin genes amplified are listed on the right of the gel. Primers and PCR conditions were from Ref. [11]. PCR products were separated on a 2% agarose gel and visualized with ethidium bromide staining.

CPE AND GI DISEASE

Disease Summary

CPE-positive strains cause *C. perfringens* type A food poisoning, which currently ranks as the third most common cause of food poisoning in the United States.[12] In addition, enterotoxin-producing *C. perfringens* is an important etiological agent of non-food-borne human GI illnesses such as antibiotic-associated diarrhea (AAD) and sporadic diarrhea (SD).[13] The symptoms of CPE-related illnesses range from acute diarrhea and abdominal

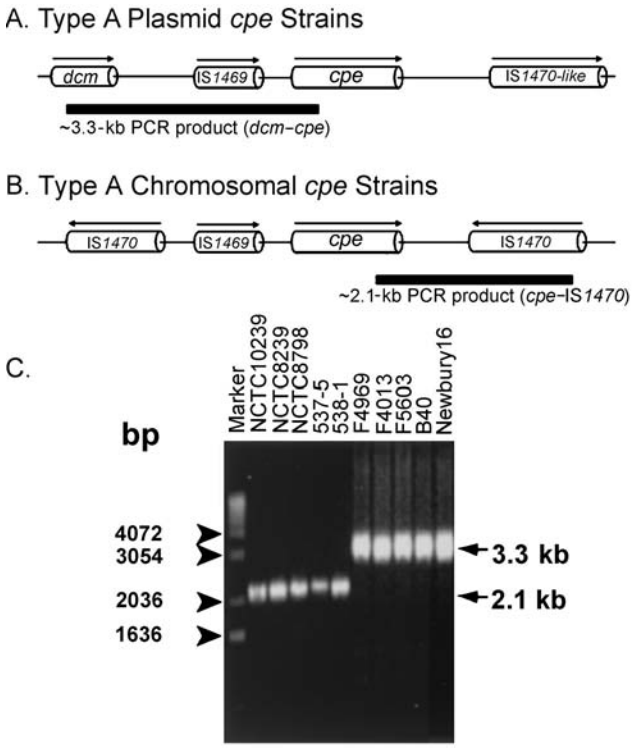

Fig. 2 Duplex PCR genotyping assay for distinguishing between *C. perfringens* type A isolates carrying a plasmid-borne *cpe* gene vs. a chromosomal *cpe* gene. This assay exploits organizational differences between different *cpe* loci to amplify either a PCR product of ~3.3 kb (*dcm–cpe*) from plasmid *cpe* type A isolates (A), or an ~2.1-kb PCR product (*cpe*–IS*1470*) from chromosomal *cpe* type A isolates (B). (C) Representative duplex PCR results obtained using purified genomic DNA as template from five chromosomal and five plasmid type A *cpe* isolates. Primers and PCR conditions were from Ref. [15]. Arrows to the right of gel depict the expected ~3.3- and ~2.1-kb products from plasmid and chromosomal *cpe* type A isolates, respectively. (From Ref. [15].)

cramping (*C. perfringens* type A food poisoning) to more severe and chronic diarrhea (AAD and SD).

Diagnosis

CPE-associated (GI) disease is now typically diagnosed by identifying the enterotoxin directly in fecal samples. CPE enzyme-linked immunosorbent assay (ELISA) and reverse passive latex agglutination (RPLA) tests are available commercially for detecting CPE present in feces, although the RPLA test has a significant false positive rate and the CPE ELISA is not yet licensed for diagnostic use in the United States.

Genetic characterization of *C. perfringens* food-borne and non-food-borne illness isolates has been performed by several groups (e.g., Ref. [14]) using genomic techniques such as ribotyping, restriction fragment length polymorphism (RFLP), and pulsed-field gel electrophoresis (PFGE). These techniques are useful in assessing the clonality of various outbreak and disease isolates. However, because *C. perfringens* is also present in the normal intestinal flora, detection of the *cpe* gene in disease isolates is crucial for identifying *C. perfringens* as the etiological source of GI disease. Multiplex PCR typing of *C. perfringens*[11] can be performed to confirm the presence of *cpe* in disease isolates (Fig. 1, lanes A and A/*cpe*).

As mentioned, the *cpe* gene can be located on either the chromosome or a large plasmid. CPE-positive *C. perfringens* isolates from cases of *C. perfringens* type A food poisoning typically carry their *cpe* gene on the chromosome, whereas *cpe* is usually plasmid-borne in AAD/SD *C. perfringens* isolates.[7] These correlations are useful for molecular diagnostic and epidemiological studies of CPE-based disease (e.g., if a CPE-positive *C. perfringens* disease isolate is shown to carry a chromosomal *cpe* gene, that finding supports identification of a food poisoning case). Alternatively, identifying a plasmid enterotoxin gene in a disease isolate would usually support a diagnosis of AAD/SD.

A recent study by Miyamoto et al.[9] compared the genetic loci of chromosomal vs. plasmid *cpe*-containing type A isolates. This study identified distinct differences in the sequences flanking the *cpe* gene between the two *cpe* genotypes (Fig. 2A and B). An assay recently put forth by Wen et al. exploits these sequence differences by amplifying different size products from each *cpe* genotype (Fig. 2). This genotyping assay can be performed with either isolated DNA or colony lysates as template DNA,[15] with the use of the latter template eliminating at least 2 days from the preparation and isolation of DNA.

This duplex PCR reaction is an ideal presumptive assay for helping to distinguish between food-borne and non-food-borne cases of CPE-associated GI illness. Because the assay provides results within 6 hr of isolating *C. perfringens* colonies from contaminated food or feces, the speed and high-throughput nature of the technique provide a distinct advantage over the classical and more cumbersome techniques of RFLP and PFGE. Limitations of the PCR method include a requirement for a special polymerase (Advantage2® Polymerase Mix; BD Biosciences Clontech, Palo Alta, CA), which is expensive and displays some lot-to-lot efficiency variation (unpublished results). Despite these shortcomings, the *cpe* duplex PCR assay is an extremely useful and time-saving assay for determining the etiological genotype of CPE-positive *C. perfringens* GI disease isolates and should prove useful for clinical laboratories investigating CPE-associated disease.

Management

C. perfringens type A food poisoning is typically self-limiting (the diarrhea removes the enterotoxin from the GI tract), so only the replenishment of fluids and electrolytes is required for treatment. Patients suffering from AAD or

SD are also given symptomatic treatment to restore their fluid/electrolyte balance, but antibiotics such as metronidazole can be prescribed for serious cases.

HISTOTOXIC INFECTIONS

Disease Summary

C. perfringens causes three histotoxic infections: simple wound infections, anaerobic cellulitis, and clostridial myonecrosis or gas gangrene. The most serious of these diseases, gas gangrene, is an aggressive invasive infection that advances rapidly despite antibiotic therapy.[16] Most gas gangrene cases result from major traumatic injuries that allow for the introduction of exogenous or endogenous *C. perfringens* (responsible for 80% of gas gangrene cases) into an ischemic environment.[16] Gas gangrene-related death can occur rapidly and is typically attributed to shock and multiorgan failure resulting from hemodynamic collapse.[17] Studies have demonstrated that α-toxin and perfringolysin O are the primary mediators of gas gangrene, with α-toxin being absolutely required for disease (for a review, see Ref. [17]).

Diagnosis

Clinical diagnosis of gas gangrene is supported by pain at the site of surgery or injury, gas pockets in the tissue (visualized with X-rays), and signs of systemic toxicity.[16] Exploratory surgery is essential for diagnosis and a definitive diagnosis of gas gangrene involves a Gram's stain from tissue smears demonstrating the presence of gram-positive, rod-shaped bacteria.[16] Although α-toxin ELISA and multiplex PCR assays are available, they are typically not used to diagnose gas gangrene because of the rapid progression of the disease and the obvious clinical signs presented by the patient.[18]

Management

Treatment typically consists of clindamycin or tetracycline combined with penicillin.[16] Aggressive surgical debridement including radical amputation (where possible) to remove the infected tissue is mandatory.[17] An alternative supplemental therapy involving hyperbaric oxygen (thought to raise the tissue redox above that required for growth of *C. perfringens*) is also available.[19] Patients with gas gangrene in an extremity have a better prognosis than patients with truncal or intraabdominal gas gangrene because it is easier to remove infected tissues in extremities.[16] Those patients presenting with shock at diagnosis have the highest mortality rate.[16]

ENTERITIS NECROTICANS

Disease Summary

Enteritis necroticans (also known as necrotizing enteritis, Darmbrand, or Pigbel) caused by *C. perfringens* type C isolates is a rare but potentially lethal enteric disease of humans. This illness was first recognized after World War II in Darmbrand, Germany and later in Papua New Guinea.[20] The β-toxin produced by type C isolates is considered as the primary virulence factor based on the relative efficacy of a β-toxoid vaccine.[20] Although the incidence of enteritis necroticans is low, risk factors include reduced intestinal motility and/or low intestinal trypsin levels (the β-toxin is trypsin-sensitive) because of preexisting conditions created by a protein-poor diet, helminthic coinfection, and/or pancreatic disease.[20] The offending type C isolates can be introduced exogenously by ingestion of undercooked meat products (commonly pork).

Diagnosis

Patients typically present with painful, swollen abdomens (with or without bloody diarrhea and vomiting). Symptoms develop 12 hr to several days following the consumption of contaminated foods, and patients may show toxemia in severe cases.[20] On surgical examination, the patient is typically found to have segmental necrotizing enteritis of the proximal intestine.[21] No current assays exist for rapid diagnosis of the disease, and culture diagnosis typically requires samples from the site of infection, along with in vitro toxin assays.[20] The multiplex PCR typing assay could be a helpful, rapid diagnostic test for distinguishing between normal flora type A isolates and type C isolates not normally present in significant numbers in the intestinal flora.

Management

As mentioned, a β-toxoid vaccine has proven useful in high-risk populations (e.g., Papua New Guinea). Therapy for necrotizing enteritis usually includes nasogastric suction, intravenous fluids, and antibiotic intervention (typically penicillin, chloramphenicol, and metronidazole).[20] In severe cases, a laparotomy must be performed to remove damaged tissues.[20] Passive anti-β-toxin adjunctive therapy has not been shown to be effective.[20]

CONCLUSION

This entry was intended to review the genomics of *C. perfringens* and the diseases caused by this bacterium,

including CPE-mediated diarrhea, histotoxic infections, and enteritis necroticans. Although some molecular techniques exist for toxin typing (multiplex PCR) and for the diagnosis of CPE-mediated disease (duplex PCR), similar methods for diagnosing histotoxic infections and enteritis necroticans are currently lacking. With the pending completion of additional genome sequencing projects, improved molecular techniques, and rapidly advancing proteomic and genomic applications, *C. perfringens* researchers will soon gain an increased ability to explore pathogenesis from a molecular perspective. This information should lead to new techniques for diagnosing and treating *C. perfringens*-mediated infections. The authors hope that this brief chapter adequately summarizes the current state of *C. perfringens* genetics/molecular diagnostics and human pathogenesis and regret the reliance on review citations due to page limitations.

Colony PCR

Gehua Wang
Canadian Science Centre for Human and Animal Health, Winnipeg, Manitoba, Canada

INTRODUCTION

The colony polymerase chain reaction (PCR) protocol is one that can be easily performed, and used widely in many fields of molecular microbiology. Various types of samples can be used in colony PCR, and because nucleic acids are relatively stable, the DNA used for colony PCR does not need to be purified or intact. Partially degraded DNA will also provide a suitable target for colony PCR amplification provided that there is enough DNA template to bridge the distance between the forward and reverse primers.

BACKGROUND

PCR is an enzyme-based in vitro method used to perform the following: 1) to amplify specific DNA fragments for molecular diagnosis of heritable disorders; 2) to screen for susceptibility to disease; 3) to identify bacterial and viral pathogens or specific target genes; 4) to biomonitor environmental changes and gene expression; 5) to study the evolutionary process at the nucleotide level. Furthermore, this technique can be used to analyze recombinant vectors to determine both the presence and orientation of the inserted DNA, determine DNA sequence, and examine gene replacement.[1–4]

Purified DNA is most often used as a template in the PCR reaction. However, it is possible to amplify specific DNA sequences without DNA purification by starting with a single living bacterial colony. This technique is known as colony PCR, or whole-cell PCR, and provides a powerful and reliable method for the rapid amplification and isolation of any gene in both gram-negative and gram-positive bacteria or any gene carried on a plasmid. As an example, repetitive element sequence-based PCR (rep-PCR) with different gram-negative bacteria (e.g., *Citrobacter diversus*, *Escherichia coli*, and *Pseudomonas aeruginosa*) and gram-positive bacteria (e.g., *Staphylococcus aureus* and *Streptococcus pneumoniae*) were demonstrated.[5]

In general, broth cultures as well as colonies from agar plates and glycerol stocks can be directly utilized in the PCR mixture. To release the DNA for PCR amplification, the bacterial cell wall can be disrupted by heating. The dH$_2$O-diluted whole-cell sample or overnight culture can also be directly applied to the PCR reaction tube with longer PCR initial denaturing time at 95°C.

DNA TEMPLATE PREPARATION

The DNA template can be prepared from broth culture with an optical density of 0.3–0.4 at 600 nm. Then the optimized whole-cell suspensions from all bacterial samples can be further diluted 300- to 500-fold in dH$_2$O; alternatively, a bacterial colony, 1 mm in diameter or less, grown on an agar plate can be picked with a sterile pipette tip and inoculated into 100 μL of sterile distilled water. This whole-cell preparation is heated at 100°C for 5–10 min in a 0.5-mL Eppendorff tube. These templates are now ready for PCR application, or may be kept at 4°C for up to 1 month.[6] Still, another method involves touching a smaller colony with a sterile pipette tip; this can then be placed directly into a PCR reaction tube for amplification, along with 5–10 min of initial denaturation at 94–95°C.

PCR REACTION

There are four major steps involved in a colony PCR reaction: 1) growing bacteria and preparation of whole cell suspensions; 2) making a PCR master mix and aliquoting this into Eppendorff tubes; 3) performing PCR with suitable cycling conditions; 4) analyzing amplification products on an agarose gel. In general, a reaction mixture of 25 μL contains a final concentration of 200 μM of each deoxynucleoside triphosphate (dNTP), 2.5 μL 10× reaction buffer (100 mM Tris–HCl at pH 8.3, 500 mM KCl), 1.5 mM $MgCl_2$, and 0.1–1.0 μM of each of the upstream and downstream primers, together with 2.5 units of *Taq* DNA polymerase. A portion (2.5 μL) of the whole-cell preparation of template DNA is also required. The final volume of this mix should be adjusted to 25 μL with sterile water. The PCR cycle should consist of an initial denaturation step at 95°C for 2–10 min (depending on the

DOI: 10.1081/E-EDGP 120020688

Taq DNA polymerase being used), followed by 30–35 cycles of amplification with denaturation at 95°C for 30 sec, annealing at 50–60°C for 30 sec, and extension at 72°C for 30 sec, ending with a final extension at 72°C for 7 min. Part (5–10 μL) of the PCR product should be loaded onto a 0.5× TBE–agarose gel for analysis. Products from 0.1 to 1.5 kb are easily resolved on a 1.5% gel under UV light after staining with 0.5 μg/mL of ethidium bromide solution for 30 min.

APPLICATIONS

Colony PCR has been found to be a useful technique applicable to both gram-negative and gram-positive bacteria.[5,7] Satisfactory PCR products were obtained while using this method with intact cells, colonies from agar plates, and even liquid cultures which were stored at 4°C for up to 3 months. Moreover, this method has also been used to identify target genes or to distinguish homologous recombination events from nonhomologous ones in yeast.[4] Performing DNA extraction is not recommended for PCR purposes when there are few bacterial cells in the sample because DNA loss is inevitable in the process, which would hinder subsequent PCR amplification.

ADVANTAGES

Colony PCR is a whole-cell-based assay, and thus will save a considerable amount of time, labor, and chemical reagents. The possibility of experimental errors or contamination is also reduced because DNA purification is not required.[3] A comparison study with two DNA extraction methods using mycobacterial isolates indicated that the heating method is more sensitive and no less specific than a conventional chemical method (phenol–chloroform). The loss of DNA during purification and the presence of inhibitory substances are the most likely explanations for the lowered PCR sensitivity results obtained via the chemical method.[8,9] PCR is a very sensitive and rapid method of detecting specific DNA sequences in a wide variety of samples. The most common problem is contamination of reagents with target DNA. However, colony PCR will be performed on bacterial colonies directly obtained from broth culture or plates, which will lower the opportunity of contamination resulting from DNA manipulation or extraction. In addition, no detergents or proteases are used to lyse the bacterial cells, which is also advantageous because these may interfere with the PCR reaction.[3]

SENSITIVITY

The detection sensitivities of colony PCR for *E. coli*, *Aeromonas hydrophila*, *Campylobacter jejuni*, and *S. aureus* were determined by both PCR and plate count methods using agarose gel electrophoresis relative to actual plate counts within the range of 10 to 10^{13} colony forming units per milliliter (CFU/mL). The detection ranges of colony PCR (in CFU/mL) for *E. coli*, *A. hydrophila*, *C. jejuni*, and *S. aureus* were $8 \times 10^{5-10}$, $3 \times 10^{4-11}$, $1 \times 10^{4-13}$, and $3 \times 10^{8-12}$, respectively. However, the capability of detecting the target gene can be reduced by the presence of higher concentrations of nontarget DNA or PCR inhibitors.[10,11] It appears that a range of 10^9 to 10^{10} CFU/mL was most effective for all of the colony PCR assays and only about 10 microorganisms were required for the detection of *Mycobacterium tuberculosis*.[6,8]

PCR INHIBITION OR CONTAMINATION

The use of an internal control is important because impurities or improper nucleic acid concentration may inhibit the PCR reaction, resulting in false negatives. The internal control will give a greater degree of confidence in the validity of a negative amplification result. Every amplification test where inhibitors [such as nontarget DNA, heme, bilirubin, bile salts, ethylenediaminetetraacetic acid (EDTA), sodium dodecyl sulfate (SDS), proteases, and bacterial extracts, etc.] are problematic should have an internal control.[5,11,12] To avoid DNA contamination or carried over false positives, the use of deoxyuridine 5′-triphosphate (dUTP) in combination with Uracil-DNA-*N*-glycosylase (UNG) is recommended. Several other precautions to avoid contamination should be taken, including specific workstations designed for PCR work alone, aseptic techniques, specific pipettes and tips plugged with sterile cotton wool or filter, small aliquots of reagents when performing PCR, and minimizing the number of operations or transfers. A negative control that does not include any target DNA should also be performed with each PCR assay.[7]

LIMITATIONS

Reduced levels of sensitivity have been encountered in the past when the technique was applied to clinical samples, the cause of which has been attributed to the presence of inhibitors. Using wooden toothpicks to transfer colonies may also inhibit PCR reactions in which the PCR mix contains a low concentration of *Taq* DNA polymerase. The character of the inhibitor remains unclear.[13] Even

when the internal positive control does not detect any inhibition in the PCR reaction, the presence of foreign DNA or nontarget DNA could still have interfered with the performance of the PCR, causing a drop in the sensitivity of the test or even leading to a false negative result when it is applied to samples with few target genes present.[10,14] Validations of PCR specificity are recommended, and may be performed with restriction fragment length polymorphism (RFLP) analysis, PCR product sequencing, or Southern blot hybridization.

CONCLUSION

Colony PCR or colony multiplex PCR assays proved to be simple to perform as well as being accurate. It is a very sensitive and reproducible method for direct PCR without the need of DNA preparation. Studies based on *M. tuberculosis* identification using PCR indicated that sonication was the most sensitive method of DNA extraction compared to other protocols such as boiling, nonionic detergents, proteinase K, and freeze-thawing. However, false negative results may occur when viscous specimens are sonicated.[15–18] Afghani and Stutman[9] concluded that boiling is a rapid, sensitive, and specific method of DNA extraction for PCR applications. Unfortunately, accurate estimation of colony PCR sensitivity is difficult. Because the number of bacterial cells used in the PCR to determine the sensitivity of the assay is often adjusted by using the optical density of the suspension, and the actual bacterial cell number per sample may have been higher as a result of the possible clumping of organisms, this will possibly lead to a miscalculated cell count.

Commercial DNA Extraction Kits

C

INTRODUCTION

Genomic DNA is used in a wide range of applications in molecular biology including disease diagnosis, food microbiology, and environmental microbiology. However, DNA analysis in many aspects of medicine and biology rely on the extraction of DNA from complex samples or environments. These may possess numerous contaminants depending on the sample type. In medicine, the extraction of human genomic DNA from tissue samples may be contaminated with commensal bacterial flora. In environmental microbiology, the analysis of water or soil samples may be contaminated by bacterial DNA, plant DNA, and minerals. Interestingly, the analysis of DNA has led to the revised classification of some soil bacteria. Even the complex environment of human blood hampers the detection of infection because of the presence of red blood cells, white blood cells, transient contaminant bacteria, and numerous components of the immune system. Therefore the technique used for DNA extraction is important, as are the steps performed during the process such as cell lysis, DNA recovery, and DNA purification. In medical microbiology, there is a growing interest in molecular methods for the laboratory confirmation of infection and advances in molecular biology have promoted the routine use of techniques such as PCR and DNA sequencing. However, difficulties exist with the extraction of genomic DNA from bodily fluids. Sensitive DNA extraction methods are required but the DNA extracted must be of sufficient quality to be used for the improved diagnosis and surveillance of microbial diseases. In all of the areas above, traditional phenol–chloroform extraction is not usually practical because of the time and safety constraints of the method. Here DNA extraction systems are compared in terms of ease of use, sensitivity, and their ability for automation. An emphasis is placed on their use in clinical microbiology, particularly in relation to the use of whole blood for the diagnosis of microbial infections.

SAMPLES

As described above, there are many areas where purified genomic DNA is required for analysis[1–8] (Table 1). In medicine, samples may include body fluids such as whole blood, serum, CSF, and tissue among others. DNA purified from these sources must be pure, nuclease free, and of good quality (i.e., not sheared). Furthermore, the DNA must be of a quality to provide long-term storage as clinical samples, and indeed others, are often unrepeatable.

MAGNETIC BEAD DNA EXTRACTION METHODS

Some methods for DNA extraction utilize silica-coated magnetic beads onto which the DNA binds and allows extraction, washing, and elution of pure genomic DNA. Such methods include the Bilatest beads DNA extraction kit and Promega bead kit. They are particularly useful for extracting bacterial genomic DNA from whole blood. Typically, a lysis mixture is prepared by mixing magnetic particle suspension with proteinase K and lysis buffer. Premixed lysis solution is then added to the sample and incubated at 55°C to achieve lysis of the red and white blood cells. This is usually performed in a microtitre plate which is then placed on a magnetic separator to allow the metallic bead–DNA complex to sediment. The supernatant is discarded, the DNA washed, and the microtitre placed on the magnetic separator to allow the particle–DNA complex to sediment, and the supernatant discarded. The DNA is then reeluted by adding sterile distilled water and incubating at 65°C.

SILICA MEMBRANE DNA EXTRACTION METHODS

These kits can be used for the extraction of genomic DNA from whole blood or other bodily fluids and are again based on the principle that DNA binds to silica. They are available in single tube or 96-well plate formats. Lysis buffer is added to the sample in order to lyse red and white blood cells and incubated at 70°C. After incubation, ethanol is added, the sample vortexed, and placed on a vacuum manifold to draw the liquid phase through the filter. Washing is repeated and the liquid phase again removed by vacuuming. Elution buffer is added directly to the silica membrane and incubated at room temperature briefly followed by vacuuming to elute the DNA.

DOI: 10.1081/E-EDGP 120030867

Table 1 Examples of use of DNA extraction methods

Type of DNA required	Sample	Reason	Reference
Human genomic DNA	Paraffin-embedded tissue	Disease diagnosis	[19,20]
Bacterial or parasitical genomic DNA	Feces	Confirmation of bacterial or parasitic infection	[8,21]
Bacterial genomic DNA	Soil	Bacterial quantification	[1]
Viral DNA	Dried blood spots	Confirmation of viral infection	[12,22]
Bacterial DNA	Blood or CSF	Confirmation of bacterial infection	[4,18,23]

FILTER-BASED DNA EXTRACTION METHODS

These kits are operationally similar to the silica membrane-based methods but, instead of the DNA binding to the silica membrane, the DNA is held on the filter by size exclusion. As for the other methods, lysis solution is added to the bodily fluid and left at room temperature for cell lysis to take place. After incubation, neutralization solution is added to the tube and mixed again. Lysate is transferred from the sample tube and dispensed into the corresponding well of a clearing plate placed on a vacuum manifold. The liquid phase is then drawn through the filter into the corresponding well of a collection plate and the filtrate discarded. The DNA remaining in the clearing plate is washed by adding wash solution followed by vacuuming, and again the filtrate is discarded. A new collection plate is placed inside the vacuum manifold and the DNA recovered by adding elution buffer.

AUTOMATION

Many methods in molecular biology require high-throughput sample processing, and therefore manual extraction of DNA extraction is not possible.[5] Although many commercial DNA extraction methods can be purchased in tube format, these still require a significant amount of hands-on time in order to add reagents, remove reagents, and perform centrifugation or vacuum steps.[4,5] Efficient methods of DNA extraction that produce pure, high-quality DNA are crucial to the success of PCR and sequencing reactions and the subsequent treatment of disease.[8,9] Current manual methods of DNA extraction are simple and reliable, and are suitable for extraction of low numbers of samples.[10] As the demand for molecular tests increases, new automated methods of DNA extraction will have to be developed to handle larger numbers of clinical samples.[11] There are a number of DNA extraction kits available, based on a 96-well plate format, which allow integration into the workstation of a robotic liquid handler. This allows a much higher throughput of samples, is less work intensive, and produces PCR-ready bacterial DNA.[4,9,11] A number of commercial robotic systems are available for such purposes from companies such as MWG Biotech, Tecan, Qiagen, Beckman, and Roche.

COMPARISON OF DNA EXTRACTION METHODS

Purified bacterial DNA is required for many procedures in modern molecular biology, but clinical microbiology now routinely utilizes DNA for the laboratory confirmation of various infections.[4,8,12] The infections requiring a laboratory diagnosis are primarily of bacterial, viral, or parasite etiology. As such, infections of public health importance are now often diagnosed by PCR, and even typing information is provided on the organism causing infection. One such example is meningococcal disease. For this infection, rapid, sensitive, and specific methods are required so that case contacts can be managed appropriately. Bacterial DNA can be amplified from clinical samples by PCR to characterize the infecting bacterium.[13–17] As well as dedicated DNA extraction robot systems, a number of commercially available DNA extraction kits can be automated[4,18] and can be modified appropriately to various platforms. Overall efficiency of such methods can be determined by throughput time, DNA yield, and labor intensity.[4] All three main methods of DNA extraction can be automated, but their overall efficiency differs according to manufacturer. Some commercial kits, such as the 96-well plate format of the Promega SV96 kit, allow easy adaptation for use on a liquid handling robot. A large number of samples can then be processed with little or no manual intervention. Such kits are extremely simple to use and can extract up to 96 samples in under 20 min. The kits based on the use of metallic beads are also very simple to automate. Some magnetic bead kits are very efficient and can rapidly extract high-quality DNA from a large number of samples

automatically. Some kits produce more DNA per reaction than others although these may not necessarily be the best for automation and test specificity. Overall, it is difficult to compare methods and decide on the best because it depends on the sample type, downstream method required, and the assay type being performed. However, kits have been compared and automated for the extraction of bacterial genomic DNA from whole blood samples and the sensitivity, specificity, and efficiency of the kits compared. In that study, the Bilatest Beads DNA 2 kit and the Promega Wizard SV96 kit were the most successful kits in all areas[4] and have subsequently been used successfully for the laboratory confirmation of septicemia and meningitis caused by *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *Heamophilus influenzae*.[18] Ultimately, the choice of kit depends on the needs of users, often whether they prefer a 96-well plate format or a metallic bead system.

CONCLUSION

DNA extraction methods are now becoming an essential component of molecular biology methods for the sensitive and specific amplification of genomic DNA. Numerous commercial kits are now available which utilize three main technologies for the purification of DNA, and these can be used in diverse applications within the specialties of medicine, environmental biology, and food microbiology. DNA extraction methods can also be automated which can provide high-throughput analysis of samples.

Comparative Genomic Hybridization (CGH)

C

Brynn Levy
Mount Sinai School of Medicine, New York, New York, U.S.A.

INTRODUCTION

Molecular cytogenetics is now considered an integral part of the modern-day cytogenetics laboratory. The ability to identify specific sequences along a chromosome by molecular cytogenetic techniques has been especially useful in 1) defining cytogenetically detected chromosomal material of ambiguous or unknown origin; 2) detecting small submicroscopic rearrangements; 3) rapidly determining the ploidy for specific chromosomes at interphase, e.g., trisomy 21; and 4) mapping particular DNA sequences to specific chromosomes (gene mapping). These specific sequences have been identified by using fluorescently labeled DNA probes that hybridize to the DNA segment of interest. This technique is referred to as fluorescence in situ hybridization (FISH) and forms the fundamental basis of molecular cytogenetics. Since its development in the 1980s, molecular cytogenetics has expanded dramatically beyond two-color FISH. Comparative genomic hybridization (CGH) is one of the more recent innovative molecular cytogenetic techniques that have provided a very unique way to detect chromosomal imbalances in a single-step global-wide scan of the genome. Many factors have made CGH an attractive technique for cancer research, the primary one being that CGH is a DNA-based technique and thus specimen culturing and the availability and quality of metaphase spreads from the specimen are not considerations. This property makes formalin-fixed paraffin-embedded neoplastic tissue and even nonviable tissues, such as that derived from the products of conception, amenable to analysis by CGH. Comparative genomic hybridization has also proved to be an invaluable tool in clinical cytogenetic analysis, especially for samples for which a complete and detailed karyotype could not be obtained by conventional methods. The ability to obtain a genome-wide search for imbalances without any prior information of the chromosomal aberration in question has been particularly useful in clinical cytogenetics. This chapter discusses the technique of CGH and describes its use as both a cancer research tool and a diagnostic technique in clinical cytogenetics.

THE BASICS OF COMPARATIVE GENOMIC HYBRIDIZATION

The development of CGH has provided molecular cytogenetics with a powerful means to scan the entire genome, in a single step, for imbalances in chromosomal material. Comparative genomic hybridization effectively reveals any DNA sequence copy number changes (i.e., gains, amplifications, or losses) in a particular specimen and maps these changes on normal chromosomes.[1,2] Comparative genomic hybridization can detect changes that are present in as little as 30–50% or more of the specimen cells.[2] It does not reveal balanced translocations, inversions, and other aberrations that do not change copy number. Comparative genomic hybridization is accomplished by the simultaneous in situ hybridization of two different genomes, the specimen (test) genome and the reference (normal control) genome. In order to distinguish the two genomes, total genomic DNA from each is labeled with different fluorescent colors and then both are hybridized to normal human metaphase chromosome spreads.[1] The relative amounts of specimen and reference DNA hybridized at a particular chromosome position are contingent on the relative excess of those sequences in the two DNA samples and can be quantified by calculation of the ratio of their different fluorescent colors.[1] Specimen DNA is traditionally labeled with a green fluorochrome such as fluorescein isothiocyanate (FITC) and the normal reference DNA with a red fluorochrome such as Texas Red. A gain of chromosomal material in a specimen would be detected by an elevated green to red ratio, whereas deletions or chromosomal losses would produce a reduced green to red ratio.[1] Figure 1 illustrates the fluorescence capture process as well as how a gain and loss are visualized and then mapped to their source chromosome.

The sensitivity of conventional CGH is in the megabase range, with a theoretical detection limit of deletions estimated to be about 2 Mb.[3] The detection limit of CGH therefore approaches that of a high-resolution karyotype (750–1000 band level) i.e., CGH can detect imbalances around 2–3 Mb in size.[4]

DOI: 10.1081/E-EDGP 120020745

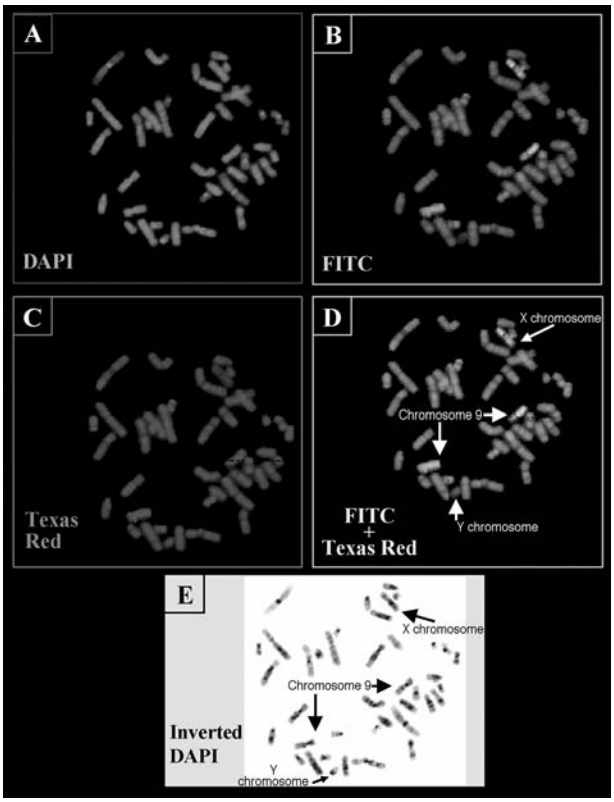

Fig. 1 Fluorescence microscopy utilizing fluorochrome-specific filters to visualize and capture color ratio differences along the chromosomes. A. DAPI image. B. FITC image. C. Texas Red image. D. Combined FITC and Texas Red image revealing an overrepresentation (greater green to red intensity) of the X and 9 chromosomes and an underrepresentation (greater red to green intensity) of the Y chromosome. E. The over- and underrepresented chromosomes are identified by their banding pattern observed in the inverted DAPI image. (*View this art in color at www.dekker.com.*)

Overview of Comparative Genomic Hybridization

The major steps in CGH involve: 1) Preparation of karyotypically normal 46,XY metaphase spreads. Male reference chromosomes are chosen so that both the X and Y chromosomes are available as hybridization targets. 2) Isolation of high molecular weight DNA from specimen (test) and reference (normal) samples. 3) Labeling of specimen and reference DNA with different fluorochromes by nick translation. 4) *In situ hybridization* of equal amounts of labeled specimen and reference DNAs together with unlabeled Cot1-DNA to normal metaphase spreads. 5) Washing off unbound DNA. 6) Counterstaining metaphase spreads with DAPI for chromosome identification. 7) Fluorescence microscopy utilizing fluorochrome-specific filters to visualize and capture color ratio differences along the chromosomes (Fig. 1). 8) Chromosome identification by the inverted DAPI banding pattern (Fig. 1). 9) Quantitation of copy number differences by generating a ratio profile of the specimen to reference DNA fluorescence intensities along each chromosome. 10) Combining the profiles from several metaphase spreads to improve the significance of the result.

COMPARATIVE GENOMIC HYBRIDIZATION IN CANCER CYTOGENETICS

Genetic alterations associated with neoplasia have been well defined in hematological malignancies by both classical and molecular cytogenetics.[5,6] In contrast, there is significantly less information known about the cytogenetics and molecular cytogenetics of solid tumors. This is because of technical difficulties in the production of metaphase spreads from these tumor cells. Karyotype analysis requires viable, proliferating cells that can be arrested in the metaphase stage of the cell cycle. Cytogenetic analysis of these tumors is often hampered as many solid tumor cells fail to proliferate in vitro. For those tumors that do divide and produce metaphase spreads, the quality of the metaphase spreads is often inadequate to allow for recognition of banding patterns. There is also the question of the significance of the cytogenetic data derived from in vitro tumor cell culture as small subclones in vivo may take advantage of the in vitro conditions and thus the nonproliferating cells that constitute the main clone in vivo may escape detection by conventional cytogenetic analysis.[7] In addition, many aberrant chromosomal regions may not be identified because of the highly complex karyotypes of cultured cancer cells carrying both multiple numerical and structural chromosomal abnormalities.

Comparative genomic hybridization allows for direct analysis of genomic DNA obtained from tumor specimens, thus overcoming the problems associated with cell culturing and poor metaphase spread quality. Also, as detection of chromosomal imbalances by CGH is dependent on the aberrations being present in 30–50% or more of cells from which the DNA is extracted,[2] the results derived using this technique reflect changes that are genuinely present in the majority of tumor cells. Comparative genomic hybridization analysis is limited by its inability to provide information about balanced rearrangements, the origins of structural anomalies, or the ploidy status of the cells. However, identification of specific regions of imbalance may be sufficient to provide a location for candidate genes (oncogenes and tumor suppressor genes) causative of the initiation and progression of these tumors.

The use of CGH in cancer genetics has revealed a number of novel recurring chromosomal gains, amplifications, losses, and deletion sites that escaped detection using traditional cytogenetic analysis in various

tumors, including prostate cancer, testicular germ cell tumors, breast cancer, uveal melanomas, small-cell lung carcinoma, gliomas, sarcomas, head, neck, and pancreatic carcinomas, and uterine leiomyomata. The chromosomal aberrations detected by CGH have also provided prognostic information in a number of neoplasms including renal cell carcinomas, bladder cancer, cervical carcinomas, node-negative breast cancer, uveal melanoma, cutaneous melanoma, and prostate cancer. Various international CGH databases have been established including Tokyo Medical and Dental University CGH database (http://www.cghtmd.jp/cghdatabase/index_e.html), the database of Humboldt-University of Berlin (http://amba.charite.de/~ksch/cghdatabase/index.htm), the Progenetix cytogenetic online database (http://www.progenetix.net), and the National Cancer Institute and National Center for Biotechnology Information Spectral Karyotyping SKY and Comparative Genomic Hybridization CGH Database (2001), (http://www.ncbi.nlm.nih.gov/sky). These databases provide a wealth of information on the CGH studies that have been done since 1992.

COMPARATIVE GENOMIC HYBRIDIZATION IN CLINICAL CYTOGENETICS

Clinical cytogenetic studies often yield karyotypes with unbalanced or unrecognizable G-banded cytogenetic material, examples of which include marker chromosomes, unbalanced translocations, intrachromosomal duplications, and deletions. The challenge is to identify the unbalanced material in order to provide the most up-to-date information for genetic counseling. Such information would directly benefit prenatally ascertained cases of unidentifiable chromosomal material, providing couples with a means to make rational and informed decisions concerning the pregnancy. In pediatric cases, such information may provide the parents with a realistic prognosis and be important for the clinical management of the infant. In the past, this required a comprehensive molecular cytogenetic workup using various FISH probes, an endeavor that is both expensive and labor intensive as numerous probes and/or whole-chromosome paints may be required until the origin of the chromosomal material is identified. In addition, the number of commercially available region-specific probes is limited and covers only a fraction of the genome. Comparative genomic hybridization has now been shown to be an effective single-step focused method for the identification of unbalanced aberrant chromosomal material of unknown origin.[8,9] The advantage of CGH over conventional FISH with whole-chromosome paints (wcps) and multicolor FISH is its ability to identify not only the chromosome from which the additional unknown material was derived but also to map the region involved to specific G-bands on the source chromosome (Fig. 2). In addition to being able

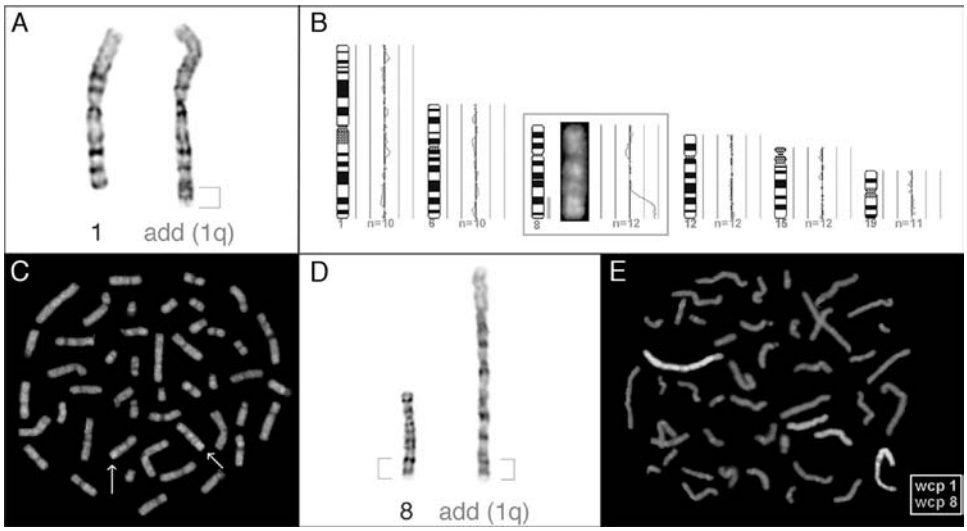

Fig. 2 CGH workup of a patient with multiple congenital abnormalities and additional chromosomal material of unknown origin on the long arm of chromosome 1. A. Partial karyotype showing the G-banded aberrant chromosome 1 with extra material (on the right) and the normal chromosome 1 (on the left). B. Partial ideogram and CGH profiles indicating a gain on the long arm of chromosome 8 from 8q23 to 8qter (orange box). The lines in the CGH profiles represent green/red ratios of (from left to right) 0.5, 0.75, 1.0, 1.25, and 1.5. A ratio of 1.0 represents the balanced state of the chromosomal copy number. C. The gain of chromosome 8 material observed in panel B can be visualized in this panel in the dual FITC/Texas Red image as the green intense regions (arrows). D. Aligning the G-banded extra material on chromosome 1 with its endogenous position on its source chromosome provides visual confirmation of the CGH results. E. Confirmation of the CGH finding by FISH with a chromosome 1 and 8 whole-chromosome paint. (*View this art in color at www.dekker.com.*)

to identify excess and/or missing chromosomal material not resolvable by G-banding, CGH can also be used as a backup method for aneuploidy analysis of specimens that have failed to grow in cell culture. This is especially effective in the analysis of nonviable fetal tissue derived from products of conception which are estimated to have a chromosome abnormality (mainly aneuploidy) approximately 50–70% of the time.[10]

To date, more than 1600 articles have been published on CGH with the greater majority reporting the utility of CGH to identify novel chromosomal imbalances in neoplastic specimens (http://www.ncbi.nlm.nih.gov:80/entrez/query.fcgi?). Less than 10% of CGH papers have dealt with technical aspects and only a limited number have described the application of CGH in a clinical cytogenetics setting. Comparative genomic hybridization has been particularly useful in clinical cytogenetics by facilitating the identification and characterization of unbalanced translocations, deletions, intrachromosomal duplications, and marker chromosomes, including neocentric marker chromosomes.[8,9,11] High-resolution identification of such aberrant material has provided clinical correlation between specific chromosomal regions and various clinical entities such as the duplication 5q phenotype[12] and partial tetrasomy 10p which resulted from an analphoid marker chromosome with a neocentromere.[11] These publications have demonstrated the power of CGH for elucidating karyotype–phenotype correlations as well its potential for providing the groundwork for the discovery of the gene(s) that are responsible for the clinical presentation observed in patients with chromosomal imbalance. The ability of CGH to detect total aneuploidy makes it an appealing diagnostic tool for use in preimplantation genetic diagnosis (PGD).[13–15] Cytogenetic analyses of human preimplantation embryos, generated using in vitro fertilization (IVF) technology, have shown a very high incidence of chromosomal abnormality, with greater than 50% of all embryos identified to have aneuploid cells.[16–18] The majority of chromosome abnormalities detected at this early stage of development are likely to be lethal and their existence may explain a significant proportion of failed IVF cycles. The use of CGH to identify nonaneuploid embryos and selectively transfer them to the mother should theoretically improve the IVF implantation rates and also lower the observed miscarriage rates and thus improve the overall efficiency of assisted reproductive techniques.[15]

CONCLUSION

Comparative genomic hybridization was originally developed as a cancer research tool and rapidly demonstrated its power by detecting novel regions of chromosomal imbalance in a large variety of neoplastic samples. These studies have led to the discovery of many new tumor suppressor genes and oncogenes that play a role in the initiation and/or progression of solid tumors. The application of CGH to prenatal and pediatric samples has also proven extremely beneficial, allowing the delineation of ambiguous and complex karyotypes that could not be defined using classical cytogenetic techniques. In addition, the use of CGH to analyze human preimplantation embryos has provided fascinating scientific data concerning the variety and rate of aneuploidy at this early developmental stage and holds a lot of promise for improving the efficiency of assisted reproductive techniques.

As technical advances improve the capabilities of CGH, future additional applications are likely to include screening for deletions as small as those observed in the microdeletion syndromes such as Prader–Willi and DiGeorge syndromes. This will be made possible by the recent development of newer CGH protocols such as matrix CGH which combines biochip and CGH technologies[19] and array CGH which uses an array of DNA sequences instead of metaphase chromosomes.[20] The use of regular CGH would still remain an attractive and powerful accessory to routine clinical cytogenetic analysis.

Competitive PCR

M. Pazzagli
C. Orlando
P. Pinzani
University of Florence, Florence, Italy

INTRODUCTION

A reliable approach to quantitative PCR is defined as competitive PCR (c-PCR) and it is based on the addition to the sample of a competitor target (DNA or RNA), acting as an internal standard, which has the same primer recognition sites as the target gene and, consequently, the same behavior during PCR cycling. The PCR amplicons can be then separated by conventional procedures and quantitation is achieved by comparing the signal of the specific target with that obtained from the known concentration of the internal standard (competitor template). This strategy seems to guarantee the independence of the results from any predictable or unpredictable variables that can affect the rate of amplification because the two species are amplified at the same rate and their ratio remains constant during PCR cycling. With this procedure, the parallelism between target and competitor is maintained even after reaching the plateau phase, with an increase in the assay sensitivity.

TECHNICAL DESCRIPTION

The Competitor Templates

Competitive PCR can be adopted for both DNA and mRNA measurements and generally requires the construction of synthetic DNA or RNA competitors.[1,2] DNA competitors have the advantage of better stability and more accurate quantification methods in comparison to RNA competitive templates. Whereas, if DNA is used, competitor quality and quantity can be compared with stable DNA standard preparations, the measurement of mRNA is complicated by the difficulty of obtaining a practicable reference standard for the calibration of the RNA competitor. The use of a DNA competitor for mRNA measurements may simplify the procedure of quantitative reverse transcript PCR (RT-PCR). However, the use of a DNA standard for mRNA measurements, even if it represents an advantage because of its stability and ease of handling,[3] cannot prevent the inaccuracy of RT-PCR which is due to the large variability of reverse transcription efficiency.

In some cases, a DNA competitor can be obtained by selecting the primers on two contiguous exons separated by a small intron, but generally, the competitor must be synthesized ad hoc. Competitors are normally cloned in plasmid vectors, transcribed in vitro to obtain large amounts of specific transcript, and measured precisely to determine competitor concentration.[4]

Synthesis of Competitors

The construction of competitor templates, their exact quantification, and their storage represent the crucial aspects of this technique. Competitors, to act as a functionally appropriate internal standard, must behave during the assay as closely as possible to the template. The efficiency of the enzymatic reactions (reverse transcriptase and PCR) on the two species must be comparable.[5,6] For this reason, the competitor must have comparable dimensions and the same primer recognition sites as the target. However, for the assay to be practical, the separation and the measurement of the two species should be performed in the simplest way possible. Different strategies have been described for the construction of the competitor for c-PCR. Some competitors have been obtained by the incorporation of a new restriction site in the native sequence,[7] and after PCR, the competitor is digested with the relevant restriction enzyme and the electrophoretic bands are then resolved and measured. The main disadvantage of this approach is the unpredictable efficiency of enzyme digestion, which can strongly influence the results of the assay. A variant of this technique is based on the insertion of a small modification in nucleotide sequence of the target (short sequence modification or single-base mutation).[8] After PCR, the competitor can be identified by differential hybridization with specific probes or by electrophoretic techniques [denaturating gradient gel electrophoresis (DGGE) or single-strand conformation polymorphism (SSCP1)]. This approach is quite complex and requires time-consuming and cumbersome post-PCR procedures. Furthermore, the

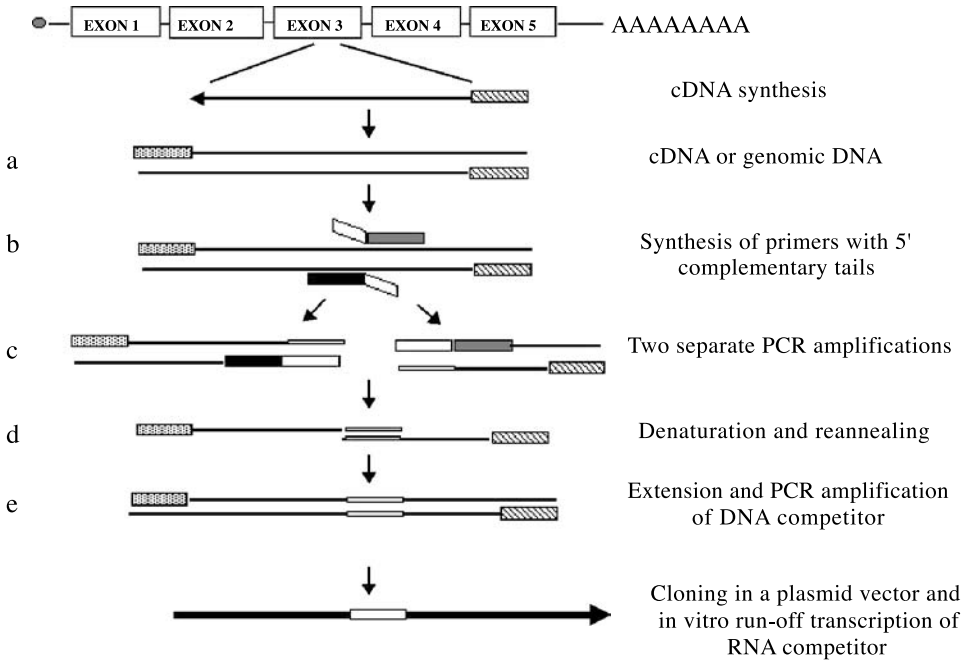

Fig. 1 Construction of competitor templates for competitive PCR or RT-PCR. The figure describes all the steps necessary to the synthesis of an RNA competitor. Steps from a to e represent the procedure to obtain a DNA competitor template.

efficiency of these techniques for discrimination of the two species is extremely variable.

The simplest approach to obtain a synthetic competitor is the introduction of a short deletion or insertion in the center of the competitor. This variation in size, if maintained within an acceptable range (10–15% of the original size), does not modify significantly the amplification rate of PCR. Several methods have been proposed for the construction of this type of competitor. A rapid and efficient method for both DNA and RNA competitor construction is based on a modification of the overlap extension technique[1,2,4] (Fig. 1). Two DNA fragments are amplified in separate PCR reactions, using the designed external primers in combination with respective internal primers containing complementary sequences to each other. The two fragments are then annealed and amplified with the external primers, in the same tube. The resulting sequence is identical to the initial target, with the exception of the added (or deleted) complementary sequence used for the ligation of the two halves of the competitor. With a similar technique, it is possible to generate multiple competitors by ligation of different PCR products (see the chapter on multiplex competitive PCR).

General Rules for Competitive PCR or RT-PCR Assays

In c-PCR, quantification is performed by comparing the final, post-PCR signal of the target with that of known amounts of the competitor. By definition, in c-PCR, the most accurate measurement is obtained when the signals corresponding to competitor and target templates are equivalent (or close to equivalence).[9] Ideally, if the target concentration is in the linear range of competitor/target ratios, a single point could provide an accurate measurement of the target gene.

However, because of the unpredictable target concentration, a variable number of tubes with a constant amount of target and variable competitor concentration must be analyzed in the same run. The number of the dilutions of competitor must be adapted to the requirements of the assay. In DNA assays, three dilutions in a 1 log range can be sufficient,[1,4] whereas for mRNA measurements, sometimes up to five tubes at 10-fold dilutions must be tested to cover the wide range of possible gene expression levels.[10] In a second assay, the range can be restricted for a closer quantification of RNA levels. Finally, an improvement in accuracy of c-PCR can be obtained performing a simultaneous amplification in the same tube of the target gene and a reporter gene.[11]

Competitive PCR for DNA measurements; assay procedure

Some quantitative alterations of DNA, such as the measurement of gene amplification or the study of the replication origin, can be evaluated with the c-PCR

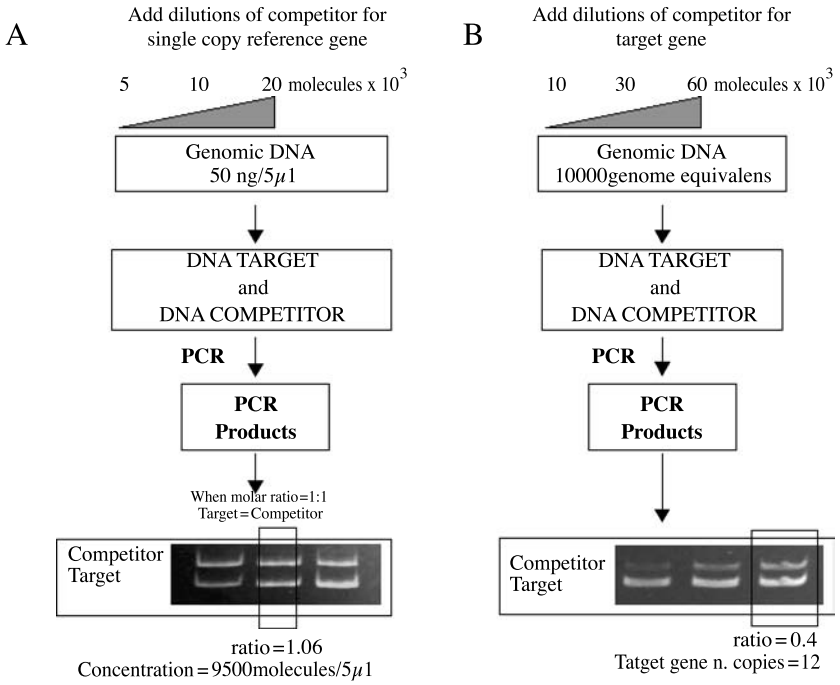

Fig. 2 Example of competitive PCR assay. The assay is performed in two-step (A and B) competitive PCR. In step A, the exact DNA concentration of each samples is accurately measured by reference to a single copy reference gene (i.e., β-globin), while in step B, the exact number of target gene copies was determined. In both PCR steps, we added three dilutions of DNA competitor (single copy reference gene competitor or target gene competitor). The competitor/genomic ratio was evaluated after acrylamide gel electrophoresis of PCR products.

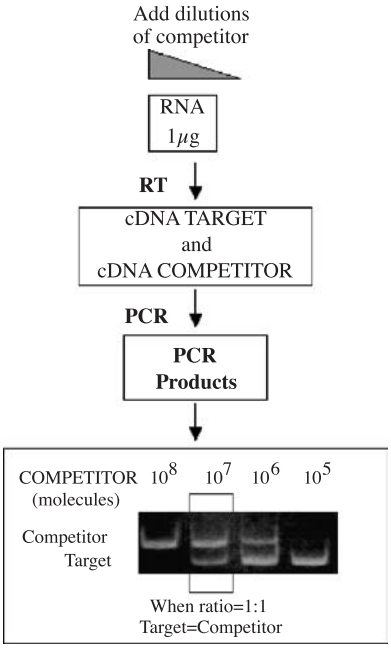

Fig. 3 Example of competitive RT-PCR assay. The assay was performed by the addition of four different dilutions of the specific RNA competitor (from 10^8 to 10^5 molecules) to the unknown sample, prior to the reverse transcriptase reaction (RT). Final quantitation was performed by evaluating competitor/target ratio, as described for DNA measurement.

technology. Because PCR procedures for gene amplification must be able to measure the increase of even a few gene copies, the exact amount of DNA in each sample must be determined more accurately than by spectrophotometric measurement. For this reason, an accurate assay must include a first competitive PCR in which the absolute number of a single copy reference gene is evaluated. This allows the performance of a second competitive PCR in which all samples are measured for gene amplification starting from exactly the same number of DNA molecules.[2–4] An example of the measurement of c-erbB-2 oncogene amplification is reported in Fig. 2. This technique is highly sensitive and allows the measurement in isolated cells obtained by flow sorting,[12] or even in samples with degraded DNA, as in the case of archived samples.[1]

Competitive PCR for RNA measurements; assay procedure

The assay procedure for c-RT-PCR requires the use of an RNA competitor to be added before the reverse transcription according to the scheme reported in Fig. 3. The calculation of the results is the same as for DNA measurements.

SPECIFICITY

Competitive PCR has been developed to overcome the limitations of the traditional PCR methods when used for quantitative measurements of nucleic acids. On the other hand, the PCR approach is maintained and, in particular, the specificity of the assay can be excellent, but, in any case, is related to the primer design and the assay amplification conditions as for the classical PCR methods.

SENSITIVITY

Sensitivity, assumed as the minimal measurable amount of nucleic acids with a reasonable precision, is also excellent and can reach, for DNA gene amplification measurements, also the detection of one gene copy increment. For RNA expression studies, sensitivity is also related to the RT efficiency and to the expression level of the target gene, but single-cell expression studies by c-RT-PCR have been reported.[13]

REPRODUCIBILITY

Coefficient of variation values of 15–20% can be obtained assuming that competitor stability is preserved and quantification of the PCR products is performed with appropriate quantitative devices.[4,14,15]

ROBUSTNESS AND LIMITS

The relative simplicity for the competitor synthesis and the low cost of the final assay make the c-PCR approach as a first choice for quantitative studies of nucleic acids. Stability of RNA competitors, however, can be difficult to maintain. In some cases, the use of a DNA competitor in c-PCR for RNA expression studies has been proposed, but with the limits above reported in ''The Competitor Templates.'' Another important limitation is the high risk of contamination depending on the procedures used for quantification of the PCR products.

CLINICAL APPLICATIONS

The use of c-PCR for DNA measurements has been applied to the study of some quantitative alterations of DNA, such as the measurement of gene amplification[1,2,4] or the study of the replication origin.[16]

The measurement of mRNA molecules with competitive PCR has found wide applications in several fields of clinical laboratory, as for cytokine expression measurement,[17] for the detection of viral nucleic acids for hepatitis C[18] and HIV,[14] and for detection of gene expression in oncology.[19]

CONCLUSION

Competitive PCR is a powerful, versatile, and low-cost technology for quantitative nucleic acid measurements, suitable for both research studies and clinical applications even if some limitations as those above indicated should be carefully evaluated on the basis of the specific experimental design and the available laboratory facilities.

Corynebacterium diphtheriae—Molecular Detection of Diphtheria Toxin

C

Jennifer K. Spinler
Randall K. Holmes
University of Colorado Health Sciences Center, Denver, Colorado, U.S.A.

INTRODUCTION

Diphtheria is an infectious disease of humans that affects the respiratory tract or skin. It is caused by toxigenic (toxin-producing; *tox*$^+$) isolates of *Corynebacterium diphtheriae* or, rarely, *Corynebacterium ulcerans*.[1,2] A pseudomembrane at the site of infection occurs commonly in respiratory diphtheria and occasionally in cutaneous diphtheria. The major bacterial virulence factor involved in pathogenesis is diphtheria toxin, which blocks protein synthesis and has a lethal dose of <0.1 μg/kg of body weight.[3,4] Diphtheria toxin is encoded by certain corynebacteriophages, and all toxigenic variants of *C. diphtheriae* or *C. ulcerans* are lysogenic for a *tox*$^+$ prophage. Toxin produced locally can spread via the bloodstream and damage vital organs, including the heart, peripheral nerves, kidneys, liver, and adrenal glands.[5] Both toxigenic and nontoxigenic variants of *C. diphtheriae* can cause infections of mucous membranes or skin, but only *tox*$^+$ strains are associated with the harmful manifestations caused by diphtheria toxin. Definitive diagnosis of diphtheria is based on clinical findings compatible with diphtheria plus isolation of *C. diphtheriae* or demonstration of characteristic histopathological findings. Respiratory diphtheria, but not cutaneous diphtheria, is reportable in the United States.

Diphtheria has been nearly eliminated in developed countries by widespread immunization with diphtheria toxoid, an immunogenic but nontoxic derivative of diphtheria toxin.[6] Antibodies raised against diphtheria toxoid by active immunization combine with diphtheria toxin and neutralize its toxic effects. When a clinical diagnosis of diphtheria is made, equine diphtheria antitoxin is administered immediately to the patient as a therapeutic measure without waiting for bacteriological cultures, because delays in administration of antitoxin are associated with greater mortality.[2] Immunization with diphtheria toxoid prevents diphtheria, but it does not eliminate carriage of *tox*$^+$ *C. diphtheriae* in the human population.[7] Diphtheria has the potential to reemerge if immunity is not maintained at a high level in the population. The most devastating recent outbreak of reemergent diphtheria occurred in Russia and the Newly Independent States (NIS) of the former Soviet Union during the early and mid-1990s, resulting in $>150{,}000$ cases and >5000 deaths.[8,9] At least 20 imported cases of diphtheria in adults were diagnosed in Central and Western European countries following exposures that occurred in the epidemic regions.

When *C. diphtheriae* is isolated from a clinical specimen, the most critical issue is to determine rapidly and accurately whether the isolate is *tox*$^+$. This is important to assure that individual patients receive proper treatment, determine if contacts require prophylactic treatment, and assess whether immunization programs or other measures are required to prevent the spread of diphtheria within the population at risk. Toxigenicity testing (originally called virulence testing) on isolates of *C. diphtheriae* can be performed either directly by using bioassays that detect specific toxic effects of diphtheria toxin or indirectly by using molecular methods that detect antigenic determinants of the diphtheria toxin protein or specific nucleotide sequences within the structural gene for diphtheria toxin (*tox*). This chapter summarizes the current status of phenotypic and genotypic tests for diphtheria toxin, with emphasis on test formats that have been used recently by several major diphtheria reference laboratories.

BIOASSAYS FOR DIPHTHERIA TOXIN

Bioassays are based on the ability of diphtheria toxin to cause death, dermonecrosis, inhibition of protein synthesis, or other toxic effects in highly susceptible animals (such as rabbits or guinea pigs) or in cultured cells derived from them. The molecular basis for the toxicity of diphtheria toxin has been well studied (reviewed in Ref. [10]). Diphtheria toxin is secreted by *C. diphtheriae* as a single mature polypeptide of 28,350 Da, containing 535 amino acid residues. Proteolytic nicking of diphtheria toxin and reduction of its two internal disulfide bonds generate fragments A and B. The receptor-binding domain of fragment B binds to the precursor form of a heparin-binding epidermal growth factor-like protein, the receptor for toxin on the surface of susceptible eukaryotic cells. The toxin–receptor complex is endocytosed, and upon

DOI: 10.1081/E-EDGP 120024073

acidification of the endosome the translocation domain of fragment B undergoes a conformational change, causing it to insert into the endosomal membrane and form a pore through which fragment A is translocated into the cytosol. Fragment A catalyzes the transfer of the adenosine diphosphate ribose moiety from nicotinamide adenine dinucleotide to a posttranslationally modified histidine residue (called diphthamide) on elongation factor 2 (EF-2), thereby inactivating EF-2 and inhibiting protein synthesis. A single molecule of fragment A within the cytoplasm is sufficient to kill a eukaryotic cell.

Because bioassays provide direct measures of toxicity, they have long been accepted as the ''gold standard'' for detecting diphtheria toxin. Because the observed biological endpoints (such as death or dermonecrosis) are not necessarily unique for diphtheria toxin, controls are needed to demonstrate specificity. Typically, duplicate assays are performed in the presence and absence of diphtheria antitoxin, and neutralization of toxicity by antitoxin proves that observed toxic effects are caused by diphtheria toxin. Assays for dermonecrosis following intradermal injections of diphtheria toxin into susceptible animals are more sensitive than tests for lethality following subcutaneous injections, and intradermal tests can detect as little as 50 pg of diphtheria toxin.[11] Several different endpoints have been used to measure toxicity for cultured cells, including cell death, cytotoxicity, inhibition of protein synthesis, etc. Tests on Vero cells in microtiter cultures using a tetrazolium dye to assess cell viability could detect 3 pg of diphtheria toxin per assay, and the results of cell culture assays were in complete concordance with toxigenicity tests performed in animals for a collection of 55 isolates of potentially tox^+ corynebacteria.[12] The advantages of bioassays for diphtheria toxin include high sensitivity and specificity. The disadvantages are that bioassays are labor intensive, costly (especially if rabbits or guinea pigs are required), slow (several days to obtain results), and require facilities for experimental animals or tissue cultures that are not always available in diagnostic laboratories.

IMMUNOASSAYS FOR DIPHTHERIA TOXIN

Immunoassays are based on the ability of specific polyclonal or monoclonal antitoxic antibodies to bind diphtheria toxin. Typically, immunoassays do not distinguish between biologically active forms of diphtheria toxin and biologically inactive forms that retain full or partial antigenicity (such as diphtheria toxoid or partially denatured diphtheria toxin). Immunoassays provide inexpensive and fairly rapid substitutes for bioassays in determining the toxigenicity of clinical isolates of *C. diphtheriae*. Each reference laboratory must perform periodic controls to demonstrate that the results of any particular immunoassay correlate well with the results of standard bioassays for diphtheria toxin.

For many years, the Elek test has been used most commonly in diagnostic laboratories to determine whether isolates of *C. diphtheriae* are tox^+. In Elek tests, a strip of filter paper impregnated with diphtheria antitoxin is applied to the surface of an agar plate containing medium that supports growth of *C. diphtheriae* and production of diphtheria toxin. Isolates of *C. diphtheriae* of unknown toxigenicity are streaked on the surface of the medium at right angles to the strip and parallel to known toxigenic and nontoxigenic control isolates. Toxin produced during bacterial growth and antitoxin from the strip diffuse into the medium, forming precipitin lines where toxin and antitoxin are present at equivalence. Precipitin lines formed by tox^+ unknown and tox^+ control isolates at adjacent positions fuse to give lines of identity. Elek tests are highly reliable when all media, antisera, growth conditions, and bacterial standards are rigidly controlled, but results are likely to be unreliable in laboratories that perform Elek tests infrequently and lack experienced personnel. Incorrect interpretation of nonspecific precipitin lines can produce false-positive results, whereas false-negative results due to low sensitivity of the assay system may occur if test conditions are not carefully controlled. The large epidemic of diphtheria in Russia and the Newly Independent States during the 1990s stimulated interest in developing improved diagnostic tests and increasing the competence of laboratory personnel for identifying *C. diphtheriae* and performing toxigenicity tests. Modifications in procedures for the Elek test improved the reproducibility of results, decreased the amounts of reagents required, and decreased the time required for results from 48 hr to 16–24 hr.[13,14]

Subsequently, a quantitative antigen-capture enzyme immunoassay and a qualitative immunochromatographic strip (ICS) test for diphtheria toxin were developed, both of which offer rapid, sensitive, and specific alternatives to the Elek test for toxigenicity testing.[15,16] The enzyme immunoassay used an equine polyclonal antibody for capture and an alkaline phosphatase-conjugated monoclonal antifragment A antibody for detection of diphtheria toxin. The limit of sensitivity was 0.1 ng of diphtheria toxin/mL, and results available within 3 hr of colony selection agreed uniformly with Elek tests. The ICS test also used equine polyclonal antibody for capture but substituted colloidal gold-labeled monoclonal antifragment A antibody for detection of diphtheria toxin. The limit of sensitivity for the ICS test was 0.5 ng of diphtheria toxin/mL, and results were available within 10 min. Furthermore, when the ICS test was used to compare 850

throat swabs that were inoculated directly into broth for 16 hr or analyzed by conventional culture methods, the concordance for detecting diphtheria toxin by the two methods was 99%, and the sensitivity and specificity of the ICS test for detecting diphtheria toxin were 98% and 99%, respectively. The ICS test has significant advantages over the enzyme immunoassay with respect to ease of test performance, stability of reagents, and documented ability to detect diphtheria toxin production within 16 hr from initial collection of a throat swab from a patient with suspected diphtheria.

GENOTYPIC TESTS FOR DIPHTHERIA TOXIN

A genotypic test is designed to detect the nucleotide sequence for a particular gene. Unlike an immunoassay for a protein, a genotypic test does not require that the gene product be produced. Therefore a genotypic test for *tox* is one step more remote from a bioassay for diphtheria toxin than an immunoassay. Because many tests for specific DNA sequences have high sensitivity, it is possible to develop tests for *tox* that will have few false-negative results. However, the converse is not true, because nontoxigenic isolates of *C. diphtheriae* may contain an inactive allele, a single fragment, or multiple fragments of *tox*. In such isolates, a positive test for the *tox* gene would not agree with the negative result of a bioassay for diphtheria toxin.

Several investigators developed polymerase chain reaction (PCR) tests to detect *tox* in DNA isolated from pure cultures of *C. diphtheriae*.[17,18] The presence of nucleic acid sequences encoding the A fragment of diphtheria toxin agreed well with positive Elek tests for diphtheria toxin production, and the sensitivity of the PCR tests was approximately 50–500 colony forming units (CFU) of a tox^+ isolate of *C. diphtheriae*. A PCR test for detecting *tox* in DNA isolated directly from throat or nasopharyngeal swabs was also developed. It eliminated the time required to culture *C. diphtheriae* and gave results within hours of collecting the initial clinical specimens.[19] Subsequently, a real-time fluorescence PCR assay decreased the limit of detection for *tox* to approximately 2 CFU/sample.[20] This real-time PCR test detected the coding regions for diphtheria toxin fragment A and fragment B in all of 23 tox^+ clinical isolates and 2 tox^+ reference strains of *C. diphtheriae*, and it was superior to routine PCR tests in detecting *tox* in DNA extracted directly from clinical specimens.

The events in Russia and the Newly Independent States during the 1990s provided an opportunity to apply molecular epidemiological methods to an evolving epidemic of diphtheria and showed that most patients were infected by clonally related *C. diphtheriae* isolates that were not highly prevalent before the epidemic.[21] Use of single-stranded conformation polymorphism and direct DNA sequencing methods demonstrated allelic variations in *tox* among clinical isolates of *C. diphtheriae*, but all mutations in *tox* were silent and did not change the amino acid sequence of diphtheria toxin.[22] Therefore the epidemic was not caused by evolution of *C. diphtheriae* strains that produced a variant of diphtheria toxin resistant to neutralization by antitoxic antibodies, and intensive immunization with diphtheria toxoid succeeded in bringing the epidemic under control by the late 1990s.[23]

CONCLUSION

The most important test for new isolates of *C. diphtheriae* is to determine if they are toxigenic, which has important implications for patient care and public health. The ideal test should be simple, sensitive, rapid, reliable, and inexpensive, and it should also correlate well with the biological activity of diphtheria toxin. Bioassays performed in susceptible animals or cultured cells are the gold standard, but unfortunately they are slow, complicated, and costly. Molecular methods based on immunochemical properties of diphtheria toxin or nucleotide sequences of the toxin structural gene serve as surrogates for bioassays and provide indirect assessments for potential toxigenicity of *C. diphtheriae* isolates. Elek tests, based on formation of toxin–antitoxin precipitates in agar during growth of tox^+ isolates of *C. diphtheriae*, require rigidly controlled execution by skilled personnel, although recent modifications have improved their speed and cost-effectiveness. An immunochromatographic strip assay for diphtheria toxin offers great advantages in sensitivity, speed, and applicability for direct use on clinical specimens. Polymerase chain reaction-based methods to detect specific segments of the *tox* gene have been optimized for speed, sensitivity, and reliability, but they do not assess the ability of *C. diphtheriae* to produce the diphtheria toxin protein. Because some isolates of *C. diphtheriae* contain all or part of the toxin gene but do not produce diphtheria toxin, some positive PCR results may lead to false-positive identification of tox^+ *C. diphtheriae* isolates unless bioassays are also performed.

Cowden Syndrome

Deborah J. Marsh
University of Sydney, Australia

Roberto T. Zori
University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Cowden syndrome (CS, OMIM#158350) can be grouped along with Bannayan–Riley–Ruvalcaba syndrome (BRR, OMIM #153480), Peutz Jeghers syndrome (PJS, OMIM #175200), and juvenile polyposis syndrome (JPS, OMIM# 174900) as one of the autosomal dominant hamartoma syndromes. The estimated incidence of CS is >1:200,000.[1] It is characterized by the appearance of hamartomas (benign developmentally disorganized tumor-like tissue overgrowths) in various organs as well as an increased risk of developing malignancies.

PTEN (*P*hosphatase and *TEN*sin homolog mutated on chromosome *TEN*; location 10q23.3) was identified in 1997 and has alternatively been named *MMAC1* or *TEP1*.[2] *PTEN* encodes a dual specificity phosphatase with homology to the cytoskeletal proteins tensin and auxillin. Using the criteria set by the International Cowden Syndrome Consortium[3] up to 80% of individuals with CS have been shown to have a germline *PTEN* mutation.[4] Genetic scanning in at-risk or symptomatic individuals is available for this syndrome.

CLINICAL DESCRIPTION

Presentation

Cowden syndrome displays a high level of variability in expression, both between and within families; however, it usually presents in the third decade. Hamartomas are derived from all three germ cell layers. Those of the inner organs most commonly involve the breast (70%); thyroid adenomas and multinodular goitres (40–60%); gastrointestinal polyps (35–40%) and can also be seen in the central nervous system and; reproductive tract. The gastrointestinal polyps seen in CS are distinct from those seen in other hamartomatous syndromes, as they are more likely to be of ectodermal and/or endodermal origin.[5] Dermatological manifestations are the most prevalent findings, with palmoplantar hyperkeratosis in 54%, trichilemmonmas (benign tumors of the hair follicle infundibulum) in 99%, and oral papillomatosis in 85% of CS patients (reviewed in Refs. [6,7]). The last two dermatological findings are considered to be the hallmarks of CS. The central nervous system may be the second most common organ system involved in CS, and includes megencephaly or macrocephaly seen in up to 80% of patients and Lhermitte–Duclos disease (LDD).

In addition to these benign findings, patients have an elevated risk for malignant tumors, most commonly in the breast (25–50% in females, and a small percentage of males) and thyroid, especially follicular thyroid carcinoma (3–10%). Cancer has also been reported in CS patients in the brain, gastrointestinal tract, urogenital tract, and skin, but whether there is a true elevated risk in these systems is less well documented.

Cowden syndrome shows partial clinical overlap with the overgrowth disorder BRR syndrome, with intestinal hamartomatous polyps, macrocephaly, and lipomas being seen in both conditions, as well as germline *PTEN* mutation. A number of families described as ''overlap'' families have been reported in which both CS and BRR segregate with the identical germline *PTEN* mutation.[9,10] Bannayan–Riley–Ruvalcaba and Cowden syndromes have therefore been considered to be phenotypic variants of the same condition and have been referred to as the ''PTEN hamartoma–tumor syndrome'' (PHTS).[10] The presence of other genetic and/or epigenetic factors are highly likely to play a role in the determination of phenotype in these conditions.

Clinical Diagnostic Criteria for Cowden Syndrome

The International CS consortium has developed diagnostic criteria for this condition.[3,11] The criterion is less sensitive in children and young adults as findings appear generally in the third decade. Studies of patients who only partially meet these criteria, 'CS-like', or who have multiple primary cancers, have yielded very few germline *PTEN* mutations, thus providing indirect evidence of the usefulness of these criteria.[12,13]

DOI: 10.1081/E-EDGP 120027615

Clinical Management of Cowden Syndrome

Clinical management of a patient with CS requires comprehensive serial screening with regular follow-up for breast, endometrial, thyroid, renal, and gastrointestinal involvement. Early onset breast cancer is seen in women with CS, with one study reporting an average age of 43.2 years at the time of surgery.[14] Thus self-examination in early adulthood and annual mammography from age 30 years onward is suggested. Annual endometrial examination from age 35 years with suction biopsies and transvaginal ultrasound with biopsy of suspicious areas is recommended. Annual physical examination of the thyroid is recommended from age 18 years, and thyroid ultrasound may be conducted every 1–2 years. Annual urine analysis in adulthood to screen for hematuria secondary to renal cancer is suggested. Annual hemoglobin screening from childhood is reasonable to guard against anemia due to bleeding from gastrointestinal polyps. It is recommend that CS patients undergo a baseline colonoscopy at age 50 years, earlier if symptoms are present, in order to detect hamartomatous polyps [Refs. [5] and [11], and in GeneReviews, Pilarski, Hample, and Eng: *PTEN* Hamartoma-Tumor Syndrome (PHTS), http://www.geneclinics.org].

MOLECULAR DESCRIPTION

PTEN—The Gene and Protein

PTEN consists of nine exons and an open reading frame of 1209 nucleotides encoding a 403 amino acid dual-specificity phosphatase with homology to the cytoskeletal proteins tensin and auxillin. Exon 5 of *PTEN* encodes a classic phosphatase core motif (I/V)HC*XX*G*XX*R(S/T)G at residues 122–132. Three potential tyrosine phosphorylation sites at residues 240, 315, and 336, as well as two potential serine phosphorylation sites at residues 335 and 338, are located in the COOH-terminus. A PDZ binding domain, important for subcellular localization and/or substrate interactions, is encoded by the last four amino acids, ITKV (Fig. 1).

The major endogenous substrate of PTEN is a phospholipid second messenger in the phosphotidylinositol 3-kinase (PI3-K) pathway called phosphatidylinositol 3,4,5-trisphosphate [Ptd-Ins(3,4,5)P_3]. Growth factors such as insulin and epidermal growth factor stimulate PI3-kinase to phosphorylate phosphatidylinositol 4,5-*tris*-phosphate [Ptd-Ins(4,5)P_2] producing Ptd-Ins(3,4,5)P_3. Thus PTEN acts as a 3-phosphatase and antagonist to this process, dephosphorylating Ptd-Ins(3,4,5)P_3 to Ptd-Ins(4,5)P_2. In syndromes such as CS where *PTEN* is mutant, Ptd-Ins(3,4,5)P_3 accumulates, activating the cell survival (antiapoptotic) factor serine–threonine kinase AKT (protein kinase B, PKB). PTEN would therefore seem to act via an apoptotic mechanism, as well as being able to cause cell cycle arrest in cells in G1 phase, possibly via the retinoblastoma protein. PTEN is also likely to have a role in cell migration and invasion as it has been shown to reduce tyrosine phosphorylation of focal adhesion kinase (FAK) (reviewed in Ref. [6]).

PTEN has a processed pseudogene located on chromosome band 9p21 that lacks the initiating methionine, but has greater than 98% homology with the *PTEN* coding region.[15] Further, the 5′ untranslated region of *PTEN* contains multiple CpG islands that are potentially epigenetically regulated by methylation; however, care must also be taken in any methylation studies as the *PTEN* pseudogene also extends into this region.[16]

Identified *PTEN* Mutations

The Human Gene Mutation Database (http://archive.uwcm.ac.uk/uwcm/mg/hgmd0.html) has recorded greater than 110 different *PTEN* mutations. In addition to being mutated in the germline of patients with CS and BRR,

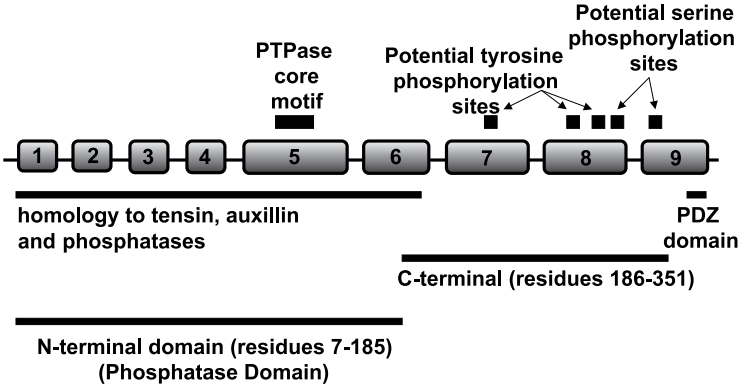

Fig. 1 Schematic of the functional domains encoded by *PTEN*.

constitutive *PTEN* mutation has also been identified in another overgrowth disorder, Proteus syndrome (PS, OMIM #176920). Further, *PTEN* has been described as ''. . .the most highly mutated tumor-suppressor gene in the post-p53 era. . .,''[17] being somatically mutated in a large number of sporadic tumors. Large-scale deletion of the entire *PTEN* gene and flanking region is rarely never reported in classic CS; however, large deletion is seen at a low frequency in both BRR and CS/BRR overlap families.[10,18] *PTEN* mutations have been found to cluster in exons 5, 7, and 8, with 40% of mutations being found in exon 5, which is the largest exon, constituting 20% of the *PTEN* coding region, but also contains the protein tyrosine phosphatase (PTPase) core motif. Recently, some patients with classic CS have been found to have heterozygous germline mutations in the *PTEN* promoter.[18] Some *PTEN* mutations have been shown to lead to loss of phosphatase activity against both protein and phospholipid substrates, whereas others, e.g., G129E, lose lipid phosphatase activity, while retaining phosphatase activity against nonphospholipid substrates.

Genotype–Phenotype Correlations in Cowden Syndrome

PTEN mutations have also been found in up to 60% of patients with BRR[10] and in some patients with hamartomas that carried the diagnosis of other conditions, namely, LDD,[19] PS or PS-like syndromes,[20] and VATER association Proteus.[21] Identical, as well as distinct, *PTEN* mutations have been found in all of these syndromes.

Preliminary genotype–phenotype correlations have been identified in CS. Firstly, in CS families (or CS/BRR overlap families), the presence of a *PTEN* mutation has been correlated with the presence of any cancer, lipomas, or breast fibroadenoma.[10] An association between the presence of a *PTEN* mutation and breast involvement, whether it be benign or malignant disease, has also been observed.[10] A study of a large number of CS families representing multiple ethnicities is required in order to confirm these findings.

Genetic Screening

Who should undergo genetic screening for Cowden syndrome?

Genetic counseling and predictive mutation testing should be offered to all at-risk members of a family with CS as part of their clinical management. As CS is an autosomal dominant condition, children of an affected parent have a 50% chance of inheriting a *PTEN* mutation. Cancer surveillance is indicated only for patients with a germline *PTEN* mutation.

Standard molecular techniques used for *PTEN* mutation scanning

Mutation scanning of genomic DNA using primers designed for intronic regions flanking *PTEN* exons has been employed for standard sequencing of *PTEN*, as well as denaturing gradient gel electrophoresis (DGGE), single-strand conformation polymorphism (SSCP), and denaturing high-performance liquid chromatography (DHPLC). One study achieved greater sensitivity of DHPLC for *PTEN* mutation detection by the addition of gc-clamps identical to those used for DGGE.[22]

Because of the presence of the highly homologous *PTEN* pseudogene, any studies conducted using *PTEN* cDNA should exclude amplification of the pseudogene by specific primer design. The recent finding of *PTEN* promoter variants suggests that the promoter region should be considered for analysis in classic CS cases where a *PTEN* mutation cannot be found in the coding, or immediately flanking, regions.[18]

CONCLUSION

Cowden syndrome is a multiorgan system disorder, requiring focused clinical surveillance and regular follow-up. Genetic screening to identify germline *PTEN* mutations is now available and can direct the clinical management of this condition, including family-planning decisions. A number of molecules in the PI3-K pathway in which PTEN functions are currently attracting attention as potential drug targets that may influence future therapies for patients with germline *PTEN* mutation, as well as those with sporadic cancers shown to have *PTEN* involvement.

Online information specifically for patients with CS is available (Burton S, Haidle JL, Hampel H and Eng C: Cowden syndrome. A guide for patients and their families, http://www.vh.org/pediatric/patient/cancercenter/cowden/). Additional detailed reviews recommended for further reading on this subject include Refs. [23,24].

Creutzfeldt–Jacob Disease M129V Polymorphism

C

Thomas R. Kreil

Friedrich Dorner
Baxter BioScience, Vienna, Austria

INTRODUCTION

The prion protein gene (*PRNP*) encodes the primary structure of a cellular protein, the prion protein (PrP). If present in a partially protease resistant isoform, caused by either mutations in the *PRNP* or an infectious process believed to involve template-directed misfolding of the PrP, the same protein can display the puzzling characteristics of a unique, presumably protein-only, infectious agent. Creutzfeldt–Jakob disease (CJD) and kuru are human transmissible spongiform encephalopathy diseases characterized by the deposition of this aberrant form of the PrP. Susceptibility to accumulation of the pathological isoform of the protein, initiated through either spontaneous or inherited *PRNP* mutation, or exposure to the infectious agent through iatrogenic or alimentary routes, as well as severity and course of disease development are influenced or even determined by the M129V polymorphism of the prion protein gene. For certain applications, it may be possible to exploit this observation for diagnostic purposes to enhance the safety of particular biological medicinal products, such as corneal grafts.

THE PRION PROTEIN GENE, *PRNP*

The human *PRNP* is located on the short arm of chromosome 20 and contains a short 5′ exon, followed by a large intron and then a 3′ exon, which encodes the entire 253 amino acids of the open reading frame of the precursor PrP.[1] Within the gene, three polymorphic regions—i.e., a single octapeptide deletion, M129V, and E219K—have been described, as well as a growing number of spontaneous or inherited mutations associated with the development of CJD.[2]

Investigations of sporadic CJD cases and people infected with CJD through the administration of human cadaveric pituitary gland hormones, such as growth hormone or gonadotropin, have revealed that the codon 129 M/V polymorphism influences susceptibility to disease as a consequence of both mutations within *PRNP*[3] and exposure to infectious material.[4] The major determinant of risk for iatrogenic and sporadic CJD seems to be homozygosity at codon 129.[5]

The same polymorphism can also determine the phenotype of disease as exemplified by the D178N PRNP mutation, which results in fatal familial insomnia (FFI) if M129 is present on the same allele, and in CJD if V129 is present on the same allele, with an additional correlation between codon 129 homozygosity and disease severity in both instances.

Variant CJD (vCJD), a new prion disease first recognized in 1996, is presumed to be caused by oral infection of humans with the bovine spongiform encephalopathy (BSE) agent. To date, approximately 140 cases have been diagnosed, principally in the United Kingdom, where the majority of BSE cases have occurred. All the cases investigated were codon 129 M/M homozygous, which indicates that either other genotypes are not susceptible, or their incubation periods are significantly longer. Experience with kuru, which—as far as we know—is the only other human prion disease acquired orally and was transmitted through ritualistic cannibalism among the Fore people of Papua New Guinea, supports the latter. In the later stages of the kuru epidemic, people carrying the most susceptible codon 129 M/M genotype had practically been depleted from the Fore survivors, and those who were heterozygous or carried the V/V genotype only developed the disease after extremely long incubation periods of 20 years or more.[6]

Determinations of the codon 129 genotype, as typically performed via oligonucleotide hybridization, or recently by a more simple and cost-effective polymerase chain reaction/restriction digestion assay,[7] have revealed approximately 50% heterozygosity, approximately 40% M/M homozygosity, and only 10% V/V homozygosity for healthy Caucasian populations.[7,4] In marked contrast, only around 8% of the Japanese population is heterozygous at codon 129.[8]

THE PRION PROTEIN, PRP

The primary translation product of *PRNP* contains signal peptides of 22 or 23 amino acids at the N- and C-termini,

DOI: 10.1081/E-EDGP 120020534

respectively, which are both removed during intracellular processing of the nascent PrP. The mature PrP 23–230 is membrane-anchored through a C-terminal glycosyl–phosphatidyl–inositol (GPI) anchor unit, and two asparagine glycosylation sites within the protein can give rise to three glycotypes (unglycosylated, monoglycosylated, and diglycosylated). Structurally, the protein features a fivefold repeat of eight amino acids each (octa-repeats) toward the N-terminus, and a globular domain that contains a short, two-stranded antiparallel beta sheet and three alpha helices in the C-terminal half.[9]

According to the protein-only hypothesis, the hallmark of the infectious process for acquired (iatrogenic or foodborne), sporadic, and inherited prion diseases is recruitment of the cellular PrP to form a self-replicating conformational PrP isomer, ultimately accumulating into aggregated deposits. As soon as this conversion is initiated, different prion strains replicate faithfully upon transmission into new hosts.

Because most available anti-PrP reagents recognize the normal and the abnormal isoform of the PrP, digestion with proteinase K is experimentally used to completely degrade the normal isoform. The same treatment results in a protease-resistant core with an apparent molecular mass of 27–30 kDa (PrP 27–30) for the pathological isoform.[10]

IATROGENIC TRANSMISSION OF CREUTZFELDT–JAKOB DISEASE

Over the last three decades, approximately 270 cases of iatrogenic CJD have been observed.[11] By far, the most frequently involved medical interventions were the surgical use of dura mater grafts (114 cases) and treatment with pituitary-derived human growth hormone (139 cases). In a few cases each, treatment with pituitary-derived gonadotropin, corneal transplantation, or the use of neurosurgical equipment such as stereotactic electrodes was implicated.

With the advent of vCJD, the presence of the pathological PrP and infectivity in lymphoreticular organs such as the tonsils and spleen,[12,13] which are in intimate contact with the circulation, generated concerns about the safety of blood products. Although the concentration of the pathological PrP is higher in the organs of vCJD patients than those with CJD, it needs to be emphasized that infectivity of these tissues is demonstrable in both diseases, and the relative levels have not been determined. For CJD, however, epidemiological data and case studies have provided strong evidence for the absence of any risk for the safety of blood products. For vCJD, neither the pathological PrP nor infectivity has been observed in human blood or plasma despite intensive research,[12,13] and accumulating clinical evidence argues that ''. . . the risk associated with vCJD and BSE is not yet demonstrably worse than the risk from non-vCJD forms of disease, which has been shown to be negligible.''[14] For plasma derivatives, in particular, their manufacturing processes have been shown to be capable of removing significant amounts of prion protein/infectivity in downscaled models,[15–17] should its presence ever be determined in plasma. Taken together, the vCJD risk for blood products can be considered very low as a worst-case scenario, and merely hypothetical for plasma derivatives.

DIAGNOSTIC POTENTIAL OF THE M129V POLYMORPHISM

Although all vCJD cases investigated so far have been found to be M/M homozygous at codon 129, the deferral of such potentially higher risk donors from blood or plasma donation is not feasible based on the already strained supply of these products and the large proportion of the population displaying this genotype. Also, any risk associated with the use of these products remains purely hypothetical at this point, and again there is mounting evidence against any risk being associated with their use.[14] However, for products carrying an identified level of risk and are needed in lower quantities, exclusion based on an identified genetic predisposition for disease development might be an option. Human growth hormone from cadaveric pituitary glands, a product that has historically led to many CJD transmissions, has already been replaced by recombinant versions of the product. Dura mater, another of the products implicated earlier,[11] is no longer in clinical use and has been widely replaced by synthetic fleece or collagen-based products. Corneal transplants have also transmitted CJD,[11] but are still being used because of their unique clinical characteristics. Selection of potential donors based on their PRNP codon 129 polymorphism to exclude homozygous donors who are at the relatively highest risk of developing CJD could add a margin of safety to the use of this product. However, despite the ample number of potential donors, cornea transplants have been in short supply. With the positive results of recent HLA matching studies and a consequent change in medical practice, the supply situation for HLA-matched corneas has been further strained.[18] Against an extremely rare event, losing half the supply of corneas by exclusion of homozygous donors to gain a slight margin

of safety might not seem appropriate. Alternatively, consideration could be given to more effective sourcing strategies, which might allow reassessment of this additional safety measure.

OUTLOOK FOR VCJD

Early estimates predicted that the vCJD epidemic could involve up to 100,000 cases,[19] but these predictions have been revised based on vCJD deaths to date to a maximum of about 500 cases.[20]

Statistical extrapolations from the monthly vCJD statistics for the United Kingdom indicate that the epidemic is already on the decline, at least for people with codon 129 M/M. If experience with the other orally acquired prion disease of humans, i.e., kuru, is predictive, any potential second wave of the vCJD epidemic in other genotypes would be smaller than the proportionate genotype distribution, because not only can the incubation periods be expected to be longer but the susceptibility to disease will be lower as well.[6] These additional cases in codon 129 heterozygous or V/V homozygous people can consequently be expected to occur in the older population corresponding to the longer incubation periods. Although it is not known whether the genotype of those who are affected later in the epidemic would alter the phenotype of vCJD, observations of kuru victims suggest that this will not be the case,[21] and thus the effective surveillance programs now in place would be expected to recognize any second wave of the vCJD epidemic.

CONCLUSION

Certain aspects of prion diseases remain puzzling, even after the Gajdusek 1976 and Prusiner 1997 Nobel Prizes. From a practical perspective, however, light has been shed on many important aspects, such as the diagnosis of disease and risk of transmission by medically important routes.

For growth hormone and gonadotropin, recombinant alternatives have been substituted for earlier versions from cadaveric pituitary glands. Dura mater grafts are no longer in clinical use, having mainly been replaced by synthetic tissues or collagen-based products. The BSE epidemic has been contained, and as a consequence of all the food protective measures, it now appears that the corresponding human disease, vCJD, is also on the decline. Regarding the initial vCJD concern in relation to blood products, available evidence converges to indicate a very low or even absent risk. This is even more apparent for plasma derivatives, which enjoy additional safety margins because of the fortuitous capacity of manufacturing processes to remove any theoretically present prion infectivity. The only identifiable—but very small—risk that remains is for corneal grafts, and genotyping to identify low-risk donors could become an option to enhance product safety as soon as an adequate supply of suitable organs has been established.

ACKNOWLEDGMENTS

We are grateful to Elise Langdon-Neuner for assistance in editing the manuscript, as well as Andrew C. Bailey, Ph.D., for many fruitful discussions.

Cryptosporidium parvum

Rebecca A. Guy
Paul A. Horgen
University of Toronto, Mississauga, Ontario, Canada

INTRODUCTION

Cryptosporidium parvum is a protozoan parasite that causes gastrointestinal disease. Infections in humans are usually acute and self-limiting, but can be life-threatening causing debilitating diarrheal disease with high morbidity and mortality rates in malnourished children in developing countries and in immunocompromised patients. *Cryptosporidium* was first documented in mice by Tyzzer in 1907. It was not until 1976 when the first human cases were recognized. Despite the recent recognition of this parasite as a human pathogen, *Cryptosporidium* has in fact a long historical association with humans as evidenced by its discovery in coprolites from ancient Andeans and Peruvians dating back 1000 to 3000 years. Two events helped to establish *Cryptosporidium* as a serious pathogen in humans: the increased diagnosis of *Cryptosporidium* in AIDS patients in the 1980s and the major waterborne outbreak in the city of Milwaukee (United States) in 1993. An estimated 403,000 individuals became infected with *Cryptosporidium* in the Milwaukee outbreak at a cost of $96.2 million in medical expenses and lost productivity. Sporadic waterborne outbreaks continue to occur globally, but on a smaller scale than the Milwaukee outbreak. A recent outbreak in North Battleford (Canada) in 2001 affected over 5000 individuals. Several factors including the ease of dissemination of *Cryptosporidium* and difficulties in monitoring in the environment led to its placement on the Center for Disease Control's B list of biological agents for use in bioterrorism.

The increase in cases and massive waterborne outbreak in Milwaukee spurred a rapid growth in research toward developing effective treatment regimes, methods of detection and inactivation of the parasite in the drinking water supply, genotyping, and understanding the interaction of *C. parvum* with its host. Research efforts have been hampered by the inability of the parasite to complete the entire life cycle in in vitro culture, and by the failure to cryopreserve these organisms or to genetically transform any of its stages. Advances in elucidating the genome will undoubtedly lead to new methods of detection, prevention of infection through novel inactivation strategies, successful drug therapy, and vaccine development.

BIOLOGY OF *C. PARVUM*

Classification

Cryptosporidium is a single-cell organism in the Phylum Apicomplexa. The taxonomy of *Cryptosporidium* is confused and is undergoing revision.[1] Recently, the species *C. parvum* was split in two based on the two major genotypes: *C. parvum* genotype 1 occurs almost exclusively in humans and has been named *Cryptosporidium hominis*;[2] *C. parvum* genotype 2, the bovine genotype, infects both humans and other animals. While *C. parvum* and *C. hominis* are the most commonly associated species of *Cryptosporidium* linked to human disease, several other species including *Cryptosporidium meleagridis*, *Cryptosporidium felis*, *Cryptosporidium canis*, and *Cryptosporidium muris* infect humans.[1] Recent information on protein and gene structure demonstrate that *Cryptosporidium* is more closely related to the early branching gregarines (such as *Monocystis* and *Gregarina* spp.) than to other members of the Apicomplexa such as *Toxoplasma* and *Plasmodium*, as was originally thought.[3]

Life Cycle

C. parvum has a complex, multistage life cycle, consisting of both asexual and sexual stages within one host.[4–6] The complete cycle is intracellular within epithelial cells. Infection is initiated through ingestion of the sporulated oocyst. Within the small intestine of the host, the oocyst ruptures releasing four sporozoites. Sporozoites rapidly penetrate the plasma membrane of epithelial cells lining the gut and undergo a series of cycles of asexual replication. The eventual production of sexual forms of the parasite leads to the development of sporulated oocysts. Two forms of oocysts are produced. Thick-walled oocysts are hardy, withstanding harsh environmental

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020838

factors until ingested by a new host. Thin-walled oocysts can rupture within the host, leading to autoinfection.[4,6]

Location in Host

Infection is most commonly localized in the lower small intestine; however, *Cryptosporidium* has been found throughout the digestive tract including the pharynx, esophagus, and stomach; in the uterus, urinary bladder, hepatobiliary, and pancreatic systems; as well as in the conjunctiva and upper and lower respiratory tracts. Biliary cryptosporidiosis is the most common extraintestinal manifestation of infection.[4]

CLINICAL DESCRIPTION OF INFECTION

Disease in human hosts greatly depends on the condition of the host, with more severe outcomes in immunocompromised and malnourished individuals.[4] Most patients present profuse watery diarrhea containing mucus, 7–10 days after acquisition of infection. In immunocompetent hosts, the disease is usually self-limiting with a median duration of 9–15 days. Acute diarrhea may be resolved in a few days or may persist for 4–7 weeks. Three major presentations of symptoms are observed: 1) asymptomatic carriage, 2) acute, usually watery diarrhea, and 3) chronic, persistent diarrhea for several weeks. Other symptoms include abdominal cramps, anorexia, nausea and vomiting, fatigue, low-grade fever, and cough. A different picture is seen in immunocompromised patients. Four clinical patterns of infection are observed in AIDS patients with chronic infection as the most common presentation: 1) asymptomatic, 2) transient infection with diarrhea cleared within 2 months, 3) chronic infection, diarrhea for 2 or more months, and 4) fulminant infection with patients passing 2 or more liters of watery stool daily.[4]

TRANSMISSION

The parasite is transmitted through the fecal/oral route by ingestion of oocysts from water, food, or direct person-to-person or animal-to-person contact.[1] Water is the main route of transmission, including drinking water, wells, surface and ground water, rivers, lakes, and swimming pools.[7] Seepage of effluents from humans and cattle into drinking water supplies are the major risk factors for humans. The oocyst wall is highly resistant to environmental stresses. Oocysts can persist for up to 6 months in water and for 2–3 months in soil. Conventional chlorine inactivation strategies used in water treatment utilities are inefficient against this pathogen. Greater success in disinfection is obtained with combined disinfection strategies, such as successive ozone and chlorine treatments[8] or ultraviolet light.[7]

PREVALENCE

C. parvum (*C. hominis*) is distributed worldwide. Prevalence rates in the human population range from 1% to 2% in developed countries and 6% to 60% in developing countries. *C. parvum* is a zoonotic disease, and numerous animals have been shown to carry infections.[9] The greatest potential for zoonotic transmission to humans is from cattle. Estimates of the frequencies of contamination of surface waters with *Cryptosporidium* are from 20% to 96% in North America. Their levels in surface waters are very low, ranging from 0.5 to 5000 organisms in 100 L water.[7] However, these low levels are still a risk for infection as it has been estimated that as few as 10 oocysts can establish infection.[9]

MANAGEMENT

No generalized therapeutic agents are available for treatment of *C. parvum* infection. Administration of oral or intravenous fluids and electrolyte replacement can be used as supportive care until the infection is resolved.

Chemotherapy

The slow advance in therapeutics is attributable to the lack of knowledge of the parasite and its isolated location within the apical membrane of the epithelial host cell, limiting drug access to the parasite.[5] Numerous drugs have been tested for therapeutic effects and none effectively eliminate the parasite. Until recently, paromomycin was the most widely used drug for treatment of *Cryptosporidium*. Nitazoxanide (Alinia) was the first drug to be approved by the Food and Drug Administration (FDA) for treatment against *Cryptosporidium* infection. Its use is currently limited to children between the ages of 1 and 11, with studies in progress to determine safety and efficacy in AIDS patients. Nitazoxanide is available in North and South American and is awaiting approval in Europe.

New genetic information and a better understanding of the intracellular parasite–host interaction will provide clues to novel targets for drug development. Some promising new areas of drug research, targeting biosynthetic pathways and proteins of *C. parvum*, include the shikimate pathway (for synthesis of aromatic compounds, amino acids, ubiquinone compounds, and folate), polyamine biosynthesis, fatty acid synthesis, antitubulin agents, and dihydrofolate reductase (DHFR) inhibitors.[5] In addition to development of new drug targets, the

growing information on the genome will speed testing of existing drugs with established limits of safety in humans. For example, anticancer drugs based on farnesyltransferase inhibitors (FTI), which disrupt protein prenylation, have action against protozoa. Screening of the *C. parvum* genome databases has revealed that this parasite contains protein prenyltransferases and may be a target for FTI inhibition.[10] Improved assays for testing the efficacy of drug action, such as real-time polymerase chain reaction (qPCR) for quantification of live parasites following drug treatment in vitro[11] will undoubtedly accelerate drug development.

Immunotherapy

Immune responses to infection are vital as evidenced by the fact that healthy, immunocompetent individuals resolve infection. An interesting correlation between administration of highly active antiretroviral therapy (HAART) and a decrease in cryptosporidiosis in AIDS patients has been observed. HAART does not directly affect the parasite but exerts its effects through enhancing the immune system of these patients. A picture is slowly emerging of the immune responses during infection. $CD4^+$ T cells play an important role as well as $CD8^+$ (α/β and γ/δ) intraepithelial T cells. Cytokines involved in clearance include INFγ, IL-12, and IL-15.[12,13]

Studies using in vitro and in vivo models demonstrate varying degrees of protection from infection upon administration of polyclonal or monoclonal antibodies that recognize parasite antigens. Targets for antigen selection have been based to a large part on antigenic molecules that are involved in adhesion and entry into the host cell including CSL, gp60/40/15, CP47, P43. Antibodies may also have application in treatment of persistent cryptosporidiosis.[13]

Pathology

Diarrhea during *Cryptosporidium* infection is associated with intestinal malabsorption and enhanced secretion. Infection can lead to blunting of intestinal villi, hyperplasia of crypt cells, and enterocyte brush border damage incurred during parasite invasion.[4] Diarrhea may be a result of increased secretion as a result of ion imbalance following responses to secreted cytokines such TNFα, INFγ, IL-8, and substance P.[12] The list of parasite molecules that may act as specific virulence factors during infection is growing[14] (Table 1). In contrast, protective host cell responses such as host cell-triggered apoptosis and secretion of TGF-β1 and IL-10 may limit epithelial cell damage.[4,12,14]

MOLECULAR CHARACTERIZATION

Genotypes

PCR/RFLP and DNA sequence analysis targeting numerous genes (small subunit ribosomal RNA, adjacent internal transcribed spacer 1, heat shock protein 70, dihydrofolate reductase, and β-tubulin) have been used to analyze variation between genotypes of *Cryptosporidium*.[1] At least eight genotypes of *C. parvum* have been identified.[3] Application of techniques such as microsatellite length polymorphisms, phage display, and strand conformation polymorphism analysis will be invaluable for detecting subtler differences in the population. This

Table 1 Potential virulence factors of *C. parvum*

Putative function	Putative virulence factor	Cellular location

will enable tracking of isolates during outbreak situations.[15]

Little is known about the infection characteristics of different species and genotypes in humans and no clear clinical symptoms have been defined for any of the genotypes. New studies in humans and animal models are starting to shed light on the infection characteristics of the different *C. parvum* and *C. hominis* genotypes.[1,15]

Genome

The *Cryptosporidium* genome is ~10.4 Mb, contained in eight chromosomes ranging in size from 0.9 to 1.54 Mb. The *C. parvum* genome contains ~5000 genes, very few introns, less than 1% repeat sequences, and is 68% and 65% AT-rich, for genotypes 1 and 2, respectively.[3,15] Two genome projects, close to completion, are sequencing the genomes from two commonly used isolates of *Cryptosporidium*: strain H representing the human genotype 1 (*C. hominis*) and the Iowa strain representing the bovine genotype 2 (*C. parvum*). A new database, CryptoDB (http://CryptoDB.org), contains the genome data and public sequences and is a very useful tool for obtaining genomic data for *Cryptosporidium*.[16]

Gene Expression Analysis

There is currently no system for transfection of *C. parvum* for gene analysis. A recent study analyzed expression of the *C. parvum* Cpgp40/15 invasion glycoprotein through transfection of the tachyzoite stage of a related Apicomplexan parasite, *Toxoplasma gondii*.[17] The first use of microarrays to analyze gene expression in epithelial cells infected with *C. parvum* demonstrated up-regulation and down-regulation of 236 genes out of a panel of 12,600. These included genes encoding heat-shock proteins, pro-inflammatory cytokines and chemokines, and structural genes, demonstrating considerable changes in host biochemical pathways.[18] In addition, a number of unknown genes were modulated, presenting new avenues of investigation.

MOLECULAR TESTING

Clinical Diagnosis

The gold standard for diagnosis of *C. parvum* is detection of oocysts in clinical samples using microscopy and indirect immunofluorescence (IF). Several enzyme immunoassay kits for detection of soluble stool antigens are available such as the Prospect T *Cryptosporidium* and Crypto CELISA. New and very rapid tests on the market are the ImmunoCard STAT! and ColorPAC solid-phase immunochromatographic immunoassays. Molecular techniques such as PCR are in development and provide a higher degree of sensitivity of detection than microscopy. One clinical trial demonstrated 83.7% sensitivity and 98.9% specificity using microscopy as compared to 100% sensitivity and specificity with PCR.[19] In another study,

Table 2 Molecular assays for detection of *C. parvum*

Assays[a]	Gene targets	Application
PCR	18s rRNA	Human and animal stool
	18s rRNA, oocyst wall	Surface waters
	COWP, Glutamate dehydrogenase	Sewage sludge
	18s rRNA	Soil/manure
	Oocyst wall	Milk, apple juice
PCR-RFLP	SSU rRNA	Shell fish
IMS-PCR	18s rRNA	River water, sewage
RT-PCR	HSP70	River, reservoir, tap water
qPCR	COWP, 18S rRNA, Cp11 rRNA,	Stool
	COWP, oocyst wall	Surface, tap and river water
	COWP	Raw sewage
CC-PCR	HSP70	Raw and filter backwash water
CC-qPCR	18s rRNA	Backwash water
CC-RT-PCR	HSP70	Surface and finished water
NASBA	HSP70	Surface water
FISH	rRNA	Laboratory water

[a]IMS = immunomagnetic separation; RFLP = restriction fragment length polymorphism; qPCR = quantitative or real-time PCR; CC = cell culture; RT = reverse transcription; NASBA = nucleic acid sequence binding assay; FISH = fluorescent in situ hybridization.

the sensitivity of PCR was shown to be comparable to an antigen enzyme immunoassay at 97%.[20]

Detection in the Environment

Intense research effort is ongoing to develop sensitive methods of detection of *C. parvum* (*C. hominis*) in environmental waters and raw and finished water in treatment facilities. Microscopy using IF is the standard used for detection of oocysts in the environment. However, numerous novel methods are being developed to provide rapid, sensitive, and automated detection. Some detection methods are antibody-based, e.g., flow cytometry, quantum dots immunofluorescent detection, and chemiluminescent immunoassays. Other methods are molecular-based[1] (Table 2). One major obstacle in monitoring water is the poor recovery of *Cryptosporidium* oocysts from the large volumes of water ($\geq$10 L) necessary for detection.[7] Another obstacle is that these complex samples contain numerous substances with potential to inhibit molecular-based assays and inhibitors vary with different sample types.[21] Appropriate adaptation of the DNA extraction method allows sensitive quantification of pathogens using assays such as qPCR in complex samples, e.g., raw sewage.[21] New technologies in development, such as electrorotation[22] for detection of live cells and DNA hybridization biosensors,[23] have the potential for extremely rapid screening of low numbers of *C. parvum* and may be the future in detection systems.

CONCLUSION

Considerable progress has been made in understanding *C. parvum* (*C. hominis*) since it was recognized as a serious pathogen of humans. Major technological advances have helped our understanding of this enigmatic pathogen and will undoubtedly continue to provide new insights in our understanding of the biology of this important parasite of humans and animals. With continued research, the complete in vitro culture systems, transfection systems, and cryopreservation methods will be developed, which will further enhance our understanding of *Cryptosporidium* and cryptosporidiosis.

INTRODUCTION

Pharmacogenetics studies the influence of heredity on the interindividual differences in pharmacological response. In detail, it can be divided into two subgroups: pharmacodynamics and pharmacokinetics. Pharmacodynamics investigates the mechanism of action of the administered drug and its consequences on the body, namely, for example, the structure of receptors or carrier proteins. In contrast, pharmacokinetics analyzes the effect of the body on a drug reflecting, for example, its absorption, transformation, and excretion. The studied proteins are most often drug-metabolizing enzymes such as oxidative enzymes. A major role in drug metabolism is played by the cytochrome P450 (CYP) enzymes, which can be subdivided into several families, e.g., CYP1A2, 3A4, 2C9, 2C19, and 2D6. These enzymes are responsible for the oxidative metabolism of the majority of all therapeutically applied drugs.

In the following, we focus on cytochrome P450 2D6 (CYP2D6) and cytochrome P450 1A2 (CYP1A2).

CYTOCHROME P450 2D6

The CYP2D6 gene is a very polymorphic gene with more than 70 alleles described today.[1,2] This diversity leads to a great variety of activity of the enzyme debrisoquine 4-hydroxylase, which is encoded by the CYP2D6 gene. Many popular drugs such as antidepressants, neuroleptics, or cardioactive drugs, e.g., amitriptyline, paroxetine, haloperidol, metoprolol, etc.,[3] are substrates of CYP2D6. This may lead to adverse drug effects or therapy resistance. Subjects with normal enzymatic activity are called extensive metabolizers (EM). Subjects with increased activity are termed ultraextensive and ultrarapid metabolizers (UM), respectively, and have a prevalence of 1–10% in a Caucasian population.[4] They often do not reach therapeutic drug concentrations and suffer from therapeutic failure. Individuals with low or absent activity run the risk of potentially increased drug concentrations and adverse drug reactions. They are named poor metabolizers (PM) and can be found in approximately 7% of Caucasians.[5] This last group has to be distinguished from subjects with impaired but residual function, called intermediate metabolizers (IM). Substantial ethnic differences are observed regarding the frequency of the different phenotypes.[6]

The high number of polymorphisms with functional consequences results in complex and time-consuming genotyping procedures requiring extensive manpower and making it difficult to employ these methods in a time-critical clinical setting.

Real-time PCR offers substantial benefits in that regard. It is much faster than conventional PCR with subsequent restriction enzyme digestion and gel electrophoresis. Further advantages are lower risk of DNA contamination, facilitated handling, automated data processing, and the lack of toxic reagents such as ethidium bromide.

In different ethnic populations, it is possible to restrict testing to a limited set of alleles without sacrificing appreciable sensitivity of the assay (for details of the different alleles, see Table 1).

In a Caucasian population, six alleles, in detail *3, *4, *5, *6, *7, and *8, cause up to 99% of all PMs.[7] Up to 50–60% of all IMs can be predicted by the additional detection of the −1584 C/G polymorphism of the promoter, which encodes for the *2 and *41 alleles.[8] Duplicated or multiplicated functional CYP2D6 genes account for 10–30% of all UMs.[9] Other UMs may be explained by the *35 allele,[10] but this has been questioned by an in vitro analysis.[11] Taken together, genotyping of less than 10 polymorphisms of the CYP2D6 gene is sufficient to classify the vast majority of subjects in a Caucasian population.

Combining a fast method and a choice of polymorphisms, a comprehensive analysis can be carried out in one working day with a hands-on time of 3–4 hr,[12] employing a long PCR of the CYP2D6 gene on the LightCycler™ as a preamplification step. A preamplification step is necessary to detect both deletion and duplication as well as to avoid confusion from the two pseudogenes CYP2D7 and CYP2D8.[13] Furthermore, the same study reported the detection of *2, *35, and *41 alleles by hybridization probes and melting curve analysis

Table 1 CYP2D6: Alleles, nucleotide changes, and enzyme activity

Allele	Nucleotide changes	Enzyme activity
CYP2D6*1	None	Normal: wild type
CYP2D6*2	−1584C>G	Normal
CYP2D6*2XN	Multiplication	Increased
CYP2D6*3	2549A>del	None
CYP2D6*4	1846G>A	None
CYP2D6*5	Deletion	None
CYP2D6*6	1707T>del	None
CYP2D6*7	2935A>C	None
CYP2D6*8	1758G>T	None
CYP2D6*35	31G>A	Normal
CYP2D6*41	−1584C	Decreased

Source: Ref. [2].

as well as a real-time PCR for detecting the *5 null allele and duplication either by hybridization probes or by SYBR Green®.[12] The null alleles *3, *4, *6, *7, and *8 were investigated by a conventional multiplex PCR[14] but can also be carried out by real-time PCR. This again improves speed and is performed by use of two primer pairs and five different pairs of hybridization probes and subsequent fluorometric melting point analysis.[15] Two separate real-time PCR reactions were performed in parallel: mutations *3 and *7 were analyzed in one capillary with two hybridization probes, one labeled with LightCycler-Red 640 and the other with LightCycler-Red 705. In a second capillary, mutations *4, *6, and *8 were investigated by dual-color hybridization with LightCycler-Red 640 or 705. In addition, the LightCycler-Red-640-labeled probes of alleles *4 and *6 had different melting points.[15]

Another possibility to verify a deletion, a duplication and, in addition, a multiplication with the definite number of alleles is a quantitative PCR. Newly, a TaqMan real-time PCR was validated for the determination of the accurate gene copy number of CYP2D6.[16] Quantitative amplification data were normalized to albumin as a reference gene with FAM-labeled and VIC-labeled probes in a single-tube assay.[16] (For further information of the used probes, please see Table 2.)

CYTOCHROME P450 1A2

The CYP1A2 gene is not as polymorphic as the CYP2D6 gene. Twenty-five alleles have been described at present.[2] It metabolizes psychoactive drugs such as antidepressants (e.g., amitriptyline, imipramine) and neuroleptics (e.g., clozapine) with variable activity[3] which may lead to treatment resistance. In addition, it may play a role in carcinogenesis. Its expression is inducible by different environmental and dietary substances, such as tobacco smoking, as well as by several polymorphisms. Especially one polymorphism, a C to A transversion of base pair 734 in the noncoding intron 1, called *1F, is discussed to affect the inducibility of the CYP1A2 gene.[17,18]

Table 3 Sequences of the probes used for real-time PCR of CYP1A2

Detected allele	Sequence of probe 5′–3′	Reference
*1F	GGGCCCAGGACGCAT-Flu LCRed640-GTAGATGGAGCTTAGTCTTTCTGGTATCCA-Ph	[20]

Phenotyping using caffeine showed no difference in CYP1A2*1F metabolic activity between different genotypes in nonsmokers but a significant difference in smokers homozygous for the A allele compared with the other genotypes in terms of a 1.6-fold increased activity.[17] Unexpectedly, another study demonstrated a lower in vivo activity in patients with colorectal cancer than in healthy controls.[19]

The frequency of the *1F allele seems to be higher in Caucasians compared with Japanese. The study which investigated this new polymorphism analyzed 159 healthy Japanese and detected a prevalence of 39% homozygous and 44.6% heterozygous subjects.[18] In contrast, another study examined 236 Caucasians and found 46% homozygous A/A alleles and 44% heterozygous A/C alleles.[17]

In routine genotyping of CYP1A2, only *1F and a second allele, *1D, the deletion of T at position −2464, need to be analyzed because all other CYP1A2 polymorphisms are in linkage disequilibrium with these two alleles.[19]

At present, only one study has described real-time PCR methodology for the detection of CYP1A2*1F. This was performed employing the LightCycler™ instrument and fluorescent hybridization probes and melting curve analysis.[20] (For detailed information of the probes, see Table 3.)

CONCLUSION

The genetics of drug-metabolizing enzymes such as CYP2D6 and CYP1A2 is one major reason for the interindividual variability in drug therapy. Further investigations and large studies are required to elucidate the exact role of the polymorphisms of Cyp1A2*1F and Cyp2D6 in predicting therapeutic drug concentrations and clinical outcome, e.g., therapeutic response and adverse drug effects. Real-time PCR is one option to analyze the patients' genotype in a simple, fast, and reliable way. New functional relevant alleles will probably be found in the future, which can be easily and fast adapted for by this technique at limited cost. Screening prior to therapy is facilitated in a routine clinical setting. Once all major polymorphisms with functional relevance are characterized, microarray assays and gene chips will, in the future, probably offer even faster genotyping at lower cost.

Cystic Fibrosis—Mutation Detection by Microarrays

INTRODUCTION

As the most common lethal recessive genetic disease in Caucasians, cystic fibrosis (CF) has assumed a preeminent place in the test menus of molecular diagnostic laboratories. While utilized for diagnosis and prenatal diagnosis since shortly after the causative gene was identified in 1989, total test volume has increased dramatically since the advent of recommendations for general population carrier screening in Europe and North America. However, CF mutation testing remains a formidable technical and genetic counseling challenge owing to the large size of the gene, the large number and variety of reported mutations, the clinical variability of the phenotype, and the uncertainty of genotype–phenotype correlations. With over 1000 mutations currently catalogued, meaningful molecular genetic screening could only proceed with the development of array-based and related technologies. This article will describe the major technologies of this type in current use for CF mutation testing and how they are applied to a genetic disease of such remarkable clinical and molecular heterogeneity.

CLINICAL DESCRIPTION

Cystic fibrosis is often considered the most common serious autosomal recessive disease in Caucasians of northern European ancestry. It is a multiorgan condition, characterized by abnormally viscous secretions from epithelial cells in various tissues, leading to duct obstruction and infections. The most prominent and potentially lethal site for these phenomena is the lung, but CF patients also may suffer from pancreatic exocrine insufficiency, intestinal obstruction (called meconium ileus in the perinatal period), diabetes, biliary cirrhosis, growth retardation and failure to thrive, dehydration because of excessive salt loss in sweat, and sinusitis. In addition, virtually all males with classical CF exhibit a congenital malformation, bilateral absence of the vas deferens (CBAVD), causing infertility.

GENOTYPE–PHENOTYPE CORRELATION

Identification of the CF gene, designated *CFTR* for ''cystic fibrosis transmembrane conductance regulator,'' occurred in 1989.[1,2] It encodes a membrane-embedded ion-channel protein responsible for transport of sodium and chloride. The gene is 230 kbp long, encompassing 27 exons that produce an mRNA of 6500 nucleotides.

Gene sequencing in an initial series of affected patients revealed a recurring deletion, a three-nucleotide mutation of codon 508, which specifies phenylalanine in the protein product.[2] This mutation, now designated ΔF508, has come to be known as the most prevalent (approximately 70% of Caucasian carriers) and ''classical'' CF mutation. It is generally associated with severe disease, including pancreatic insufficiency, although this is not always the case. Since that original discovery, we have come to appreciate the remarkable molecular heterogeneity of CF, perhaps the most dramatic of any Mendelian disorder under study. There are now over 1000 mutations documented in the *CFTR* gene (www.genet.sickkids.on.ca/*CFTR*), and the range of clinical manifestations can be quite wide. Unfortunately, attempts to predict disease severity based on genotype have been frustratingly inconsistent, making genetic counseling for couples at risk rather difficult. Although some mutations are less likely to cause pancreatic insufficiency,[3] there are exceptions to all of the rules. Even the classic ΔF508 mutation may not always produce severe lung disease, even in the homozygous state.[4]

PREVALENCE

Cystic fibrosis is a relatively common recessive disorder in Caucasian populations, having a carrier frequency of about 1 in 29 and a birth incidence of 1 in 2500. Carrier rates in the other major ethnic groups of the United States have been estimated at 1 in 46 for Hispanic Americans, 1 in 65 for African Americans, and 1 in 90 for Asian Americans.[5] As noted, the predominant mutation in

DOI: 10.1081/E-EDGP 120020572

Caucasian carriers is ΔF508, but most of the other >1000 mutations are extremely rare or even ''private'' (found only in a single family). Perhaps the most accessible population for general carrier screening are Ashkenazi Jews, in whom the high prevalence of the W1282X mutation (45% of carriers) and three others in addition to ΔF508 yields a high screening sensitivity of 97%.[6] At the other end of the spectrum are Asians (and Asian Americans), in whom the disease frequency is low and the mutations are rare and/or not characterized, leading to some controversy over whether these populations should be screened.

DIFFERENTIAL DIAGNOSIS

The characteristic pulmonary and gastrointestinal presentations of CF in its classic form usually allow for accurate diagnosis even in the absence of DNA testing. However, there are atypical and less severe presentations that may mimic other causes of failure to thrive in early childhood, various malabsorption syndromes, and immune deficiencies. Diagnosis can be confirmed by the observation of elevated levels of chloride or sodium in sweat (>60 mEq/L), although sample collection may be difficult in very young infants. Molecular testing is useful to further confirm the biologic basis of the disease, to accurately diagnose individuals with borderline sweat chloride levels, and to provide the family with a precise mutation genotype that can then be used for prenatal diagnosis in future pregnancies.

MANAGEMENT

Whereas in prior decades CF typically resulted in early childhood or adolescent death from end-stage pulmonary disease, aggressive antibiotic therapy with modern agents, supplemented with medical and physical therapies to clear the viscous bronchial secretions, has led to a steady increase in life expectancy, currently extending into the mid- to late 30s (although some patients still die early of meconium ileus or intractable pulmonary infections). More heroic measures, such as lung or heart–lung transplantation, have also become available, and there is great hope for the future (although scant success to date) for gene-replacement therapy.

Because there is still no cure and the disease has a high morbidity, significant mortality, and economic burden, a major thrust of management efforts has been toward prevention. This takes the form of carrier screening to identify couples at risk, followed by prenatal diagnosis for those who wish to avoid the birth or recurrence of an affected child.

GENETIC COUNSELING

As a true recessive trait, *CFTR* mutations in heterozygosity are silent and asymptomatic, and because even their sweat chlorides are entirely normal, CF carriers are unidentifiable unless they have produced an affected child or have undergone mutation testing. Obviously, anyone of reproductive age who has a positive family history of the disease is considered a candidate for carrier testing. But because most CF carriers have negative family histories and only find out they are carriers after the birth of their first affected child, screening of the entire reproductive population has long been discussed as a preventative, public health measure.[7] This is justified because of the high carrier frequency in the general populations of North America and northern Europe. Under current recommendations,[5] couples who are pregnant or contemplating pregnancy are offered DNA-based carrier screening with a standard panel of the 25 most prevalent *CFTR* mutations. If both members are found to be carriers of identifiable *CFTR* mutations, they are referred for genetic counseling to inform them of their 25% risk of producing an affected child and to discuss the options for pregnancy termination. Naturally, such discussions are conducted in a nondirective and noncoercive manner, with full disclosure about the variability of CF symptoms and the uncertain genotype–phenotype correlations.

Couples with a positive family history should ideally first seek mutation testing of the affected index case. If one or both *CFTR* mutations are not detected with the core 25-mutation panel, the case may be referred for extended panel testing or even complete *CFTR* gene sequencing.

MOLECULAR GENETICS

The technical challenge of CF mutation detection derives from the large size of the gene, the myriad possible mutations, and the lack of any mutational ''hotspots'' in the gene, which could be used to limit the necessary targets for analysis. The core panel of 25 mutations designated for population screening in the United States was chosen on the basis of their prevalence (>0.1%) among a large cohort of genotyped affecteds, rather than their convenient location within the gene (on the contrary, they are spread throughout its length).

As more patients and mutations have been studied, the range and complexity of the molecular genetics have continued to grow. For example, some male individuals with *CFTR* mutations may present only with CBAVD and no classical CF symptoms, being ascertained during workups for infertility. Furthermore, one of the more common mutations, R117H, may be associated with either CF or CBAVD, depending on which form of an intronic

repeat polymorphism it is coupled with. When R117H is on the same chromosome (in *cis*) with a run of 5 thymidines (5T) in intron 8 of the gene, it behaves as a CF mutation (albeit usually mild); when in *cis* with the 7T allele it becomes a CBAVD mutation.

An analogous situation has emerged for one of the other mutations in the core panel, I148T, but not until after widespread screening had commenced. Reports from large testing laboratories[8,9] indicated that this mutation was seen in carriers at almost 100 times the expected frequency based on its appearance in affected patients. Rohlfs et al.[8] identified a genetic modifier, a deletion of 6 base pairs, 3199del6, which was an obligate covariant for I148T to behave as a disease-causing allele. In retrospect, these findings are not surprising, as the clinical variability of CF patients with the same primary mutations must be due to the presence of genetic modifiers, both within the *CFTR* gene and elsewhere in the genome, of which we still know all too little.

MOLECULAR GENETIC TESTING

Given the ever-growing list of *CFTR* defects, molecular genetic testing has evolved from relatively simple assays directed only at the predominant ΔF508 mutation[10] to increasingly complex multiplex mutation detection systems. Not all of these are on micro- or miniarray platforms, although the first practical assays for detecting more than a few mutations at a time utilized allele-specific DNA probes bound to solid supports in the form of nylon strips or membranes.[11,12] Originally all such assays were in-house-developed tests (''home brews''), but as the commercial potential of CF testing has exploded with the advent of nationwide population carrier screening,[5] several vendors have come forward with manufactured systems.

The systems available and in use at this time include reverse dot blots (Inno-LiPA CFTR33 Probe Array, Innogenetics; Linear Array CF Gold 1.0, Roche), amplification refractory mutation detection system (ARMS; Elucigene CF29, Orchid), and the oligonucleotide ligation assay (OLA; CF V3.0, Abbott/Celera). More recent additions to the *CFTR* testing arena include the invader assay (Third Wave Technologies) and various microarray platforms (e.g., Nanochip CFTR, Nanogen). Other emerging technologies include matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry (Sequenom) and real-time PCR (LightTyper, Roche). In addition, a handful of research and clinical laboratories offer complete sequencing of the *CFTR* gene, which can be used to identify rare mutations and polymorphisms and resolve ambiguities not defined by the allele-specific methods.[13] Several of the more popular (and more established) technologies are described in the American College of Medical Genetics (ACMG) *Standards and Guidelines for Clinical Genetics Laboratories*.[14] While these systems include both array-based and nonarray technologies, the remainder of our discussion here will focus on the array-based platforms that are now commercially available.

Reverse Dot Blot

Reverse dot blots entail a hybridization-based technology in which the oligonucleotide probes complementary to the normal and mutant sequences are attached to a membrane in a miniarray format. Patient DNA is subjected to one or more multiplex PCR reactions using biotin-tagged primers for all exons containing mutations of interest, and the resulting biotinylated PCR products (the target) are hybridized to the array (the probes). Both mutant and wild-type alleles are interrogated simultaneously. A streptavidin–peroxidase conjugate complex, which binds to the biotinylated PCR product hybridized to the arrayed oligonucleotide probe, is used to visualize the test results.[12] Current commercially available versions of this technology (Roche, Innogenetics) incorporate the 25 mutations and variants (5T/7T/9T) recommended for population screening. The reverse blot platform has numerous advantages including direct genotyping, nonisotopic detection, and the potential for automation.

Microarray

The true microarray formats are basically sophisticated ASO dot blots on a smaller scale within an electronically controlled hybridization instrument. The current NanoChip from Nanogen consists of 33 mutations, including the ACMG-recommended panel. Each NanoChip consists of 99 test sites (electrodes) attached to platinum wire connections. The negatively charged DNA is electronically guided to a test site where biotinylated samples bind to streptavidin in the site. Following denaturation, fluorescent probes are hybridized to the array and signal is detected after stringent washing procedures. Advantages of this technology include the flexibility of reflex testing, the adaptability of chip design to customization and addition/deletion of mutations in the panel, and the self-contained nature of the constituents. Other manufactured microarrays for *CFTR* mutations in slightly earlier stages of development include those from Motorola Life Sciences, BioArray Solutions, GeneOhm, and Autogenomics. Depending on the density of the array on the manufactured chip, theoretically there would be no limit to the number of *CFTR* mutations that could be addressed, going well beyond the current recommended panel of 25. Indeed, by using an ultra-high-density array of the type

manufactured by Affimetrix, one could theoretically detect all possible mutations and polymorphisms in the *CFTR* gene, both known and unknown. However, the clinical utility of such high-density arrays would need to be examined carefully, because most of the additional mutations will be extremely rare and not well characterized as to their clinical expression. Still, the mutational heterogeneity of the *CFTR* gene and the demand for high-throughput population screening make microarrays an obvious choice of assay platform, even more so in the future than at present.

CONCLUSION

It would probably be fair to say that mutation detection in the *CFTR* gene has been simultaneously one of the greatest successes and one of the greatest disappointments of the molecular genetic testing era. It is perhaps unfortunate, but endlessly instructive, that the first genetic disease targeted for widespread population screening by molecular methods has proven to be so complex at both the genotypic and phenotypic levels. For these reasons, molecular diagnostic laboratories and genetic counselors are still struggling to meet the challenge of delivering and explaining this complex test to large populations of generally healthy people who are not personally familiar with the disorder. Such widespread screening would not even be conceivable without the availability of user-friendly DNA array technologies, and the perceived market afforded by large-population screening has induced manufacturers to develop and market such products as analyte-specific reagents. These products are well adapted to screening for a limited number of *CFTR* mutations (e.g., the standard screening panel of 25 in the United States), but it is clear that a new generation of array techniques will be required if the screening panels are to be expanded appreciably. A number of manufacturers are working on such products, although even if technically robust, expanded mutation panels bring with them yet another level of clinical complexity and genetic counseling challenges. In this way, the CF testing situation provides a foretaste of what we may expect as we embark on molecular genetic screening for even more complex diseases in the future.

Cytochrome P450 Enzyme Genotyping—Clinical Applications

C

Magnus Ingelman-Sundberg
Karolinska Institutet, Stockholm, Sweden

INTRODUCTION

Interindividual variability in drug metabolism and drug response is extensive. The causes for this are of genetic, physiological, pathophysiological, and environmental origin. Genetic variability is known for drug absorption, drug metabolism, and drug interactions with the receptors. Pharmacogenetics is defined as the genetics behind interindividual differences in drug response and includes studies of variants of genes encoding drug transporters, drug-metabolizing enzymes, and drug receptors. The aim is to understand the genetic factors of importance that explain no drug response in a large part of the population and the occurrence of adverse drug reactions. Today, we have most knowledge about the importance of the drug-metabolizing enzymes in this respect, whereas the research is progressing to yield a better understanding about to what extent genetic variability in drug transporters and drug receptors can explain adverse drug reactions and lack of drug response.

PHARMACOGENETICS OF DRUG-METABOLIZING ENZYMES

Polymorphism of genes encoding drug-metabolizing enzymes is the major known genetic cause for the interindividual variability in drug response.[1–6] Based on the occurrence of mutations in these genes, gene deletions, and gene duplications, the populations can be divided into poor (PM), intermediate (IM), efficient (EM), or ultrarapid (UM) drug metabolizers. The PMs lack the enzyme in question, the IMs are heterozygous for a defect gene, the EMs have two functional alleles, whereas the UMs have multiple functional gene copies on a single allele.[2]

All enzymes participating in the metabolism of drugs in phase I (functionalization) and phase II, where the modified drugs are conjugated to water-soluble end products usually excreted in the urine, are polymorphic. This genetic polymorphism can thus cause abolished, quantitatively or qualitatively altered or enhanced drug metabolism. The evolutionary basis for this variability is adaptation to the environment in the form of dietary habits and genetic drift, the founder effect. Because the genes usually are not essential for survival but of importance for detoxification of environmental constituents including dietary components, no selection pressure is put on the conservation of functionally active genes; subjects lacking one or several types of these genes usually have a normal physiological phenotype. The major part of the interethnic differences in the genetic constitution of these genes is a result of incidental mutations in the genes, amplified in certain areas because of population expansion. The lack of endogenous function of the gene products has thus allowed this extensive heterogeneity with respect to allelic distributions in different parts of the world.

The major influence of interindividual variability of drug metabolism is caused by polymorphism in the cytochrome P450 (*CYP*) genes. These enzymes are responsible for about 75–80% of the phase I-dependent drug metabolism,[1] and this variation often influences the clearance of drugs to a great extent.

CYTOCHROMES P450

The cytochrome P450 enzymes participate in the metabolism of a huge number of xenobiotic chemicals. The polymorphic forms of P450s are many times responsible for the development of adverse drug reactions. It has been described that 56% of drugs which are cited in adverse drug reaction (ADR) studies are metabolized by polymorphic phase I enzymes of which 86% are P450s. One estimates that: 1) ADRs cost the U.S. society about $100 billion; 2) they cause more than 100,000 deaths annually in the United States; and 3) up to 7% of all hospital admissions are due to ADRs (see Ref. [2] for references). In addition, the costs for treating patients with polymorphic forms of P450s are much higher than for those carrying nonpolymorphic alleles.

POLYMORPHISM OF THE P450 GENES

Today, we know about 57 active cytochrome P450 genes (http://drnelson.utmem.edu/CytochromeP450.html, Ref. [7]). All P450 genes in families 1–3 are polymorphic. The functional importance of the variant alleles is, however, different and the frequencies of their distribution in different ethnic groups are tremendously different. On the Human CYPallele Nomenclature Web site at our server

DOI: 10.1081/E-EDGP 120020981

at Karolinska Institutet (http://www.imm.ki.se/cypalleles), updated information in this area is obtained. About 40% of P450-mediated drug metabolism is carried out by polymorphic enzymes. The rate of hepatic metabolism of a certain drug can differ 1000-fold between the phenotypes. Particularly high penetrance of the genetic polymorphism is seen because of variation in the *CYP2C9*, *CYP2C19*, and *CYP2D6* genes. CYP2D6 is responsible for the metabolism of about 25% of the clinically used drugs, and the polymorphism is relevant for interindividual variability in about 50% of these drugs, i.e., of about 10–15% of all drugs used today (cf. Ref. [8]). Required dosing to achieve the same plasma levels of a drug mainly metabolized by CYP2D6 can differ 10–20-fold between individuals. In Europe, 5.5% of the population are UMs for CYP2D6, and here, no response is often to be expected because of too rapid metabolism. Seven percent of the European population are PMs, where too high plasma levels of the drugs are to be expected at ordinary dosage and a higher frequency of adverse drug reactions is seen. In contrast to the extensive span in metabolic capacity, dosing today is, however, principally only based on the average in the population. By predictive genotyping, a more appropriate initial dosing could be achieved in 50–60 million people only within Western Europe.

About 50% of all drug metabolism in phase I is carried out by CYP3A4. This enzyme is highly conserved and no functionally important variant forms are seen in Caucasians or Orientals. There is a relatively high interindividual variability in CYP3A4 activity, but any genetic origin has to be addressed in future studies.

CLINICAL RELEVANCE OF CYTOCHROME P450 POLYMORPHISM

It is the author's estimate that 15–20% of all drug treatment is influenced by the polymorphism of the cytochrome P450 genes. The clinical importance of the polymorphism of the CYPs is summarized in Tables 1 and 2.

PSYCHIATRIC DISORDERS

Upon treatment with antipsychotic drugs, adverse reactions are more likely to be seen in PMs for CYP2D6. In addition, the costs for treatment of patients are higher and estimates have been made that costs $4000–6000 more per year to treat patients of the variant UM and PM phenotypes.[9] Parkinsonism-like side effects are

Table 1 Relative importance of polymorphisms in human P450s involved in drug metabolism

Enzyme	Estimated fraction of drug metabolism[a] (%)	Substrates	Major allelic variants[b]	Clinical effects of the polymorphism	Significance of polymorphism[c]
CYP1A2	5	Drugs, carcinogens	*CYP1A2*1K*	Less expression and inducibility	+
CYP2A6	2	Nicotine, drugs, carcinogens	*CYP2A6*4* *CYP2A6*9*	Altered nicotine metabolism	+
CYP2B6	2–4	Drugs		Relatively high	+
CYP2C8	1	Drugs	*CYP2C8*3*	Taxol metabolism	+
CYP2C9	10	Drugs	*CYP2C9*2* *CYP2C9*3*	Side effects Drug dosage	+++

Table 2 Examples of clinical impact of cytochrome P450 pharmacogenetics

Disease	Enzyme	Percentage of dose		Examples
		UMs	PMs	
Depression	CYP2C9			Bipolar disorders and valproate
	CYP2C19		40	PMs and SSRIs
	CYP2D6	200	30	Nonresponders (UMs) and side effects of tricyclics (PMs)
Psychosis	CYP2D6	160	30	Haloperidol and parkinsonian side effects
				Oversedation and perphenazine, thioridazine
Ulcer	CYP2C19		20	Dosing of PPIs
				pH and gastrin changes
Cancer	CYP2B6			Cyclophosphamide metabolism
	CYP2D6	250	60	Nonresponse of antiemetic drugs (UMs)
CV	CYP2C9		30	Warfarin dosing (acenocoumarol)
				Irbesartan and blood pressure response
	CYP2D6	160	30	Perhexiline neuropathy and hepatotoxicity
Pain	CYP2D6			Codeine no response (PMs)
Epilepsia	CYP2C9			Phenytoin pharmacokinetics and side effects

The doses shown for depression and psychosis are weighted as related to the size of samples in all studies published, as reviewed by Kirchheiner et al.[8] The other doses are based on data presented in the text and from Ref. [2]. PPIs: protein pump inhibitors.
Source: Ref. [2].

significantly seen at higher frequency in PMs according to several prospective and retrospective studies.[2] Oversedation is often seen in PMs after treatment with perphenazine, thioridazine, and other antipsychotics, whereas no significant relationship with CYP2D6 polymorphism has been described for tardive dyskinesia, acute dystonia, or akathisia.[10]

Regarding antidepressants, the tricyclic ones are almost entirely metabolized by CYP2D6 and dosage much related to the CYP2D6 phenotype, whereas several of the SSRIs are metabolized by the polymorphic CYP2C19. The kinetics of nortriptyline is much dependent on the number of active *CYP2D6* genes, and the appropriate dosage to receive a therapeutic plasma level varies from 30 and 50 mg in PMs to 500 mg in UMs. One pilot study indicates that the UM phenotype is 10-fold more common in nonresponders of antidepressant therapy than among responders.[11] Treatment with the SSRI drug sertraline, a CYP2C19 substrate, has been found to display adverse drug reactions such as nausea and dizziness, an effect possibly caused by toxic concentrations of the accumulated drug in CYP2C19 PMs, and the pharmacokinetics of citalopram are influenced by the CYP2C19 polymorphism. In addition, the metabolism of valproate, commonly used in bipolar disorders, has been found to be much influenced by the CYP2C9 polymorphism. With respect to both depression and psychosis, Kirchheiner et al.[8] have performed an impressive investigation and concluded that receptor polymorphism hitherto investigated is of no value for prediction of drug therapy, but that dosing of about 50–60% of the drugs used in such therapy to a great extent is dependent on the polymorphism of *CYP2D6* and *CYP2C19*.

ULCER AND GASTROINTESTINAL DISORDERS

Dosing of antiulcer agents to reach a specific plasma level is highly dependent on the CYP2C19 phenotype. Higher efficacy in treatment of ulcer is seen in PMs.[12] Changes in gut pH after treatment of, for example, omeprazole are more pronounced in CYP2C19 PMs. Long-term treatment of proton pump inhibitors leads to a more extensive gastrin release in PMs as compared with EMs. Dosing for long-term treatment is advantageously adjusted to the CYP2C19 genotype/phenotype.

CANCER

Pharmacogenetics has an increased role in cancer treatment.[13] CYP2B6 metabolizes several anticancer drugs, among them cyclophosphamide, and preliminary indications exist for an increased metabolism among subjects carrying a variant allele, *CYP2B6*6*. Tamoxifen is metabolized to its active metabolite by CYP2D6, and a smaller therapeutic effect has been observed in PMs for CYP2D6 and predictive phenotyping/genotyping could be relevant before entering the treatment.[14] The effect of antiemetic drug treatment of cancer patients with drugs

such as the 5-hydroxytryptamine type 3 receptor antagonists tropisetron and ondansetron has been found to be highly related to the CYP2D6 phenotype. Lower plasma levels and higher frequency and intensity of vomiting were seen in subjects carrying more active gene copies of *CYP2D6*.[15]

CARDIOVASCULAR DISORDERS

Both warfarin and coumarols, such as acenocoumarol, as anticoagulants are metabolized by CYP2C9. The maintenance dose of warfarin has been found to differ in many different studies between individuals carrying *2*, *1*, or *0* functionally correct *CYP2C9* alleles.[16] A study indicates that subjects carrying variant alleles required 95 days more to achieve stable warfarin dosing and has increased risk (OR 2.3) for life-threatening bleeding events,[17] findings which are also seen in several other studies. *CYP2C9* genotyping to predict a more safe and individually based warfarin treatment with less side effects might be valuable. In addition, the *CYP2C9* genotype has been described to predict the blood pressure response to irbesartan, and a four- to fivefold higher incidence of side effects has been described in CYP2D6 PMs upon treatment with metoprolol.[2]

The antianginal drug perhexiline has concentration-related hepatoxicity and peripheral neuropathy, and determination of *CYP2D6* genotype has been shown to predict dose requirements and reduce the risk of perhexiline concentration-related toxicity.[2]

PAIN

Codeine and tramadol need to be metabolized by CYP2D6 before pain-relieving effects are observed. No efficacy is thus seen in CYP2D6 PMs. In addition, adverse drug reactions of codeine treatment have been described in CYP2D6 ultrarapid metabolizers when treated with ethylmorphine, oxycodone, and hydrocodone probably because of an extensive formation of morphine.

EPILEPSIA

The CYP2C9 polymorphism influences the pharmacokinetics of phenytoin, and several examples of ADRs have been described in patients with defect *CYP2C9* alleles upon phenytoin treatment like CNS intoxication such as ataxia, diploidia, and other neurological symptoms.

GENOTYPING METHODS

Cytochrome P450 genotyping includes the analysis of single SNPs as well as major gene rearrangements. A major outline of the methods is given in Ref. [18]. Southern blotting including reduction fragment length polymorphism (RFLP) analysis is extremely useful for determination of major differences in gene arrangements, including gene deletion and gene duplications of the various *CYP* gene loci. A desired region of the gene is PCR-amplified and nicktranslated and labeled with ^{32}P, after which hybridization is varied out.[19] Southern blotting is generally extremely informative for the specific locus in question and should be carried out more frequently than is actually seen in the literature. RFLP in combination with gene-specific PCR amplification (PCR-RFLP) can also be used to determine specific mutations in the *CYP* genes, where the polymorphic site must alter or generate a restriction site, resulting in a change in the DNA fragmentation pattern on the gel.[20] Real-time PCR analysis of specific mutations allows rapid and automatized methods for detection of *CYP* single nucleotide polymorphisms (SNPs) and *CYP* gene copy number. Two fluorescently labeled probes are used: one wild-type probe and a mutation probe. During the reaction, amplification of the desired sequence is obtained and can give information after careful optimization of the single mutation present or the number of gene copies. Rapid detection of SNPs within the *CYP* genes can also be obtained using the pyrosequencing technique (Pyrosequencing Inc.). For detection of several SNPs in the CYP genes, DNA Chip array techniques can also be used either by hybridization reactions (Affymetrix Inc.) or by primer extension (CodeLink, Amersham Biosciences). The techniques are developing in a rapid fashion, and several different platforms for detection of CYP gene variants are continuously presented.

CONCLUSION

It is the author's estimate that predictive cytochrome P450 genotyping will improve the clinical efficacy of 15–25% of all drug therapy and reduce the incidence of ADRs by 10–20%. Other aspects that underlie interindividual variability in drug metabolism, such as bad compliance, unfavorable drug–drug interactions, and pathophysiological conditions, must of course remain primary factors of concern in drug treatment. The knowledge in the area of cytochrome P450 pharmacogenetics has, however, now increased to such an extent that it would be possible to put labels on those drugs where we know that the individual response to the drug would benefit substantially by predictive genotyping of the cytochrome P450 gene in question. In relation to the costs for prolonged hospital

visits, etc., the costs for such genotyping are minimal and would increase the health in a substantial part of the population and decrease the costs for the society.

Denaturing Gradient Gel Electrophoresis (DGGE)

Luciana Cresta de Barros Dolinsky
Universidade Federal do Rio de Janeiro (UFRJ) and Universidade do Grande Rio (UNIGRANRIO), Rio de Janeiro, Brazil

INTRODUCTION

Denaturing gradient gel electrophoresis (DGGE) is a DNA-based method that permits small mutation detection and single nucleotide polymorphism (SNP) analysis. Denaturing gradient gel electrophoresis is the most sensitive mutation detection technique (detection rate close to 100%) and can be used for human hereditary disease diagnosis, large-scale mutation screening, and predictive genetic testing, including prenatal diagnosis and counseling. Denaturing gradient gel electrophoresis can also be used to analyze SNPs in hereditary complex disease traits. As DGGE is usually less expensive and less labor intensive and time consuming than other point mutation detection techniques it is an excellent method to use in medical routine procedure.

DENATURING GRADIENT GEL ELECTROPHORESIS

Denaturing gradient gel electrophoresis is a DNA-based method that permits small mutation detection and SNP analysis with high detection rate (close to 100%)[1] and is less labor intensive and time consuming than other point mutation detection techniques. Despite this, it is easy to reproduce and can be used as a routine method.

TECHNICAL DESCRIPTION

The DGGE method is based on the electrophoretic mobility of a double-strand DNA molecule through linearly increasing concentrations of a denaturing agent (urea and formamide) on a polyacrylamide gel with ethidium bromide staining. As the DNA fragment proceeds through the gradient gel, it will reach a position where the melting temperature (T_m) of its lowest melting domain equals the denaturing agent concentration, resulting in denaturation and consequent marked retardation of the DNA fragment mobility. As the T_m of a melting domain is dependent on its nucleotide sequence, even DNA fragments differing by a single nucleotide in their lowest domain will suffer branching and consequent retardation of their mobility at different positions along the DGGE gel, allowing DNA fragment separation.[2] The choice of the gel denaturant range is based upon the T_m of the fragment to be analyzed, and the electrophoretic runs can be performed at a constant temperature (58°C) that exceeds the T_m of an A–T-rich DNA fragment in the absence of denaturing agents.

Denaturing gradient gel electrophoresis cannot resolve fragments differing by nucleotide changes in the highest melting domain because of complete strand dissociation. This problem is overcome by introducing a GC clamp tail as short as 40 bp to serve as a high T_m domain and prevent complete dissociation of the DNA fragment. The GC clamp tail introduction increases the DGGE mutation detection percentage to close to 100%.[1] It is also possible to split DNA fragments into two segments to allow efficient mutation detection. The melting behavior of a DNA fragment can be simulated by computer software analysis.[3]

The DGGE method is conceptually similar to heteroduplex analysis.[4,5] The PCR–DGGE combination is extremely efficient when applied to heterozygous nucleotide variants because of continuous denaturation and reannealing of single-strand molecules during PCR, allowing for the formation of heteroduplex and homoduplex molecules.[6] The presence of a single nucleotide change within heteroduplexes decreases their melting domain temperature allowing separation from the homoduplexes and easy visual detection of the mutants (Fig. 1). If working with an X-linked disease it is necessary to mix male mutated DNA with a normal male DNA during PCR to ensure heteroduplex formation. To reduce workload, DNA fragments can be amplified in multiplex combinations. A further sequencing of the altered DNA fragment can determine the exact molecular alteration.

SENSIBILITY

Many different techniques such as single-strand conformation polymorphism (SSCP),[7] hydroxilamine and osmium tetroxide (HOT) chemical cleavage,[8] protein truncation test (PTT),[9] and heteroduplex analysis (HA)[4,5] are available to identify single nucleotide variants. However, in many cases, there is not a very high mutation detection rate when we use each one of

DOI: 10.1081/E-EDGP 120020752

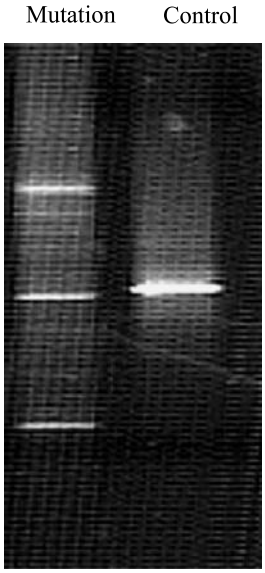

Fig. 1 Small mutation detection in exon 17 of the dystrophin gene.

these techniques principally because of technical difficulties. For example, RNA-based techniques are difficult to use in a diagnostic setting because RNA expression is oftentimes extremely low.

Some laboratories are using haplotype analysis to assess risk status; however, this strategy may be inconclusive because in many cases there is intragenic recombination and high mutation rate. This represents a great obstacle to genetic analysis of patients with small mutations and genetic counseling of their relatives.

Recently, many diagnostic and research laboratories are using denaturing high-performance liquid chromatography (DHPLC)[10] to scan for single nucleotide variations, but even with this method (best detection rate close to 92%) many families remain excluded from the analysis because the detection rate is not 100%. It is important to know that only mutation detection gives absolute certainty about diagnostics and counseling.

Denaturing gradient gel electrophoresis is the most sensitive electrophoretic method (mutation detection rate close to 100%)[1] and, despite this, does not require radioisotope use, is less labor intensive and time consuming, is easy to reproduce, and is usually cheaper than the other routinely used methods for point mutation detection.[7]

CLINICAL APPLICATIONS

Denaturing gradient gel electrophoresis can be used for genetic diagnosis of hereditary human diseases caused by small mutations even when doing diagnosis for X-linked human diseases. It is also possible to analyze SNPs (genetic alterations where at least one allele frequency is higher than 1%) to associate with hereditary complex disease traits.

In many cases, mutation detection can be used in choosing adequate healthcare, as some mutation positions are associated with the worst prognostic. Knowing the exact mutation position makes it possible to establish the prognostic prior to the disease development course and, based on this, to decide which one is the best therapy. Knowing the polymorphism makes it possible to associate some polymorphisms with hereditary complex disease traits for each different population; for example, renin–angiotensin system polymorphisms are associated with high blood pressure in Japanese and African American.[11,12]

Denaturing gradient gel electrophoresis can also be used for predictive genetic testing, including prenatal diagnosis. Knowing a priori if a patient has inherited a familiar mutation with late expression, a polymorphism, or knowing during pregnancy if a baby has inherited a hereditary human disease can help health-care professionals in choosing an adequate strategy to care for the disease, to delay the disease development, or to establish the best life conditions during the disease course.

Denaturing gradient gel electrophoresis is also useful for counseling in an effort to avoid new cases of human hereditary diseases. In X-linked human diseases, for example, carrier couples can alternatively do in vitro fertilization with male embryo implantation to avoid new disease cases. Because mutation detection is close to 100% when using DGGE, we can do prenatal diagnosis and counseling knowing that we will give an answer to the family question and that not one family member will remain excluded from the analysis.

Denaturing gradient gel electrophoresis can also be used to perform large-scale population screening to improve genetic analysis. It is important for this kind of study as some mutations or polymorphisms have a high frequency in one population and a low frequency in another. Analyzing these frequency changes makes it possible to establish specific health-care rules for each different population, principally in hereditary complex disease traits where ethnic factors have an important role in inherited genes.[13]

Denaturing gradient gel electrophoresis is usually cheaper and less labor intensive and time consuming than other routinely used point mutation detection techniques, does not require radioisotope use, is easy to reproduce, and, despite this, has a high detection rate (close to 100%). Considering all these related qualities DGGE can be used as a medical routine procedure for practicing clinicians in hospitals and ambulatory settings.

CONCLUSION

We can conclude that DGGE is an excellent method for small mutation detection principally because it has a high detection rate (close to 100%) and is less labor intensive and time consuming than other point mutation detection techniques.

It can be useful for practicing clinicians in hospitals and ambulatory settings for diagnosis and predictive genetic testing, including prenatal diagnosis and counseling. It can also be used for large-scale mutation and single nucleotide polymorphism screening to improve genetic analysis and to establish adequate healthcare for each different population.

ACKNOWLEDGMENTS

I would like to acknowledge the diagnostic and research group from Leiden and Groningen Universities (The Netherlands), especially Drs. Johan T. Den Dunnen, Egbert Bakker and Robert M.W. Hofstra for the important help during the beginning of this work. Thank you very much!

Differential Display (DD) Analysis

D

Farid E. Ahmed
East Carolina University, Greenville, North Carolina, U.S.A.

INTRODUCTION

Differential display (DD) technique was developed 13 years ago as a systematic method for studying eukaryotic gene expression. The updated method utilizes a combination of three frequently used molecular biology techniques: reverse transcription (RT) of messenger ribonucleic acid [Pol $(A)^+$ mRNA] followed by polymerase chain reaction (PCR) of the resulting complementary deoxyribonucleic acid (cDNA); polyacrylamide gel (PAG) electrophoresis; and cDNA cloning to visualize and compare gene expression patterns between two or more samples. Reverse transcription uses one of three individual one-base fluorescently labeled anchored oligo-dT primers to amplify the 3′ terminal of the mRNA by PCR, instead of the original isotopic labeling method, in combination with one of the various 10–13 arbitrary (random) nucleotide primers. The resulting cDNAs are separated on a denaturing, and sometimes nondenaturing, PAG. A fluorescent scanner views the pattern of bands. The cDNA fragments of interest are retrieved from the gel, purified, reamplified, and either cloned or directly sequenced to identify the differently regulated genes. Finally, confirmation of the differential expression of resulting cDNAs can be carried out by a method such as Northern blotting, RNase protection, or quantitative real-time RT-PCR. Following confirmation, the cloned cDNA probes can be used either to screen a cDNA library for a full-length clone, or more easily to carryout rapid amplification of cDNA ends (5′-RACE).

PRINCIPLES AND GUIDELINES

The genome of higher eukaryotes contains close to 50,000 genes, of which between 10% and 15% are believed to be expressed at a given time in a cell to determine the regulatory mechanisms that control cellular processes controlling our lives such as development and differentiation, homeostasis, response to insult, cell cycle regulation, aging, programmed cell death, and pathological changes such as cancer. Monitoring the pattern of gene expression under various physiological and pathological conditions is a critical step in understanding these diverse biological processes, and comprehending the mechanisms involved allows for needed interventions. Because of the large numbers of expressed genes, powerful tools are needed to characterize the overall pattern of gene expression.[1]

Older methods of identification of differentially expressed genes relied on differential or subtractive hybridization (SH), which although sensitive requires large amount of RNA, is error prone, nonsystematic, laborious, and time consuming, and results are not seen until the end of the process.[2]

The original DD protocol utilized the idea applied earlier for random amplification of fingerprinted genomic sequences. It was published in 1992 by prominent investigators at the Dana-Farber Cancer Institute in Boston, MA.[3] The principle of the method is to detect different types of gene expression patterns using three techniques: 1) RT of DNase I-treated total RNA (to remove any chromosomal DNA) using anchored primers, 12-mer long consisting of a stretch of 11 Ts plus one last non-T base to anchor primers to the pol $(A)^+$ tail of many RNAs. Use of total RNA is preferable to mRNA as it involves less preparatory steps and avoids background smearing;[2] 2) choosing 5′ arbitrary 10 mers that hybridize to cDNA in a degenerate manner for setting lengths of cDNAs corresponding to mRNAs (tags) to be amplified by PCR. For a 5′ primer of arbitrary base sequence, annealing position to cDNA should be randomly distributed from the pol $(A)^+$ tail. Therefore the amplification provided from various mRNAs will differ in length; and 3) employing sequencing gels for isolation of cDNAs. The aim is to obtain a tag of a few hundred bases, long enough to uniquely identify mRNA, but short enough to electrophoretically separate by size. Pairs of primers are selected so that by probability each will amplify DNAs from 50 to 100 (average $\sim$75) mRNAs, as this number can be adequately displayed on one lane of the gel.[3] This method was later on named DD-PCR[1] (Fig. 1), to distinguish it from other DD methods discussed below.

Problems intrinsic to DD were soon encountered such as high noise level due to smearing, misrepresentation of rare messages, bias toward high copy number mRNAs, not revealing differences due to mutational changes, incomplete cDNAs, contamination of purified PCR fragments by unrelated DNA sequences, and additional bands generated by arbitrary primers alone from palindromic

DOI: 10.1081/E-EDGP 120020805

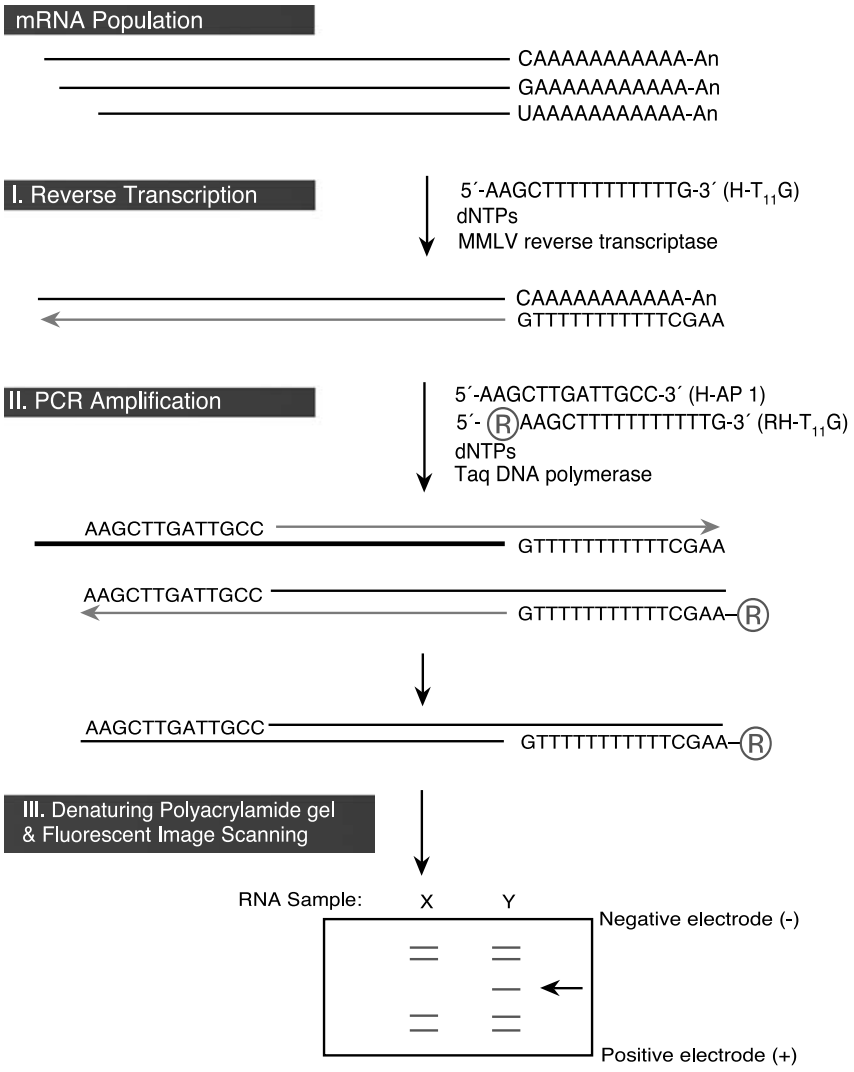

Fig. 1 Schematic of fluorescent DD–PCR method. Total RNA is isolated from cells in culture or tissues. Then, I. A reverse transcription reaction is carried out using one of three specific one-based anchored oligo-dT primers (e.g., H-T_{11}G). II. PCR amplification is performed by using the corresponding fluorescent-labeled anchored oligo-dT primer (RH-T_{11}G; R, rhodamine labeling) in different combination with arbitrary 13-mer primer (H-AP1). III. The amplified PCR products are separated on a denaturing polyacrylamide gel, and the fluorescent-labeled cDNA fragments visualized by a fluorescence scanner. A differentially expressed cDNA fragment in the electropherogram is denoted by an arrow. (Adapted from Ref. [7] with permission.) (*View this art in color at www.dekker.com.*)

sequences within a mRNA molecule; all led to high false-positive rates.[1–7] Therefore many modifications were periodically made to the original protocol to improve these intrinsic problems and to achieve specificity and efficiency as discussed below.

The original primer design was two-base anchored primer, but it resulted in suboptimal amplifications.[2] Three one-base anchored oligo-dT primers differing only at the last 3′ non-T base are now used. This modification cuts down the number of RT reactions needed for each RNA sample and minimized the redundancy and under-representation of certain RNA species due to the degeneracy of the process. Substitution of decamer arbitrary primers with rationally designed 13-mers has increased the accuracy of priming.[5] Furthermore, even longer primers (25–29 mers) and optimal dNTPs concentrations were reported to allow arbitrary priming after an annealing temperature of 40°C in the first PCR cycle, followed by more stringent PCR annealing at 60°C to provide specificity. Additionally, use of hot-start PCR and

other thermostable enzyme mixes suitable for long-length PCR resulted in highly reproducible and representative cDNA bands.[6] Moreover, the introduction of a restriction site at the 5′ end of both the anchored and arbitrary primers facilitated cloning of the cDNAs.[4]

Initially, isotopes labeled oligos, α-[^{35}S] dATP and later on [^{32}P]-end-labeled oligo-dT primer or α-[^{32}P] dATP, were used to autoradiographically detect amplified PCR products on sequenced gels.[2] Introduction of nonisotopic methods using digoxigenin and fluorescent dyes such as tetramethyl rhodamine allowed coupling of the display with digital data analysis, resulting in increased throughput.[2,7] Use of nondenaturing 6% PAG (i.e., without urea) to reduce double bands into a single band was found to reduce band complexity and eliminated several bands of DNA molecules derived from different fragments that occupied the same position in the gel.[8] Differential display–polymerase chain reaction is only capable of determining the 3′ region of the gene, so full-length cDNA can only be achieved either by doing rapid amplification of cDNA ends (5′-RACE) or by probing a cDNA library.[1,7]

Differential display was reported to tolerate a broad range of annealing temperatures and elongation times. However, the major factors that impacted the reproducibility of the method were low concentration of dNTPs and random primers, which made PCR amplifications susceptible to pipetting errors. A final concentration of dNTPs >2 μM and arbitrary primers to 0.2 μM improved the reproducibility of DD.[9] In a recent study utilizing cervical cancer cell line Caski, it was found that—for most primer combinations—fourfold less cDNA and only 25 high-stringency PCR cycling produced reproducible complex band patterns with intensities that reflected 2- to 10-fold differences in expression levels (the most common levels of regulation).[10] To reduce or exclude the bands that are subject to statistical noise from consideration, it has been suggested to start with enough cDNA (i.e., about 30,000 to 100,000 molecules) to obtain 15 ng/mL of amplified product in 25–27 PCR cycles.[11] Although some publications reveal that as little as 1.1-fold amplification is detectable by DD-PCR, the threshold is not precisely known as an upper detection limit may be reached in this technique.[11]

If we consider that there are 15,000 genes expressed in a cell and each fingerprint contains ~70 mRNA species, then in an ideal situation if all mRNAs have the same probability of being displayed in each round, ~600 fingerprints (or 45,000 bands) are required to cover 95% of all mRNAs.[8] For a comprehensive analysis of all mRNA species in a given cell, statistical modeling that predicted at least 240 different DD primer combinations is needed.[3] Recently, an empirical determination of the comprehensiveness of DD-PCR in Chinese hamster ovary fibroblast HA-1 cell line that received (or not) hydrogen peroxide treatment used saturation DNA screening of 324 primer combinations. Results showed that a 100% comprehensive analysis by this technique is not possible regardless of the number of primer combinations. This may be due to a selective resistance to the identification of certain sequences by DD.[12]

Once the first few primer combinations have been tested, the results of the display should be examined keeping in mind that a redesign of the experiment should be made when >5% of the transcripts are differentially expressed, or if no differences exist.[11] It is instructive to keep in mind a few guidelines when performing DD-PCR: 1) drastically different conditions should not be compared; 2) the DD reaction should be repeated for each sample to control for false positives; and 3) multiple samples should be used for each DD experiment in order to provide internal controls.[13]

OTHER DD STRATEGIES AND IMPROVEMENTS TO THE ASSAY

Another strategy to provide RNA fingerprints employed an arbitrary primer instead of an anchored oligo-dT primer in the first step of RT, selecting those regions internal to the RNA that have 6–8 base matches with the 3′ end of the primer. As in DD-PCR, this is followed by arbitrary priming of the resulting first strand of cDNA with the same or a different arbitrary primer, and then PCR amplification. This method is known as RAP-PCR.[14] This method samples anywhere in the RNA, including opening reading frames, and can be used on RNAs that are not polyadenylated (such as bacterial RNA). A limitation of this method too is that rare RNAs will be underrepresented.[1]

Differential display strategies designed to target specific sequences in bacteria, such as highly iterated palindromic (HIP) elements found in half of the genes in the genome of cyanobacteria, provided a convenient global expression strategy for identifying light intensity-regulated genes in bacteria using a limited number of primers.[15] Another area of wide application of DD is a study of scarcely sequenced and complex plant genes, which contain large families of homologous genes.[16]

In order to improve the specificity of DD, attempts were made to replace the 10–13-base arbitrary primers—which hybridize nonspecifically to cDNA templates causing mismatches—with primer sites produced by restriction enzyme digests of double-stranded (ds) cDNAs; thus allowing adapters for priming sites to be ligated into specific regions on the cDNA. These ds cDNAs are then amplified with either anchored oligo-dT

primers combined with ligated primers, or with ligated primers alone, followed by cloning into a vector, amplifying, restriction digest again, sequencing, and identifying the produced fragments. Several of these restriction fragment length polymorphism (RFLP)-based DD strategies, which are variation on the same theme, have been devised, each with its name such as amplification of ds cDNA ends restriction fragments (ADDER), amplified differential gene expression (ADGE), gene calling, ordered differential display (ODD), RFLP-coupled domain-directed DD (RC4D), and total gene expression analysis (TOGA).[1,7] However, RFLP-based strategies require more experimental steps such as second-strand cDNA synthesis, restriction digestion, and ligation of adapter primers over traditional DD, which can lead to error, and their precision over DD-PCR has not been substantiated in controlled experiments.[7]

APPLICATION OF DD TO BIOLOGICAL SYSTEMS

Because of the simplicity, specificity, and versatility of DD, it has been applied to countless applications more than any other genome expression profiling method in different fields of biomedical research as: studying gene expression in many phyla, polymorphism and gene silencing, identifying substrates for RNA-binding proteins, disease diagnosis and prognosis, cell cycle regulation, apoptosis, cancer research, cardiovascular diseases, neuroscience, endocrinology, immunology, and plant science.

A comprehensive compilation of DNA publications in various fields can be accessed through the website of GenHunter® Corporation (http://www.differentialdisplay.com), a company established by inventors of the DD-PCR.[3]

COMPARISON WITH OTHER EXPRESSION PROFILING TECHNOLOGIES

The number of methods employed for gene expression analyses is numerous; however, there are now only a few DD routinely used approaches such as PCR-based, subtractive hybridization (SH), serial analysis of gene expression (SAGE), and microarrays. Additionally, there are variations on the theme that modify or combine features of these basic approaches.

A bottleneck in all variants of DD has been the confirmation of differential expression. Isolation and identification of clones, Northern blots, or RT-PCR analyses are time- and labor-intensive techniques. Therefore several attempts have been made to combine DD with microarrays to facilitate parallel identification of frequently expressed tags simultaneously in many biological systems.[17,18] Furthermore, probes generated by DD from archived experiments can now be reamplified and used as sensitive probes for cDNA microarray studies, revealing more information than was yielded when originally resolved as fingerprints on PAG.[19] The use of fluorescent probes[20] combined with robotics for liquid dispensing and tube handling/rotation, digital analysis, and specialized computer programs for data acquisition, analysis, and storage increases method throughput and facilitates data interpretation.[1,7]

Another strategy combined DD with SH, rationalizing that removing the most commonly expressed mRNA and then displaying the remaining mRNAs might improve displaying.[21]

Table 1 illustrates the advantages and disadvantages of major approaches to gene expression studies. It can be seen that no one method is superior to any other in all parameters surveyed. Ultimately, the correct identification of the gene and its transcript in the hand of the

Table 1 Comparison among major approaches to genome expression profiling

experimenter will attest to the appropriateness of the method to its intended application.

CONCLUSION

Differential display is a systematic, sensitive, and convenient approach that allows many samples to be tested in parallel, and does not require any previous knowledge of mRNA or gene sequence, making it an open system. Initially, DD analysis suffered from a high rate of false positives (or noise) due to the use of short primers and low annealing PCR temperature, and from redundancy in display because short primers may anneal to different parts of the same transcript. However, progressive technical improvements as well as care in experimental design have reduced these shortcomings. Because of its simplicity, sensitivity, reproducibility, and yield to automation, which increases throughput and accuracy, DD, either by itself or in combination with another expression profiling method, has become one of the most widely used methods for studying differentially regulated genes in many biological systems.

INTRODUCTION

The publication of the human genome sequence in 2001 and the completion of about 140 prokaryotic genomes affirm the success of worldwide genome sequencing projects. The availability of new reference sequence information of various organisms is continuously growing.[1]

Differential sequencing—the systematic comparison of genomic sequences with respect to reference sequences, also called resequencing—represents a central focus of current genome analysis. The exploration of single-nucleotide polymorphisms (SNPs) is one of the most prominent approaches to extract the medical and biological value of genome-sequencing data and to elucidate inter- and intraspecies genetic variations.[2] The analysis of SNPs in the human genome will have a significant impact on the identification of disease susceptibility genes and drug targets and will facilitate the development of new drugs and patient care strategies. Large-scale analysis, detection, and discovery of genetic variability and implementation of dense SNP maps are eminent and push technological development toward high-throughput, cost-efficient applications.

Differential sequencing of infectious agents for fast and reliable identification and typing is an important aspect in the field of molecular diagnostics and epidemiology, including outbreak tracking and classification of pathogens. Fast and highly accurate tools for identification, monitoring, and treatment control are in demand. This article describes the use of mass spectrometry to rapidly identify and localize variable genomic regions based on reference sequences, thus facilitating high-throughput differential sequencing with a gamut of applications.

GENOME ANALYSIS BY MASS SPECTROMETRY: HISTORY AND STATE-OF-THE-ART

Analysis of nucleic acids by mass spectrometry has mainly been accomplished by two common soft ionization techniques—ElectroSpray Ionization (ESI) and Matrix-Assisted Laser Desorption/Ionization (MALDI) mass spectrometry (MS).

The use of MALDI coupled with time-of-flight mass spectrometry (MALDI-TOF MS) has become one of the leading technologies for high-throughput analysis and high-fidelity measurement of nucleic acid sequence variations. Unambiguous detection of known polymorphic sequences has been demonstrated, even in various formats.[3–5]

Early attempts to apply MALDI-TOF to de novo sequencing as an alternative to separation and detection of Sanger sequencing ladders[6] were hindered by physical analyte fragmentation, limited mass resolution, and mass accuracy in the high mass range. Despite several promising biochemical strategies, which generate truncated DNA sequence fragments of a sequencing primer analogous to dideoxy sequencing, routine-read lengths exceeding 100 bp have never been achieved.[7–9]

In addition to the primer extension-based Sanger sequencing approach, several chemical and enzymatic DNA fragmentation approaches have been proposed to generate short-based specifically cleaved MALDI-TOF analytes.

A chemical cleavage approach utilized P3′–N5′-phosphoamidate-containing DNA replacing dCTP or dTTP by their analog P–N modified nucleoside triphospates. Acidic reaction conditions induce base-specific cleavage. However, the required acidic conditions produce unwanted depurination by-products and base loss of adenine and guanine.[10]

A uracil–DNA–glycosylase (UDG)-treatment approach uses strand-separated polymerase chain reaction (PCR) products to generate T-specific abasic sites. Subsequent alkaline and heat treatment induces base-specific DNA cleavage at each T-specific positions.[11] DNA regions of interest require incorporation of dUTP instead of dTTP during PCR. Strand separation is performed by solid-phase separation on streptavidin-coated magnetic beads, which complicates the automatic handling of the assay.

Homogeneous assay formats requiring only subsequent addition of reagents are preferred. Post-PCR in vitro transcription systems combined with base-specific cleavage of the RNA transcripts overcome the issues

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021461

encountered with classical DNA amplification and primer extension reactions.

The current state-of-the-art differential sequence analysis concept uses a Maxim–Gilbert-like approach: base-specific cleavage of nucleic acid amplification products. PCR amplification of the locus of interest is followed by in vitro transcription and base-specific cleavage.[12] This novel comparative resequencing scheme combines a homogenous in vitro transcription/RNAse system with MALDI-TOF analysis of molecular fragment masses—an intrinsic molecule property. No labeling is required. PCR products of up to 1 kb are subjected to in vitro transcription. Subsequent cleavage of the in vitro transcripts by ribonucleases (e.g., RNase A) generates base-specifically cleaved RNA fragments. Sequence-specific mass signal pattern within a mass range of 1000–9000 Da—equivalent to 3–30 nucleotides—are obtained. The result is a characteristic pattern of RNA fragment masses indicative of the original reference sequence.

RNase T1 (a guanine-specific endonuclease) cleaves in vitro transcripts base—specifically at every G-position.[13] An available alternative is RNase A, which cuts specifically at the 3′-end of the pyrimidine residues C and U.

RNA analytes are more stable and less prone to depurination than DNA during the desorption/ionization process in MALDI-TOF MS because of a balancing effect

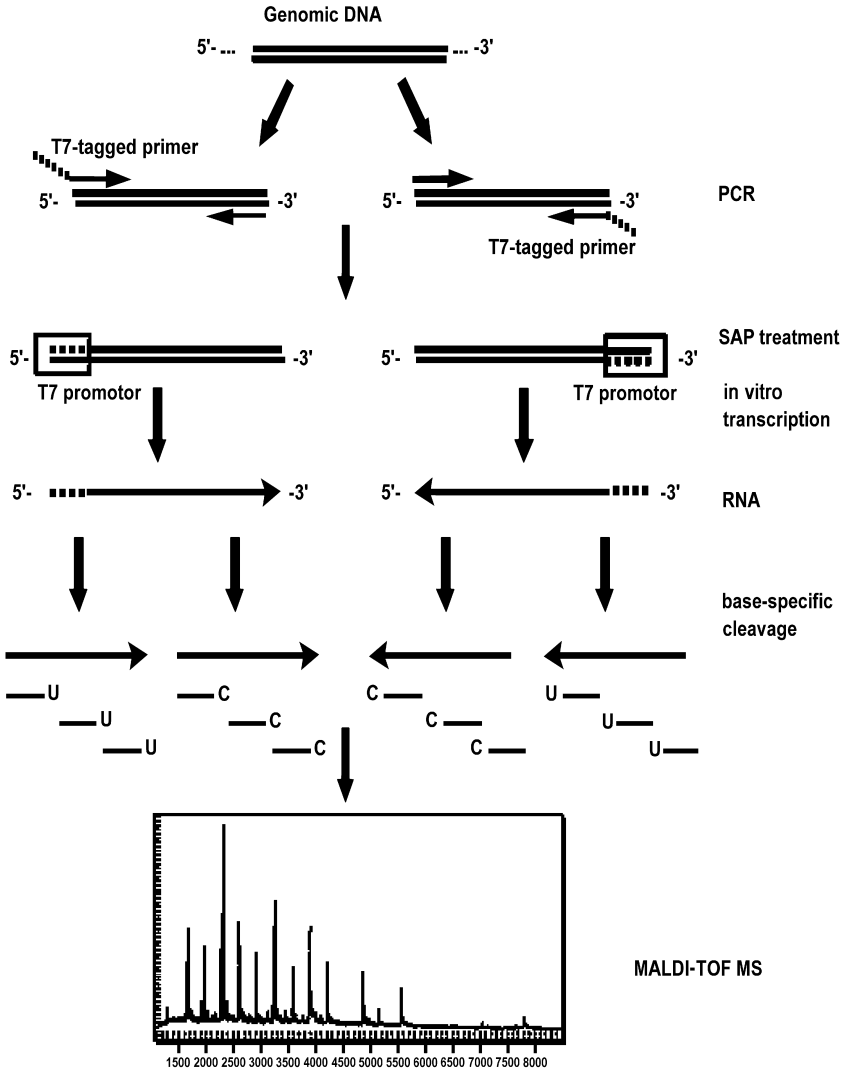

Fig. 1 Base-specific cleavage by MALDI-TOF mass spectrometry. A single-stranded copy of a PCR-amplified target sequence is generated by T7-mediated in vitro transcription and cleaved in four reactions at positions corresponding to each of the four bases. RNA of the forward strand is cleaved at U or C. An A- and G-specific cleavage of the template sequence is facilitated by U or C cleavage of the reverse RNA strand. MALDI-TOF acquisition of spectra of each of the cleavage reactions is followed by comparison to reference sequence derived in silico cleavage pattern.

of the 2′-hydroxy group on the polarization of the *N*-glycosidic bond of the protonated base.

Figure 1 illustrates this robust biochemical scheme for high-throughput differential sequencing. Two PCR reactions of the DNA region of interest introduce a T7-promotor in the forward strand as well in the reverse strand of the amplification product. PCR is followed by shrimp alkaline phosphatase (SAP) treatment to dephosphorylate any unincorporated desoxy-NTPs. RNA polymerase, ribonucleotide, and nuclease-resistant nucleotides are added to the mixture. In vitro transcription generates single-stranded RNA and facilitates further amplification. The RNA is subject to four base-specific cleavage reactions corresponding to each of the four bases. Reactions are driven to completion. This reduces the RNA target to a specific set of RNA compomers in each of the reactions. Analytes are desalted by addition of ion-exchange resin, conditioned, and identified in a single MALDI-TOF MS measurement per reaction. Four sequence-specific mass signal patterns are generated. All cleavage products are consistent with 5′-OH and 3′-phosphate groups, except for the 3′-fragment of the full-length transcript possessing a 3′-OH group.

The experimental set of compomers is used to reconstruct the sequence by cross-comparing the information of the four cleavages to the in silico cleavage pattern of the known reference sequence. Deviations of the pattern indicate sequence changes (Fig. 1).

Figure 2 shows base-specific, cleavage-mediated discovery of a [C/T] sequence change in a 500-bp DNA region of interest. The target region is analyzed by C- and T-specific cleavage of the forward, as well as the reverse strand—equivalent to four base-specific cleavage reactions. Overlays show spectra of the wild-type as well as heterozygous and homozygous mutant samples.

For the wild-type sample [C/C], mass signals of all cleavage reactions can unambiguously be identified based on the reference sequence derived in silico cleavage

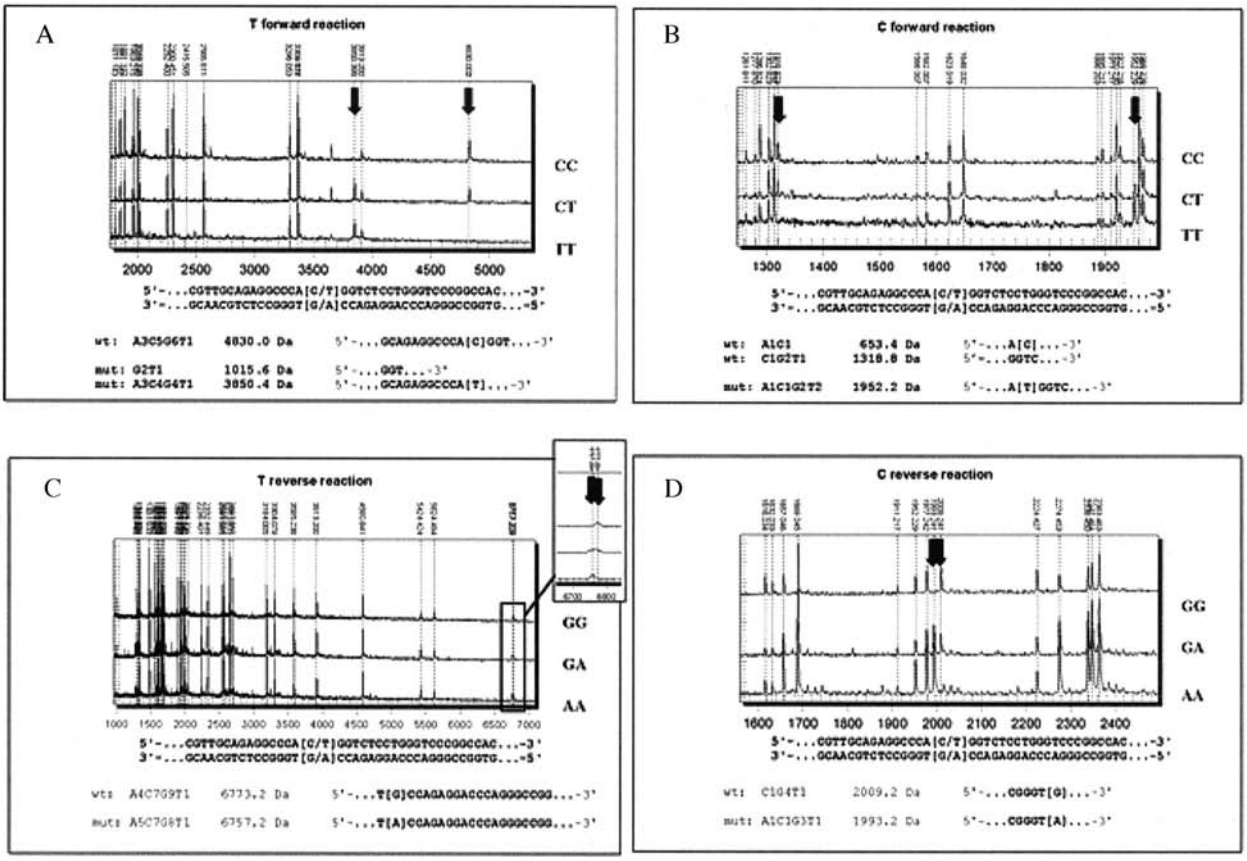

Fig. 2 Identification of a single nucleotide polymorphism by MALDI-TOF MS analysis. Panels A–D show the four base-specific cleavage reactions. Each spectrum reveals the changes resulting from the substitution of a C wt-allele for a T mutant-allele. Spectra of all three different genotypes are overlaid. Changes are indicated by arrows. (A) T-specific cleavage of the forward transcript. (B) C-specific cleavage of the forward transcript. (C) T-specific cleavage of the reverse transcript. (D) C-specific cleavage of the reverse transcript. Spectra are shown covering all detected signals. All signals affected by the sequence change are indicated.

pattern. Deviations from the in silico pattern, detected as a mass shift, the absence of an existing peak, or the appearance of an additional signal, lead to the identification of the sequence variation.

In the T-specific cleavage reaction of the forward transcript, a sequence change from C to T at position 371 of the target region introduces a new cleavage site and splits the 15-bp wild-type fragment into a 12- and a 3-bp fragment. For the mutant [T/T] sample, this results in the disappearance of a mass signal at 4830.0 Da and the appearance of mutant-specific mass signals at 3850 and 1015.6 Da (signal not shown). Spectra containing all of the signals correspond to the heterozygous sample [C/T].

The C-specific cleavage reaction on the forward strand confirms the observation of the identified [C/T] substitution. A cleavage site is removed from a dimer A[C] and generates a 6-bp fragment of 1952.2 Da with the adjacent 4-bp fragment of 1318 Da.

Confirmatory information is generated from the reverse RNA transcript of the target region. Both the T- and the C-specific cleavage reaction generate mass shifts of −16 Da corresponding to an exchange of G vs. A in the affected fragment (Fig. 2).

In conclusion, a heterozygous sequence change can generate up to five discriminatory observations in a mass spectrum by adding or removing a cleavage site, as well as shift the mass of single products by the mass difference of an exchanged nucleotide. Up to 10 observations might be the result of a homozygous sequence change, because not only additional but also missing signals can be utilized for SNP identification.

Mono-, di-, and trimer nucleotides are usually non-informative. They are excluded from the analysis because of coinciding fragments, and their detection is also diminished because of analyte carrier matrix signals within the low mass range.

The combined observations of all cleavage reactions allow for the unambiguous detection, identification, and localization of almost all sequence changes. The inherent redundancy of information from all cleavage reactions substantiates the reliability of the results. Additional supportive information is obtained when signals are correlated across a multitude of samples.

A simulation of arbitrary 500-bp amplicons in the human genome showed that about 99% of all theoretical sequence changes can be detected and characterized.[12]

A homogeneous 384-assay format enables automated processing with liquid handling devices. Nanoliter dispensing onto matrix-coded chip arrays are utilized for automated, reproducible MALDI-TOF measurements. TOF instruments acquire data with turnaround times of 2 sec per sample at a standard 20-Hz laser repetition rate as opposed to hours of analyte separation in conventional sequencing gel electrophoresis. A single MALDI-TOF mass spectrometer can thus scan 2.5 million bp in every 24 hr.

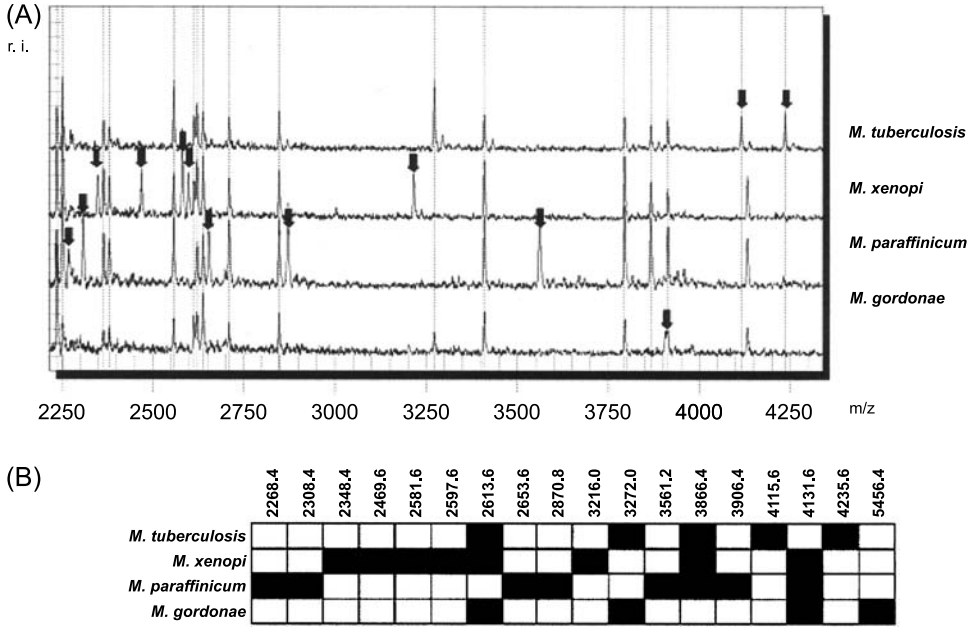

Fig. 3 Pathogen identification by mass spectrometry. (A) Overlay of mass spectra of C-specific forward 16S rDNA fragments of *Mycobacterium tuberculosis* ATCC27294, *Mycobacterium xenopi* DSM43995, *Mycobacterium paraffinicum* DSM44181, and *Mycobacterium gordonae* DSM44160. Identifier peaks are marked with arrow. (B) Barcode of C-specific forward 16S rDNA discriminatory mass fragments.

Real-time quality control of mass spectra results in highly reproducible mass signal patterns facilitating automated peak-pattern interpretation. Signal-to-noise ratio changes can be used as supporting information for sequence changes. A recent software enables automated high-throughput SNP discovery and mutation detection. Time-efficient algorithms calculate the most reasonable explanations for observed mass signal changes, and discover and pinpoint sequence variations based on the information content of the four cleavage reactions.[14]

DIAGNOSTIC APPLICATIONS

MALDI-TOF MS of nucleic acids after base-specific cleavage improves the odds of differential sequence analysis and sets a significant milestone in the field of comparative genomics and genetics. The feasibility of the system exceeds SNP discovery applications. The method facilitates efficient scoring of large numbers of genetic markers in selected populations determining genotypic and phenotypic correlations.

Base-specific cleavage of signature sequences results in species-specific mass signal pattern of the region of interest. These species-specific fingerprints can be utilized to discriminate prokaryotes—bacterial or viral organisms—to the genus-, species-, or strain-specific level and thus facilitate pathogen identification.[15] Figure 3 gives an example of the unambiguous identification and differentiation of four mycobacterial species based on their characteristic mass signal fingerprints of the 16S rRNA gene sequences. All expected signals were identified in the spectra and unique identifier signals marked by arrows could be unambiguously assigned to expected discriminatory species-specific fragments (Fig. 3).

Further expansion of the application portfolio includes the detection of epigenetic modifications, molecular haplotyping, and mutation detection.

Analysis of DNA methylation-mediated gene silencing is seen as a valuable diagnostic tool in cancer research and diagnostics. Qualitative as well as quantitative high-throughput MALDI-TOF DNA methylation analysis relies on bisulfite treatment of genomic DNA, PCR amplification followed by base-specific cleavage. The bisulfite treatment converts nonmethylated cytosine to uracil, while methylated cytosines remain unmodified. As a result, methylated vs. nonmethylated mass signal patterns show significant differences, which allow for differentiation as well as identification of individual sites of methylation in a target sequence. In addition, comparative quantitation of mass signals can be utilized to determine the relative abundance of methylated vs. nonmethylated target gene regions.[16]

Haplotypes are defined as the collection of genotypes found in a single allele or chromosome. Their unambiguous identification provide additional power in the detection of genes involved in common diseases. This can contribute to a better understanding of the complex etiology of diseases. Long-range, allele-specific PCR using nonextendable exonuclease resistant competitor oligonucleotides is performed to isolate desired alleles/chromosomes prior to base-specific cleavage and MALDI-TOF detection. The analysis is not exclusive to known markers, and novel associated subhaplotypes can be discovered resulting in comprehensive haplotype information of the loci of interest.[17]

Additional fields of application include large-scale characterization of cDNAs and alternative splice variants—further steps in the attempt to elucidate the genetic code and individual variations.

CONCLUSION

MALDI-TOF mass spectrometry of base-specifically cleaved nucleic acids is a valuable expansion of the method portfolio in the field of comparative genomics, and opens new routes for diagnostic sequencing applications. MALDI-TOF MS combines the determination of an analyte-specific physical property—the molecular mass—with speed of signal acquisition and high accuracy. This results in a high degree of automation and throughput. The inherent redundancy of observations supporting the discovery of sequence changes is up to five times higher compared to sequencing. This feature should propel MALDI-TOF MS as a gold standard in the fields of SNP discovery, mutation detection, pathogen identification, methylation detection, haplotyping, and cDNA characterization.

INTRODUCTION

This article examines what it means to patent a gene. Numerous ethical concerns have been raised about the effects of such patents on clinical medical practice, as well as on research and development. I describe what kinds of inventions are covered by human gene patents, give examples, and summarize the small body of empirical research performed in the United States that examines the effects of these patents. There is little evidence that early fears about restraining research and constraining the promises of genetic medicine will come to fruition. Nonetheless, there are areas of concern, and policy makers, physicians, and the public should keep their eyes on how genetic patents are being used to ensure that the net social benefits of patenting human genes are maintained.

GENE PATENTS

Nearly 30,000 human genes have been patented in the United States (R. Cook-Deegan, personal communication, 2003). Patents will often be secured in countries throughout the world where the patent owner thinks there may be a viable market. Patents are granted by the U.S. government to inventors for new, nonobvious, and useful inventions and discoveries, and similar standards of patentability are applied around the globe. A patent grants to its owner the right to exclude others from making, using, or selling a patented machine or composition of matter, or from using a patented method, for a period of 20 years from the date of filing a patent application.

A patent grants what is called a negative right—the right to enjoin others from using the invention without permission, and a patent owner may turn to the federal government to use its judicial and police powers to block others from making, using, or selling the invention, and to collect damages from those who infringe. A patent owner generally is not under any legal compunction to ''work'' or license others to use a patented invention, and, as a general rule, a patent even may be used wholly to keep products from coming to market.[1]

Human gene patents result from the cloning and description of the sequence of a gene, the role or function of which is somewhat understood. The U.S. Patent and Trademark Office requires that a patent applicant make a credible assertion of the specific and substantial utility of the genetic invention.[2] Under this kind of rationale, early patent applications by the U.S. National Institutes of Health covering thousands of expressed sequence tags, which are unique nucleotide strings randomly culled out of the genome but have no known function other than as a distinctive marker, were disallowed.

Gene patents cover three distinct types of invention: 1) diagnostics; 2) compositions of matter; and 3) functional use. I will discuss each in turn, with examples and highlights of areas of concern and what is known about each. This overview is centered on U.S. patent law and what is known about how gene patents are being used in the United States. Some of the problems discussed have begun to spill over to Europe and Canada. This is not meant to be a comprehensive international review,[3] but only an attempt to demonstrate the breadth of gene patents, discuss concerns about how they are being used, and summarize relevant empirical data.

First, what we have called disease gene patents *claim* (claims define the scope of patent protection) the characterization of an individual's genetic makeup at a disease-associated locus when performed for the purpose of diagnosis or prognosis.[4] These patents typically cover all known methods of testing, including the use of hybridization, Southern analysis, polymerase chain reaction (PCR), and even DNA chips. Because the fundamental discovery patented is the statistical observation of a genetic difference and a phenotypic difference (such as the occurrence of disease), then any method for testing for that genetic difference can be covered by the patent.[5]

Well-known examples of disease gene patents include those covering genes implicated in breast and ovarian cancers (*BRCA1* and *BRCA2*), colon cancers (*HNPCC* and *FAP*), cystic fibrosis (*CFTR*), hemochromatosis (*HFE*), and a growing number of neurological diseases including late-onset Alzheimer's disease (AD; *Apo-E*), Canavan disease, Charcot–Marie–Tooth disease (*CMT-1A* and *CMT-X*), spinal muscular atrophy (*SMN1*), spinocerebellar ataxia (*SCA1–SCA12*), and others.

There are several characteristics of genes and disease gene patents that demonstrate how the genome is being divided by small patent claims to overlapping genetic

DOI: 10.1081/E-EDGP 120025588

territory. First, any one gene may have multiple patents claiming the diagnosis of different polymorphisms. Thus several patents have been issued for testing of different mutations in the *CFTR* gene.[6] Furthermore, some diseases (at least the phenotypic expressions of them) are caused by multiple genes, such as Charcot–Marie–Tooth disease.[7] Questions about ownership and access get messy when there are many hundreds of known mutations in multiple causative genes, as exemplified by *BRCA1* and *BRCA2*, for which there are at least a dozen U.S. patents on tests of these two genes.[8] Finally, patents can issue on the same exact molecular test when it is performed for different diagnostic or prognostic purposes. For example, an *Apo-E* test, in which the number of E2, E3, and E4 alleles carried by a patient is assessed, can be performed to: 1) determine whether a patient is at risk for early-onset AD;[9] 2) assess an AD patient's prognosis;[10] 3) determine a course of therapy based on pharmacogenetic receptivity;[11] and 4) assess a patient's prostate cancer risk.[12] In each of these cases, a patent thicket is created, which can lead to difficulties in securing licenses and expenses in paying multiple ''stacked'' royalties to multiple patent owners.[13]

To the best of our knowledge, the owners of the overwhelming majority of issued gene patents have not aggressively enforced their rights against clinical molecular diagnostics laboratories. Nonetheless, a majority of genetics laboratories across the United States report that they have had one or more of the above disease gene patents asserted against them.[14,15] In some cases, these patent owners have been willing to grant a license to laboratories performing a home-brew test. Per-test royalties of which we have become aware include US$2 for the *Δ*F508 mutation of *CFTR* (University of Michigan), US$5 for Gaucher's disease (Scripps Institute), US$12.50 for Canavan disease (Miami Children's Hospital), and, reportedly, more than US$20 for *HFE* (Bio-Rad). In some cases, an up-front license fee has been demanded as well.[16]

Of course, clinical and research laboratories typically pay royalties for the use of patented technologies. For example, the price of widely used PCR machines and reagents includes a premium paid for the exclusivity granted by the patents. In addition, a royalty of about 9% is paid for all testings done by licensed laboratories.[14] The most recent patents enforced against biotechnology companies and testing laboratories are those that claim the extremely broad uses of intronic sequences for generating haplotypes and identifying allelic variation.[17] Disease gene patents vary in significant ways from these more typical patented tools that are used by laboratories for testing a variety of specific disease genes. Critically, because a disease gene patent claims all methods of testing for a specific gene, there is no plausible way of working around these patents and the patents may be used to monopolize a test.

Fortunately, in only a handful of cases have patent owners refused to grant licenses to laboratories to allow them to perform specific tests. Instead, these owners have used the patents to monopolize the testing service and to require physicians and laboratories to send samples for testing to the owner or its limited licensees. Thus, tests for breast and ovarian cancer genes (Myriad Genetics) and a set of neurological disorders (Athena Diagnostics) are generally available from only these commercial laboratories. SmithKline Beecham Clinical Laboratories made a brief attempt at capturing the testing market for hemochromatosis before the business unit was sold to Quest Diagnostics.[16] Myriad has extended its reach beyond the U.S. borders, seeking to enforce its *BRCA* patents in France,[18] Canada,[19] and the UK.[20] The test for Canavan disease, despite being easily included in panel assays that many laboratories can run, was restricted to selected laboratories around the United States by the patent owner.[21]

In these cases, laboratories have been told where patient samples must be sent to have the patented tests performed and how much it will cost. Being compelled to stop providing testing services has serious implications for the ability of molecular pathologists to maintain currency in their field, to treat their patients with comprehensive medical services, to train residents and fellows, to perform research, and to run their laboratories in an efficient manner. Hospital-based laboratories must often eat part of the fixed monopoly costs of the tests, which they are compelled to offer patients but for which health insurance may not cover the full price. Seen in this light, these patents raise the costs of clinical services and restrict physicians' ability to practice medicine.[1,22]

The second broad type of genetic invention relates to compositions of matter (i.e., chemicals and materials), including the isolated and purified gene (cDNA) and all derivative products (e.g., recombinant proteins or drugs, viral vectors, and gene transfer ''therapies,'' and transfected cells, cell lines, and higher-order animal models in which the patented gene has been inserted or knocked out). Examples of recombinant products include insulin and human growth hormone. According to the Biotechnology Industry Organization, there are more than 155 biotechnology drugs and vaccines that have been approved by the U.S. Food and Drug Administration, and more than 370 others in clinical trials.[23]

The primary concern about gene patents is that they will make it more difficult to perform research. In the United States, there is no statutory research exemption, but only an extremely narrow court-defined exemption. As recently summarized by the Court of Appeals for the Federal Circuit in a suit against Duke University,

''regardless of whether a particular institution or entity is engaged in an endeavor for commercial gain, so long as the act is in furtherance of the alleged infringer's legitimate business and *is not solely for amusement, to satisfy idle curiosity, or for strictly philosophical inquiry*, the act does not qualify for the very narrow and strictly limited experimental use defense.''[24] Duke University was not excused from potential infringement of patents covering laboratory equipment simply because the equipment was used solely for research and educational purposes, which are the core of Duke University's business. A strong argument can be made that the research exemption should be much broader, encompassing research aimed at better understanding of the claimed invention, such as how it works and whether it works as taught by the patent, how to improve on it, and how to work around it. Indeed, practically speaking, this may in fact be how patents are most commonly used. The patent law trades a period of exclusivity for disclosure and the teaching of an invention to the trade, and competitors should not have to wait for the period of exclusivity to end before learning from that disclosure and attempting to improve on it.

Little is known about how gene patents are being used, and whether they have a net beneficial or detrimental effect on scientific research and commercial product development. Patents clearly are seen as a necessary stimulus for the infusion of venture and risk capital in the biotechnology industry; less clear is the role patents play in motivating academic researchers. Little data have been generated about the licensing of biotechnology patents. These studies suggest that most genetic inventions are not patented, but when they are, they are licensed on exclusive terms.[25,26] In turn, researchers and firms appear to have developed various strategies to minimize the potential detrimental effects of the patents.[27] Nonetheless, much remains unknown about the effects of these practices on basic research and commercial competition.

Finally, a third and emerging class of gene patents is that claiming the functional use of a gene. These patents are based on the discovery of the role of genes in disease or other bodily and cellular functions or pathways, and claim methods and compositions of matter used to up-regulate or downregulate the gene. For example, a patent that was recently invalidated claimed methods and compositions of matter for the selective inhibition of the *Cox-2* gene, which prevents inflammation and pain. The patent was invalidated because the patentee, the University of Rochester, failed to disclose a chemical entity that would perform such selective inhibition.[28] The patent claimed the mechanism by which two drugs, which later came to market, work—Celebrex, which is comarketed by Pharmacia (of which Searle is part) and Pfizer, and Vioxx, which is marketed by Merck.

A case similar to the *Cox-2* litigation involves a patent awarded to Harvard and MIT and exclusively licensed to Ariad Pharmaceuticals. The patent claims the basic regulation of any gene by reducing the intracellular activity of the transcription factor NF-kB.[29] On award of the patent, Ariad Pharmaceuticals sued Eli Lilly for infringement by their osteoporosis drug Evista and their sepsis drug Xigris, and has asserted the patent against numerous other companies. Eli Lilly's patent applications for these two compounds themselves predate the filing of the NF-kB application.[30] Ariad Pharmaceuticals should have a hard time winning, both because, like the *Cox-2* inhibition patent, the NF-kB patent fails to disclose specific agents for regulating the factor and because the company is trying to assert its patent in a way that would remove from the market chemical entities that predated the discovery and disclosure of the functional pathway by which those drugs work.

Finally, we have the case of Viagra. Pfizer, which has had its erectile dysfunction drug Viagra on the market for several years, recently received a patent claiming the molecular pathway by which Viagra works. The patent claims any selective PDE5 inhibitor used to treat impotence.[31] Immediately on allowance of its patent in late 2002, Pfizer sued Bayer and GlaxoSmithKline for their drug Levitra, and Eli Lilly and their partner Icos for their drug Cialis, both of which were proceeding toward Food and Drug Administration (FDA) approval.[32] The difference between the Viagra case and the *Cox-2* case is that Pfizer actually has and claims a specific class of drugs that work by the claimed functional pathway. Whether this is an adequate basis on which to allow Pfizer to lay claim to all drugs that work by the same molecular mechanism is a fundamental legal question that looms over the pharmaceutical industry.

CONCLUSION

We see that ''gene patents'' cover a broad range of invention. Each type has its own potential uses and marketable products, and each raises potential problems depending on how the patents are used in the relevant marketplace. Much remains unknown, and, indeed, the market is still adapting to these patents. Thus it is extremely important to continue to study and monitor how gene patents are being used, licensed, and enforced to develop policy interventions if deemed necessary.

ACKNOWLEDGMENT

Support for underlying research for this article has been provided by the Ethical, Social, and Legal Issues Program

of the National Human Genome Research Institute of the U.S. National Institutes of Health. Thanks are extended to the many colleagues and collaborators who have worked with me on the various studies cited, especially Mildred Cho, Debra Leonard, and Michelle Henry, and thanks to Michelle Henry for comments on a previous draft of this chapter.

INTRODUCTION

Electrochemical DNA hybridization biosensors have been a major research field for over a decade, because their rapid, simple, and low-cost detection capabilities provide several advantages to clinical, forensic, and environmental monitoring. Basically, DNA biosensors convert the Watson–Crick base-pair recognition event into a readable analytical signal. A DNA biosensor is prepared by the immobilization of a single-stranded (ss) oligonucleotide (probe) onto a transducer surface to recognize its complementary (target) DNA sequence via hybridization. The DNA duplex formed on the electrode surface is called a hybrid. This binding event is then converted into an electrochemical signal by the transducer. The most important advantage of utilizing electrochemistry for transducing hybridization is its suitability for microfabrication. Thus compact, user-friendly, and handheld devices can easily be designed by combining electrochemistry and microfabrication.

THE ADVANTAGES OF USING DISPOSABLE ELECTROCHEMICAL DNA BIOSENSORS

The miniaturization of electrochemical DNA biosensors[1–3] enabled the mass production of disposable sensor strips. These sensor strips have gradually taken the place of the conventional three-electrode system consisting of bulky working, reference, and counter electrodes, and beakers with a large amount of buffer and analyte solution volume, mostly ranging between 1 and 2 mL. However, the disposable sensor strips alone can be described as disposable electrochemical cells, which contain the working, reference, and counter electrodes together on a minimal scale and space. A small droplet of the buffer and an analyte solution of about 20 μL would be sufficient for an electrochemical reaction to take place. Especially, the ''memory-effects'' resulting from the insufficient cleaning of the electrode surface have been completely eliminated with these single-use sensor strips. Thus more reproducible results could be obtained by using a new electrode for each experiment. Such a significant decrease in the required analyte volume, and increase in reproducibility while shrinking the required space in the laboratory, had a revolutionary impact on the field of electrochemical biosensors, so that the term ''on-field analysis'' has become possible with the help of the miniaturization of such electrochemical potentiostats and sensor strips, enabling ''bedside clinical diagnosis'' and ''on-site environmental monitoring.'' Even the diabetes patients themselves have become capable of measuring their own blood glucose levels by using such small handheld electrochemical devices in connection with sensor strips.[4] Nowadays, the biggest challenge facing electrochemists is to develop such a small device, which can perform nucleic acid-based tests with a simple and rapid procedure, as well as high sensitivity and selectivity.

DISPOSABLE ELECTRODE MATERIALS

Nowadays, two important electrode materials are in widespread use for disposable sensor technology: carbon and gold (Au).[5] Especially, carbon is desired because of its rich surface chemistry, low background current, wide potential window, low-cost, and chemical inertness. Disposable carbon electrodes are suitable for various kinds of surface modifications, thus enabling a major number of applications in many fields. However, the electron-transfer rates obtained from carbon electrodes are reported to be slower than those obtained from metal electrodes.[6] Recently, this major drawback has been overcome by the modification of the carbon surface with carbon nanotubes (CNT). Carbon nanotubes enabled enhanced electron transfer on electrode surface owing to their small size providing a larger active surface for easy DNA attachment.[7] Recently, CNT-based screen-printed electrodes (CNTSPE) have been fabricated by Wang and Musameh.[8] Carbon nanotube-based screen-printed electrodes with their well-defined electrochemical activity and mechanical stability are promising candidates for DNA-based testing.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120030807

Highly oriented pyrolytic graphite electrodes (HOPGE) have also been attractive for electrochemical DNA biosensor research.[9–12] The renewal of HOPGE surface is also simple and rapid. A freshly cleaved surface of HOPGE can easily be prepared by contacting a piece of adhesive tape to the graphite surface, and then removing a thin layer of graphite with the tape. Thus the same electrode can be used for several different measurements. DNA and DNA–drug interaction were examined on thin-film mercury-coated HOPGE by Hason et al.[9] Voltammetric microanalysis of DNA adducts with osmium tetroxide,2,2′-bipyridine (Os,bipy) using a HOPGE provided the detection of 140 pg of DNA-Os,bipy after a 5-min accumulation period.[10] Anodic voltammetry and atomic force microscopy (AFM) imaging were performed for the detection of adriamycin and DNA interaction on HOPGE surfaces.[11] Atomic force microscopy surface characterization of the effect of pH and applied potential on the adsorption of DNA on HOPGE has recently been reported by Oliveira-Brett and Chiorcea.[12]

The use of a rigid carbon–polymer composite material as an electrochemical transducer in hybridization genosensors has recently been reported by Alegret and coworkers.[13–15] Graphite–epoxy composites (GEC) have an uneven surface suitable for strong DNA adsorption. Especially, ssDNA was reported to bind strongly to GEC in a way that prevents the strands from self-associating, while permitting hybridization with complementary DNA. Hybridization was detected by monitoring guanine oxidation signal[15] and also through biotin–streptavidin interaction using a streptavidin conjugated to horseradish peroxidase without nonspecific adsorption onto GEC, even when the surface was treated by blocking reagents.[14] Thus screen-printed GEC-based electrodes are also promising candidates for highly specific DNA hybridization detection.

Au is the noble metal of choice for screen printing of disposable sensor strips. Au strips offer a very favorable electron-transfer kinetics and a wide anodic potential range. The main disadvantage would be the limitation of the cathodic potential window.

The disposable electrode designs can be classified into two groups. The most generally used one is the screen-printed (thick-film) electrode (SPE). The second one is the recently developed pencil graphite electrode (PGE). Screen-printed electrode technology has developed rapidly with the help of the recent advancements in microfabrication; however, the PGEs still need to be improved to eliminate the use of external reference and counter electrodes. Whereas SPE is sufficient to perform an electrochemical analysis, a PGE still requires a beaker-type system. The important advantage of using PGE would be that the preparation does not require sophisticated instruments, because commercially available carbon graphite leads constitute the main source of PGEs. A carbon graphite lead with 1-mm i.d. provides a more comfortable electrode system in a beaker as well as a significantly bigger electrode surface with its cylindrical shape in comparison with the planar surface of the traditional Teflon-encased electrodes. A simple mechanical extrusion enables the renewal of the surface of PGE-based biosensors, hence obviating the need for an additional regeneration step and erasing memory effects.

DISPOSABLE DNA BIOSENSORS BASED ON PENCIL GRAPHITE ELECTRODES

Thus these low-cost and easy-to-prepare PGEs have been the ideal choice for several electrochemical DNA biosensor reports. An electrochemical DNA biosensor for the detection of the Factor V Leiden single-nucleotide polymorphisms (SNPs) from polymerase chain reaction (PCR) amplicons using the oxidation signal of colloidal gold (Au) was described by Ozsoz et al.[16] A pencil graphite electrode (PGE) modified with target DNA (Fig. 1A), when hybridized with complementary probes conjugated to Au nanoparticles, responded with the appearance of Au oxide wave at $\sim$+1.20 V (Fig. 1B).

The discrimination against homozygous and heterozygous genotypes has become possible by using specific oligonucleotides, which are full complementary to either wild-type (WT) or mutant (MT) real samples. When the WT probe, which had a complementary DNA base sequence to the WT target, was immobilized on Au nanoparticles, a high Au oxidation signal (Fig. 2a) showed

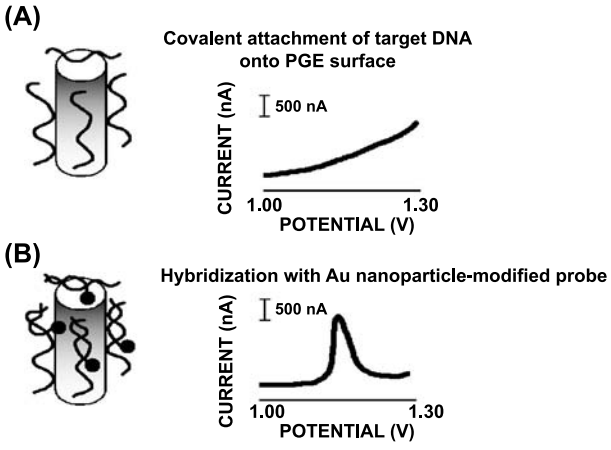

Fig. 1 Detection of hybridization using Au nanoparticle-modified probes. (A) Covalent attachment of target DNA onto pencil graphite electrode (PGE); (B) Au oxide signal appears after hybridization with the complementary Au nanoparticle-conjugated probe.

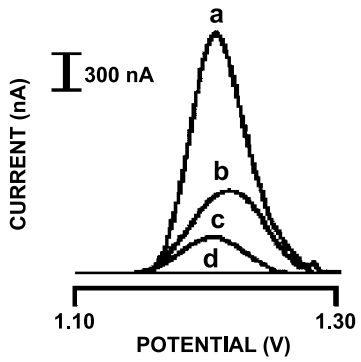

Fig. 2 Differential pulse voltammograms for the oxidation signal of Au at PGE in TBS at (a) wild-type (WT) probe-modified Au nanoparticle after hybridization with WT target; (b) mutant (MT) probe-modified Au nanoparticle after hybridization with WT target; (c) WT probe-modified Au nanoparticle after hybridization with no target on PGE surface; and (d) WT probe-modified Au nanoparticle after hybridization with non-complementary target.

that the PCR product contained WT DNA. When the MT probe was hybridized with the WT target, about one-half of the signal was obtained indicating the presence of SNP (Fig. 2b). Nearly a similar electrochemical response was obtained from the attachment of Au nanoparticle-modified WT probe onto bare PGE (Fig. 2c). No electrochemical signals could be obtained when the noncomplementary target was immobilized on the PGE surface (Fig. 2d).

The intrinsic redox activity of DNA was employed for detecting the duplex formation on a PGE-based biosensor by Wang et al.[17,18] Inosine-substituted probes and monitoring of the electrochemical guanine oxidation signal for hybridization events offer several advantages over the common use of external indicators including the appearance of a new peak, a flat background, and simplicity. Inosine is a hypoxanthine ribonucleoside, one of the basic compounds comprising cells, and also a precursor to adenosine and uric acid. In guanine signal-based electrochemical DNA biosensor schemes, inosine-substituted probes have been intensively used,[19,20] because they are electrochemically inactive. When an inosine-substituted probe-modified electrode is exposed to the target DNA, the guanine signal appears after hybridization. The selectivity of the new device of Wang et al.[17] was demonstrated for the detection of a SNP in the BRCA1 breast cancer gene. Such low-cost, renewable graphite transducers provided an attractive alternative to conventional carbon electrodes used for transducing DNA hybridization. The device offered a greatly simplified operation and held promise for decentralized genetic testing by eliminating the regeneration step and an external electroactive indicator.

DISPOSABLE DNA BIOSENSORS BASED ON SCREEN-PRINTED ELECTRODES

Recent progress in screen-printing technology with PC-controlled, fully automatic, and sophisticated instruments enabled the large-scale fabrication of the SPEs in various electrode layout designs. The printing patterns of conductors and insulators onto the surface of plastic or ceramic planar substrates can be designed and controlled by the software of these instruments. The most suitable substrate material as well as the conducting and insulating ink materials should be chosen for the purpose of the electrochemical test. The most commonly applied conducting inks are the carbon- and Au-based ones. There are mainly four steps involved in the screen-printing process. First, the conducting ink suspension is deposited onto the screen, followed by the loading of the screen mesh with the conducting ink, then the ink is forced through the screen with the help of a squeegee. Finally, the printed pattern is dried and cured. The printing of the insulating layer and the other cover layers, which can vary according to the electrochemical test, is also performed as described above onto the conducting ink-printed surface. However, the overall performance of the SPEs is greatly influenced by the chemical composition of the ink materials and the printing conditions such as applied pressure and temperature.

Screen-printed electrode is the commonly used electrode type in reports not only for clinical but also environmental and food monitoring purposes. As for the clinical applications, Lucarelli et al.[21] have recently reported carbon SPEs for the detection of SNPs related to apolipoprotein E from PCR-amplified samples. The duplex formation was detected by measuring the guanine oxidation signal. The biosensor format involved the immobilization of an inosine-substituted probe onto a SPE and the voltammetric detection of the duplex formation with the appearance of the guanine signal.

Recently, gold electrode-based indicator-free DNA hybridization detection has been reported by using a conventional-type gold electrode.[22] Figure 3 shows the oxidation signal of guanine at about $\sim$+0.73 V by using differential pulse voltammetry on self-assembled L-cysteine monolayer (SAM)-modified screen-printed gold electrode (AuSPE). The electrochemical determination of hybridization between an inosine-substituted probe (Fig. 3b) and native target DNA (Fig. 3a) was accomplished. The indicator-free detection of hybridization on AuSPE is greatly advantageous over the existing carbon-based materials, because of its potential applicability to microfabrication techniques.

Indicator-free, disposable electrochemical DNA-modified carbon SPEs have also been successfully applied to environmental monitoring. The device of Chiti et al.[23]

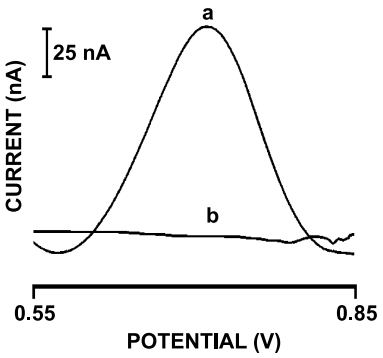

Fig. 3 Differential pulse voltammograms for the oxidation signal of guanine (a) after and (b) before hybridization with target DNA at inosine-substituted probe modified AuSPE.

relied on the intercalative or electrostatic collection of toxic aromatic amines onto an immobilized double-stranded DNA (dsDNA) or single-stranded DNA (ssDNA) layer in connection with chronopotentiometric analysis. The anodic signal of the guanine bases of DNA-coated SPEs was affected by structural or conformational modifications of the DNA layer due to the DNA–analyte association. The changes in the guanine oxidation signal were taken as an index for the affinity of the analyte toward nucleic acids. Submicromolar detection limits were obtained for molecules with more than two aromatic rings after a 2-min accumulation.[23]

Indicator-based disposable electrochemical DNA biosensors were also described by using carbon SPEs in connection with a well-described intercalator, daunomycin, as an indicator of the hybridization reaction by Marrazza et al.[24,25] Synthetic probes have been immobilized onto carbon SPEs using adsorption at a controlled potential. The hybrids formed on the electrode surface were evaluated by chronopotentiometric stripping analysis of daunomycin. The DNA biosensor was able to detect 0.2 mg L^{-1} of a 21-base target sequence. The determination of low-molecular weight toxic compounds with affinity for DNA, such as polychlorinated biphenyls (PCBs) and aflatoxin B1, was carried out by monitoring their effect on the guanine oxidation signal.[25] River water samples were also used as real matrices for monitoring of these compounds by using the disposable DNA-modified SPEs.[25]

CONCLUSION

The attractive performance of disposable PGEs and SPEs for the biosensing of DNA hybridization has been reviewed. Such performance compares favorably with that of conventional beaker-type electrodes commonly used for transducing DNA hybridization. The simple and fast utility of these test strips provides the basis of the day-to-day practicality of the biosensor and holds great promise for decentralized genetic testing. An electrochemical device based on such single-use electrodes, thus, is a strong alternative to other optical, gravimetric, or surface plasmon resonance (SPR)-based DNA biosensors, when rapid and cost-effective hybridization assays are concerned. Various electrochemical protocols, such as indicator-free or intercalator-based ones, can be readily combined with a disposable DNA biosensor. However, the integration of a battery-operated electronic microprocessor, as well as the reference and counter electrodes, is crucial for the improvement of PGEs. The excellent performance of the electrochemical self-care devices for blood glucose in connection with disposable electrodes provides an encouraging example for electrochemists to develop a similar device for genetic testing. In the near future, we are looking forward to the entrance of an electrochemical self-care DNA-based device into the booming biotechnology market.

INTRODUCTION

The first cyanine dye, named cyanine because of its blue color, was serendipitously synthesized by C. H. G. Williams as early as 1856. Since the end of the 19th century, the class of cyanine dyes have dominated the field of photography as photosensitizers and are unrivalled even today. The generic cyanine dyes consist of two nitrogen centers, one of which is positively charged and linked to the other center by a conjugated chain of an odd number of carbon atoms (Fig. 1). Symmetrical cyanine dyes commonly contain two benzazole moieties connected by a polymethine chain, whereas the unsymmetrical cyanines usually consist of a benzazole group and a quinoline or pyridine heterocycle, also connected by a methine bridge. The extensive conjugation and the delocalization of charge lead to long-wavelength absorption maxima and large molar absorptivities. Apart from use as photosensitizers, cyanine dyes have been employed as laser materials, photorefractive materials, antitumor agents, and in optical disks as recording media to name but a few applications.

DNA-BINDING CYANINE DYES

In recent years, unsymmetrical cyanine dyes have received considerable interest because of their excellent nucleic acid staining properties. In 1986, Lee et al.[3] showed that the unsymmetrical cyanine dye Thiazole Orange (TO; Fig. 2) exhibits 3000-fold enhancement in fluorescence intensity upon binding to RNA. Later, Rye et al.[4] showed that TO, and the similar dye, Oxazole Yellow (YO) with a benzoxazolium moiety instead of benzothiazolium, have a dramatic increase in fluorescence also upon binding to DNA. Both these studies indicated that the dyes bind in a nearest-neighbor exclusion stoichiometry typical of intercalators.

To obtain stains with high affinity for DNA, Rye et al.[5] developed TOTO and YOYO (Fig. 2), which have two dye moieties connected by a biscationic amine linker. Their affinity for double-stranded DNA is about the square of that of the monomers as a result of bisintercalation and their high positive charge. To enhance the affinity for DNA of monomeric dyes, positively charged substituents (3-propyl trimethyl ammonium bromide) were added in TO-PRO and YO-PRO (Fig. 3).[6]

The absorption maximum of cyanine dyes depends on the length of the conjugated chain and the nature of the heterocyclic moieties. Today dyes are available whose absorptions span a broad range of the visible spectrum (Fig. 3).[6] They typically have several hundredfold enhancements in fluorescence upon binding DNA and a quantum yield in bound state of at least 0.1.

The fluorescence quantum yield of cyanine dyes increases when torsional motion around the methine bridge is restricted, which reduces the probability of nonradiative relaxation from the excited singlet state.[7,8] When the dyes bind DNA, internal rotation is likely to be strongly hindered, which causes the dramatic increase in fluorescence.

The interactions of cyanine dyes with nucleic acids have been thoroughly investigated. Early flow linear dichroism studies indicated that YO-PRO and YOYO intercalate in DNA.[9] Intercalation was also supported by circular dichroism, fluorescence anisotropy, and dye–nucleobase energy transfer measurements. By nuclear magnetic resonance (NMR), the solution structures of TOTO bound to short oligonucleotides have been determined.[10] Frequently, more than one complex was observed. A preferred binding site was bisintercalation in a central CTAG:CTAG binding site with the cationic linker located in the minor groove. The DNA complex is unwound by $\sim 30^\circ$ and extended ~ 2 Å per TO moiety, which is typical of intercalation.

Thermodynamic studies of TO binding to nucleic acids of different base compositions showed that binding has little sequence selectivity.[11] At elevated dye:base pair ratios, a secondary binding mode was observed for both monomeric and dimeric dyes.[9,12] In a spectroscopic study, Nygren et al.[13] determined thermodynamic parameters of TO binding to DNA both as monomer and

YO	O	quinoline	480

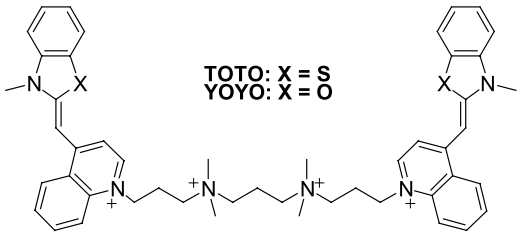

Fig. 2 General structure of the monomeric unsymmetrical cyanine dyes (top), and the homodimeric cyanine dyes TOTO and YOYO (bottom).

as dimer. With several sequences, the dimer complex was found to have lower fluorescence than the bound monomer. By fluorescence polarization measurements of TOTO–DNA complexes, evidence for external binding was obtained.[14] In hole-burning studies, external binding of TO-PRO-3 to DNA was revealed.[15] Atomic force microscopy and viscometry studies support the notion that TO and in particular TOTO bind in more than one mode to DNA.[16] Clearly, the interaction of cyanine dyes with DNA is complex and yet far from fully understood.

Most cyanine dyes have strong affinity also for single-stranded DNA and obtain high fluorescence upon binding.[13,17] This makes them less useful as specific probes for double-stranded DNA. Similar affinity for single- and double-stranded DNA is typical of intercalators of low complexity that mainly gain binding energy through stacking with bases. Minor groove binders, on the other hand, typically show strong preference for double-stranded molecules. In recent years, some symmetrical cyanine dyes have been found to bind in the minor groove. Seifert et al.[18] showed that the symmetrical pentamethine cyanine dye 3,3′-diethylthiadicarbocyanine ($DiSC_2[5]$) (Fig. 4) cooperatively binds as head-to-head dimer in the DNA minor groove forming helical H-aggregates. Mikheikin et al.[19] showed that a series of trimethine symmetrical cyanine dyes, e.g., $DiSC_2$,[3] bind in the minor groove mainly as monomers. These studies suggested that the hydrophobicity of the heterocyclic group is a critical determinant for dimerization. Recently, Sovenyhazy et al.[20] showed that the trimethine cyanine dye TO-PRO-3 (Fig. 4) cooperatively binds in the minor groove of poly(dA–dT)$_2$, although it has previously been considered to mainly intercalate in DNA.

A characteristic of classical minor groove-binding ligands such as Hoechst 33258 and DAPI is its crescent-shaped molecular structure.[21] To improve the preference of cyanine dyes for double-stranded DNA, Karlsson et al.[22,23] designed a series of crescent-shaped unsymmetrical cyanine dyes based on the BO and TO chromophores (Fig. 5). Flow linear dichroism, circular dichroism, and electrophoresis unwinding measurements revealed that these dyes prefer minor groove binding in mixed sequence DNA. Like the intercalating dyes, the minor groove binders exhibit large increase in fluorescence upon binding (Table 1).

PROBING POLYMERASE CHAIN REACTION (PCR)

In 1992, Higuchi et al.[25] showed that it was possible to follow the amplification of DNA in real time by adding ethidium bromide to the reaction tube and monitor the increase in fluorescence when the dye binds to the accumulating DNA product. A variety of dyes and probes have been developed for the detection of DNA in homogeneous solution since then. To be useful, the dyes should bind DNA with little sequence selectivity in one dominant-binding mode. They should have strong preference for double-stranded DNA and exhibit large fluorescence enhancement upon binding. Binding should be strong enough to give a signal proportional to the amount of DNA present, but without interfering with the amplification reaction. For the same reason, dissociation kinetics should be fast. Although YO-PRO was used in some early assays,[26] the most common dye is SYBR Green I from Molecular Probes.[27] Its chemical structure has not been published in scientific reports, but its spectral characteristics suggest that it is based on the TO-chromophore, probably with a cyclic substituent (U.S. patents 5,436,134 and 5,658,751). Recently, Bengtsson et al.[28] tested the minor-groove binder BEBO as reporter in real-time PCR (Fig. 6) and found it to compare well with SYBR Green I in all important aspects.

Dyes are excellent reporters in real-time PCR, but they do not distinguish between products. Taqman,[29] Molecular Beacons,[30] Scorpion Primers,[31] and LightCycler

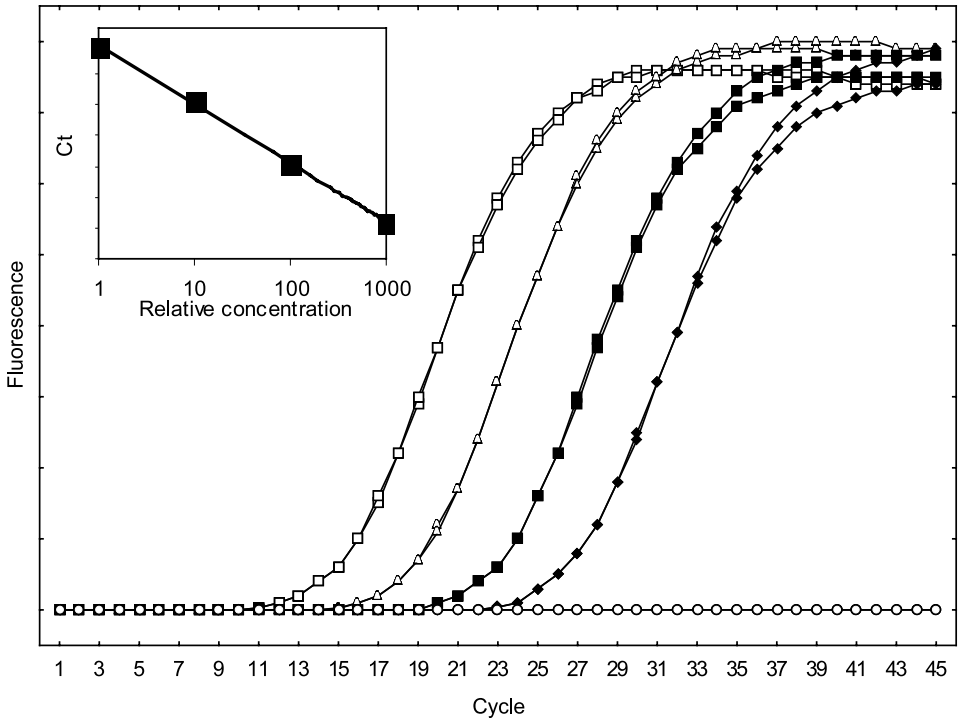

Fig. 6 Real-time PCR amplification with BEBO (0.2 μM) detection. Amplification was performed in a RotorGene with 470-nm excitation and 510-nm detection. Background is subtracted and the amplification curves are normalized. Samples are duplicates of a 1:1, 1:10, 1:100, 1:1000 dilution series of a 222-bp beta tubulin fragment and NTC. Inset: Standard curve (R=0.99955, Slope −3.8, Efficiency 0.83).

hybridization probes are examples of sequence-specific probes that are based on fluorescence resonance energy transfer (FRET) between two dyes tethered to an oligonucleotide. When these probes bind target DNA, the distance between the dyes changes as a result of either probe degradation or conformational change resulting in fluorescence enhancement. Common dyes in these probes are laser dyes with very high fluorescence quantum yields. An interesting alternative to the two-dye probes is the LightUp probe.[32] The LightUp probe has only one dye, which is a cyanine dye, whose fluorescence greatly increases when bound to DNA. Instead of using an oligonucleotide to identify the target sequence, the LightUp probe uses peptide nucleic acid (PNA), for which charged cyanine dyes have negligible affinity. The LightUp probes have been found to be excellent reporters in both real-time PCR and post-PCR applications.[33,34]

CONCLUSION

Fluorescent probes have replaced radioisotopes as labels of nucleic acids. They have important advantages in being nonhazardous and stable upon storage. Moreover, some dyes have different fluorescence in free and bound state, which opens for probing in homogeneous solution, eliminating the need to separate bound and free probes. These dyes were accidentally discovered. Based on detailed structural and thermodynamic investigations of the dyes and their interactions with nucleic acids, we are rapidly learning what governs their properties. This will make it possible to improve the dyes in terms of solubility and sequence nonspecificity, and also to design dyes of different colors. Particularly exciting is the use of the dyes as labels in sequence-specific probes because enhancement in fluorescence can be much more sensitively measured than a change in fluorescence as a result of energy transfer. Also, multiplexing is expected to be much simpler with single-labeled probes.

DNA Extraction from Mummified Tissues

Yayoi Sato
Chiba University, Chiba, Japan

INTRODUCTION

Nucleic acids extracted from mummified tissues are considered valuable materials for the identification of forensic cases and for the study of ancient human beings in the field of archaeoanthropology and the emergence of pathogens in Paleontology.

After the powerful polymerase chain reaction (PCR) technology was developed, amplification of a minute amount of DNA extracted from various archived tissues could be performed. In the analysis of degraded or ancient DNA, the extraction process represents one of the critical stages. However, significant difficulty in extracting nucleic acids from mummified tissues has been reported due to chemical modification, degradation, the small amounts, inhibition, and contamination over a long period. These problems can make amplification of the nucleic acids very difficult. From a variety of tissue samples including aorta, brain, skin, genitals, ilium. penis, lung, muscle, connective tissue, DNA extraction was carried out using either organic solvents (such as phenol/chloroform) or nonorganic solvents (salt) method. The amount of DNA retained in the mummy is assumed to be minute and degraded, so several modification methods are applied so as to achieve efficient extraction.

Here, several representative protocols for extracting DNA from mummified tissues are presented and the precautions in the analysis are described.

SAMPLES

A variety of tissue samples from mummies have been subjected to DNA extraction, including aorta,[1] brain,[2,3] skin,[4,5] genitals, ilium, penis,[6,7] lung,[8] muscle, connective tissue.[9]

SAMPLE PREPARATION

Samples should be obtained with extreme caution to avoid contamination from other DNA sources. Pre- and post-PCR operations should be performed in separate rooms, and a laminar flow cabinet is used during extraction and purification steps. In each run, there is a negative control (water) used to detect contamination in the reagents.

The surfaces of the biopsy sites are cleaned and tissue samples are obtained from deep sites. After washing with sterile distilled water, tissues are cut into small pieces and then homogenized with phosphate-buffered saline (PBS)[5,6] or pulverized with a mill after lyophilization in the liquid nitrogen.[1,6,8] The sample sizes were 1.6 g, 0.5–1 g, 5 mm^3 size,[2,4,6] and 50 mg, 0.5 g, 1 g,[1,5,6] respectively.

DNA EXTRACTION

DNA extraction from mummified tissues is carried out using either organic solvents (such as phenol/chloroform) or nonorganic solvents (salt) to remove proteins. The amount of DNA retained in the mummy is assumed to be minute and degraded, so several modification methods are applied so as to achieve efficient extraction. The representative methods are described here. The sample size is determined depending on the degree of degradation and the amount of retained DNA in the mummified tissues.

Method 1 (Nonorganic Solvents Method: PUREGENE™ DNA Isolation Kit)

The PUREGENE™ DNA Isolation kit (Gentra Systems Minneapolis, MN) is used to extract DNA from mummified tissues.[1,10]

In this kit, purification of genomic DNA is carried out using ammonium acetate as a substitute for toxic organic solvents in the protein precipitation step. The pulverized tissue is mixed with cell lysis solution containing Tris–HCl, ethylenediaminetetraacetic acid (EDTA), and sodium dodecyl sulfate (SDS), and incubated at 65°C for 60 min. After proteinase K solution (20 mg/mL) was added to the lysate, incubation at 55°C is carried out until tissue particulates have dissolved. RNase A solution (4 mg/mL) is added to the lysate and incubated at 37°C for 60 min. Protein precipitation solution (ammonium acetate) is added to the solution and vortexed vigorously then centrifuged. The DNA is precipitated with 100% isopropanol (2-propanol). After centrifugation, the pellet is

DOI: 10.1081/E-EDGP 120027897

washed several times with 70% ethanol and then air-dried. Purification is carried out with a Microcon™ YM-100 microconcentrator (Millipore, Bedford, MA). Finally, the DNA is hydrated with sterile distilled water. The extract is quality-checked by agarose gel electrophoresis and determined by a UV spectrophotometer. The E_{260}/E_{280} ratio is recommended to be greater than 1.5, as the success rate of PCR is thought to depend on the purity. When the DNA yield is expected to be low (<1 μg), DNA carrier such as glycogen solution (20 mg/mL) is added.

Method 2 (Organic Solvents Method: Phenol/Chloroform Extraction)

This method has been used conventionally and is still widely used for degraded and aged samples. Many modifications are presented for the kind of organic solvents or reagent of digestion and so on. Here the representative method is described as applied to the extraction of mummified tissues.

5 M GTC digestion method

Guanidium thiocyanate (GTC) is a chaotropic agent commonly used for tissue lysis of archived specimens.[6,7] After homogenization, the pellets are lysed in a 5 M GTC buffer containing 5 M GTC, 0.5% bovine serum albumin, 80 mM EDTA, 400 mM Tris–HCl (pH 7.5), and 0.5% sodium-*N*-lauroylsarcosine at 60°C for 1 hr and then at 37°C overnight. DNA is extracted twice with phenol–chloroform at a 1:1 ratio, followed by chloroform once, and then precipitated by the addition of a 1/10 volume of 3 M sodium acetate (pH 5.2) and 2.5 volumes of absolute ethanol. The pellets are washed with 70% ethanol and air-dried. They are then dissolved in Tris–EDTA [10 mM Tris–HCl (pH 8.0), 1 mM EDTA] buffer.

Proteinase K digestion method

Samples are put into digestion buffer (10 mM Tris–HCl, pH 8.0, 10 mM EDTA, 50 mM NaCl, 2% SDS) containing proteinase K solution (10 mg/mL) and incubated for several hours at 56°C.[1,8] Additional aliquots of proteinase K are added to achieve complete digestion. Next, the solution is extracted with phenol/chloroform/isoamyl alcohol (25:24:1) by a mild mixer. After centrifugation, the upper phase is transferred to a new tube. The extraction is repeated until the interface is clear. Finally, one more extraction is performed with chloroform to remove phenol, and the aqueous phase is put into another tube. After the addition of 5 M NaCl solution, DNA is precipitated with 100% ethanol. The recovered DNA is washed three times with 70% ethanol and air-dried. It is hydrated with sterile distilled water.

Microconcentrator-Based Method. Samples are put into the solution containing 10 mM Tris–HCl (pH 8.0), 2 mM EDTA, and 10 mM NaCl.[2,8,11] The tissue is broken up into small pieces by vortexing, and then collagenase is added. The tubes are incubated at 37°C with slow agitation for 3 hr. Sodium dodecyl sulfate is then added as well as dithiothreitol (DTT) and proteinase K. Incubation is continued for approximately 20 hr. The solution is extracted twice with water-saturated phenol of neutral pH and once with chloroform/isoamyl alcohol (24:1). It was concentrated by a Centricon 30 microconcentrator.

Silica-Based Method. Extracts of DNA are made from each sample by a silica-based method that is highly efficient in the retrieval of ancient DNA.[5,12]

DNA extraction is carried out with the supernatants in an automated nucleic acid extractor, starting with proteinase K digestion at 56°C for 1 hr. A standard phenol/chloroform extraction is carried out, followed by mixing the samples with a silica powder (glass milk, Dianova). This process produces a binding of DNA to the glass beads in the presence of isopropanol and sodium acetate (2.0 M, pH 4.5). In the last phase of the automated extraction procedure the DNA/glass milk samples are collected on filtration membranes and washed with ethanol. Finally, the DNA is manually eluted from the silica beads with sterile water and run on a 3% agarose gel.

CONCLUSION

The results obtained from the method described above are listed in Table 1.

A PEREGENE™ DNA Isolation kit is useful for extracting DNA from relatively fresh mummified tissues, compared to the archaeological samples, and it presents no hazard.[1,10] For tissues preserved for thousands of years, the phenol/chloroform method may be superior to the kit. Konomi et al.[6] have compared nine extraction methods and concluded that GTC-based methods are more efficient than proteinase K/detergent-based methods for the recovery of both DNA and RNA from mummified tissues. However, proteinase K is a powerful protein lysis reagent and has been widely used. It is not clear which is better for digestion, as both are quite useful.

Although mummified tissues are well-preserved for thousands of years, the integrity of nucleic acids for molecular biological study still remains as an issue.[13] Cooper and Wayne[14] has commented that the extracted DNA from a 2400-year-old mummy was, in hindsight, likely a contaminant both because of its size and nature. Furthermore, it has been shown that more than 99% of DNA isolated from mummified tissues is depolymerized and chemically modified.[2,4,15]

Table 1 DNA extraction from mummified tissues

Sample	Time after death	Extraction method	PCR success rate	Ref.
Aorta	1.5 years old	NO	1/1 (HLA)	[1]
Skin of leg	2400 years old	PC(P)	1/23 (cloned and sequenced)	[4]
Brain	7000 years old	PC(PM)	1/1 (mtDNA)	[2]
Skin of hip, extremities	>500 years old	PC(PS)	8/17 (Y-specific 3.4 kb repeat sequence)	[5]
Genitals, ilium, penis	>800 years old	PC(G)	12/12 (GAPDH), 0/12 (hepatitis viruses)	[6]
Lung	3600 years old	PC(P)	25/48 (*Mycobacterium tuberculosis*)	[8]
Brain	8000 years old	PC(P)	1/1 (mtDNA)	[3]
Genitals	>800 years old	PC(G)	12/12 (GADPH), 2/12 (*M. tuberculosis* complex)	[7]

GAPDH: glyceraldehydes 3-phosphate dehydrogenase; NO: nonorganic method; PC: phenol/chloroform method; (G): GTC digestion; (P): proteinase K digestion; (PM): proteinase K digestion + microconcentrator; (PS): proteinase K digestion + silica.

It is important to prevent contamination, to remove the inhibitors, to achieve efficient recovery, and to confirm authenticity when DNA is extracted from mummified tissues preserved for a long time. The study of ancient DNA poses numerous problems, some of which are presented below.

Small Size of DNA

The DNA recovered from ancient tissues is severely degraded, so it is difficult to amplify successfully more than approximately 200-bp-long fragments.[2,12] In the typing of HLA alleles from aorta tissue of an approximately 1.5-year-old mummy, we have been able to obtain specific PCR fragments sized approximately 100–200 bp long, but have sometimes failed in amplifying a 429-bp fragment used as a positive control.[1]

Low Amount of DNA

DNA yields of approximately 70 ng/μL can be measured for bone samples, and yields of less than 2 ng/μL can be measured for soft-tissue samples.[5] We have recovered 23 ng of DNA per milligram of dried aorta tissue naturally preserved for approximately 1.5 years. Polymerase chain reaction amplification fails when the amount of available DNA is too minute.[16] Both bone and soft-tissue samples are suitable for ancient DNA analysis, but that skeletal remains should be given preference when source materials are severely degraded.

Authenticity of Amplified DNA

It is important to confirm whether the recovered DNA is authentic or not. For example, it should be noted whether it was derived from an authentic human, a modern human, an animal, a pathogen, or some other source. It remains possible that a sample can be contaminated during the experiment. It is therefore necessary for rigid quality criteria to be established to avoid more spurious and unsubstantiated reports.

Marota et al. have reported that DNA would be entirely degraded after slightly more than 800 years, and this result provides an indirect argument against the reliability of claims regarding the recovery of authentic DNA from Egyptian mummies and bone remains.[13]

Inhibitors

DNA extracts from ancient tissue remains often contain an unidentified component that inhibits polymerase activity. Inhibition can result from either reducing sugars[17] or an excess of coextracted microbacterial DNA,[18] the remains of porphirines,[19] degraded nucleic acids,[20–22] and soil components such as humic and fulvic acids, tannins, or iron ions (Fe^{2+}),[23–25] or collagen type.[26] This inhibition may be overcome by the addition of bovine serum albumin and increased amounts of enzyme. Through the purification step by the microconcentrator device described above, the success rate of PCR is increased.

DNA Storage

C. William Kilpatrick
University of Vermont, Burlington, Vermont, U.S.A.

INTRODUCTION

The successful extraction or amplification of DNA from fossils at least thousands of years old,[1–9] from preserved tissues at human burial sites,[10–16] and from museum specimens,[17–25] clearly demonstrated the potential for the storage of DNA. Spontaneous decomposition of DNA primarily results from depurination/β-elimination[26] and free radical oxidation pathways.[27] In solution DNA will spontaneously degrade to short fragments over a time period of several thousand years at moderate temperatures.[26] Numerous methods have been developed for the storage of DNA or for tissue for the extraction of DNA; however, relatively few studies have been published that examine or compare the ability of these methods to prevent or reduce DNA degradation, especially over periods of times greater than a few months.

MECHANISMS OF DNA DEGRADATION AND LOSS

Degradation or loss of DNA during storage primarily results from depurination/β-elimination,[26] free radical oxidation,[27] action of endogenous nucleases,[28] and binding of DNA to storage tubes.[29] At high ionic strengths, a large proportion of a DNA sample may be bound to the walls of polyethylene and most polypropylene tubes.[29] At moderate or low ionic strength, where DNA is more often stored, most polypropylene tubes bind less than 5% of the DNA; however, some tubes may bind as much as 25% of the DNA and considerable variation was reported among batches from the same manufacturer.[29] Storing short DNA fragments in polypropylene tubes often induces a significant amount of strand separation[30,31] and, at high salt concentrations, leads to the formation of multistranded complexes.[31,32] Polyallomer tubes show no binding or denaturation of DNA under any condition.[29]

In an aqueous solution, DNA is known to degrade by the two-step process of depurination and β-elimination.[26] The depurination reaction is mainly acid-catalyzed under physiological conditions.[33] At sites of depurination, the DNA chain undergoes cleavage by a β-elimination process within a few days.[34] The pH of the storage solution is expected to have a large effect on DNA stability. DNA bases and deoxyribose sugars are also susceptible to degradation by free radical oxidation.[27] Use of specific chelators, such as EDTA, has been found to be extremely effective at reducing free radical oxidation for at least 1 year of DNA stored at room temperature.[35]

Degradation of DNA in a sample may also result from the action of endogenous enzymes, endo- and exo-nucleases, that cleave DNA strands.[28] Temperature, pH, and salt concentration are known to influence enzymatic activity.[36] Nucleases are divalent cation-dependent enzymes and their activity is much reduced at high concentrations of EDTA or diaminocyclohexanetetraacetate (CDTA).

STORAGE OF DNA EXTRACTS

Traditionally, purified DNA is stored in either sterile water or TE (10 mM Tris, pH 7.5–8.0, 1 mM EDTA). In either of these solutions, DNA may be stored for several months at either 4°C or −20°C with little degradation. Extracted DNA stored in TE at temperatures between −70°C and 37°C for 6 months demonstrated little degradation, whereas DNA stored at 45°C to 65°C shows signs of degradation within 24 hr and was completely degraded by 8 days.[37] Repeated freezing and thawing of DNA does not appear to result in degradation. For longer cryogenic storage, DNA should be stored in nuclease-free solutions at −70°C (ultrafreezers) to −196°C (liquid nitrogen).

Alternatively, DNA may be precipitated and stored in ethanol often layered with chloroform at room temperature or 4°C. Although lyophilized DNA stored at −20°C is protected from degradation, problems with rehydration after prolonged storage have been reported.[37] Buffers containing EDTA have been used to store DNA at room temperature with little degradation for periods of time of less than a year[35,38] to over 2 years.[39] High concentrations of EDTA[38] and the addition of ethanol[35] have been found to further enhance DNA stability.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021398

STORAGE OF TISSUES FOR DNA EXTRACTION OR AMPLIFICATION

Blood samples in vacuum tubes containing EDTA stored for 4 weeks at temperature from 4°C to 37°C yielded high molecular weight DNA, although degradation was evident in samples stored at room or higher temperatures.[40] Interestingly, blood samples stored at 37°C demonstrated less DNA degradation than those stored at 23°C.[40]

CRYOPRESERVATION

Cryopreservation is an effective method of preservation of tissues for DNA extraction and is often reported as the preferred method;[41–43] however, freeze–thaw cycles have been found to produce degradation.[38,44] Numerous noncryogenic methods have been developed and appear to be effective for the preservation of tissues for DNA extraction.[39]

DEHYDRATION

Ethanol or isopropanol has been suggested[45,46] for the storage of tissues for DNA extraction. Tissues stored in ethanol have been reported to yield highly degraded DNA fragments;[44,47] however, much of this degradation appears to occur during the extraction procedure rather than during storage.[39] For short-term storage of up to 1 year, 70% ethanol appears to function as well as 100% ethanol; however, 100% ethanol is recommended for storage exceeding 2 years.[48] Other organic solvents have been examined for DNA preservability of insects and their intracellular symbiotic bacteria.[49] At room temperature for 6 months of storage, acetone, diethyl ether, and ethyl acetate were as efficient as ethanol or isopropanol at DNA preservation, whereas chloroform and methanol were poor preservatives.[49] In addition, acetone was found to be more robust against water contamination than ethanol[49] and may prove to be a better storage solution than ethanol.

Genomic DNA in dried blood spots on filter paper[50] or other media (i.e., Guthrie cards or FTA® cards) stored at room temperature is reported to be stable for at least 7.5 years.[51] This method of tissue storage is widely used in human genetic studies; however, some degradation has been reported.[44,52] The utility of this method of storage has proven effective[53] and recent advancements allow direct PCR amplification without DNA extraction.[54]

LYSIS BUFFERS AND OTHER SOLUTIONS

A number of different ''lysis buffers'' have been developed for the storage of tissues at room temperature.[44,55,56] The various formulations for ''lysis buffers'' generally consist of a Tris buffer at a pH between 7.5 and 8.0, EDTA (chelator), and sodium dodecyl sulfate or *n*-lauroylsarcosine (detergents to lysis cells). These buffers have demonstrated to be effective at room temperature in the preservation of DNA in blood samples for 6 months[44] and tissue samples for 2 years or more.[39]

The use of a dimethyl sulfoxyde (DMSO) salt solution for the preservation of DNA in various tissues has been demonstrated to be effective for storage from 6 months to over 2 years.[39,44,48] This solution of 20% DMSO, 0.25 M EDTA, and NaCl 5% to saturation, pH 7.5[44,48] was found to be the most effective method of noncryogenic storage for the prevention of DNA degradation.[39]

STORAGE OF DNA IN OTHER BIOLOGICAL MATERIAL

Forensic methods of extracting DNA from a wide variety of different types of biological material (feces, hair, nails or claws, bones, teeth, dried skins, formalin-fixed, ethanol preserved specimens) and pathological materials (blood smears, chromosomal spreads, and paraffin-embedded tissues) have provided new sources of DNA for PCR amplification from stored materials. Storage methods for most of these materials have not been evaluated. Absorption of DNA to hydroxyapite is reported to result in a twofold decrease in the rate of depurination of DNA[26] and improves the chance of recovering DNA from old bones and teeth.

Storage of fecal samples in DMSO salt solution was most effective for preserving nuclear DNA, whereas storage in 70% ethanol, freezing at -20°C and drying performed about equally well for preserving mitochondrial DNA and short (<200 bp) nuclear DNA fragments.[57] Four different drying methods of fecal samples were evaluated,[58] and freeze drying and oven drying produced the greatest DNA amplification success.

CONCLUSION

Storage methods for DNA extracts and tissues for the extraction of DNA have been developed that prevent or greatly reduce the primary pathways of DNA degradation. The action of endogenous nucleases and the rates of depurination/β-elimination and free radical oxidation pathways can be greatly reduced by freezing, dehydration, or storage in buffers containing cation chelators, usually EDTA. Extracted DNA is very stable under a variety of cryogenic and noncryogenic storage methods.

Tissues stored for DNA extraction are more susceptible to degradation. Although cryopreservation is the preferred

method by many laboratories, samples are degraded by repeated freeze–thaw cycles. Dried blood spots have proven to be a reliable method to store material for DNA extraction and amplification. A variety of organic solvents, including ethanol, isopropanol, and acetone, have been shown to be effective for the storage of tissue for DNA extraction, although degradation may occur during the extraction process. The use of ''lysis buffer'' or DMSO salt solution is an effective noncryogenic method that greatly reduces degradation that may occur during both the storage and the extraction procedure.

DNannotator—Annotation Software Tool Kit for Regional Genomic Sequences

Chunyu Liu
University of Chicago, Chicago, Illinois, U.S.A.

INTRODUCTION

Genome annotation is a process of identifying the location and function of genes and many other elements in a genome. Genome annotation documents the true meaning of the genome sequence and serves ongoing biomedical research that is based on genomics information. Public annotation efforts and data sources have some limitations. High-throughput technologies used in many labs produce more and more local data at an increasing rate. Translating discoveries in a local laboratory into genome annotation in a manner that integrates the local data with the public data is another recurrent challenge that requires general software support. DNannotator provides a series of software tools for local batch annotation. The annotation target can be either user's own genomic DNA (gDNA) sequence or public-assembled human chromosomal sequences. The annotation source can be genes, oligos/primers, sequence tag sites (STSs), and single nucleotide polymorphisms (SNPs). Annotation quality can be relatively easily managed as several log data files are provided by DNannotator.

BACKGROUND

Genome annotation is a process that involves procedures in both the wet and the dry lab. The wet lab performs experiments, identifies genes, polymorphisms, and other genomic elements, and studies genes' functions. The dry lab maps those identified elements onto genomic sequences. In this article, we restrict the term of ''annotation'' to dry lab sequence mapping. The terms annotation and mapping can be used alternatively here. To perform an annotation, two basic inputs are required: gDNA sequence data and interesting genomic elements (feature source data) such as genes and markers. Based on the ATGC sequence data, annotations of genes and their regulatory elements can reveal the true functional units of the genome. Annotations of other elements such as genetic markers, oligos, and primers are essential for genetic studies as they are the basis of many genetic experiments.

Ever since the sequence data were obtained from the genome sequencing project, scientists started to perform *large-scale systematic genomewide annotation* on those sequence data. Today, the human genome sequencing is just about finished. The human genomic sequences were assembled by National Center for Biotechnology Information (NCBI) and Celera. The sequence data have been annotated by several public or private institutes using their own tools and data sources. The data can be accessed at Web-based databases, including NCBI's Map Viewer (http://www.ncbi.nlm.nih.gov/mapview/map_search.cgi?taxid=9606), University of California Santa Cruz's (UCSC's) Genome Browser (http://genome.ucsc.edu/) and Sanger Center's Ensembl (http://www.ensembl.org/), and Celera (http://www.celera.com/). For the public annotation, both gDNA sequences and the genomic feature source data are available. For example, the human chromosomal sequences can be found at NCBI's human genome database; human gene data can be found at either Genbank or Unigene database; SNP data can be accessed at dbSNP.

In the course of many research projects, investigators need to perform *regionwide local annotation*. As lab technologies have improved, especially with introduction of high-throughput experimental methods, many investigators produce large amounts of experimental data and knowledge on genes, regulatory elements, and variants. For example, one ABI 3730 sequencing machine can resequence 1.8-Mb sequence in 1 day. Hundreds of SNPs could be discovered in 1 day. Besides the data generated in the investigators' own lab, many new data can be found in the latest journal publications. Often enough, these new data cannot be found at the time of publication in the existing public genomic annotation databases because of the significant time gap between the time of data deposit to public databases and the time of releasing an updated genome annotation using the corresponding data, assuming all the data are collected by the public databases. Normally, this kind of delay would be more than 3 months. Unfortunately, this assumption about public data collection is not always true either. SNP data are not required to be deposited into any centralized database when a paper is published. It is frequently observed that some SNPs studied or discovered are absent in dbSNP. But dbSNP is the only SNP database used in all public annotation. An effective research design requires efficient

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120030821

use of existing knowledge. Hence data produced in an individual investigator's lab and all other data outside of public annotation databases are as valuable as data from public annotation. They need to be integrated with data existing in the current version of public genome annotation. This basic requirement poses an important challenge to current bioinformatics technology because of the following major problems:

1. Heterogeneous annotation target sequence or platform. Because of the human genome sequence assembly, annotation is kept updated at a speed of several months per release, different annotation databases could use different versions of sequence assembly at certain time period. Investigators may want to use different gDNA sequences either for a small regional sequence or a whole chromosome. Sequence assembly is difficult for some genomic regions because of enriched repeat sequences or difficulty of cloning in the public sequencing project. An individual investigator might have better quality sequence assembly of one region than the public assembly. All these different flavors of gDNA sequences created needs of user's local annotation.
2. Enormous amount of data. As described above, an individual lab could generate or collect large amount of data for local annotation.
3. Heterogeneous data formats. Different data source could use very different data format. Preparing input data for annotation tools and formatting output data to meet requirement of data integration and further data mining are not trivial.
4. Annotation quality control. For any intent of feature mapping, the results can be either success or failure. The annotation quality is highly dependent on the sensitivity and specificity of the mapping methods and parameter settings. Any simple bug in the annotation algorithm could cause major defects of the annotation results. The observed problems in public annotation include missing of features which should be mapped, wrong mapping positions, and so on. Because the current public annotation does not provide much log information, it is difficult to detect errors and to find out the causes.

There are a number of tools supporting region-wide local annotation. They can be roughly put into three categories:

1. Use public source data (stored in databases) and some gene prediction algorithm to annotate user's gDNA sequence. Genotator,[1] NIX (Williams et al., http://www.hgmp.mrc.ac.uk/Registered/Webapp/nix/), GeneMachine,[2] GAIA,[3] Alfresco,[4] GESTALT,[5] RUMMAGE,[6] and Oak Ridge National Laboratory Genome Analysis Pipeline (http://compbio.ornl.gov/tools/pipeline) provide integrated annotation, including mapping of known or predicted genes and/or regulatory elements by running multiple gene-prediction programs and searching against static public databases. But none of them incorporate methods for SNP mapping, which is essential for positional cloning projects for complex diseases. None of these systems takes source data supplied by the end-user, unless the user can modify the databases in the annotation system.
2. Annotate user's own source data to user's own gDNA sequence. Freeware, such as Artemis,[7] Sequin,[8] and some commercial software such as Vector NTI, provides a good interface to do manual annotation. They do not support batch annotation. Some other programs can be used to assist annotation. For example, BLAST[9] is good at homolog sequence searching. Sim4,[10] est_genome,[11] and Spidey[12] could be used to define the intron–exon structure of a gene. e-PCR[13] can be used to map STSs. However, most of these programs produce data in their own formats which cannot be directly converted into standard format annotation. Therefore, strictly speaking, they are not real annotation tools.
3. DNannotator can use user's own collection of source data (either from public places or generated in the labs) to annotate both user's own gDNA sequence and public chromosomal sequences. DNannotator complements the existing tools mentioned above. It is the first toolkit providing SNP mapping and the only one with the capability to migrate annotations from one sequence platform to another. DNannotator was first described in *Nucleic Acids Research* (2003).[14] It can be accessed at http://sky.bsd.uchicago.edu/DNannotator.htm.

Design and Function of DNannotator

DNannotator takes annotation source data, such as SNPs, genes, primers, etc., prepared by the user, and/or a specified target of genomic DNA, and performs de novo annotation. DNannotator can also robustly migrate existing annotations in Genbank format from one sequence to another given that the new sequence covers the same genomic region. The annotation migration function is useful when we are dealing with different versions of sequence assembly or different scope of a region, e.g., one is small regional sequence and another is whole chromosome sequence. The major functions of DNannotator are illustrated in Fig. 1. The functions of DNannotator are divided into two groups: one for annotation over

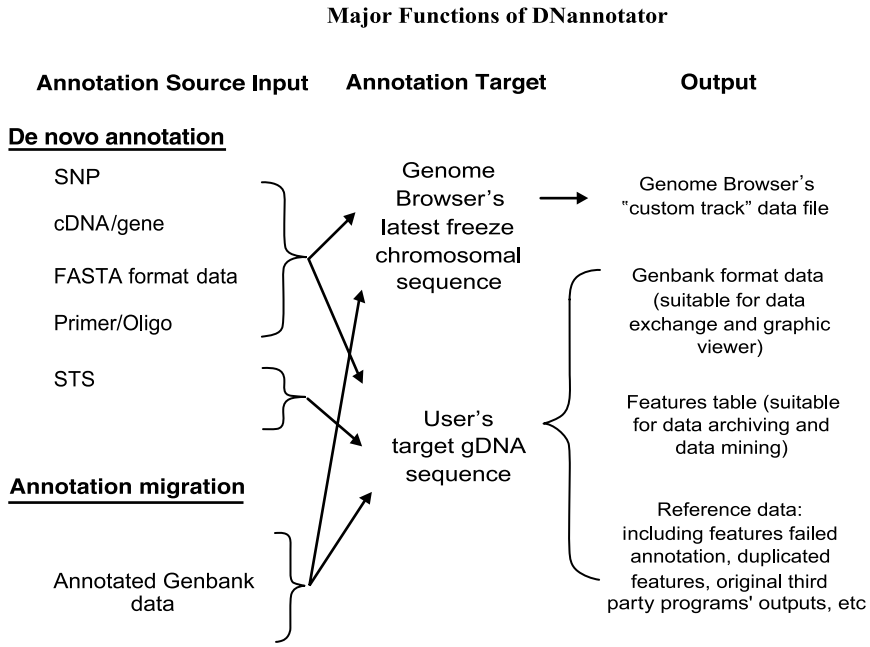

Fig. 1 Major functions of DNannotator. Using input source data of STSs, SNPs, primers, general FASTA, or tab-delimited text data, de novo annotation can be performed on target gDNA sequences through different function modules of DNannotator. A single Genbank format data file can be used as input to perform annotation migration. Similar inputs and outputs are used for the two types of annotation targets.

user's own gDNA sequence and another for annotation over chromosomal sequence (from UCSC Genome Browser's latest version human genome sequence assembly). Both groups can handle similar types of input source data. The input source data can be SNPs, genes, primers/oligos, and STSs. Besides de novo annotation using raw source data, annotated sequence data in Genbank format can be used as input to perform annotation migration, transferring annotated features to another sequence platform—either user's own gDNA or a public chromosomal assembly.

There are four types of optional outputs generated by DNannotator: 1) annotation results in Genbank format; 2) annotation results in tab-delimited text as feature table; 3) reference data reporting features failed at annotation, or features mapped to multiple locations, as well as some sequence analysis raw data such as BLAST's results; 4) besides those, for annotation over a public chromosomal sequence, a GFF format feature data can be provided.

Tab-delimited text output can be imported and managed in a database or spreadsheet and can be combined easily with existing annotation from elsewhere. Genbank format data can be graphically viewed in Artemis (Fig. 2). GFF format annotation results can be viewed in Genome Browser side by side with other annotation provided by Genome Browser (Fig. 3). Reference data can help user to evaluate and improve annotation quality.

MAJOR FEATURES OF DNannotator

DNannotator has four major features: ''local,'' ''batch,'' ''transparent,'' and ''user- and data-friendly.''

1. Local: All functions of DNannotator were designed to handle the user's own local data collection.
2. Batch: All functions were designed to process batch of input source data.
3. Transparent: Log data are provided with the annotation results, so that the annotation quality can be managed. Some major analysis parameters can be adjusted through the Web interfaces.
4. User- and data-friendly: DNannotator not only provides a user-friendly Web interface for data input, but also accepts data on a large scale needed by a research data pipeline. The input data normally can be prepared or organized easily from the lab data or other source; the output data are in multiple optional formats either ready for graphic view, or for databasing, or for further data mining or wet-lab assay design.

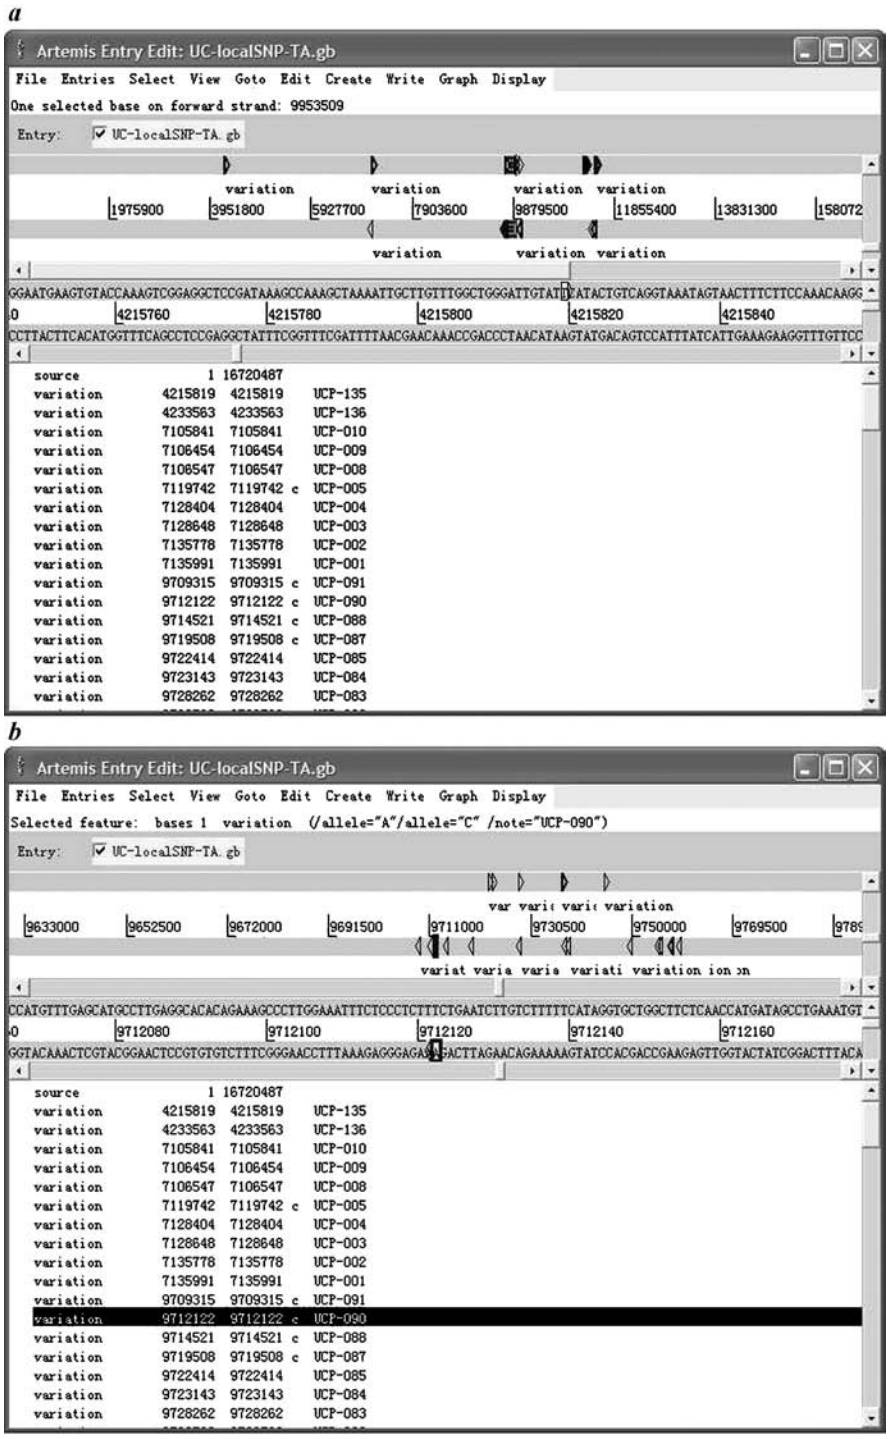

Fig. 2 Graphic view of SNPs annotated onto local sequence assembly. Genbank format output from DNannotator was read in as ''Entry'' by Artemis. One hundred SNPs discovered locally were displayed. (a) Overview of annotations. (b) Zoom-in view of annotations. The window is composed of three panels. Features listed in lower panel, graphic icons in upper panel, and sequence data in middle panel are internally linked to each other. Clicking one of them will activate highlight of corresponding elements in the other panels. (*View this art in color at www.dekker.com.*)

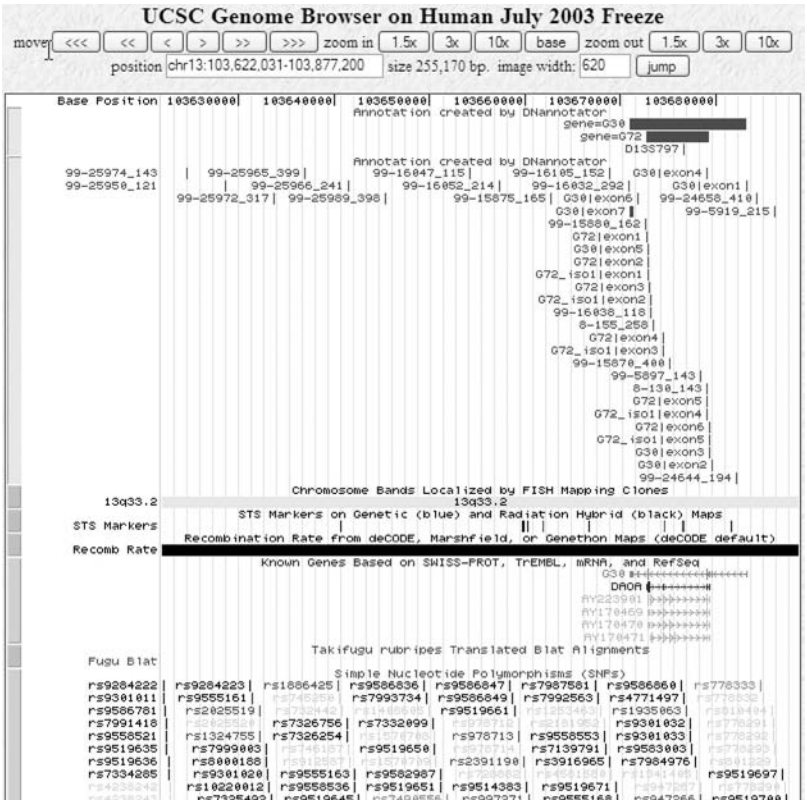

Fig. 3 Viewing annotation created by DNannotator in Genome Browser. The SNPs and genes reported (on small DNA fragment AE014312) by Chumakov et al. were migrated to Genome Browser's latest freeze of chromosome 13 by DNannotator, with an output of custom track data file for Genome Browser, which can be directly viewed side by side with all other annotations provided by Genome Browser. (*View this art in color at www.dekker.com.*)

APPLICATION EXAMPLES OF DNannotator

De novo Annotation

Example 1: from local discovery or newly published data to genome annotation.

In the lab, we sequenced several genes and discovered 100 SNPs. At that time (early 2002), public assembly of human gDNA sequence on 13q32–33 still had a lot of errors. We manually assembled a 17-Mb regional sequence with much better quality, which was later replicated by a subsequent public assembly. DNannotator was then used to annotate all 100 SNPs on this self-made sequence assembly. SNP data were prepared using Microsoft Excel spreadsheet and saved into a tab-delimited text file. DNannotator takes this SNP data file with gDNA sequence in FASTA format and maps all the SNPs to the self-made regional sequence. The Genbank format output is viewed in Artemis as shown in Fig. 2.

Annotation Migration

Example 2: from newly published Genbank data to genome annotation.

Chumakov et al.[15] reported association between G72 gene and schizophrenia. In this paper, 191 SNPs and two novel genes (G72 and G30) on chromosome 13 were reported. Most of these data could not be found in public annotation. Chumakov et al. deposited a series of Genbank format sequence data for chromosome 13 fragments. DNannotator was used to migrate annotations from these fragments to public assembly of chromosome 13 to find out how these SNPs and genes are mapped on human chromosome 13 and how these SNPs and genes related to the other SNPs and genes. As an example, AE014312 is one of the Chumakov's deposit with 250-kb sequence and contains 20 SNPs, 2 genes, and 1 STS. DNannotator takes this input and produced annotation on human public assembly chromosome 13. All features (SNPs, genes, and STSs) were mapped to chromosome 13

in one step. The GFF format data are viewed in Genome Browser as in Fig. 3. In this figure, we can view all annotations provided by Chumakov's group with all the other data created by public annotation.

SUMMARY

DNannotator provides services of batch local annotation which are not available elsewhere. With these tools, user can map SNPs, genes, and STSs to user-specified genomic DNA sequences including the public-assembled human chromosomal sequences. Thus integration of genomic data can be performed easily. DNannotator incorporates the ideals of ''batch,'' ''local,'' ''transparent,'' and ''user and data-friendly'' throughout its tool kits. Lack of these four features is the major shortcoming of many existing bioinformatics tools. We often see new tools handling only a single request, producing outputs without any log information, or ignoring user's own data.

Because of limits of computing power, DNannotator currently only annotates on a single human chromosome per analysis. Therefore the user could meet an obstacle if the source data's chromosomal source is unknown or it is a mixture from multiple chromosomes. We are working toward having biogrid as our computing platform. Once implemented, DNannotator should be able to perform genome-wide annotation.

ACKNOWLEDGMENTS

Duchenne Muscular Dystrophy

Masafumi Matsuo
Kobe University Graduate School of Medicine, Chuo, Kobe, Japan

INTRODUCTION

Duchenne muscular dystrophy (DMD) is a common inherited disease with a worldwide incidence of 1 in 3500 male births. DMD is a lethal disorder of childhood characterized by progressive muscle wasting. Affected individuals are wheelchair-bound by the age of 12 and succumb to cardiac or respiratory failure in their mid to late 20s.

Dystrophin, the gene defective in DMD was isolated in 1986. Since then, genetic diagnosis of DMD has been done leading to better understanding of the disease process. Based on the molecular pathogenesis of DMD, molecular therapies for DMD have been proposed.

CLINICAL DIAGNOSIS

Patients with DMD show normal growth and development in their early childhood. In DMD, affected boys start to show disturbance of walking and frequently fall because of muscle weakness at 4 to 5 years of age. Patients are shown to have a positive Gower's sign wherein the child climbs up his thighs to extend the hips and push his trunk up. He manages to walk but his muscle strength gradually decreases. He loses the ability to climb up stairs. Lumbar lordosis becomes more exaggerated and the waddling gait increases. Patients usually are wheelchair-bound by the age of 12. Muscle wasting progresses as the patients get older until finally respiratory or cardiac failure develops due to muscle wasting.

Serum creatine kinase (CK) is markedly increased 50 times more than the normal range in infantile DMD. This marked elevation of serum CK is the most important hallmark for the diagnosis of DMD. During the asymptomatic period, elevation of serum CK is the sole sign for DMD. Some DMD patients are accidentally identified due to elevations of AST or ALT, which are commonly examined for liver function, because serum CK elevation is accompanied with elevations of AST and ALT.

GENE DIAGNOSIS

Duchenne muscular dystrophy is caused by mutations of the dystrophin gene.[1] The dystrophin gene is 3000 kb in size and consists of 79 exons encoding a 14-kb mRNA.[2,3] At least eight alternative promoters that are regulated in a tissue- or development-specific manner have been identified on the dystrophin gene. The unusually high incidence of DMD in all human populations could be simply a reflection of the enormous mutation target size of the gene, but the recombination rate is reported to be four times the rate expected for a gene of this size.[4] Nearly two-thirds of mutations identified on the dystrophin gene are deletions or duplications occupying a single or multiple exons, with the rest of the DMD cases having other types of mutations including point mutations. Remarkably, deletion mutations have been localized to two deletion hot spots of the dystrophin gene, the 5′ and the central regions.

Multiplex PCR Analysis

Currently, multiplex PCR analyses that amplify deletion-prone exons are used as the first step for gene diagnosis. Two sets of PCR amplification are used to screen 19 deletion-prone exons (exons 1, 3, 4, 6, 8, 12, 13, 17, 19, 43–45, 47–52, and 60).[5,6] Using this method of examination, one finds that nearly half of the DMD cases are shown to have deletion mutations. Therefore, the rest of the cases need further examination to identify the responsible mutation in the dystrophin gene.

Southern Blot Analysis

To examine the deletion/duplication in every exon of the dystrophin gene, Southern blot analysis is used, using segments of the dystrophin cDNA as probes.[7] Two-thirds of DMD patients are shown to have recombination events of deletions or duplications spread in one or more exons at the genomic DNA level.[8] However, Southern blot analysis not only needs high-quality DNA and radioisotope, but it is also time-consuming.

Detection of Fine Mutation

In DMD cases that have no large recombination event, identification of the causative mutation remains a laborious goal because of the difficulty in detecting a single point mutation in the 3000-kb-sized gene. To

DOI: 10.1081/E-EDGP 120025798

facilitate the identification of mutations in the dystrophin gene, more than 99% of which is made up of introns, dystrophin mRNA that is 100 times smaller than the dystrophin gene has been analyzed.[9] Analysis of dystrophin mRNA expressed in lymphocytes leads to not only identification of rare genomic mutations, but also to disclosures of nonauthentic alternative splicing.[10–12] In addition, several ways to identify small mutations have been proposed.[13–17] In the advent of recent advances in mutation analysis techniques, more than 90% of DMD cases are shown to have mutations in the dystrophin gene.[18,19]

PATHOLOGICAL DIAGNOSIS

The pathological examination of biopsied skeletal muscle confirms the diagnosis of DMD. Immunohistochemical analyses of normal muscle demonstrate that dystrophin is present along with muscle cell membranes. In DMD, dystrophin is missing from skeletal muscle.[20] Western blot analyses using dystrophin antibody reveals a band corresponding to 427 kDa, close to the predicted size of dystrophin, in extracts of normal muscle tissue, whereas no protein can be detected in DMD.

TREATMENT

For DMD patients, supportive therapies such as rehabilitation or ventilator support are clinically employed but no effective way to improve the clinical course is available. Since the discovery of the dystrophin gene, gene therapy is now considered an attractive way to cure the disease. The main aim of DMD gene therapy is to establish a way to inject constructed dystrophin genes consisting of partial- or full-length cDNA joined to an appropriate promoter. Although much progress has been made in this field of study, we still seem to be a long way from achieving a clinically significant result. As an alternative for gene transfection, molecular therapies have been studied including antisense oligonucleotide treatment[21–23] or translational readthrough treatment using gentamicin.

Antisense Oligonucleotide Treatment

An alternative strategy for DMD treatment is to retard the progression of the clinical symptoms, i.e., to convert DMD into the BMD phenotype. Theoretically, this therapy can be done by changing a frame-shift mutation causing DMD into an in-frame mutation characteristic of BMD by modifying the dystrophin mRNA. Artificial induction of exon skipping with antisense oligonucleotides is a way to make the out-of-frame dystrophin mRNA in-frame. Artificial induction of exon 19 skipping using an antisense oligonucleotides against the splicing enhancer sequence has been reported,[24] and this treatment was shown to produce dystrophin expression in exon-20-deleted DMD myocytes.[23] Disruption of the splicing enhancer sequence to induce exon skipping was further evidenced by the fact that in the nonsense mutation of exon 27 the dystrophin gene resulted in exon 27 skipping, producing an in-frame dystrophin mRNA.[25] In addition, another natural example causing conversion of DMD to BMD was identified in a nonsense mutation in exons 25 and 29.[26,27] Furthermore, BMD has been shown to have a nonsense mutation in in-frame exons.[28,29]

Antisense oligonucleotides against a purine-rich sequence have been used to induce skipping of exons 44, 45, 46, 49, 50, 51, or 53.[22,30,31] In these studies, induction of exon skipping led to the expression of dystrophin in their respective dystrophin-deficient myocytes by correcting the translational reading frame. Recently, double exon skipping of exon 43 and 44 or exon 45 and 51 has been induced.[32] This extends the application of the antisense oligonucleotide treatment to more varieties of deletion mutations of the dystrophin gene.

Phosphorothioate DNA has been the standard choice for the clinical application of antisense technology.[33–37] However, phosphorothioate DNA is associated with a variety of potentially toxic non-antisense effects.[38] In order to develop less toxic antisense oligonucleotides, nucleic acids have been modified in various ways.[39,40] Recently, morpholino modified oligonucleotides were shown to be delivered to muscle cells efficiently.[41] Furthermore, the chimera of 2′-*O*-methyl RNA and 2′-*O*, 4′-*C*-ethylene-bridged nucleic acid (ENA) was shown to induce exon 19 skipping of the dystrophin gene 40 times stronger than the conventional phosphorothioate oligonucleotides.[42]

Translational Readthrough of Stop Codon

Aminoglycoside antibiotics have been suggested as possible therapeutic interventions for treating patients who carry a nonsense mutation because of the ability of these antibiotics to lead translational readthrough of stop codons. To evaluate whether aminoglycosides can be used to suppress the nonsense mutation in a human DMD case, four DMD/BMD cases with various stop codon sequences were tested once daily with intravenous gentamicin at 7.5 mg/kg/day for 2 weeks. However, the full-length dystrophin protein was not detected in posttreatment muscle biopsies.[43] The possible reason for the failure of gentamicin treatment in human cases is the difference in efficiency of aminoglycoside-induced readthrough among the different types of nonsense mutations.

CONCLUSION

Duchenne muscular dystrophy is a fatal disease without any effective treatment. Recent studies opened a door to the establishment of molecular therapy for DMD.

Echinococcus granulosus and *Echinococcus multilocularis*—Molecular Diagnosis

Donald P. McManus
The Queensland Institute of Medical Research, Queensland, Australia

INTRODUCTION

Echinococcosis (hydatid diseases) is a near-cosmopolitan zoonosis caused by adult or larval stages of dog tapeworms (cestodes) belonging to the genus *Echinococcus* (family Taeniidae). The two major species of medical and public health importance are *Echinococcus granulosus* and *Echinococcus multilocularis* that, respectively, cause cystic echinococcosis (CE) and alveolar echinococcosis (AE). Both CE and AE are serious and severe diseases, the latter especially so, with high fatality rates and poor prognosis if managed incorrectly. Molecular techniques are proving of value in the study of both CE and AE, in particular for investigating genetic variation in the causative organisms, for the detection of parasite nucleic acids in clinical samples, and in the identification of *Echinococcus* eggs. Detecting minute amounts of parasite DNA and mRNA, not only to identify but also to characterize the biological status of parasite material, is becoming recognized as a powerful complementary method to conventional methods such as immunodiagnosis.

CLINICAL FEATURES OF CE AND AE

A comprehensive account of the clinical features of both diseases is available[1] so only a brief description is presented here. Hydatid cysts of *E. granulosus* develop in internal organs (mainly liver and lungs) of humans and other intermediate hosts as unilocular fluid-filled bladders. The cyst (metacestode) of *E. multilocularis* is a tumor-like infiltrating structure consisting of numerous small vesicles embedded in the stroma of connective tissue. The metacestode mass usually contains a semisolid matrix rather than fluid. The initial phase of primary *Echinococcus* infection is always asymptomatic. The incubation period of CE is unclear but probably lasts for many months to years. The infection may become symptomatic if the cysts either rupture or exert a mass-effect. Recurrence may occur following surgery on primary cysts. Cystic echinococcosis has been reported to present for medical attention in subjects ranging in age from below 1 year old to more than 75 years old. The mortality rate is estimated to be 0.2 per 100,000 population with a fatality rate of 2.2%. Over 90% of cysts occur in the liver, lungs, or both. Symptomatic cysts have been reported occasionally in other organs.

Alveolar echinococcosis typically presents later than CE. Cases of AE are characterized by an initial asymptomatic incubation period of 5–15 years duration and a subsequent chronic course. Untreated or inadequately managed cases have high fatality rates. The peak age group for infection is from 50 to 70 years. The metacestode develops almost exclusively in the liver (99% of cases). Parasitic lesions in the liver can vary from small foci of a few millimeters in size to large (15–20 cm in diameter) areas of infiltration.

Early diagnosis of CE and AE can provide significant improvements in the quality of the management and treatment of both diseases. The definitive diagnosis for most human cases of CE and AE is by physical imaging methods such utrasonography. Immunodiagnosis complements the clinical picture while molecular techniques have been recently developed and adapted to advance laboratory diagnosis of AE and CE.

GENETIC VARIATION IN *ECHINOCOCCUS*

E. granulosus comprises a number of intraspecific variants or strains that exhibit considerable variation at the genetic level.[2–4] Conversely, there is very limited genetic variation within *E. multilocularis*[2,3] although recent microsatellite analysis has shown such markers can be used to examine *E. multilocularis* population structure.[5] There are no available data to indicate that either *Echinococcus vogeli* or *Echinococcus oligarthrus*, the other recognized *Echinococcus* species, is variable.

The term strain defines variants that differ from other groups of the same species in gene frequencies or DNA sequences, and in one or more characters of actual or potential significance to the epidemiology and control of echinococcosis. The extensive variation in nominal *E. granulosus* may influence life cycle patterns, host specificity, development rate, antigenicity, transmission dynamics, sensitivity to chemotherapeutic agents, and

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020842

pathology with important implications for the design and development of vaccines, diagnostic reagents, and drugs. For example, the adult parasite of the cattle strain of *E. granulosus* exhibits precocious development in the definitive host with a short prepatent period of 33–35 days, nearly a week earlier than that of the common sheep strain.[6] This complicates control efforts where drug treatment of definitive hosts is utilized as a means of breaking the cycle of transmission, as it necessitates an increase in frequency of adult cestocidal treatment.

A number of well-characterized strains are now recognized that all appear to be adapted to particular life cycle patterns and host assemblages.[2,3] To date, molecular studies, using mitochondrial DNA (*mt* DNA) sequences, have identified nine distinct genetic types (genotypes G1–9) within *E. granulosus*.[2] This categorization follows very closely the pattern of strain variation emerging based on biological characteristics.

TECHNIQUES AND APPROACHES FOR IDENTIFICATION OF *ECHINOCOCCUS* ISOLATES

Genetic variation in *Echinococcus* has been investigated in both the nuclear and mitochondrial genomes. The advent of the PCR has provided a highly sensitive approach that is now widely used for *Echinococcus* identification purposes, including discrimination of eggs. The various techniques applied for studies of this genetic variation have been described in detail.[2] A brief synopsis follows.

RFLP/RAPD Analysis

Earlier studies of molecular genetic variation in *Echinococcus* involved restriction fragment length polymorphism (RFLP) analysis using the conventional Southern blotting approach. It was able to distinguish several distinct strains of *E. granulosus*, and extensive study showed that RFLP patterns were stable within a particular strain. The conventional RFLP procedure was simplified, without loss of resolution or accuracy, by linking RFLP analysis with PCR targeting the nuclear rDNA ITS1 region. The random amplified polymorphic-PCR (RAPD-PCR) has also been used under carefully controlled conditions for distinguishing the four recognized *Echinococcus* species and genetically distinct forms of *E. granulosus*.

PCR-Amplified DNA Sequences

Comparison of the nucleotide sequence of defined DNA segments between organisms provides the most direct and sensitive means of detecting genetic variation. Mitochondrial sequences, particularly fragments of the mitochondrial protein-coding genes, *cox1* and *nad1*, have proved invaluable for *E. granulosus* strain identification.

Mutation Scanning Methods

Mutation scanning methods provide alternatives to DNA sequencing for the high-resolution analysis of PCR-amplified fragments. One such method is single-strand conformation polymorphism (SSCP) that has been used to rapidly screen large numbers of *Echinococcus* isolates. Another useful mutation scanning method is dideoxy fingerprinting (ddF), which is a hybrid between SSCP and conventional dideoxysequencing. The technique has been used for the direct display of sequence variation in the *cox1* gene to type and differentiate all of the *Echinococcus* genotypes examined by their characteristic and reproducible ddF fingerprinting profiles.

Microsatellite Markers

A virtually untapped area for studying diversity in *Echinococcus* is the use of microsatellite DNA. Some microsatellite markers are available for *E. multilocularis*, following the earlier studies of Bretagne et al.[7] who were able to use microsatellite DNA to divide isolates of *E. multilocularis* into three groups: European, North American (Montana), and Japanese. More recently, Nakao et al.[5] isolated two microsatellite loci that were used to demonstrate population-level polymorphisms in *E. multilocularis* adult worms derived from wild red foxes collected from a limited geographical area of Hokkaido, Japan. The provision of microsatellite markers for *E. granulosus* and additional microsatellites from *E. multilocularis* will provide exquisitely sensitive tools for studying the population genetics and transmission biology of *Echinococcus* species.

DNA-BASED IDENTIFICATION OF *E. GRANULOSUS* STRAINS

The various genotypes of *E. granulosus* that have been identified using DNA analysis together with their host range and geographical distribution are presented in Table 1. A brief description of the major findings is presented here and reviewed in Refs. [2,3,8].

Sheep–Dog (G1 Genotype) and Horse–Dog (G4 Genotype) Strains

Discrete horse–dog and sheep–dog forms of *E. granulosus* occur that differ in a wide spectrum of biological criteria.

Table 1 Genotypes/strains of *E. granulosus* categorized by DNA analysis with their host and geographical range

Genotype (strain)	Host origin	Geographic origin
G1 (common sheep strain)	Sheep	United Kingdom, Spain, China, Australian mainland, Tasmania, Kenya, Uruguay, Turkey, Jordan, Lebanon, Italy, Argentina, Brazil, Iran, Nepal
	Cattle	United Kingdom, Spain, Kenya, Tasmania, Jordan, China
	Human	Australian mainland, Tasmania, Jordan, Lebanon, Holland, Kenya, China, Argentina, Spain
	Goat	Kenya, China, Nepal
	Buffalo	India, Nepal
	Camel	China
	Pig	China
	Kangaroo	Australian mainland
	Dog (adult)	Kenya
	Dingo (adult)	Australian mainland
G2 (Tasmanian sheep strain)	Sheep	Tasmania, Argentina
	Human	Argentina
G3 (buffalo strain?)	Buffalo	India
G4 (horse strain)	Horse	United Kingdom, Ireland, Switzerland
	Donkey	Ireland
G5 (cattle strain)	Sheep	Nepal
	Goat	Nepal
	Cattle	Switzerland, Holland, Brazil
	Buffalo	India, Nepal
	Human	Holland, Argentina
G6 (camel strain)	Camel	Kenya, Somalia, Kenya, Sudan, China, Iran, Mauritania
	Cattle	China, Iran, Mauritania
	Human	Argentina, Nepal, Iran, Mauritania
	Sheep	Iran
	Goat	Kenya
G7 (pig strain)	Pig	Poland, Slovakia, Ukraine, Argentina, Spain
	Wild boar	Ukraine
	Beaver	Poland
	Cattle	Slovakia
	Human	Poland, Slovakia
G8 (cervid strain)	Moose	United States
	Human	United States
G9 (?)	Human	Poland

Source: Modified from Ref. [2].

Confirmation of species identity was obtained by phylogenetic analysis (Fig. 1) using data from the complete mitochondrial genomes recently obtained for both strains. Of public health significance is the fact that the sheep strain is infective to humans but, probably, noninfective to horses. The horse strain appears to be poorly infective to sheep and may be noninfective to humans. This is borne out by the DNA data as, to date, the horse strain (G4 genotype) has not been reported in sheep or humans, and the sheep strain (G1 genotype) has not been identified in horses.

It has been recognized for some time that *E. granulosus* is maintained in two cycles of transmission on mainland Australia. One principally involves domestic sheep, whereas the other involves numerous species of macropod marsupials (kangaroos and wallabies). There is interaction between these cycles through a range of carnivores (domestic dogs, feral dogs, dingoes, and red foxes) which are definitive hosts. Early evidence led to their proposed designation as distinct strains but subsequent molecular analysis indicates that only the common sheep strain is present. In biological, epidemiological, and molecular features the common sheep strain can be regarded as homogeneous except in Tasmania where morphological distinctiveness, a significantly shortened prepatency period, and molecular evidence have indicated that a variant of the common *E. granulosus* genotype (designated genotype G2) occurs there. The G2 genotype is also

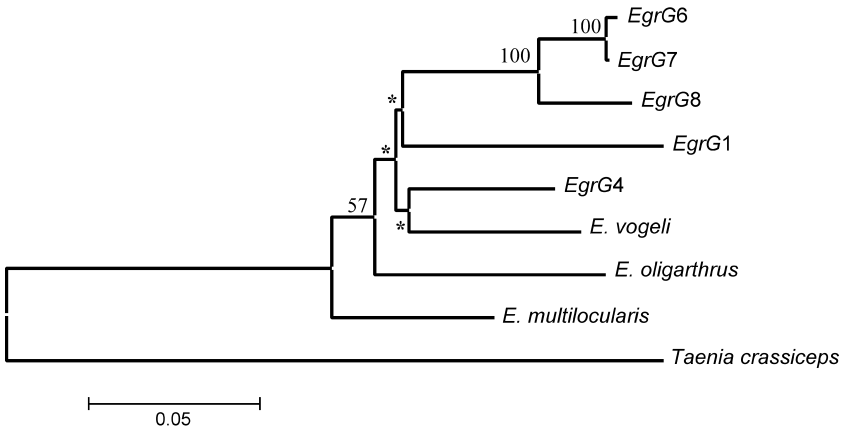

Fig. 1 Inferred relationships among species and genotypes of *Echinococcus*, using *Taenia crassiceps* as an outgroup. (From Ref. [9].) Concatenated sequences of mitochondrial DNA genes [*atp6*, *nad1* (partial) and *cox1* (partial)] were analysed. A distance matrix was constructed from inferred amino acid (aa) sequences (alignment was 451 aa long with 168 variable aa sites 67 aa parsimony-informative sites) using a Poisson correction for multiple hits and the tree constructed using the minimum evolution approach. Five hundred bootstrap resamplings were carried out. Branches with bootstrap support values less than 50% are indicated with an asterisk. EgrG1, EgrG4, EgrG6-EgrG8 are the different genotypes of *E. granulosus*. Units on scale bar: changes per site. The branches indicated by an asterisk were supported by fewer than 50% of the resampled data sets and therefore should be regarded as poorly supported. It is clear that EgrG4, EgrG1, *E. vogeli*, and *E. oligarthrus* are almost equidistant from each other in terms of mt sequences. Furthermore, the *E. granulosus* G1 and G4 genotypes are also almost equidistant from the G6-8 genotype cluster, although there is some structure in this latter group. *E. multilocularis* appears as basal within the genus, but again the branch placing it there is rather poorly supported. Given this, recognition of the sheep–dog (G1 genotype) and the horse–dog (G4 genotype) strains (and possibly also the G6-8 genotypes) as separate species is appropriate. The discrete nature of the two forms is quite clear and the molecular and phylogenetic evidence from this and previous studies suggests the case for reinstatement of their formal taxonomic status as subspecies/species is now proven.

present in Argentina, possibly having been introduced with Merino sheep exported from Australia to Argentina.[10]

Camel–Dog (G6 Genotype) Strain

Two distinct strains of *E. granulosus* have been identified by molecular methods in Kenya. The sheep strain of *E. granulosus* occurs in sheep, cattle, goats, and man, with the camel strain (G6 genotype) infecting camels and occasionally goats. DNA analysis has clearly indicated that the camel–dog strain (G6 genotype) of *E. granulosus* as well as the cosmopolitan, common sheep strain (G1 genotype) also occurs in Iran and China. DNA studies have indicated that the camel strain is infectious to humans and circulates between intermediate hosts including camels and cattle in Mauritania; if the sheep strain is present, it is rarely found there.

As well as Mauritania, molecular studies of *E. granulosus* from Argentina, Iran, and Nepal have reported the presence of the G6 genotype in several human subjects. This has potentially important implications for public health and implementation of hydatid control programs where the camel strain is involved in *E. granulosus* transmission. The camel strain has a shorter maturation time in dogs than the common sheep strain which is the form generally associated with human infection.

Bovine Strain (G5 Genotype)

Until the early 1990s, all surgically obtained human isolates of *E. granulosus* examined by isoenzyme and DNA analysis conformed to the common domestic sheep strain. However, a partly calcified hydatid cyst removed from an 11-year-old Dutch boy typed by PCR/RFLP analysis and *cox1* and *nad1* sequence comparisons with known genotypic sequences showed clearly that the patient was infected, not with the sheep strain, but with the genetically distinct bovine or cattle strain (G5 genotype) of *E. granulosus*. This strain has also been shown to infect humans in Argentina.[11] Thus, in regions where the bovine strain occurs, cattle may act as reservoirs of human infection. As is evident from scrutiny of Table 1, DNA analysis indicates that several *E. granulosus* genotypes (G2, G5, G6, G7, G8, and G9) are infective to humans.

Pig–Dog Strain (G7 Genotype)

Analysis of *E. granulosus* from Polish patients indicated they were not infected with the common sheep strain (G1 genotype) of *E. granulosus*. Instead, the isolates shared similar DNA sequence with the previously characterized pig–dog strain (G7) genotype but exhibited some clear

differences. Accordingly, it was proposed that these human isolates represented a distinct *E. granulosus* genotype (designated G9). Subsequent studies of human and pig isolates from Poland, Slovakia, and Ukraine failed to confirm the existence of this genotype but have provided evidence for the almost exclusive presence of the G7 genotype.[12] Confirmation of the existence of the G9 genotype and identification of the reservoir(s) of human hydatid disease in Poland and other countries in Central and East Europe remain unresolved.

Cervid Strain (G8 Genotype)

The ''cervid'' strain (also called ''sylvatic strain'' or ''northern form'') of *E. granulosus* occurs in North America and Eurasia. The wolf is the principal definitive host, and moose and reindeer (family Cervidae) serve as intermediate hosts; cycles involving sled dogs and domesticated reindeer also occur. Based on its unique *nad1* sequence and ITS1 PCR-RFLP pattern, a cervid strain obtained from Alaskan moose appeared to represent a distinct genotype of *E. granulosus* which was designated G8.[13]

Case-based data have suggested that the course of sylvatic disease is less severe than that of domestic disease, which led to the recommendation to treat cystic echinococcosis patients in the Arctic by careful medical management rather than by aggressive surgery. The first two documented *E. granulosus* human cases in Alaska with accompanying severe sequelae in the liver were recently reported.[14] The results of molecular analysis of the cyst material of one of the subjects supported the identification of the parasite as the sylvatic (cervid) strain (G8 genotype) and not the domestic (common sheep strain), which was initially thought to be implicated in these unusually severe Alaskan cases.[15] The adverse outcomes could have been rare complications that are part of the clinical spectrum of sylvatic CE, an indication that the sylvatic form of *E. granulosus*, especially when affecting the liver, has potential for severe clinical consequences.

DETECTION OF PARASITE NUCLEIC ACIDS IN CLINICAL SAMPLES

Clinical findings require sophisticated investigations to confirm echinococcosis. Usually, primary identification and characterization of echinococcal lesions occur by imaging techniques. However, the diagnostic potential of such techniques is sometimes limited by the atypical appearance of the visualized lesions that may also be insufficient in providing information about the involved species or about the viability of the parasite. Immunodiagnosis is a useful complementary diagnostic tool for the identification of infection and disease.[16] Recent efforts have been undertaken to apply molecular identification methods for direct detection of parasite RNA or DNA in clinical samples by Southern/Northern blotting or PCR.[17] These molecular methods have been used mainly in the clinical context for the primary diagnostic identification of parasite materials in biological specimens resected or biopsied from patients, and also for the assessment of the viability of parasite samples after chemotherapy or other treatment. Detection of parasite nucleic acids in clinical samples from AE or CE patients has been substantially improved by the use of the PCR. Generation of specific primers and their use in PCR and RT-PCR allows the detection of minute amounts of parasite RNA/DNA collected during surgical removal of cyst material or by fine needle aspiration biopsy (FNAB).

CONCLUSION

The range of DNA techniques now available for the study of genetic variation in *E. granulosus* and the molecular epidemiology of cystic echinococcosis is impressive, and much valuable information on the molecular categorization of the different genotypes is now available. Importantly, in many cases, molecular techniques have validated the genetic basis of important morphological and other biological differences that can now be used with confidence as a reliable and simple means of identifying and differentiating between strains and species of *Echinococcus*. The recent publication of the complete sequences of the *mt* genomes of the horse and sheep strains of *E. granulosus*[9] and *E. multilocularis*[18] and *mt* DNA sequences for a number of other *E. granulosus* genotypes[9] has provided additional genetic information that can be used for even more in-depth strain characterization and phylogeny of *Echinococcus* spp. Already, the availability of sequence information has provided a solid molecular basis for revising the taxonomy of the genus *Echinococcus*.[4,19]

Furthermore, the accumulating genetic data may allow insight to several other unresolved questions such as confirming the presence and precise nature of the G9 genotype and its reservoir in Poland, whether it occurs elsewhere, why the camel strain (G6 genotype) appears to affect humans in certain geographical areas but not others, more precise delineation of the host and geographic ranges of the genotypes characterized to date, and whether additional genotypes of *E. granulosus* remain to be identified. In this context, an important recent study by Gonzalez et al.[20] highlights the complexity and genomic organization differences in *E. granulosus*. Based on two *E. granulosus* DNA multiplex-PCR amplification fragments they developed three PCR protocols (Eg9-PCR, Eg16-PCR, and Eg9-PCR-RFLP) for discrimination of

E. granulosus genotypes. They used the approach to identify distinct G1 and G7 genotypes within *E. granulosus* Spanish pig isolates. Sequencing of the *nad1* and *cox1* genes and ITS1-PCR coupled to RFLP confirmed these observations. The Eg9-PCR-RFLP and Eg16-PCR protocols could thus be used as additional methods to discriminate the recognized *E. granulosus* genotypes and they might be especially useful for resolving the issue of the G7/G9 genotypes and human infection in Poland.

Finally, it should be emphasized that as well as proving of value for investigating genetic variation in *Echinococcus* and in the detection of parasite nucleic acids in clinical samples, molecular approaches can be used to identify and discriminate *Echinococcus* eggs (deposited in the feces of dogs and other carnivores) from those of other taeniid eggs in definitive hosts. A PCR-based assay has been developed for detecting DNA of *E. multilocularis* in fecal samples of foxes after isolation of the parasite eggs by a sieving procedure.[21] There is no similar test available yet for *E. granulosus* although one is being developed.[22] The copro-PCR is a valuable method for confirmation of positive coproantigen results by ELISA and for diagnosis in individual animals.

Ehlers–Danlos Syndrome

Anne De Paepe
Paul Coucke
Fransiska Malfait
Center for Medical Genetics, University Hospital, Ghent, Belgium

INTRODUCTION

The Ehlers–Danlos syndrome (EDS) comprises a clinically and genetically heterogeneous group of connective tissue diseases of which the principle clinical features are skin hyperextensibility, joint hypermobility, and generalized connective tissue fragility. These clinical manifestations are present, to varying degrees, in each subtype of the condition. The latest classification of EDS, the Villefranche nosology, recognizes six subtypes for which major and minor diagnostic criteria were defined. The classic, hypermobile, and vascular type of EDS are the most common, whereas the kyphoscoliosis, arthrochalasis, and dermatosparaxis type constitute very rare conditions. Several EDS subtypes are caused by mutations in the structural genes for type I (arthrochalasis type), type III (vascular type), or type V collagen (classic type) or in genes involved in the processing of type I collagen (kyphoscoliosis and dermatosparaxis type).

EHLERS–DANLOS SYNDROME: CLASSIC TYPE

Clinical Description

Classic Ehlers–Danlos syndrome is inherited as an autosomal dominant trait.[1] The former EDS type I and type II are now reclassified as the ''classic subtypes'' of EDS for which major and minor diagnostic criteria have been established (Table 1).[2]

Major diagnostic criteria for classic EDS are skin hyperextensibility, widened atrophic scarring, and joint hypermobility. Skin hyperextensibility should be tested at a neutral site, meaning a site not subjected to mechanical forces or scarring, such as the volar surface of the forearm. It is measured by pulling up the skin until resistance is felt. The skin is hyperelastic, which means that it extends easily and snaps back after release.

Widened atrophic scarring is a manifestation of tissue fragility and occurs mainly over the knees, elbows, shins, forehead, and chin. It is characterized by splitting of the skin following relatively mild trauma, and formation of ''cigarette-paper scars,'' which are wide and thin scars, often with pigment deposition. Joint hypermobility is general, affecting both large and small joints. It is usually noted when a child starts to walk. It should be assessed using the Beighton scale,[3] the most widely accepted grading system for the objective semiquantification of joint hypermobility. The maneuvers used in this scoring system are listed below.

1. Passive dorsiflexion of the little fingers beyond 90° (one point for each hand).
2. Passive apposition of the thumbs to the flexor aspects of the forearm (one point for each thumb).
3. Hyperextension of the elbows beyond 10° (one point for each elbow).
4. Hyperextension of the knees beyond 10° (one point for each knee).
5. Forward flexion of the trunk with knees fully extended so that the palms of the hands rest flat on the floor (one point).

A score of 5/9 or greater defines joint hypermobility.

Minor diagnostic criteria for classic EDS are smooth, velvety skin, easy bruising, molluscoid pseudotumors, which are fleshy lesions associated with scars over pressure points such as elbows and knees, and subcutaneous spheroids, which are small, hard cystlike nodules, freely movable in the subcutis over bony prominences of the legs and arms. Other minor features include complications of joint hypermobility (e.g., sprains, dislocations, subluxations, and pes planus). Occasional or habitual dislocations of joints, such as the patella, shoulder, and hip, are common and are usually resolved spontaneously or easily reduced by the patient.

Cause and Laboratory Diagnosis

The genes encoding type V collagen, *COL5A1* and *COL5A2*, are known to be associated with the classic form of Ehlers–Danlos syndrome. Type V collagen is a quantitatively minor fibrillar collagen that is widely

Table 1 Classification of Ehlers–Danlos syndrome

Subtype	Inheritance pattern	Protein	Gene	Methods for laboratory diagnosis
Classic type (EDS type I/II)	AD	Type V procollagen	*COL5A1/COL5A2*	*COL5A1* ''null-allele'' testing Molecular screening for mutations in *COL5A1* or *COL5A2*
Hypermobility type (EDS type III)	AD	Not known	Not known	Not available
Vascular type (EDS type IV)	AD	Type III procollagen	*COL3A1*	Biochemical analysis of type III collagen by SDS-PAGE Molecular screening for mutations in *COL3A1*
Kyphoscoliotic type (EDS type VI)	AR	Lysyl hydroxylase-1	*PLOD1*	Increased ratio deoxypyridoline to pyridoline cross-links in urine by HPLC Measurement of lysyl hydroxylase-1 activity Molecular screening of *PLOD1* gene
Arthrochalasis type (EDS type VIIA /VIIB)	AD	Type I procollagen	*COL1A1/COL1A2* Partial loss or complete skipping of exon 6	Biochemical analysis of type I collagen by SDS-PAGE Detection of complete or partial skipping of exon 6 in *COL1A1* or *COL1A2*
Dermatosparaxis type (EDS type VIIC)	AR	Procollagen-*N*-proteinase	*ADAMTS*-2 gene	Biochemical analysis of type I collagen by SDS-PAGE Molecular screening of *ADAMTS-2*-gene

distributed in a variety of tissues. In skin, tendon, and bone it is present mainly as [α1(V)]2 α2(V) heterotrimers. Type V collagen forms heterotypic fibrils with type I collagen and regulates the diameter of those fibrils.[4] It is thought that the huge amino-terminal propeptide of type V collagen is responsible for this regulatory function.

Biochemical studies on cultured fibroblasts, performed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) of metabolically labeled collagens produced by dermal fibroblasts, are usually not useful in confirming the diagnosis because type V collagen is synthesized by fibroblasts at low levels, so that quantitation and evaluation of alterations in electrophoretic mobility are poorly reproducible. Rarely, an abnormal electrophoretic pattern for type I collagen is detected because of nonglycine substitution (R134C) in the *COL1A1* gene coding for the proα1(I) collagen chain of type I collagen.[5] A *COL5A1* ''null-allele'' test is available for clinical testing. This test detects a nonfunctional *COL5A1* allele by genotyping polymorphic markers at the genomic and the cDNA level, hence requiring cultured fibroblasts. This test detects a *COL5A1* null-allele in approximately 30% of individuals with classic EDS. Sequence analysis of the *COL5A1* and the *COL5A2* gene is available on research basis only. Approximately 50% of patients with classic EDS have an identifiable mutation in one of these genes. Most molecular defects identified for classic EDS lead to haploinsufficiency of the *COL5A1* mRNA. In approximately one-third of classic EDS patients, nonsense, frameshift, or splice site mutations that introduce a premature termination codon are responsible for a nonfunctional *COL5A1* allele.[6,7] Several mechanisms lead to nonsense-mediated decay of the mutation-bearing mRNA or to failure of the chains to associate. The predicted consequence is synthesis of about half the amount of normal type V collagen. Structural mutations in the *COL5A1* and the *COL5A2* gene, which exert a dominant negative effect, have been demonstrated in approximately 15–20 patients with classic EDS. These structural mutations are most commonly splice site

mutations leading to exon skipping, and remarkably few point mutations that result in the substitution of a glycine in the triple-helical region of the collagen molecule by a bulkier amino acid. A unique point mutation in the *COL5A1* gene that changes a highly conserved cysteine residue to a serine in the C-terminal propeptide of the α1(V) collagen chain has also been identified.[8] A G530S substitution located in the amino-terminal propeptide of the α1(V) collagen chain may be disease modifying in the heterozygous state and disease causing in the homozygous state.[9,10]

Recently, mutations in a noncollagenous protein, tenascin X, have been demonstrated to cause an autosomal recessive condition with great similarity to classic EDS, including hyperextensible skin, hypermobile joints, and easy bruising, but without delayed wound healing or atrophic scarring.[11]

EHLERS–DANLOS SYNDROME: HYPERMOBILITY TYPE

Clinical Description

The hypermobility type of EDS (the former EDS type III) is inherited as an autosomal dominant disorder; it is characterized by severe generalized joint hypermobility, as assessed by the Beighton scoring system, and associated signs, such as recurring (sub)luxations, swellings, and tendinitis. This results in early-onset, chronic, generalized joint pain, which is often debilitating. In particular, temporomandibular and sternoclavicular joints, wrist, shoulder, and patella dislocate frequently. The skin is involved, with smooth, velvety skin, or mild atrophic scarring. Hypermobility type of EDS has to be distinguished from familial articular hypermobility syndrome (FAHS), also called benign joint hypermobility syndrome (BJHS), a separate autosomal dominant condition, which is characterized by severe joint laxity, joint dislocations, and chronic pain, but no skin changes. It is currently under discussion whether BJHS is a mild form of a heritable disorder of connective tissue, and is in fact identical to the hypermobility type of EDS, or whether BJHS represents the upper end of the Gaussian distribution of the ''normal'' range of joint movement. In the absence of biochemical or molecular markers, the relationship between BJHS and hypermobility type of EDS will remain unclear.

Cause and Laboratory Diagnosis

The cause of the hypermobility type of EDS is unknown and hence laboratory diagnosis is currently not available.

EHLERS–DANLOS SYNDROME: VASCULAR TYPE

Clinical Description

The vascular type of EDS (the former EDS type IV) is inherited as an autosomal dominant trait. It deserves special attention because its natural history and prognosis are different from those of the other subtypes. The typical clinical features of vascular EDS comprise a thin, translucent skin with a prominent venous pattern over the chest, the abdomen, and the extremities, increased bruising and bleeding tendency, and proneness to sudden rupture of blood vessels, internal organs, or the gravid uterus. Patients often have a characteristic facial appearance with large prominent eyes, small, pinched nose, small lips, and lobeless ears. Hypermobility is usually limited to the small joints of the hands. Other features include acrogeria, which is characterized by an aged appearance of the extremities, particularly the hands, tendon or muscle rupture, talipes equinovarus, early-onset varicose veins, arteriovenous, carotid-cavernous sinus fistula, pneumothorax or pneumohemothorax, and gingival recession. Family history may be positive for sudden death in a close relative.

A retrospective review of the health history of more than 400 individuals with vascular EDS has delineated the natural history of the disorder.[12] The median age of death is 48 years. Complications are rare during childhood, but 25% of index patients have experienced a first complication by the age of 25 years and 80% by the age of 40 years. Vascular complications and gastrointestinal perforation or organ rupture are presenting signs in 70% of adults with vascular EDS. Such complications are dramatic and unexpected, often presenting as sudden death, stroke, acute abdomen, retroperitoneal bleeding, uterine rupture at delivery, and shock.[13] The average age for the first vascular or gastrointestinal complication is 23 years. Arterial rupture may be preceded by aneurysm, arteriovenous fistulae, or dissection, but may also occur spontaneously. Rupture of the gastrointestinal tract, most of which affect the sigmoid colon, occurs in about 25% of affected individuals. Bowel rupture is usually not lethal. Pregnancy for women with the vascular type has a risk of 12% for death from peripartum arterial rupture or uterine rupture.

Cause and Laboratory Diagnosis

The condition is caused by mutations in the *COL3A1* gene coding for the α1 chain of type III collagen. This homotrimer is a major structural component of skin, blood vessels, and hollow organs. The diagnosis of vascular EDS is based on compatible clinical findings

and confirmed by biochemical testing. Biochemical testing includes analysis by SDS-PAGE of radioactively labeled collagens from skin fibroblast cultures. This is a highly sensitive investigation and probably identifies more than 95% of individuals with structural alterations in the proteins synthesized. It allows one to detect quantitative (reduced amounts of collagen type III) or qualitative (mutant collagen type III with altered electrophoretic mobility) abnormalities of type III collagen. For example, substitution of a glycine residue by a bulkier amino acid destabilizes the helix and delays its formation, causing excessive posttranslational modification and hence an altered electrophoretic pattern. Molecular genetic testing to identify mutations in the *COL3A1* gene is available to patients with a biochemically confirmed diagnosis of vascular EDS. To date, more than 250 *COL3A1* mutations have been identified. These include point mutations leading to substitutions for glycine in the triple-helical region of the collagen molecule, splice site mutations resulting in exon skips, intron inclusion or complex and multiple outcomes, partial gene deletions, and, less commonly, mutations resulting in haploinsufficiency.[14] Vascular EDS is an autosomal dominant disorder, but parental somatic mosaicism for *COL3A1* mutations has been documented.

EHLERS–DANLOS SYNDROME: KYPHOSCOLIOTIC TYPE

Clinical Description

The kyphoscoliotic type of EDS (the former EDS type VI) is a rare, autosomal recessive condition that is characterized by generalized joint hypermobility, severe muscle hypotonia at birth, progressive kyphoscoliosis, which may be present at birth or develop within the first year of life, and scleral fragility with rupture of the globe. Another prominent finding is arterial rupture of medium-sized arteries or aortic dilatation and dissection. The life span of patients is significantly reduced because of these arterial ruptures or because of cardiopulmonary insufficiency as a result of severe kyphoscoliosis. Other features are tissue fragility and atrophic scarring, easy bruising tendency, marfanoid habitus, microcornea, and osteopenia, although without tendency toward fractures.

Cause and Laboratory Diagnosis

This autosomal recessive disorder is caused by deficient activity of the enzyme procollagen-lysine, 2-oxoglutarate 5 dioxygenase-1 (lysyl hydroxylase-1, PLOD), a collagen-modifying enzyme. Deficiency of this enzyme results in a deficiency in hydroxylysine-based pyridinoline cross-links in types I and III collagen. As a result, cross-linked peptides are excreted in urine as by-products of collagen turnover. The diagnosis relies on the demonstration of the presence of an increased ration of deoxypyridinoline to pyridinoline cross-links in urine, quantitated by HPLC, which is a highly sensitive and specific test.[15] Activity of the lysyl hydroxylase-1 can also be measured in cultured fibroblasts.[16] Molecular testing of the *PLOD-1* gene is available on a research basis only. An intragenic duplication caused by an Alu–Alu recombination in introns 9 and 16 is the only common mutant allele, with a frequency of 19% in 35 families with EDS, kyphoscoliotic form.[17]

EHLERS–DANLOS SYNDROME: ARTHROCHALASIS TYPE

Clinical Description

The arthrochalasis type of EDS (the former EDS type VIIA and B) is inherited as an autosomal dominant trait. The clinical hallmark of this type is congenital bilateral hip dislocation.[18] There is also severe generalized joint hypermobility with recurrent dislocations of large and small joints and ligamentous tears. The skin is moderately involved, with skin hyperextensibility, a velvety touch, and poor wound healing with formation of atrophic scars. Other features include easy bruising, muscular hypotonia and delay in gross motor development, kyphoscoliosis and osteopenia with wormian bones and sometimes a history of fractures.

Cause and Laboratory Diagnosis

The cause of the arthrochalasis type of EDS is the result of mutations leading to loss of exon 6, or part of it, of the mRNA coding for one of the α1 chains (EDS type VIIA) or for the α2 chain (EDS type VIIB) of type I collagen.[18] This exon-skipping mutation leads to the loss of the amino-terminal telopeptide, which links the *N*-propeptide to the main, triple-helical domain. This *N*-telopeptide contains the *N*-proteinase cleavage site as well as the critical cross-linking lysyl residue and the cleavage sites for proteinases such as pepsin and α-chymotrypsin. Hence, lack of this segment leads to deficient processing of the *N*-propeptide of type I collagen. The biochemical confirmation of the diagnosis is based on electrophoretic demonstration of pNα1(I) (type A) or pNα2(I) (type B) chains of collagen type I extracted from dermal collagen or harvested from cultured skin fibroblasts. Molecular analysis can be performed to confirm the biochemical

findings and shows complete or partial skipping of exon 6 at the cDNA level of the *COL1A1* or the *COL1A2* gene, respectively, usually caused by splice site mutations at the genomic DNA level.

EHLERS–DANLOS SYNDROME: DERMATOSPARAXIS TYPE

Clinical Description

This rare condition is inherited as an autosomal recessive condition. The clinical picture is characterized by premature rupture of the membranes, extreme skin fragility and laxity, easy bruising, large fontanels, umbilical hernia, short stature and characteristic facies with epicanthic folds, downslanting palpebral fissures, puffy eyelids, blue sclerae, and micrognathia. During childhood and puberty, increased bruising and severe skin fragility predominate the clinical picture. Wound healing is not delayed and initial scar formation is only minimal.[19] In older patients, however, more typical atrophic scarring with pigmentation is seen, probably because of repeated skin tearing and bruising. Joint hypermobility, although not obvious during the first years of life, seem to become more important with age. Fragility of internal tissues is an important feature during childhood, as is illustrated by spontaneous bladder rupture at the age of 5 years in two children with the dermatosparaxis type of EDS (personal observation).

Cause and Laboratory Diagnosis

EDS dermatosparaxis type and the related animal disease dermatosparaxis are recessively inherited connective tissue disorders, caused by a deficient activity of procollagen-I-*N*-proteinase, the enzyme that excises the N-terminal propeptide in procollagen type I, type II, and type III. As a consequence, there is accumulation of pN-procollagen,[20] resulting in polymerization of abnormal collagen fibers that appear thin, irregular, branched and ''hieroglyphic'' in cross section.[21] The diagnosis can be made based on these characteristic clinical, biochemical, and electromicroscopic findings. Molecular confirmation of the diagnosis is available on a research basis. Homozygous mutations in the gene encoding procollagen-I-*N*-proteinase or ADAMTS-2 (a disintegrin and metalloproteinase with thrombospondin-like repeats), an enzyme belonging to an expanding family of zinc metalloproteinases found in vertebrates and invertebrates, have been identified in all reported patients with dermatosparaxis.[22]

CONCLUSION

The Ehlers–Danlos syndrome is a clinically and genetically heterogeneous group of connective tissue diseases. At least six different subtypes are currently recognized, and several fibrillar collagens are involved in the etiology of the condition. Structural mutations in collagen type I, III, and V are causal in the dominant subtypes of the condition, whereas recessive EDS subtypes are associated with defects in enzyme activity involved in the biosynthesis of type I collagen. Developments in the elucidation of the biochemical and molecular basis of EDS, together with increasing clinical experience, add a new dimension to diagnosis, genetic counseling, and management of these heritable disorders. Future research will further increase the understanding of the molecular mechanisms involved and open perspectives for gene therapy.

ACKNOWLEDGMENT

Electrospray Tandem Mass Spectrometry for Newborn Screening

Yosuke Shigematsu
Fukui Medical University School of Nursing, Fukui, Japan

INTRODUCTION

Newborn screening programs for inherited diseases are well established in many developed countries. Dried blood spots on screening cards are collected from newborns for early detection of diseases and improvement of their health. Before the recent application of tandem mass spectrometry (MS–MS) to newborn screening, one test on one sample of blood was used to screen a single disease, phenylketonuria (PKU), which was screened originally by a bacterial inhibition assay of phenylalanine.

However, MS–MS enables the sensitive and quantitative analysis of many ionic compounds with high polarity, such as acylcarnitines and amino acids, in a single process. The first proposal of this technology for newborn screening was reported in 1990. More than 30 inborn errors of metabolism (IEM) in the categories of fatty acid oxidation disorders, organic acidemias, and aminoacidopathies can be diagnosed simultaneously by MS–MS measurement of one small punch of a blood spot. In clinical settings, fatty acid oxidation disorders and organic acidemias were known to cause sudden death in infancy, which could be prevented by early recognition of these diseases by MS–MS. The phenylalanine/tyrosine ratio determined by MS–MS was demonstrated to be a sensitive marker in PKU screening among newborns discharged from hospitals less than 24 hr. Thus the use of MS–MS technology has expanded rapidly into newborn screening.

However, most target diseases in MS–MS screening are rather rare and heterogeneous in clinical severity, and the screening's clinical validity, clinical utility, and cost-effectiveness have not yet been fully established. Further careful data collection regarding the sensitivity of MS–MS screening and outcomes of patients in whom disorders are detected is required.

INSTRUMENTATION AND BASIS OF ANALYSIS

Instrumentation for MS–MS screening consists of a triple quadrupole mass spectrometer controlled by a computer system, an electrospray ionization (ESI) interface, and a liquid chromatograph equipped with an autoinjector.

A mass spectrometer is a ''mass'' detector by which gas-phase ions can be analyzed.[1] The masses of ions are recorded as ratios of molecular weight to charge (m/z). Through an ESI device, ionic compounds in the liquid phase can be introduced into MS as gas-phase ions. ESI plays an important role in MS–MS screening by the sequential introduction of sample solutions, which are injected automatically into the continuous flow of a liquid chromatograph at 2-min intervals without chromatographic separation.

A triple quadrupole MS system comprises two mass analyzers, which are separated by a collision chamber that induces the fragmentation of ionic compounds by the introduction of argon gas. Using a computer algorithm, the intensities of the masses of ionic compounds in the first mass analyzer (precursor ions) and those of their fragment ions in the second mass analyzer (product ions) are recorded in synchronized manners. In acylcarnitine analysis, a fragment ion of m/z 85, which characterizes the structure of butylester derivatives of acylcarnitines (Fig. 1), is monitored in the second mass analyzer, whereas the masses of ionic compounds are analyzed in the first mass analyzer. In amino acid analysis, the masses are analyzed synchronously in both mass analyzers to record the intensities of the masses of fragment ions produced from the precursor ions after the loss of 102 atomic mass units (Fig. 2). Thus, without chromatographic separation of the sample mixture, the information on the characteristic fragmentations enables the measurement of acylcarnitines and amino acids with high specificity. Quantification is performed using stable isotope-labeled compounds as internal standards.

Data are recorded by class-specific analysis or target compound analysis.[2] In the latter analysis, called selected or multiple reaction monitoring, a certain transition of the precursor to the product is monitored to analyze a single compound. The degree of fragmentation can be optimized to improve sensitivity by controlling both the amount of argon gas in the chamber and the energy of the compounds entering the chamber and argon. If target disorders in MS–MS screening are restricted, the latter analysis allows for monitoring of the selected compounds.

DOI: 10.1081/E-EDGP 120020810

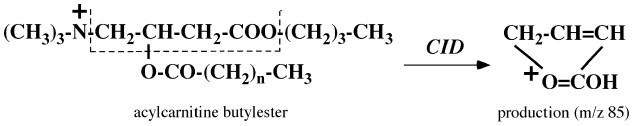

Fig. 1 Fragmentation of acylcarnitine butyl esters in a collision chamber by collision-induced dissociation (CID).

Otherwise, the former analysis, such as the precursor scanning of *m/z* 85 for acylcarnitines, where a certain range of masses of ionic compounds is analyzed sequentially, is more comprehensive and useful to confirm the quality of the processed samples.

PROCEDURES FOR MS–MS SCREENING

Specimen preparation for MS–MS screening requires an extraction and derivatization process,[3] which is performed using 96-well polypropylene microplates in routine analysis.[4–6] One 3.2-mm disk of dried blood spot is punched out into the individual wells of a microplate. To the disk in each well, a methanol solution containing known concentrations of stable isotope-labeled standards is added. The microplate is covered and the samples are mixed. The extract is transferred to a second microplate and dried. The residue in each well is derivatized with butanolic HCl. After removing the excess reagent in each well, the derivatized residue is dissolved in an acetonitrile–water mixture. Then the microplate is sealed and placed in the autoinjector tray for ESI–MS–MS analysis.

In routine analysis under the control of the computer system, intensities of designated ionic compounds of the sample are measured in multiple modes of analysis, and a set of data for the sample is recorded sequentially. The amounts of the compounds as diagnostic markers are calculated using the assumed volume of blood in a punch and the intensities of both the compounds and the respective stable isotope-labeled internal standards. At present, not all internal standards for acylcarnitine analysis are available, and the amounts of some acylcarnitines are calculated using the labeled acylcarnitine with different acyl groups (e.g., deuterium-labeled C_{14}-acylcarnitine for C_{14}:1-acylcarnitine measurement and deuterium-labeled C_{16}-acylcarnitine for hydroxy-C_{16}-acylcarnitine measurement).

For samples with abnormal values for any diagnostic marker, repunched blood spots are analyzed to confirm the initial screening. Then resamplings for newborns with abnormal values are performed to obtain additional clues to the suspected disease and to confirm that the correct specimens have been tested. If the values are very abnormal, a full metabolic workup is initiated immediately.

E

TARGET DISORDERS AND DIAGNOSTIC MARKERS

Target diseases in MS–MS screening are listed in Table 1.

The clinical severity of target diseases, except for PKU and homocystinuria (HCU), is quite heterogeneous.[7,8] Patients with severe forms of the diseases present clinical crises with metabolic acidosis, hyperammonemia, and/or hypoglycemia in the newborn period and may not survive in spite of intensive care. Liver transplantations have been tried for patients with severe forms of organic acidemias and urea cycle disorders. Patients with milder forms may experience intermittent and sometimes life-threatening crises because of catabolic conditions with or without progressive brain dysfunction. Other symptoms of fatty acid oxidation disorders are muscle weakness and pain with high CK values. Some patients with mild forms of the diseases may not show any symptoms without medical intervention.

Long-term therapies for most diseases include low-protein and/or low-fat diets. Depending on the respective diseases, carnitine supplementation, coenzyme administration, avoidance of fasting, and treatment of acute episodes with intravenous infusion of glucose may be required. Medium-chain triglycerides are used for some fatty acid oxidation disorders, and sodium benzoate or alternatives are for hyperammonemia of urea cycle disorders.

Diagnostic Markers for Target Diseases

The cutoffs for diagnostic markers (Table 1) are set empirically in most laboratories based on the data from the retrospective analysis of the patients and the prospective studies. High false-positive rates have been reported in newborns with very low birth weights or those requiring intensive care.[6] To improve the sensitivity for screening, additional markers, such as the ratio of the main marker to the second marker, are proposed.

High levels of free carnitine and low levels of long-chain acylcarnitines in blood spots characterize carnitine

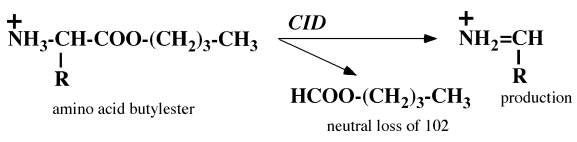

Fig. 2 Fragmentation of amino acid butyl esters in a collision chamber.

Table 1 Target diseases in MS–MS newborn screening

Disease	Primary diagnostic marker
Fatty acid oxidation disorders	
Carnitine transport defect	Free carnitine
Carnitine palmitoyltransferase I deficiency	Free carnitine
Carnitine palmitoyltransferase II deficiency	C_{16}-AC
Carnitine/acylcarnitine translocase deficiency	C_{16}-AC
Very long chain acyl-CoA dehydrogenase deficiency	C_{14}:1-AC
Long-chain hydroxy acyl-CoA dehydrogenase deficiency	Hydroxy-C_{16}-AC
Mitochondrial trifunctional protein deficiency	Hydroxy-C_{16}-AC
Medium-chain acyl-CoA dehydrogenase deficiency	C_8-AC
Short-chain acyl-CoA dehydrogenase deficiency	C_4-AC
Short-chain hydroxy acyl-CoA dehydrogenase deficiency	C_4-AC
Multiple acyl-CoA dehydrogenation deficiency or glutaric aciduria type II	Multiple ACs
Organic acidemias	
Methylmalonic aciduria	C_3-AC
Propionic acidemia	C_3-AC
Multiple carboxylase deficiency	Hydroxy-C_5-AC
3-Methylcrotonyl-CoA carboxylase deficiency	Hydroxy-C_5-AC
3-Ketothiolase deficiency	Hydroxy-C_5-AC
3-Methylglutaconyl-CoA hydratase deficiency	Hydroxy-C_5-AC
3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	Hydroxy-C_5-AC
Isovaleric acidemia	C_5-AC
2-Methylbutyryl-CoA dehydrogenase deficiency	C_5-AC
Isobutyryl-CoA dehydrogenase deficiency	C_4-AC
Glutaric aciduria type I	C_5-DC
Malonic acidemia	C_3-DC
Aminoacidopathies	
Phenylketonuria	Phenylalanine
Maple syrup urine disease	Leucine
Homocystinuria	Methionine
Argininosuccinate synthetase deficiency	Citrulline
Citrin deficiency	Citrulline
Argininosuccinate lyase deficiency	Citrulline
Ornithine transcarbamylase deficiency	Citrulline
Arginase deficiency	Arginine
Tyrosinemia type I	Tyrosine

AC = acylcarnitine; DC = dioylcarnitine.

palmitoyltransferase I deficiency, and the increased ratio of free carnitine to the sum of C_{16}-acycarnitine and C_{18}-acylcarnitine (cutoff of 100) is used as a marker for this disease.[9] Although medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is screened using the cutoff of 0.5–1.0 nmol/mL in most laboratories, a retrospective investigation indicated the diagnostic criterion as a C_8-acylcarnitine concentration of more than 0.3 nmol/mL with a C_8-acylcarnitine/C_{10}-acylcarnitine ratio of more than 4.0.[10]

To detect patients with a mild form of propionic acidemia (PA) and methylmalonic aciduria (MMA), a cutoff of 0.25 for the ratio of the intensity of *m/z* 274 (propionylcarnitine) to that of *m/z* 260 (acetylcarnitine) seems useful.[11] Transient increases in propionylcarnitine have been frequently observed in infants with ABO incompatibility to the mother.[6] In spite of the application of such a marker, some MMA patients with defects in cobalamine metabolism have been missed.[1]

In PKU screening, a high phenylalanine-to-tyrosine ratio is a specific and sensitive marker to detect PKU using specimens collected in the first 24 hr[12] and to distinguish this disease from liver dysfunction and amino acid infusion.[13] The leucine-to-phenylalanine or methionine-to-phenylalanine ratio also may be useful to minimize the false-positive rate in maple syrup urine disease (MSUD) or HCU screening.[6]

Argininosuccinate synthetase (ASS) deficiency, argininosuccinate lyase (ASL) deficiency, and citrin deficiency are detected using high levels of citrulline. The increased argininosuccinic acid concentration, which can be monitored using the designated product ions, is another diagnostic marker for ASL deficiency. Most patients with citrin deficiency have citrulline levels higher than 50 nmol/mL in the neonatal period, together with high values of such amino acids as methionine, phenylalanine, tyrosine, and/or arginine.[11]

Ornithine transcarbamylase deficiency may be screened by the combination of low citrulline and high glutamine levels. Because glutamine is hardly quantified in a routine analysis of MS–MS screening, a second-tier screening method to measure glutamine levels is proposed to reexamine a blood spot with a low citrulline concentration.[14] Similarly, a succinylacetone confirmation test using a blood spot with a high tyrosine level is performed to distinguish tyrosinemia type I from transient neonatal tyrosinemia.[12]

Several organic acidemias share the same diagnostic markers, and urinary organic acid analysis is necessary to distinguish these diseases. Elevated C_5-acylcarnitine due to therapy with antibiotics containing pivaryl ester can be distinguished from isovaleric acidemia by urinary organic acid analysis. High levels of hydroxy-C_5-acylcarnitines because of a maternal 3-methylcrotonyl-CoA carboxylase

(3MCC) deficiency can be also detected by urinary organic analysis of the newborn and the mother.

Prevalence of Target Diseases Detected by MS–MS

MCAD deficiency and PKU are most prevalent among target diseases in Western countries, and the estimated incidence of these diseases is 1:10,000–20,000.[15,16] However, in Asian countries, these two diseases are rather rare, but some organic acidemias and citrin deficiency may be common.[11]

Of 1.0–1.2 million newborns studied in the Neo Gen Screening,[12] the following were detected: 65 patients with MCAD deficiency, 3 with very long chain acyl-CoA dehydrogenase deficiency, 3 with short-chain acyl-CoA dehydrogenase deficiency, 2 with long-chain hydroxy acyl-CoA dehydrogenase deficiency, and 2 with carnitine palmitoyltransferase II deficiency among fatty acid oxidation disorders; 68 patients with PKU, 65 with hyperphenylalaninemia, 12 with MSUD, 5 with ASS deficiency, and 2 with ASL deficiency among aminoacidopathies; and 13 patients with glutaric aciduria type I (GA-1), 15 with 3MCC deficiency, 9 with MMA, and 6 with PA among organic acidemias. Of about 0.18 million newborns in Japan,[11] the following were detected: six patients with PA, two with MMA, three with GA-1, two with multiple acyl-CoA dehydrogenation deficiency, two with MCAD deficiency, four with citrin deficiency, and two with PKU.

EVALUATION OF MS–MS SCREENING PROGRAMS

Clinical validity, such as sensitivity and specificity, may vary depending on different cutoffs among laboratories. In an Australian program, a quite low overall false-positive rate of 0.18% and five false-negative cases in 343,244 newborns were reported.[17] In the North Carolina Newborn Screening Program, an overall abnormal rate of 0.64% in 320,503 newborns was reported, although a majority of abnormal samples were due to tyrosine (0.30%) and propionylcarnitine (0.15%).[18] In our study, an overall false-positive rate of 0.58% in 102,200 newborns included that of 0.39% because of the use of pivalic acid-containing antibiotics.[11]

Clinical utility and cost-effectiveness may also vary depending on the sensitivity and the severity of the diseases. It is reported that MS–MS screening for MCAD deficiency alone appears to be cost-effective; adding the incremental costs for the 13 other disorders still yields a result well within accepted norms for cost-effectiveness in Wisconsin.[19] This report is based on the assumption that, in MS–MS screening for MCAD deficiency, 10% of patients are missed and the false-positive rate is 0.1%. A report from California based on the screening of 32,000 newborns plus other published data indicated that the cost of MS–MS screening per quality-adjusted year of life compared favorably with costs of other accepted screening procedures.[15] However, in this report, discounted treatment costs per case for MCAD deficiency were not calculated. Based on the assumption of a low rate of clinical presentations leading to death and handicap and on the assumption of a 0.25% rate of false-positive results for MCAD deficiency, the cost of false-positive results was estimated as quite high owing to hospital visits, laboratory tests, consultations, and admission.

CONCLUSION

ESI–MS–MS will be introduced into most newborn screening programs around the world because of its ability to deal with a large number of samples and to quantify multiple compounds in one blood spot disk in a single process, and because of the substantial benefit most patients with target diseases and their families can be provided through early treatment. However, it is important to recognize the limitation of this screening in view of the false-negative and false-positive rates. In addition, to patients with some target diseases, informed counseling and therapy based on the evidence cannot be offered at present. Furthermore, unexpectedly high incidences of some target diseases, as compared with those before the initiation of this screening, indicate that this screening may be detecting many patients who will not present the symptoms of the disease. Thus ESI–MS–MS screening programs should be further evaluated in terms of quality control in methodology, selection of target diseases, protocols for differential diagnosis, healthcare systems to follow the patients, and psychosocial burdens on the patients and their families.[20]

Entamoeba histolytica, Entamoeba dispar

Patrick Gonin
Généthon, Evry, France

INTRODUCTION

Amebiasis is a parasite of high public health importance. It is one of the most important cause of death from parasitic disease in the world. Higher risks are in the countries where the barriers between feces and food/water are insufficient. It is now well established that of the two morphologically identical amoebas, *Entamoeba histolytica* and *Entamoeba dispar*, only the former is pathogenic. Around 500 million individuals in the world are infected with amebiasis caused primarily (90%) by *E. dispar*. *E. histolytica* is a powerful pathogen that uses proteases to destroy hosts' tissues, kill some hosts' cells, and ''phagocyte'' red cells. It may cause amebic colitis, and after breaching the mucosal barrier, reach the liver via the portal tract and induce liver abscesses. Since the first description of this agent, a significant amount of molecular data has now accumulated. This review will describe rapidly the main epidemiological and clinical characteristics of this organism, and focus mainly on the advances made in diagnosis, thanks to *Entamoeba* genomics knowledge.

TYPE OF PATHOGEN

E. histolytica is a nonflagellated protozoan parasite. The parasite life cycle consists of two forms: infective cyst and invasive trophozoite. This latter form can be responsible for liver abscess and amebic colitis, invasion of intestinal epithelium being harmful by direct destruction of tissues. As *E. histolytica* is morphologically undistinguishable from *E. dispar*, differential diagnostic is not easy. *E. dispar* has been described quite a long time ago (Brumpt), but the real scientific evidence of two distinct species is quite recent.[1,2] *E. dispar* has been, for a while, described as the ''nonpathogenic'' form of *E. histolytica* and was supposed to be able to convert to ''pathogenic'' in culture, a contamination artifact of cultures.[3]

CLINICAL DESCRIPTION OF INFECTION SPECTRUM

E. histolytica illness is characterized by chronic diarrhea, which may or may not contain gross blood, and weight loss. However, asymptomatic colonization may occur. Intestinal amebiasis and its complications are amebic colitis, ameboma, toxic megacolon, peritonitis, and cutaneous amebiasis.[4] Extraintestinal amebiasis includes amebic liver abscess, splenic abscess, brain abscess, empyema, and pericaditis.[4]

PREVALENCE

E. histolytica/dispar parasitize approximately 10% of the world population (90% asymptomatic). It has been estimated that there are 40 million amebiasis cases which cause around 110,000 deaths a year.[4,5] Detailed data about the prevalence in asymptomatic individuals in several populations are reviewed by Stanley.[6] The cyst form is resistant for several weeks in a moist environment.[4] Because cysts are resistant to low amounts of water chlorination, special precautions should be taken in endemic zones and known infected households (boil water, wash vegetables and fruits with soap, and if possible, soak for 15 min in vinegar).[4]

MANAGEMENT

Noninvasive *E. histolytica* should be treated using a luminal agent; *E. dispar* infection should not be treated, emphasizing the need for differential diagnostics (see below). Luminal agents include diloxanide furoate, paromomycin, and iodoquinol, with respective treatment duration of 10, 7, and 20 days.[7] Metronidazole is usable as a second choice if luminal agents cannot be used.[4] Invasive amebiasis (colitis, liver abscess) should be treated with metronidazole (10 days). More precise management of invasive form is described in Refs. [8] and [9]. Dehydroemetine might also be considered in fulminant colitis or ruptured amoebic liver abscess.[6]

DIAGNOSIS

Diagnosis has relied for many years on microscopic examination of stools of patients with diarrhea. However, the WHO recommends differentiation of *E. histolytica*

DOI: 10.1081/E-EDGP 120020845

and *E. dispar*, which is not feasible using this technique.[10] Molecular techniques discussed below have been described, which in many cases are more specific, and allow for differentiation.

MOLECULAR CHARACTERIZATION OF PATHOGEN AND MOLECULAR TESTING

E. histolytica and *E. dispar* genome shotgun sequencings are underway as a joint effort from TIGR[11] and the Sanger Centre,[12] funded by the National Institute for Allergy and Infectious Diseases and the Wellcome Trust, respectively. The genome is around 18–20 Mb in size in 14 chromosomes.[11–13] However, partial genomic data from these organisms are available since the end of the 1980s.[14,15] These data allowed designing molecular assays that are sensitive to detection and, more interestingly, that can differentiate between both.[16,17] Following these pioneering works, other early molecular techniques were designed as well.[18–21] To be readily used in the clinic, molecular detection and differentiation techniques have to be usable on feces, and as any infectious disease diagnostics technique, to be both sensitive and specific (or in fact, have good positive and negative predictive values). As these values depend on prevalence, it is quite clear that a ''good'' technique in a Western country, where *E. histolytica* is not endemic and quite rare, will not be as good as in a developing area, where it is much more prevalent. Moreover, there is a cost issue, regarding techniques such as PCR.

Nowadays, to distinguish between *E. histolytica* and *E. dispar*, there are mainly two alternate means: protein differentiation using monoclonal antibodies[22–25] or genetic differentiation using probes and/or PCR. As a commercial kit, the only available is the Techlab ELISA on stool samples. Numerous PCR techniques have been developed since 1989[18–21,26,27,29–33] (see Table 1 for a comparison). So far, only one real-time quantitative technique has been published, using the Roche Light-Cycler, and thus no internal probe.[26] The authors claim a sensitivity of 0.1 parasite per gram of feces, which is high, with a 100% specificity. Samples were from Vietnam and South Africa, and data are provided allowing for predictive value calculations.

On top of the requirements cited above, a ''good'' PCR technique should be usable on clinical feces such as sodium acetate–acetic acid–formalin (SAF) fixative or frozen samples. As SAF-fixed samples are the easiest to obtain and ship (because they are used for other examinations, and because they have no temperature requirements for shipping), they would be the best. Several authors have tried to design such techniques and investigated the effect of SAF fixative on PCR subsequent detection. It was shown that even if its effect on DNA is indirect, concentrations of formalin higher than 1% seemed to inhibit PCR amplification from 4 days of fixation.[34] This was confirmed by the work of Troll et al.[29] who showed that sensitivity of PCR usually decreased within 2 days in feces stored in SAF fixative. Both teams concluded that the effects of formalin are time-dependent. However, provided that PCR assay is carried out swiftly after fixation, SAF fixative-prepared samples are suitable and have been successfully used in the field by several teams.[35,36]

Several works are underway to design a vaccine, and the completion of *E. histolytica* and *E. dispar* genomes will open new avenues for diagnostics and vaccination.

Significant data have also now been accumulated on the molecular pathways of *E. histolytica* infection (reviewed in Refs. [6] and [4]). Briefly, the amoeba

Table 1 Comparison of several published PCR techniques for *Entamoeba histolytica/dispar* detection/differentiation

Gene target	PCR type	Amplicon size[a]	Specimen	Reference
30 kDa antigen	Classic	100/101	Stools	[16]
SSU rDNA	Classic	876	Stools	[1]
P145/B133	Classic	145/133	Stools	[18]
SSU rDNA	Nested–Hot-Start	900 bp	Stools/cultures	[33]
SSU rDNA	Classic	135 bp	Frozen samples	[32]
P145/B133	Multiplex	132/96	Stools	[28]
SSU rDNA	Classic + hybrid	NI[b]	Frozen samples	[20]
SSU rDNA	Light cycler quant	310	Stools	[26]
SSU rDNA	Classic + hybrid	880	SAF fixed	[29]

Most PCR techniques rely on the amplification of specific regions of the episomal multicopy SSU rDNA gene. Starting specimen is important in the field (freezing not always user-friendly) and because of potential inhibitory problems with SAF-fixed samples. Amplicon size is also important. Techniques yielding amplicons of around 100 bp in size are likely to be much more sensitive than around 1 kb. Only Gonin and Trudel[32] provide an internal control, which allows for inhibition monitoring.

[b]NI: Not indicated in paper.

attaches to the intestinal epithelial cell through Gal/GalNAc lectin receptor. The amoebic virulence program is then activated and amoebapores are formed. Amoebic cysteine protease enters into action, which induces cell damage and pIL-1β release. IL-1β then activates NF-κB in distal cells, which promotes proinflammatory cytokines production. IL-8 promotes neutrophils influx which damages the epithelial barrier, and amoebas then cleave extracellular proteins through proteases and invade. In parallel, macrophages arrive and release TNFα, which triggers further inflammation. Once amoebas have gone through the mucosal barrier, the way is open to the liver. However, although inflammation contributes to pathogenesis, innate immunity response seems key in the containment of amoebic colitis, which does not always evolve to liver abscess.

CONCLUSION

Since the discovery of the pathogenic agent of amoebic dysentery, several genomic data have been accumulated. These data have first shown the evidence of two different species: *E. histolytica* and *E. dispar*, and have allowed for a better understanding of pathogenesis, for the design of several laboratory diagnosis and differentiation techniques, and for the investigation of vaccination strategies. However, given the utmost public health importance of this pathogen, relatively few research effort has been devoted till now. The expected rapid completion of both genomes should help researchers and clinicians all over the world to design integrated strategies against this pathogen.

ACKNOWLEDGMENTS

I wish to thank Louise Trudel, Micheline Fauvel, and Gilles Delage, Laboratoire de Santé Publique du Québec, Institut National de Santé Publique du Québec, Canada, for shared efforts and interest on molecular diagnostics, particularly Entamoeba.

Epstein–Barr Virus (EBV)

Fritz Schwarzmann
Hans Wolf
Hans Helmut Niller
Universität Regensburg, Regensburg, Germany

INTRODUCTION

In 1958, the British physician Denis Burkitt described a pediatric tumor endemic in equatorial Africa. Burkitt set up the hypothesis of an infectious particle being involved in the pathogenesis. Six years later, particles with herpesviral morphology were detected in cultured cells derived from an African Burkitt's lymphoma. According to the three discoverers, the virus was called Epstein–Barr–(Achong) virus (EBV) by Werner and Gertrude Henle, who did the essential work to describe this virus as a separate entity apart from the morphologically similar Herpes simplex virus. Since 1968, when EBV was first shown to be the causative agent of infectious mononucleosis by Volker Diehl and the Henles, the virus has been related to a number of acute and malignant diseases such as Burkitt's lymphoma, nasopharyngeal carcinoma, or gastric carcinoma. Nowadays, complications because of virus reactivation or transformation become increasingly important.

CLASSIFICATION/TYPE OF PATHOGEN

The Epstein–Barr virus (EBV) belongs to the family of herpesviruses.[1] With respect to morphology, EBV is hardly distinguishable from other family members. Based on pathogenesis, characteristics of replication, and host cell tropism, herpesviruses can be classified into three subfamilies: alpha-, beta-, and gamma-herpesvirus. EBV belongs to the genus *Lymphocryptovirus* of gamma-herpesviruses, which are characterized by a narrow host (cell) range and a slow rate of replication in cell culture.

Depending on the type and the differentiation of the infected cell, EBV follows one of the two alternative strategies to survive: latent persistence or productive replication.[2] During latency, no infectious progeny is released and expression of viral genes is tightly restricted. In comparison, at least 80 viral genes are activated in a timely coordinated manner during lytic productive replication.

CLINICAL SPECTRUM AND PREVALENCE OF EBV-ASSOCIATED DISEASES

Primary Infection and Infectious Mononucleosis

Infection with EBV is widespread and the prevalence of the virus in Western populations is more than 90%. The virus primarily spreads via the oral route (saliva) and at a time, approximately half of the asymptomatic virus carriers shed EBV. In nonindustrialized nations, primary infection takes place between 2 and 5 years of age and is mostly asymptomatic. However, infection later in life increases the risk to develop infectious mononucleosis (IM), which is a transient and self-limiting lymphoproliferative disease characterized by lymphadenopathy, high-grade fever, hepatosplenomegaly, and pharyngitis or tonsillitis.[3] Atypical mononuclear cells and an inverted ratio of CD4+ vs. CD8+ cells are hematological markers of IM. Generally, IM lasts for 4 to 6 weeks, eventually establishing an asymptomatic persistent infection.

Complications of Primary Infection

In rare cases, mostly in children, EBV may cause fatal IM or infection takes a severe chronic active course (SCAEBV).[4] Affected individuals develop life-threatening complications suffering from extensive lymphadenopathy, hepatosplenomegaly, pancytopenia, polyclonal gammopathy, as well as B cell or T cell lymphoproliferative diseases. EBV-specific antibody titers (anti-VCA and anti-EA) are extremely high, indicating uncontrolled systemic viral replication.

Another milder form of chronic active infection (CEBV) affects mainly adults and often starts with IM lasting for months to years.[5] Patients are heavily impaired in daily life by chronic and relapsing mononucleosis-like symptoms often associated with malaise, fatigue, and hepatosplenomegaly. A role in the pathogenesis of EBV for the chronic fatigue syndrome (CFS) has not been proven.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020841

X-linked lymphoproliferative syndrome (XLPS, Duncan syndrome)[6] is a hereditary immunodeficiency that predisposes affected males to fatal IM characterized by aplastic anemia, hemophagocytic syndrome, dysgammaglobulinemia as well as extensive lymphoid infiltration leading to organ failure. Those surviving primary infection develop different forms of malignant B cell lymphoma later on. The defect has been localized on the X chromosome (Xq25–q27) and specifically to a deficient SH2D1A/SAP gene causing feedback regulation of T cell activation.

Hematological Disorders Associated with EBV

EBV is associated with a number of malignant diseases harboring latent virus.[1] Burkitt's lymphoma (BL), a monoclonal B cell lymphoma with germinal center markers, is endemic and represents the most prevalent tumor in children in Africa. Chromosomal translocations between the protooncogene c-myc and the loci for the immunoglobulin heavy and light chains are characteristic for BL. Association with EBV is variable and depends on the geographical distribution. Whereas endemic BL is positive for EBV in more than 90% of cases, only about 15% are positive in sporadic BL and 30–40% in AIDS-associated BL.

Hodgkin' s disease (HD) is also variably associated with EBV depending on age, geographical distribution, and on the subtype of the tumor.[7] There are at least four subtypes of HD: the ''mixed cellularity'' and ''nodular sclerosis'' types, which are the most prevalent types that are EBV-positive in 32–96% and 10–50%, respectively. The ''lymphocyte predominant'' type seems to be mostly EBV-negative, but the ''lymphocyte depleted'' type is EBV-positive in approximately 50% of cases. AIDS-related cases of HD are EBV-infected in more than 95% of cases.

Immunosuppression significantly increases the risk to develop EBV-associated malignant diseases because of the immortalizing and transforming properties of the virus. More than 90% of posttransplantation lymphoproliferative disorders (PTLD) are related to EBV. PTLD is variable with respect to morphology and clonality. In general, monoclonal tumors are more aggressive than polyclonal ones, likely because of additionally acquired genetic mutations enabling immune escape. Polyclonal proliferation often progresses to oligoclonality or monoclonality without intervention.

AIDS-associated non-Hodgkin's lymphoma (AIDS-NHL) is usually of B cell origin. In contrast to NHL in the course of iatrogenic immunosuppression, there is no clear association with EBV.

Although T cells are not the primary target of EBV, various T cell lymphomas are clearly associated with the virus including T cell lymphocytosis, nasal T cell lymphomas, T cell lymphomas with angioimmunoblastic lymphadenopathic appearance, and NK/T cell lymphoma.[8]

Epithelial Tumors and EBV

EBV is also related to a series of epithelial malignancies.[9] Of these, nasopharyngeal carcinoma (NPC) is the most prevalent tumor in Southeast Asia and is endemic in Southern China and Hong Kong (9 per 100,000), in Northern Africa, and among the Inuits. According to the differentiation of the tumor tissue, NPC is classified into three subtypes: ''squamous,'' ''nonkeratinizing,'' and ''undifferentiated'' NPC. The undifferentiated type of NPC is virtually always associated with EBV. Besides EBV, both the genetic background and diet are cofactors for the development of NPC.

Tumors of the glandular epithelium of the stomach, the salivary gland, the lung, and the thymus are other EBV-related lymphoepithelial tumors. EBV can be detected in 75–100% of the rare lymphoepithelioma-like gastric carcinomas and in approximately 27–35% of gastric stump carcinomas. In addition, EBV is detected in 2–16% of gastric adenocarcinomas.

MANAGEMENT OF EBV-ASSOCIATED DISEASES

Infection with the EBV invariably leads to lifelong persistence. B lymphocytes are supposed to be the primary target cells of EBV in vivo. Memory B cells, which become latently infected, are invisible from an immunological point of view and serve as a lifelong reservoir of the virus.[10] In contrast, activated and differentiating B cell blasts support lytic replication such as differentiating epithelial tissues that have also been demonstrated to be infected in vivo.[11] In immunologically privileged tissues such as lymphoepithelial tissues of the oropharynx, e.g., the parotis,[12] infectious viral particles are shed into the saliva.

Most cases of infectious mononucleosis do not require therapeutic intervention. In cases of clinically severe IM and life-threatening forms of SCAEBV, intravenous application of the nucleoside analog acyclovir or gancyclovir may be necessary to reduce active viral replication.[4] In addition, but not alone, antiphlogistic drugs to reduce the unspecific effects of the cellular immune response may be beneficial. Tonsillectomy is frequently used and was found to reduce symptoms of IM possibly

on cost of later recurrences.[13] In SCAEBV, underlying immune dysfunctions such as insufficient NK cell activity or production of IFN-γ may be treated with various cytokines.

However, chemotherapy cannot access the viruses latently persisting in quiescent B cells nor the viruses in tumor cells. Solid EBV-associated tumors are removed by surgery followed either by chemotherapy, such as in the case of BL and HD, or combined chemotherapy and radiotherapy as for NPC.

Bone marrow transplantation is the state of the art to control the fatal consequences of XLPS, which is known to rely on a regulatory defect in lymphocytes.

Immunotherapy of EBV-Associated Malignancies

EBV-associated monoclonal tumors in otherwise immunocompetent individuals are known to be mostly invisible from an immunological point of view. In comparison, lymphoproliferative diseases after hematopoetic stem cell transplantation or solid-organ transplantation usually arise as polyclonal proliferations of EBV-infected immortalized cells that are subject to immune control. Immediate partial reconstitution of immune surveillance is the first action to take. Without treatment, benign polyclonal proliferations often progress to oligoclonality or monoclonality with greatly reduced chances for successful therapy.

New immunotherapeutic approaches[14] aim at the elimination of B cells through monoclonal antibodies such as anti-CD20, anti-CD21, or anti-CD24. Alternatively, EBV-specific cytotoxic T cells (CTL), which are generated in vitro by cocultivation of donor-derived T cells with EBV-infected B-lymphoblastoid cells, are adoptively transferred in the otherwise immunosuppressed recipients in the case of a developing LPD.

Depletion of B cells and adoptive transfer of T cells are often complemented by the administration of interferons IFN-γ and IFN-α or in vivo blocking of interleukin IL-6 by the addition of anti-IL-6 antibody resulting in remission and prolonged survival of some cases.

Vaccination Against EBV

The development of a vaccine against EBV is still in the preliminary stages. Attempts mainly concentrate on subunit vaccines based on the viral membrane glycoprotein gp350.[15] Gp350 delivered as recombinant protein, as synthetic peptides, or recombinant vectors expressing this antigen offered protection against EBV-induced lymphomas in the Tamarin model. Two human Phase I/II clinical trials, which have been conducted with the gp350 protein, and a live recombinant virus vaccine,[16,17] proved safety and showed sterilizing immunity in more than 50% of vaccinees, with no answer possible on efficacy for disease protection in the rest. Recently, clinical trials with an EBNA3A epitope peptide vaccine were also conducted, showing no adverse reactions.

MOLECULAR CHARACTERIZATION OF THE EPSTEIN–BARR VIRUS

Classification of EBV is based on both phenotypic and genomic sequence variations.[18] Type 1 (type A) and type 2 (type B) EBV strains are distinguished on the molecular level by sequence variations in the viral genes encoding the EBV-associated nuclear antigens (EBNAs). Both types of EBV can be easily identified by PCR.

Characterization and identification of EBV strains has also been reported by Western blot assays based on variations in the molecular weight of the EBNA proteins.

In the context of NPC, a number of sequence variations within the transforming viral LMP-1 gene have been found. Virus strains with a characteristic 30-base-pair deletion have been statistically detected more often in NPC compared to asymptomatic virus carriers. Another strain variation reported to be present in southern Chinese patients with NPC is the ''f'' variant.

In context with severe chronic active infections with EBV, virus strains with a bias to lytic replication and an impaired or even absent capacity to establish latent infection have been reported.[19–21]

In conclusion, molecular characterization of Epstein–Barr viral strains is only of minor importance for routine diagnostics and therapy. The role of distinct EBV strains in pathogenesis is only indicated by circumstantial evidence. Furthermore, molecular analysis of EB viral strains in individuals revealed infection with multiple strains of EBV, with the type of strains in the oropharynx and in the peripheral blood shifting over time.

MOLECULAR TESTING OF THE EPSTEIN–BARR VIRUS

Laboratory testing of Epstein–Barr virus infection involves immunological, hematological, and molecular markers depending on the differential diagnosis required.[18,22]

Serology of EBV is based on the timely coordinated appearance of virus-specific antibodies of the immunoglobulin classes IgG, IgM, and IgA specific for a number of viral proteins. Serology is mainly used to define the carrier status and to differentiate primary infection and

infectious mononucleosis on the one hand from remote infection and cases of virus reactivation on the other hand.

Although high titers of antibodies against early antigens (EA) and the virus capsid antigen (VCA) are suggestive for EBV-associated tumors, an association of EBV with a tumor needs to be confirmed by histological and cytological assays demonstrating a spatial relation of the virus to the tumor cells. Nevertheless, depending on the type and subtype of the tumor, EBV is not present in every malignant cell. This has been suggested to be a consequence of a ''hit-and-run event'' with secondary loss of the virus.

Demonstration of the viral RNA transcripts EBER-1 and EBER-2 by in situ hybridization is the gold standard to show latent EBV infection in tumor tissues, although there is some discussion whether EBV-positive cancer without transcription of the EBERs exist. There, and in cases of oral hairy leukoplakia (OHL), characterized by lytic replication of EBV, DNA in situ hybridization using simple copy genes or the W-repeat fragment may be performed. Because of infiltrating EBV-infected bystander lymphocytes, PCR and Southern blot are less well suited to prove EBV association.

EBV infection of cells can also be demonstrated by immunohistochemical assays. The viral antigen BZLF-1, which is a key protein of the lytic replication of EBV, is particularly useful to demonstrate EBV in cases of OHL. The viral latent membrane protein LMP-1 is used to reliably demonstrate EBV in cases of PTLD and HD in the tumor although not in every EBER-positive cell. In carcinomas such as NPC or in non-Hodgkin lymphomas, LMP-1 is not regularly expressed and therefore EBER in situ assay is more reliable.

Monitoring the viral load over time in the peripheral blood is increasingly used for the adjuvant diagnosis of EBV-associated diseases such as PTLD, HD, and NPC, and is suitable to determine the tumor burden indicative of a relapse of the malignant disease.

CONCLUSION

Epstein–Barr virus is clearly related to a number of acute and malignant diseases. However, pathogenesis is mainly dependent on insufficient immunosurveillance and cofactors such as continuous overstimulation of the immune system, chemicals and diet, and genetic predisposition. Against the background of the high prevalence of the virus within any population, demonstration of EBV infection by serology or by PCR is not sufficient to confirm an EBV-associated disease. Careful analysis of more specific serological markers with respect to particular viral antigens and different classes of immunoglobulins as well as virus load and clonality and physical presence of EBV in the affected tissues and the malignant cells is necessary to discriminate EBV-associated disease from the normal carrier state or opportunistic reactivation. In addition, determination of the cellular immunity against EBV might become an important tool for early diagnosis. In the end, a vaccine against EBV would be desirable to timely treat individuals who are at high risk to develop EBV-associated diseases.

Escherichia coli Serotypes (Enterohemorrhagic)—Detection by Multiplex PCR

Peter C. H. Feng
Steven R. Monday
United States Food and Drug Administration, College Park, Maryland, U.S.A.

INTRODUCTION

This chapter discusses the gene targets most often used for developing EHEC-specific PCR assays, including the common major and putative virulence genes, and markers that are O157:H7-specific or specific for other serotypes (Table 1). This chapter also includes selected examples of multiplex PCR assays that use combinations of various markers to detect O157:H7 or other EHEC serotypes.

OVERVIEW

Enterohemorrhagic *Escherichia coli* (EHEC) has emerged as an important foodborne pathogen and a predominant cause of hemorrhagic colitis (HC) in humans. This illness, with characteristic symptoms of bloody diarrhea and severe abdominal cramps, may progress into the potentially life-threatening complication known as hemolytic uremic syndrome (HUS).[1,2]

The pathogenicity of EHEC is thought to be attributable to the production of Shiga toxins (Stx), also referred to as Verotoxins, which inhibit protein synthesis by interfering with the functions of the 23S rRNA.[3] Stx1 and Stx2 are most often produced by EHEC strains causing illness, but Stx2 is most often implicated in HUS; hence, it appears to be more important in human infections. There are several variants of Stx2 (Stx2c, Stx2d, Stx2e, Stx2f, etc.),[4] and although many of these are produced by animal or environmental strains, recent evidence suggest that some variants may also cause human illness. It is estimated that there are over 200 *E. coli* serotypes that produce Stx. Collectively known as Shiga toxin-producing *E. coli* (STEC), many of these may be found in the feces of animals or healthy humans and have not been implicated in illness. Therefore EHEC is a small subset of STEC composed of strains sharing the same clinical, epidemiological, and pathogenic features[2] that can be distinguished from STEC via the presence of other virulence traits.

While many EHEC serotypes, including O157:H7, O111:H8, O26:H11, O103:H2, O113:H2, O104:H21, and their nonmotile (NM) counterparts,[5] have been implicated in illness, the O157:H7-type strain is still the predominant pathogen causing most of the EHEC foodborne infections and outbreaks worldwide. The O157:H7 group is clonal and only distantly related to other *E. coli*, except for enteropathogenic *E. coli* (EPEC) of O55:H7 serotype.[6] Enterohemorrhagic *E. coli* strains are serologically and genetically diverse with significant phenotypic and genetic diversity observed even within serologically identical groups, such as with the O157:H7 group.[7] As a consequence, the development of diagnostic assays for EHEC can be complicated. However, these difficulties can be overcome by using polymerase chain reaction (PCR) technology that can differentiate variations within genetic sequences to the level of single nucleotide polymorphisms.

EHEC GENETIC MARKERS

Detection of *stx* genes is fundamental to PCR assays for EHEC, and there are easily a few dozen primers that have been developed for *stx1* and *stx2* genes. However, because there are some homologies between toxins, some primers also detect variant types of *stx*. A study evaluated 14 *stx*-specific PCR primer pairs by using several STEC strains known to produce *stx1*, *stx2*, and/or various Stx variants.[8] All primers specifically detected *stx1* and *stx2*, but varied in the detection of variant forms. However, other primers amplified variant *stx* genes that, when coupled with restriction fragment length polymorphism (RFLP) analysis, distinguished variant Stx types. PCR for *stx* identifies only STEC, hence EHEC detection is more complex and requires testing for other markers. Most EHEC carry the chromosomal locus for enterocyte effacement (LEE) pathogenicity island that encodes several virulence factors, including a type III secretion system that mediates the injection of virulence factors into host cells. Among the LEE-encoded virulence genes are *eae* and *tir* that encodes for intimin and the translocated intimin receptor, respectively, which coordinately interact to mediate bacterial attachment to the intestinal epithelial cells that initiates the development of the characteristic attachment/effacing lesions.[2] Although there seems to be a strong correlation between the presence of the *eae* and

Table 1 Genetic markers used in multiplex PCR assays for detection of EHEC

Target	Genes
Shiga toxin	stx_1, stx_2, stx_2 variants
Intimin	α-eae, β-eae, γ-eae
Enterohemolysin	*ehxA* (cluster I and II)
Serine protease	*espP*
STEC agglutinating adhesin	*saa*
O157:H7	+92 *uidA*
O157, O111, O113 antigens	*rfb*
H7 flagellin	*fliC*

stx2 genes with the ability of EHEC to cause illness,[9] LEE is also present in EPEC and, therefore, PCR using *eae*-specific primers detect both EPEC and EHEC. Consequently, it is essential that *eae* and *stx* primers are used in conjunction to distinguish EPEC, which do not produce Stx. There are several *eae* alleles (α, β, γ, σ, etc.),[10] which exhibit significant degree of homogeneity, but possess genetic differences that can be exploited to design allele-specific PCR primers to facilitate the identification of EHEC.[10–12] For instance, the β-intimin allele is found in some EHEC serotypes, such as O26 and O111, while the O157:H7-type strain carries the γ-intimin gene.[11]

Other putative EHEC virulence factors are found on a 90-kb EHEC plasmid. One of these is EHEC hemolysin, encoded by the *ehxA* (*ehlyA*) gene produced by O157:H7 and other EHEC serotypes. The *ehxA* gene has been proposed as a detection marker for EHEC; however, its presence in some non-STEC strains and absence in strains causing HUS casts some doubts on its role in pathogenesis. Analysis of 79 STEC strains showed that, while highly conserved, there are two distinct *ehxA* genetic alleles sharing 98% nucleic acid homology.[13] EHEC serotypes such as O157:H7, O26:H11, O111:H8, and O103:H2 maintain cluster I allele, while cluster II is found in EHEC serotypes such as O113:H21 and O104:H21.

Another putative virulence factor on the EHEC plasmid is the *espP* gene that encodes for serine protease. Although the *espP* gene is found in O157:H7 serotype, it is absent in atypical German sorbitol-fermenting O157 strains causing HUS.[7,14] Similarly, the *saa* gene encoding for the STEC autoagglutinating adhesin is found in many strains that do not have *eae* and speculated to be an alternate mechanism for bacterial attachment. However, *saa* is more prevalently found in bovine than human STEC strains,[15] hence the role of these adhesins in EHEC pathogenicity remains to be elucidated.

The *uidA* (*gusA*) gene, which encodes for β-glucuronidase, is expressed by most *E. coli*. One exception, O157:H7, contains the *uidA* gene but produces a nonfunctional enzyme because of a frame-shift mutation in the *uidA* gene.[6] The O157:H7 *uidA* also carries a +92 T to G base substitution that is highly conserved and found only in strains of O157:H7 group.[6] Although not a virulence factor, the +92 *uidA* mutation has been found to be a unique marker and useful for developing O157:H7-specific PCR assays.[16]

EHEC SEROTYPE-SPECIFIC MARKER

Production of the O157 antigen is a distinguishing characteristic of O157:H7 serotype; however, serotyping is problematic because of the cross-reactivity of anti-O157 polyclonal sera with strains of *Citrobacter freundii*, *Escherichia hermanii*, and others. However, serotype-specific genetic markers are specific and provide a viable alternative to serotyping. One such marker is the *rfbE* gene, which encodes for perosamine synthethase that is essential for O157 antigen expression.[17] PCR primers to the *rfbE* locus have been designed that detect O157 strains; however, these primers are not O157:H7-specific and detect other O157 strains that do not produce H7. Similarly, PCR primers specific to the serotype O111[18] and O113[19] *rfb* locus have been designed that detect these serotypes, some of which are EHEC and have been implicated in causing illness.

Production of the flagellar H7 antigen is another trait phenotype of O157:H7 strains. However, as in the case of the O157 antigen, other *E. coli* serotypes also express the H7 antigen. Flagellin is encoded by the *fliC* gene, which genetic analyses have shown to contain polymorphisms that can be distinguished by RFLP analysis of H7 *fliC*-derived PCR amplicons.[20] All O157:H7 and its Stx-producing nonmotile variants have identical H7 *fliC* RFLP profiles that are distinct from that of other H7-producing serotypes, except the EPEC O55:H7 strain, which has not only an identical H7 *fliC* RFLP profile,[20] but also has the H7a,c serological subtype.[21] Genetic studies show that O55:H7 is an ancestral strain of O157:H7, which is closely related and belongs to the same clonal group.[6] Although different, at present PCR primers specific for the H7 *fliC* gene detect all H7-producing strains regardless of its O serotype,[22] and none are specific for the H7 *fliC* allele exclusively found in the O157:H7 and O55:H7 strains.

MULTIPLEX PCR FOR DETECTION OF EHEC

Theoretically, any of the target-specific primers mentioned (Table 1) can be combined to develop multiplex PCR assays for EHEC. However, considerable testing will be required to optimize primer combinations, concentrations, and assay conditions. Some primer sequences may also need to be modified to provide an annealing

temperature that is more suited to all the primer pairs, or to change the size of the amplicons to enable better visualization/detection. Multiplex PCR assays are very useful for characterizations of culture isolates, but when used for testing samples, which most likely contains mixed cultures, the amplicon patterns obtained may not necessarily have been derived from a single bacterial strain.

Selected EHEC multiplex PCR assays and the targets that were successfully combined, optimized, and used to specifically detect O157:H7 or other EHEC serotypes are listed in Table 2. In the following sections, a few of these multiplex PCR assays are presented.

Paton and Paton[23] designed an agarose gel-based, two-reaction system to identify EHEC strains. The first reaction selectively targets *stx*1, *stx*2, *eae*, and *ehxA*, while the second reaction differentiates O111 and O157 strains based on their *rfb* gene. Analysis of 52 previously characterized STEC strains isolated from food, human, or animal sources showed that the assays correctly identified all of the isolates and the determinants carried by each strain with no cross-reactivity to closely related strains. The *stx*2 primers also amplified all *stx*2 variants, except for stx_{2f}, but the *eae* primers were designed for the conserved region of *eae*, and therefore did not identify the specific *eae* alleles carried by the strains.

Another gel-based multiplex PCR described by Feng and Monday[16] used a single PCR reaction to detect *stx*1, *stx*2 (including stx_{2c}, stx_{2d}, and stx_{2e}), and both *ehxA* alleles to identify STEC. However, unlike other assays, this multiplex also incorporated primers to the γ-intimin (*eae*) gene, the only allelic variant expressed by the O157:H7 group, and the +92 *uidA* mutation that has, thus far, only been observed in the O157:H7 serotype. This assay bears the advantage of being able to detect STEC and simultaneously identify EHEC of the O157:H7 serotype. Analysis of 38 strains showed that the assay correctly identified the determinants carried by EHEC, STEC, and EPEC, and also identified all the O157:H7 strains tested. This assay will not identify other EHEC serotypes, which do not possess the +92 *uidA* mutation and may express intimins other than the γ-allele.

Gel-based PCR assays can detect many genetic determinants in one reaction; however, it is time-consuming and provides data that are difficult to quantitate. Furthermore, gel-based results are solely based on amplicon sizes with no means to confirm that the product was derived from specific target amplification or was a consequence of a rare mispriming event. These limitations can be overcome by using real-time PCR (rt-PCR), which enables rapid amplification and real-time monitoring of results, and—when coupled with sequence-specific internal probes—guarantees the amplification of specific targets, which can also be quantified to estimate bacterial load. Reischl et al.[24] used rt-PCR and Fluorescence Resonance Energy Transfer (FRET) technology to develop two assays that amplified and detected sequence-specific EHEC virulence determinants in approximately 60 min. The first assay used a single primer pair to amplify *stx* genes, which were then differentiated into *stx*1 (at 640 nm) and/or the *stx*2 (at 705 nm) genes by toxin-specific, fluorophore-tagged hybridization probes. Melting temperature analysis of probe-hybridized amplicons also allowed the determination of some *stx* allelic variants, except for $stx2_f$, which is genetically distinct and found in STEC isolated from pigeons. The second assay is similar, but uses two separate primer sets and target-specific, fluorophore-tagged hybridization probes to detect the *eae* (at 640 nm) and *ehxA* (at 705 nm) genes. The *eae* primers and probes appeared to be specific to the conserved regions, as the assay did not differentiate *eae* allelic variants. In the analysis of 431 STEC strains, 73 Stx-negative *E. coli*, and 118 other bacterial species, rt-PCR was found to be 100% sensitive and specific for *stx1*, *eae*, and *ehxA*, and had 96% and 100% sensitivity and specificity, respectively, for *stx2*.

Although rt-PCR offers many advantages, reaction kinetics and the limited number of distinct fluorophores presently available limit the number of targets that can be combined in a multiplex format. Furthermore, the cost of the equipment and special order reagents often precludes its current use in routine testing.

CONCLUSION

Most PCR assays developed for the detection of EHEC target the *stx* and *eae* genes and their various alleles. However, because the EHEC group comprises many serotypes that are genotypically and phenotypically diverse, identification of specific strain requires the detection of other putative virulence genes or markers that are unique to O157:H7 or other serotypes. Multiplex

PCR assays, which enable the simultaneous detection of multiple genes, are very useful in the diagnosis of specific EHEC serotypes and the virulence factors carried by these pathogens.

ESTAnnotator—A Tool for High-Throughput EST Annotation

Agnes Hotz-Wagenblatt
Deutsches Krebsforschungszentrum, Heidelberg, Germany

Thomas Hankeln
Johannes Gutenberg Universität Mainz, Mainz, Germany

INTRODUCTION

The protein-coding genetic information of higher eukaryotic genomes represents only a minor percentage of its total DNA, e.g., 1.5% in the human genome, meaning that genes are usually separated by large stretches of noncoding intergenic DNA. Additionally, eukaryotic genes are organized mosaic-style: rather short exons (with an average size of 150 bp in humans), which form the mature mRNA and contain the essential coding information, are separated by introns, which are spliced out from the primary RNA transcripts and do not contribute to protein-coding. Because of this complex architecture of higher organism genomes, it is notoriously difficult to recognize exons in large stretches of genomic DNA sequences, e.g., obtained in the framework of genome projects, and to identify those exons correctly which altogether make up a complete gene. As a ''shortcut'' alternative to the sequencing and identification of the protein-coding gene repertoire of an organism, Adams et al. introduced a strategy called ''EST sequencing'' (EST = expressed sequence tag). This approach bypasses all complexities of genome structure by focusing only on the transcribed portions of a genome: the procedure starts with the isolation of an mRNA population from a certain tissue. After converting the mRNA molecules into their complementary DNA (cDNA), all resulting cDNA molecules are cloned into suitable vector/host systems. Then, usually thousands of clones are being chosen at random for a DNA sequencing of their cDNA integrates, yielding a catalogue of EST sequences which essentially represents a collection of the transcribed portion of the genome (i.e., the genes). Gathering of sequence information from the protein-coding parts of the cDNA can be optimized by producing 5′EST reads instead of 3′EST reads, which usually cover the 3′untranslated gene regions.

The EST approach is extremely cost-effective and fast, and it gives a good overview of those genes that are active in the tissue used as source for the initial RNA preparation. A dedicated freely searchable database (dbEST), a division of GenBank (http://www.ncbi.nlm.nih.gov/Genbank/GenbankOverview.html), has been set up to collect EST data from a huge number of diverse organisms (see http://www.ncbi.nlm.nih.gov/dbEST/dbEST_summary.html), and this database currently contains more than 5.6 million human EST reads alone. Despite this wealth of data, EST sequencing is still an essential tool for the discovery of novel genes that have not been identified by genomic sequencing and gene prediction alone.

The production of a gene catalogue from EST data requires several steps of bioinformatical sequence analysis: 1) Because of the single-pass, ''quick but dirty'' sequencing strategy, bad sequence data and EST sequences contaminated with vector or repetitive noncoding DNA have to be removed. 2) Overlapping EST reads have to be clustered to obtain a contig sequence of their underlying cDNA. 3) Both EST singletons and EST clusters have to be annotated by searching for similarity to known genes or proteins already existing in nucleotide and protein sequence databases. Here we describe an EST annotation tool that automates these steps and which was successfully used in categorizing 5000 EST sequence reads during a search for genes involved in differentiation and disease processes in human fetal cartilage tissue.

METHODS AND RESULTS

The basic methodology of generating a gene catalogue by EST sequencing is outlined in Fig. 1. The reader may refer to Refs. 1–3 for details on the EST production process and for the importance of having EST sequence information in the framework of a genome project.

The EST annotation pipeline of ESTAnnotator[4,5] (Fig. 2) can be divided into the following subsections: the preparation of quality-checked input EST sequences (shown in the upper part), the initial analysis of EST reads by database searches (shown at the left lower part), and the clustering of overlapping EST sequences as well as subsequent contig analysis (shown in the right lower part).

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120030822

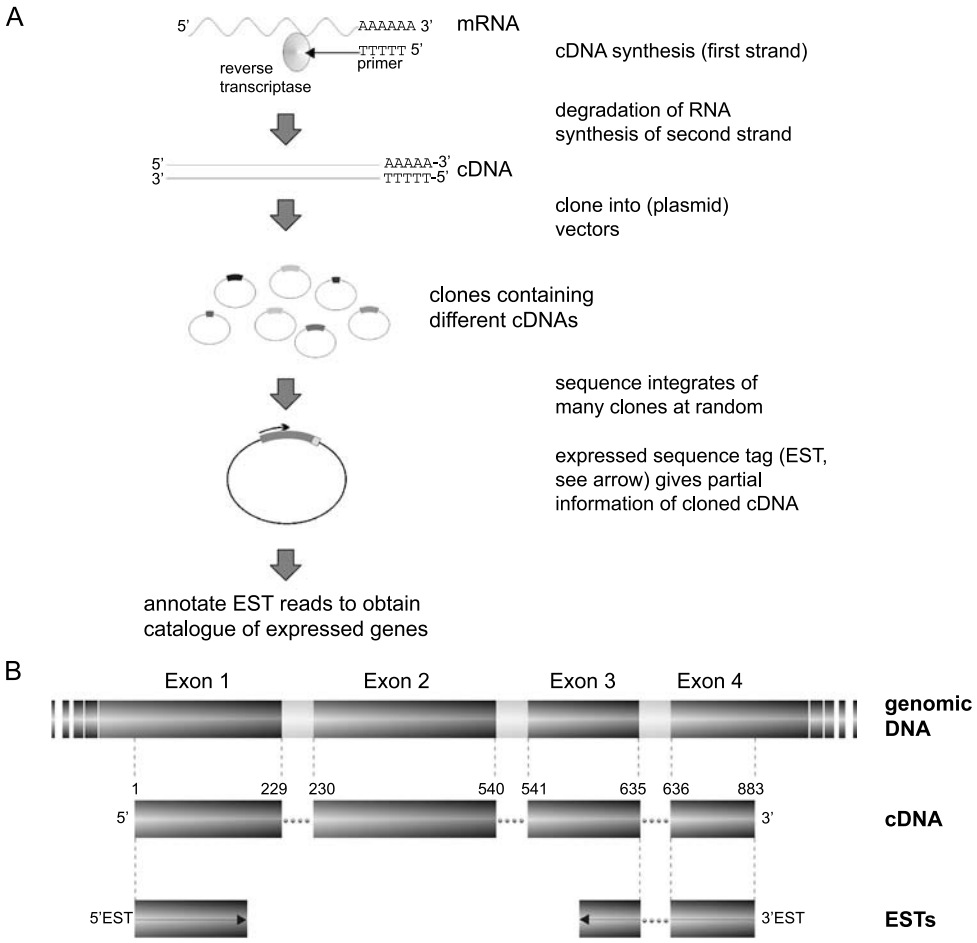

Fig. 1 (A) Outline of an EST sequencing project. Note that the mRNA and cDNA molecules schematically depicted represent the population of all transcribed genes in the analyzed tissue. (B) Positional relationships of exons and introns on the genomic level, the complete cDNA derived from the mature mRNA transcript of the gene, and the partial cDNA sequence information (arrows) present in the 5′ and 3′ EST sequences.

Preparation of Input EST Sequences

ESTAnnotator was designed for processing raw trace files (sequence chromatograms) or sequence text files. As EST sequences are generated by complex cDNA cloning procedures, they are often contaminated with vector and linker sequences. For generating high-quality input EST sequences, vector sequences and naturally occurring repetitive elements are masked by default. If too much sequence information is lost due to quality trimming or masking, no further analysis of the input sequence occurs and the task automatically stops. This was the case for about 2.6% of the EST reads in the cartilage EST project.

BLAST Similarity Analysis

Sequence similarity searching is an important methodology in computational molecular biology. Initial clues to understanding the structure or function of a molecular sequence arise from homologies to other molecules that have been previously studied. Genome database searches reveal biologically significant sequence relationships and suggest future investigation strategies. Database search algorithms are used to compute pairwise comparisons between a candidate query sequence and each of the sequences stored within a database in order to find all the pairs of sequences that have a similarity above a defined threshold. The basic local alignment search tool (BLAST) algorithm is an approximate heuristic algorithm used to compute suboptimal pairwise similarity comparisons. Because of its speed, the BLAST algorithm has become the dominant search engine for biological sequence databases. The EST sequences were run against four different databases using the gapped BLAST program.[6] The search against the NCBI (National Center for Biotechnology Information, Bethesda, USA)

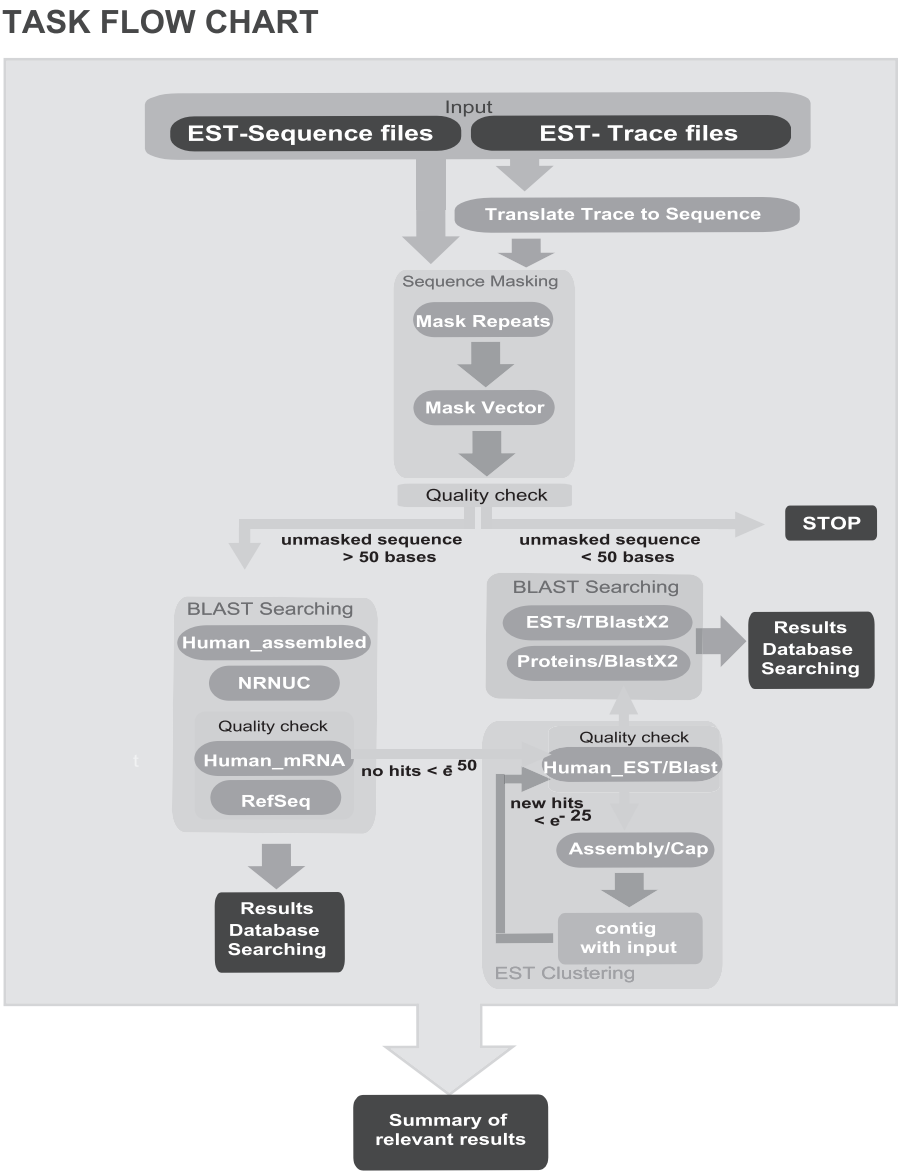

Fig. 2 Flow chart of the ESTAnnotator: programs and rules used for high-throughput annotation of ESTs. (Modified from Ref. [4].) (*View this art in color at www.dekker.com.*)

nonredundant nucleic acid database (ftp://ftp.ncbi.nih.gov/blast/db) should reveal any similar nucleotide sequence deposited in the public databases. For the chromosomal location of the EST within the human genome, another BLAST search was performed against the NCBI human genomic sequence contig assembly database (ftp://ftp.ncbi.nih.gov/genomes/H_sapiens), which contains the nucleotide assemblies of the human chromosomes. For the identification of known, complete cDNA sequences matching our EST reads, additional searches were performed against the NCBI human mRNA database (ftp://ftp.ncbi.nih.gov/genomes/H_sapiens/RNA), which contains human ''model mRNAs'' constructed by prediction from genomic sequence data, and the RefSeq database (ftp://ftp.ncbi.nih.gov/refseq/, mRNA part), which contains curated mRNA data from human and other model organisms. If a highly similar mRNA corresponding to our EST read was found in any one of these mRNA databases, no clustering and further database searching were needed. Among the cartilage EST sequences 69.6% showed significant similarity to known genes/mRNAs in the human RefSeq collection, and another 4.8% were found homologous to human model RNAs. Approximately 23% of the cartilage EST sequences could not be identified as known transcripts, but showed significant similarity to genomic regions

and/or other anonymous ESTs.[5] A subset of these potentially novel gene sequences is currently under detailed experimental scrutiny for expression in cartilage tissue using RT-PCR, Northern blotting, and mRNA in situ hybridization.

Using the NCBI human assembly database, a corresponding genomic location could be identified for more than 90% of the EST sequences. This information will be valuable in selecting possible candidate genes from regions of the human genome to which diseases related to malformations of the skeleton have been mapped genetically.

Clustering of Overlapping ESTs and BLAST Analysis at the Protein Level

Expressed sequence tag sequences which could not be reliably assigned to a known mRNA or gene were processed further to finally obtain an annotation. As each gene may have many alternative transcripts that contain exons in different combinations, it is not a trivial task to assign each EST to its progenitor gene. A BLAST search against other human EST sequences from dbEST was therefore used to find homologous, overlapping EST reads in order to extend the original EST sequence by clustering.

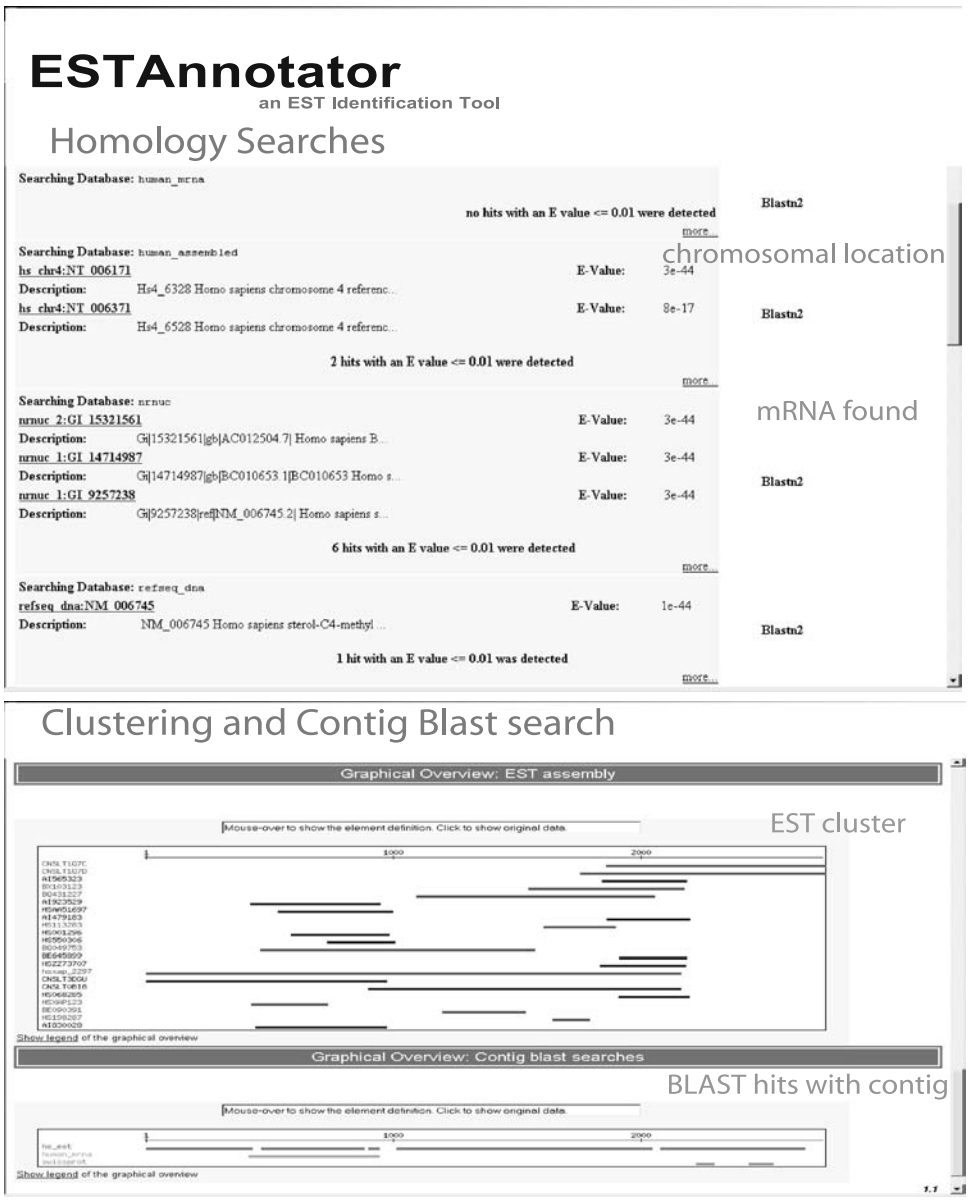

Fig. 3 Parts of the ESTAnnotator report: database search results list and graphical display of the EST contig assembly and protein BLAST hits. (*View this art in color at www.dekker.com.*)

Assembly of such EST clusters, each containing the input EST sequence, was performed by a contig assembly program (CAP),[7] and the resulting consensus sequence of each cluster was saved. The EST cluster consensus sequences (or the input EST sequence alone, in case no cluster was formed) were used for further similarity searching on the protein sequence level in order to detect even remote similarities to known proteins or other anonymous EST sequences in the databases. These searches were performed by BLASTX against the Swissprot protein database (ftp://ftp.ebi.ac.uk/pub/databases/swissprot/) to check for matching, already annotated proteins, and by TBLASTX against all ESTs of all organisms in dbEST to detect similarities to anonymous coding sequences of other organisms.

The ESTAnnotator Report

The final ESTAnnotator report (Fig. 3) is a web page that displays the database ID and the description line of the top three hits of the BLAST search results if their expectation value is below 0.01. Additionally, a link to the original BLAST output is provided. To illustrate the position of the BLAST hits and the clustered EST sequences, corresponding graphical outputs are displayed in the lower part. The alignment information can be accessed by clicking on the hits within the graphical output. By downloading the XML (Extensible Markup Language) report file from the server, the results from the database searches for each EST sequence can easily be parsed into a database file.

WWW Access by the Web Interface to HUSAR (W2H)

Using the W3H task system[8] allowed the immediate integration of ESTAnnotator into the W2H web interface.[9] The ESTAnnotator is available at http://genius.embnet.dkfz-heidelberg.de/menu/biounit/open-husar/.

CONCLUSION

Expressed sequence tag sequencing and annotation are highly useful for identifying the repertoire of genes transcribed in tissues involved in human diseases, and—even in the well-studied human genome—the approach still represents a valuable tool for the identification of novel genes and alternatively spliced mRNAs. The ESTAnnotator facilitates processing and annotation of medium- to large-scale EST datasets. The successive steps of initial EST read quality control, followed first by the identification of ESTs which correspond to already known genes and mRNAs, and then by the clustering and further annotation by database searching of the remaining EST reads have been automated to avoid manual intervention. ESTAnnotator successfully led to the immediate bioinformatical annotation of about 75% of 5000 EST sequences originating from a human fetal cartilage cDNA library.[5] The tool could be further improved by producing a functional classification of the identified cDNAs (e.g., according to GeneOntology criteria; http://www.geneontology.org) together with known splice variants and single nucleotide polymorphisms.

Ethical Issues Related to Genetic Testing

E

Carol Isaacson Barash
Genetics, Ethics & Policy Consulting, Inc., Boston, Massachusetts, U.S.A.

INTRODUCTION

We now know that genes affect virtually all human characteristics and diseases. Experts anticipate substantial potential for developing health care innovations based on advances in genomics.

Ethics (the science of moral principles) and genomics (the science of the function of genes) have been intertwined for centuries. Humans pondered the heritability of traits as long as 6000 years ago with Babylonian engravings evincing the earliest known pedigrees. Aristotle and Hippocrates deduced that most important human characteristics were inherited and transmitted through semen. Thematic in this history is a continued desire to harness genetic knowledge to improve humanity's lot. Genetic testing offers a conduit to that end, with the benefits of testing potentially huge. Gene testing can inform potential parents of the risk of having a child with a genetic disease, permitting them to plan for such, and in many cases permitting them to decide to terminate an affected fetus. Genetic testing of newborns permits immediate treatment to reverse the lethal effects of disease, such as in the case of phenylketonuria (PKU). Other gene tests promise to promote health by indicating the need for increased medical surveillance, a change in lifestyle, or which medications will be safe and effective. Moreover, genetic testing can evaluate the toxicity of chemical compounds and facilitate the development of genetically modified organisms to improve health by removing allergens and adding key nutrients. However, use of genetic testing presents numerous complex ethical issues involving individuals, families, and the society at large.

Concern that use of genetic technologies may create injustices derives both from past injustices[a] the predictive nature of genetic information and the fact that one's genotype is informative not only of that individual but of their blood relatives as well. Potential adversity continues to engage stakeholder organizations around the globe. The two primary ethical concerns arising from the use of genetic technologies are 1) ensuring equitable sharing of the benefits of genetic technology throughout the world, and 2) maximizing the benefits vs. harms in each instance of use. Despite international agreements and recommendations, concerns remain formidable challenges.

WHAT ETHICAL CONCERNS ARISE AND WHY?

Given that the major diseases are known to have genetic components, knowledge of an individual's genotype will be increasingly important to understanding disease development and expression. The mere availability of genetic testing does not ensure that more good than harm will result from use. Ethically appropriate use of gene testing will require not only compliance with practice standards, but physician ability to accurately interpret a test result and manage patient care accordingly, particularly as the majority of tests will predict relative risk (not yes or no) for a specific disease. Although the fund of genomic knowledge is rapidly growing, a clinician's ability to predict health risk based on a gene test result will be in many instances variable and limited. A gene test result will neither indicate *when* a person is likely to become ill nor *how severe* illness will be when it strikes, because *nongenetic* factors significantly influence health status. Determining the medical meaning of a test result will involve synthesizing various factors in addition to the presence or absence of a gene variant, such as an individual's present, past, and anticipated exposures; other biological processes involved; and even one's socioeconomic situation, such as the extent of health benefits and whether one can pay treatments not covered by insurance.

All humans share 99.9% of the same genes. Despite this overwhelming homogeneity in genotype, the 0.1% differences may prove so divisive as to create a genetic underclass of individuals whose genetic lot imposes societal cost burdens. In efforts to ensure that all humanity can benefit from genomic advances, the United Nations Education, Scientific, and Cultural Organization, in 1997, promulgated the Universal Declaration on the Human Genome and Human Rights.[1,2] This document

[a]The American Eugenics Movement spawned forced sterilization laws in many states and mandatory sickle cell testing in the 1970s that led to discrimination.

DOI: 10.1081/E-EDGP 120020937

commands international commitment to advancing genomics only through the preservation of the fundamental sanctity of human dignity, freedom, and fundamental human rights. Of primary concern to international bioethics committees is that genomic testing improve the world's health rather than increase existing health disparities.[3–6]

The ethical concerns about the use of genetic testing are vast and complex.[b]

The primary ethical issues arising in provision of genetic tests are:

Who owns genetic information?
What constitutes fair use of genetic information?
How can we ensure that genetic tests will be evaluated for accuracy, reliability, and utility before they are commercially available?
Can informed consent, for research and clinical testing, be assured given low levels of understanding of genetics, difficulties in enforcing nondirective counseling standards, when interpretation is required?
Can we ensure that all testing is voluntary?
Should parents always have the right to have their underage children tested?
Can we ensure the privacy of genetic information?
Can we ensure the appropriate handling of biological samples?
Can we ensure the appropriate introduction and use of genetic tests and genetic data?

The bulk of ethics research, recommendations, and policy setting has identified and clarified potential for harm and spurred measures to prevent or mitigate that potential. While most of these measures have yet to be tested, a smattering of high-profile situations illustrate some of the types of ethical quandaries that can arise.

[b]Should genetic tests be regulated differently from other medical tests? Should they be used in locales lacking regulation? How can the use of tests be regulated to ensure that they give factual results? Should regulation exist for all types of genetic defects or just some; for example, are tests for poor eyesight the same as tests indicating a tendency to baldness? Are tests to be used in in vitro embryos to ensure that positive embryos are not implanted? Are tests to be used if no proven disease treatment or strategy to mitigate risk exists, even if individuals desperately want to know? What if one wants to know, not for themselves, but for his/her future offspring, children, or grandchildren? Can we protect individuals from harm when their genetic test result years later means something else, something very negative, which they could not have possibly consented to? For example, if the gene variant associated with malabsorption of codeine, indicating codeine is ineffective or unsafe for the individual, years later comes to be also associated with very high risk for a lethal disease, given certain environmental exposures, and the individual who had a pharmacogenetic test for treatment purposes then has additional information he/she did not expressly consent to, chooses not to know and is psychologically traumatized.

DUTIES AND OBLIGATIONS

What should the states' obligations be, particularly in light of competing needs for limited resources? Mandatory screening adopted with public health rationale does not necessarily mean that everyone benefits from testing. Health care consumers, particularly those in areas using multiplayer systems of care, have widely differing levels of access to tests and interventions. Changes to one's health insurance can create substantial potential for harm if insurers refuse to pay for expenditures associated with a ''preexisting'' (genetic) condition, or impose premium increases that make treatments (even co-pays) unaffordable. Furthermore, the type of genetic test reporting can have devastating consequences. For example, California's newborn screening reporting requirements does not require reporting actual values, but rather only abnormal results. A recent case resulted in permanent injury because the actual values, which showed consistency for congenital hypothyroidism, were not reported. The physician received the results well after the critical point at which harm results if untreated. In court, the state was not held liable.[7] In all cases, beneficence competes with other state demands. Particularly in areas of the world where the state imposes substantial restrictions on individual freedom, the state clearly cannot be relied on assuring ethical principles in practice.

Genomic medicine also challenges physician duties in the context of doctor–patient relationships. Physicians have a duty to protect a patient's confidentiality, but such is not absolute. Doctors are obligated to override patient confidentiality to report infectious disease, and warn people whom their patients have specifically threatened with violence. Whether genetic risks warrant similar exceptions, and if so, when, remains an important clinical concern, although several advisory committees have said that physicians may be permitted to breach confidentiality to warn third parties *only* as a last resort to avoid serious harm. A recent court case involved a daughter who sued her father's physician's estate for failure to warn her about her 50% risk of developing diffuse adenomatous polyposis coli. What ''serious'' harm is, though, is clearly different for different people depending on psychological factors and other situational factors.[7]

There are other questions of physician obligations including, but not limited to, whether a physician is obligated to offer a genetic test, and if so, when and why? In the absence of appropriate indications and established standards of care, physicians have no special duty to offer a specific test. However, physicians have an ethical obligation to be knowledgeable about genetic disorders that occur with increased frequency in certain populations, such as sickle cell anemia in African-Americans, thalassemias in Mediterranean and Southeast Asian

groups, and Tay-Sachs in the Ashkenazi Jewish population. Physicians have an ethical obligation to provide nondirective counseling in support of a patient's voluntary decision making.[8]

VOLUNTARY AUTONOMOUS DECISION MAKING

There is essentially universal agreement at the international level that all decision making about whether or not to undergo a genetic test must be voluntary. The would-be testee should exercise autonomy freely and without coercion. The exceptions involve individuals who are deemed incompetent, and children. Practice standards and policy state that children should be tested only if there is proven medical benefit in doing so. In practice, the benefits of childhood testing depend on the family's ability to access services indicated by a test result. Furthermore, although the law supports parental prerogative, parents, the test deciders for children, may not always have their child's best interest in mind, and ethical dilemmas could easily arise when existing law is insufficient to protect the interests of children against abuses instigated by parents or the state.

The potential to coerce individuals into testing should not to be minimized. Third parties with a financial stake in a genetic test result have tested individuals without their consent, and future instances are quite possible. Recently, the Burlington Northern Santa Fe Railroad tested 35 employees seeking disability compensation for job-related carpal tunnel syndrome for mutations associated with hereditary neuropathy. The testees learned of this by accident, the U.S. Equal Employment Opportunity Commission halted the practice, and a class action suit was settled out of court. In point of fact, the scientific basis for the testing undertaken was inappropriate.[9] Hereditary neuropathies very rarely occur in the population and while carpal tunnel syndrome can be a symptom of the condition, it is one of many that characteristically arise and furthermore arise well before midlife, which is when the workers developed the syndrome.

The government also has a stake in the health of its citizenry. Therefore, it is not implausible that it require genetic testing, particularly to limit its financial burden. In 1992, the state of Colorado considered mandating Fragile X screening believing that large-scale screening, coupled with reproductive counseling, would result in fewer births of affected individuals and thus reduce the state's financial burden arising from the care of such individuals. Studies indicated that the state spends $1,609,852.63 over the lifetime of a person with Fragile X Syndrome, over and above expenditures for ''normal'' children. Extrapolating to a national burden of $280 billion, researchers argued mandated screening could relieve financial burden by 50%.[11]

Other types of state action are equally imaginable. A government might require those on state assistance to undergo pharmacogenetic testing, as a condition of having their medication paid for, to avoid paying both for unsafe and ineffective medications. (Insurers, similarly, might want to as well.) Here, a concomitant ethical concern is that such individuals might unwillingly have personal genetic information they never consented to, and never wanted to know. While the risk that information obtained from a genetic test comes to mean more than one initially consented to exists for anyone undergoing testing, it is particularly problematic in cases where testing is directly, or indirectly, coerced.

GENETIC DISCRIMINATION

A genetic test result can have profoundly adverse effects on an individual, their family members, and on society. A genetic diagnosis might affect a person's ability to perform a job that could not be accommodated for in reasonable ways. For example, an individual with recurrent and untreatable cardiac arrhythmia that leads to loss of consciousness owing to an inherited ion-channel defect would be ineligible to work as a long-distance truck driver. An individual at risk for chronic beryllium disease, given sufficient exposure, may be ''protected'' out of jobs that increase exposure and so, risk of disease. In both cases, individuals could be barred from their preferred occupation, raising the question of how to balance competing rights—an individual's right to self-determination (to choose for themselves which risks he/she is willing to incur), and an institution's right to protect individuals against harm to themselves, and/or the public, including itself (the public from dangerous driving or an individual from increased risk of serious disease). Balancing competing interests is complicated not only by potential for greater good (say, the brilliant chemist with inherited susceptibility for chronic beryllium disease, who, if permitted to work in his risky, but preferred occupation might make a discovery of enormous benefit to society) but also uncertainty about the likelihood of various outcomes associated with a test result. For example, should an asymptomatic individual with a predisposing, but incompletely penetrant mutation for the ion-channeling defect be similarly restricted, as asymptomatic individuals with complete penetrant mutation? Framing the risk benefit question is far from simple.

Determining whether distinguishing individuals' ability to obtain social goods based on genetic information is ever ethically acceptable is likely to remain contentious,

because discrimination is typically covert and so is difficult to identify and remedy. For example, individuals often disclose private information in the context of interpersonal trust, such as friend to friend. Conflict of interest in such disclosures exists when one person has competing obligations, obligations to the friend but also obligations to, say, an insurance agency employer. Information obtained in confidence may then be used against the individual disclosing, if the recipient determines their primary obligation is to an outside entity. Here the disclosure is not entirely consensual, because of the unknown ends. Other types of involuntary disclosures exist as well, as in the case of small rural areas where one's family history may well be public knowledge. Equally, if not more troubling, may be the potential for self-imposed exclusions based on personal beliefs about self-worth and entitlement connected to one's understanding of their genetic test result. Individuals may deny themselves education, marriage, children, etc. because they believe a test result means they are unworthy. Given that we all harbor deleterious mutations, we are all theoretically vulnerable to genetic discrimination at any point in our lives.

INFORMED CONSENT

The ethical constraints that apply to any medical test also apply to genetic testing, although ensuring informed consent complicated by not only the inherent complexity of genetics, but the fact that the patient is not only the individual, but his or her blood relatives as well. Ensuring the genetic literacy of all is a major unmet need. Whether individuals are told all that they need to know may be compromised by practitioner information and level of understanding (also an important as yet unmet need). Whether individuals truly understand the information provided may be questionable, as the consent process itself is not foolproof. Understanding genetic risk is particularly challenging because the tendency to simplify to ensure comprehension can backfire by reinforcing incorrect notions of biological determinism. Conveying information via interpreters is especially challenging from an ethical standpoint for several reasons. Interpreters are not required to be trained in genetics, ethics, or cultural norms associated with nonnative speakers and so may unintentionally use language that conveys nonneutral meanings. Often, children are used to interpret for parents raising a host of issues including patient privacy, the appropriateness of involving children in the intimate issues raised, and the effect of such exposure on a parent's future relationship with the child.

Furthermore, because genetic testing can require family history information, there is potential for harm to the patient (would-be testee), if family members are unwilling to participate. Balancing the privacy rights within families may be contentious. In 1998, a participant in a clinical genetics research study provided her father's family history information, as per the study protocol. But the father blocked researchers' access to his medical record, arguing that he did not consent to disclosure, and disclosure without his consent amounted to a right to privacy violation.[12] The question of whether disclosure of family history information requires the consent of each, and all, family relatives remains uncertain, as does whether consent applies to deceased individuals, and if so, how. Moreover, in the case of identical twins where one wants to know and the other does not, determining whose right merits priority is difficult, particularly in light of the fact that it is highly improbable that both rights could be exercised and adequately guarded.

CONCLUSION

The ethical issues discussed here are by no means the only ones. Despite our best efforts to anticipate and resolve ethical quandaries arising from using genetic technologies, it is likely that unforeseen dilemmas will arise. Despite protective laws and policy recommendations by numerous international organizations, the future impact of such may be substantially challenged.

Medical genomics is here and will be increasingly so in the future. Therefore, ensuring that genetics confers far more benefit than harm is a formidable challenge. Assuring equitable access to the benefits of genetic testing remains an urgent consideration. Ongoing involvement by international organizations will be required to ensure that developing countries are not ultimately harmed and that individuals in such countries can reap the benefits of genetic technologies, as well as engage in policy setting.

Each of us has a stake in how genetic research unfolds and the resulting technologies are applied. The stakes are particularly high because of the magnitude of unknowns involved. High-speed easy chip testing for information A may result in the unanticipated generation and release of information B and C as well. Active involvement by stakeholders may go far in fostering just outcomes. In 2000, the Cannavan's Disease Support Group, which has been instrumental in helping a company develop treatment through raising research funds as well as supplying willing research participants, filed suit against the company for the right to ownership of the research, not to reap financial rewards for profits made from test use, but rather to be actively involved in decisions about the future use of the new knowledge and technology.

The value of a genetic test lies not in the test itself, but rather in what we, as individuals and society, choose to do with that result. What we do with genetic information arguably will have far more impact on health status than the genetic information itself. Whether individuals use test results to alter their behavior to improve their health remains uncertain, especially given evidence that despite high levels of motivation, psychological and other factors have the potential to drive people to act in ways that are contrary to long-term health goals.

In the greater scheme of things, it is unlikely that genetic information will *not* matter. The relevant question is how much it does, or will, matter. Ensuring the just treatment of individuals will involve deciding the appropriate weight of genetic vs. nongenetic factors, lest we reify genetics as the sole arbiter of an ethical decision.

Fabry Disease

Catherine Caillaud
AP-HP, Institut Cochin, Paris, France

INTRODUCTION

Fabry disease (also known as Anderson–Fabry disease) is an inborn error of glycosphingolipid metabolism caused by a deficiency of the enzyme α-galactosidase A (α-Gal A). It is a lysosomal storage disorder characterized by intracellular accumulation of globotriaosylceramide (Gb3) and related glycosphingolipids, particularly in the vascular endothelium, leading to renal, cardiac, and cerebrovascular manifestations. Fabry disease is an X-linked recessive disorder, caused by mutations in the α-Gal A gene (*GLA*) localized in Xq22. It affects predominantly hemizygous males, but heterozygous females may also have either moderate or severe manifestations. It is a panethnic disease with an estimated incidence of 1:117,000 male births and a reduced median survival rate compared with the general population (50 years for male patients; 70 years for obligate carriers). Fabry disease can be diagnosed reliably in males by the measurement of the α-Gal A activity, and in carrier females by the identification of the *GLA* mutation. Genotype–phenotype correlations are restricted because of the wide variety of mutations involved in the pathogenesis of the disease. Even if enzyme replacement therapy using recombinant α-Gal A has recently demonstrated its efficacy in the management of this severe disease, other therapeutic approaches are also under investigation.

CLINICAL MANIFESTATIONS

Hemizygote Males

The first clinical signs usually occur during childhood or adolescence, but may be delayed until the second or third decade. They predominantly include corneal opacities, acroparesthesias, angiokeratomas, and hypohydrosis, but also symptoms linked to cardiac, cerebral, and renal vascular involvement.[1,2] Acroparesthesias constitute the earliest and the most debilitating symptom of Fabry disease. These painful crises, present in more than 70% of patients, are often misdiagnosed unless other clinical elements provide diagnostic clues. Angiokeratomas are also early manifestations of the disease. They are telangiectases predominantly localized in the umbilical area, on the buttocks, and the scrotum. Hypohydrosis is common, resulting in high-temperature intolerance. Corneal and lenticular opacities are frequent in Fabry disease, such as conjunctival and retinal vascular lesions.

With increasing age, cardiac signs such as left ventricular enlargement, valvular involvement, and conduction abnormalities occur. Cerebrovascular manifestations may include transient ischemic attacks, hemiplegia, thromboses, diplopia, or vertigo. Renal disease due to progressive glycosphingolipid deposition is also one of the major complications in affected hemizygotes. Proteinuria is the first manifestation, followed by a gradual deterioration of renal function. In the third or fourth decade of life, end-stage renal failure may require dialysis and renal transplantation. In contrast with the classical phenotype described above, atypical variants have been described, among which the most common is a cardiac variant exhibiting manifestations limited to the heart (left ventricular hypertrophy).[3]

Heterozygote Females

Heterozygote carriers have often been reported to be asymptomatic, or with attenuated forms of the disease. Corneal dystrophy is present in about 70% and is useful for heterozygote detection. Approximately 30% of heterozygotes have isolated skin lesions and less than 10% acroparesthesias. With age, severe cardiac, cerebrovascular, and renal manifestations may occur, explained by skewed X inactivation. A few carriers exhibit a disease as severe as that observed in classically affected males.[4,5]

DIAGNOSIS OF FABRY DISEASE

Enzymatic Defect in Fabry Disease

α-Gal A: A Lysosomal enzyme

The metabolic defect in Fabry disease is a deficiency of the lysosomal enzyme α-Gal A, which catalyzes the hydrolytic cleavage of the terminal molecule of galactose from Gb3 and other neutral glycosphingolipids (Fig. 1). Therefore undegraded glycosphingolipids accumulate mainly in lysosomes of vascular endothelial and smooth

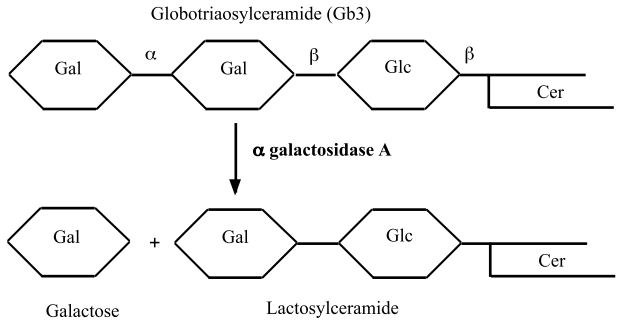

Fig. 1 Degradation of Gb3 or CTH by the lysosomal enzyme α-Gal A.

muscle cells, as well as in epithelial and perithelial cells of most visceral tissues.

The native α-Gal A enzyme is a glycoprotein of approximately 101 kDa with a homodimeric structure. Multiple forms are observed on isoelectric focusing of purified preparations from different tissues, differing in the amount of sialic acid on carbohydrate chains. Transport of enzyme to lysosomal compartments is dependent on mannose-6-phosphate receptors. α-Gal A is an entity different from the isozyme called α-galactosidase B (α-Gal B). This glycoprotein was shown to be an α-*N*-acetylgalactosaminidase, whose activity is deficient in Schindler disease—a recently described neuroaxonal dystrophy.

Direct diagnosis: Enzymatic deficiency

α-Gal A can be specifically assayed by using the synthetic fluorogenic substrate 4-methylumbelliferyl-α-D-galactopyranoside, in conjunction with *N*-acetylgalactosamine in the reaction mixture, to inhibit α-Gal B activity.[6] The assay can be performed in plasma, serum, leukocytes, fibroblasts, or lymphoblasts. This method is simple and reliable, and facilitates routine laboratory diagnosis in hemizygotes by demonstration of a profound α-Gal A deficiency. Some atypical variants may exhibit a residual activity requiring the determination of the Gb3 level to establish their definitive status. In carrier females, the biochemical diagnosis is less reliable because of random X chromosomal inactivation. In many heterozygotes, an intermediate level of α-Gal A can be detected, but activities ranging from zero to normal have been found, even in obligate carriers.

Indirect diagnosis: Gb3 accumulation

The Gb3, also referred to as ceramidetrihexoside (CTH), accumulates in many critical organs of patients with Fabry disease. Conventional methods for Gb3 measurement in plasma or urine sediment require lipid extraction, glycolipid isolation, oligosaccharide hydrolysis, and quantitation of liberated monosaccharides either by gas–liquid chromatography (GLC) or high-pressure liquid chromatography (HPLC).[7,8] These methods are reliable, but tedious and not routinely used. An alternative method using an immunoassay based on the specificity and avidity of the B subunit of *Escherichia coli* verotoxin (VTB) for Gb3 has been developed.[9] More recently, tandem mass spectrometry has also been used for the rapid quantitation of Gb3 by using novel internal standards.[10]

Molecular Basis of Fabry Disease

α-Galactosidase gene

The α-galactosidase (*GLA*) gene is mapped to the long arm of the X chromosome (Xq22.1). It is a 12-kb-long

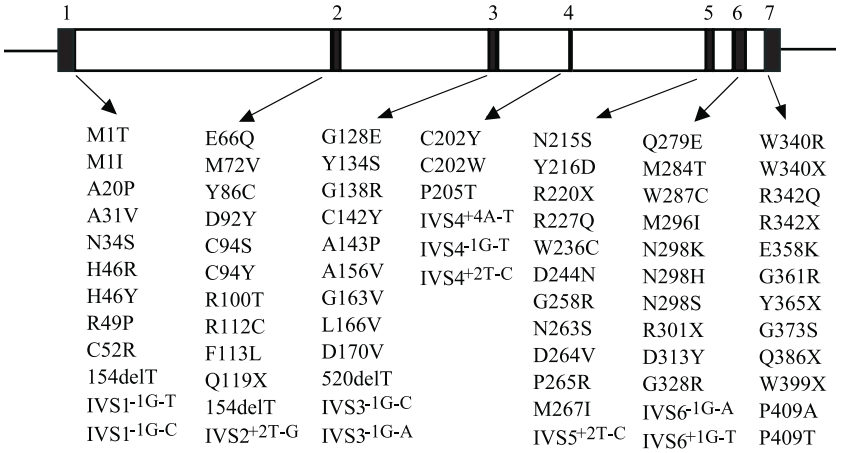

Fig. 2 α-Galactosidase gene representation showing the position of exons and the distribution of some mutations (del = deletion; IVS = intervening sequence).

gene comprised of seven exons, with introns ranging from 200 bp to 3.7 kb (Fig. 2).[11,12] Exon 1 contains the 5′ untranslated region, the sequence encoding the signal peptide, and a sequence for the first 33 residues of the mature enzyme. The full-length cDNA, containing a 1290-bp coding sequence, encodes the 398 residues of the mature enzyme subunit.[13] A particularity of the α-galactosidase cDNA is the absence of 3′ untranslated region. The polyadenylation signal sequence is in the coding region, 12 bp from the termination codon, which is followed by the poly (A) tract.

Mutations in the α-Gal A gene

Identification of mutations in the *GLA* gene can be easily performed by amplification of all seven exons using polymerase chain reaction (PCR) and direct sequencing of the DNA fragments.[14] Gene rearrangements are rare (<5%) in the *GLA* gene, and no whole gene deletion has been detected. To date, over 300 mutations have been identified. Details are given in the Human Gene Mutation Database (see the following web site: http://archive.uwcm.ac.uk/uwcm/mg/search/119272.html). The most frequent lesions are nucleotide substitutions, including missense and nonsense mutations. Small or partial deletions, small insertions, splice mutations, as well as complex mutations (insertion–deletion, inversions) have also been reported. Mutations have been found in all seven exons (Fig. 2). Most of the mutations are private (present in single families). Therefore genotype–phenotype correlations that require clinical information from unrelated patients with the same genotype are limited. Most genotypes are associated with classical forms of the disease. Some missense mutations, initially identified in cardiac variants, have also been found to be associated with classical phenotypes. A model of the human α-Gal A enzyme has recently been obtained, based on the X-ray structure of the highly homologous α-*N*-acetylgalactosaminidase sequence.[15] It will probably further our understanding of the structural basis of Fabry-causing mutations.

Genetic Counseling and Prenatal Diagnosis

Because Fabry disease is transmitted as an X-linked trait, all sons of affected males are unaffected, but all daughters are obligate carriers (Fig. 3). For all heterozygous females, there is a 50% risk of passing the deleterious allele to a son who will be affected, and a 50% risk of passing the mutant gene to a daughter who will be a carrier. Therefore determination of the status of females, either clinically affected or related to affected males, is critical to be able to offer them a reliable genetic counseling. This can be performed more accurately by the characterization of the responsible mutation. In females identified as carriers, prenatal diagnosis can be performed using α-Gal A assay and/or molecular analysis on chorionic villi or cultured amniotic cells, after assessment of the fetal gender.

TREATMENT

Symptomatic Treatment

Fabry disease has been managed with palliative measures, most of which are standard interventions for a specific symptom: analgesics for painful crises, valve replacement for valvular disease, anticoagulants for prevention of stroke, and so on. In patients with chronic renal disease, dialysis and renal transplantation are life-prolonging because renal failure is the most frequent cause of death in Fabry disease.

Enzyme Replacement Therapy

Recently, an enzyme replacement therapy has been developed for Fabry disease. Two different recombinant molecules have been obtained: agalsidase β or Fabrazyme® produced in Chinese hamster ovary cells (Genzyme Corporation), and agalsidase α or Replagal® produced in human fibroblasts (Transkaryotic Therapies, Inc.). After preclinical studies in animals, both molecules have been tested in humans in two independent randomized trials.[16,17] Even if studies differed in the enzyme preparation, dose per infusion, and entry criteria, both of them suggested that enzyme replacement therapy was safe and likely to be effective, as demonstrated by the decrease in Gb3 concentrations and the renal histology improvement.[18] The two enzymes have been approved in Europe and other countries and are now available for patients.

Chemical Chaperons

Enzyme enhancement by chemical chaperons has also been proposed in some cases of Fabry disease. This strategy is based on the stabilization of catalytically active but unstable enzymes, either by reversible competitive inhibitors or by substrate analogues. In a cardiac variant of Fabry disease exhibiting a missense mutation associated with a residual α-Gal A activity, intravenous infusions of galactose for 2 years resulted in a significant improvement of cardiac function.[19] This supports the use of chaperon-mediated therapy in Fabry disease and other late-onset enzymopathies with selected mutations.

Substrate Depletion

An alternative treatment for Fabry disease is substrate deprivation, based on the inhibition of the synthesis of the accumulating glycosphingolipid. This approach has been tested in α-Gal A knockout mice using D-threo-1-ethyl-endioxyphenyl-2-palmitoylamino-3-pyrrolidino-propanol (D-t-EtDO-P4), a potent inhibitor of glucosylceramide synthase—an enzyme involved in the synthesis of glucosylceramide, which is the precursor of neutral glycosphingolipids.[20] Treatment with D-t-EtDO-P4 resulted in a reduction in renal Gb3. These data suggest that Fabry disease may be amenable to substrate deprivation therapy, in particular if more specific and less toxic components are developed.

Gene Therapy

Gene therapy has been explored in the murine model of Fabry disease by using different viral vectors such as retrovirus, adenovirus, and adeno-associated virus, demonstrating the feasibility of this approach.[21–23] However, deleterious consequences recently described with retroviral and adeno-associated viruses have delayed gene therapy applications in humans for Fabry disease and other genetic disorders.

CONCLUSION

Fabry disease is a complex disorder with a wide clinical variation concerning the severity and onset of symptoms. As it has an influence on the quality of life and the survival rate of both affected males and females, enzyme replacement therapy is a major advancement for this disease. Therefore prompt and accurate diagnosis is now crucial to be able to initiate treatment before irreversible organ damage occurs. Many questions concerning appropriate time for therapy, choice of dose, long-term benefits, and risks still need to be addressed. Novel emerging therapies, such as substrate deprivation, enzyme enhancement by chemical chaperons, or gene therapy, are now in development.

Facioscapulohumeral Muscular Dystrophy

F

Meena Upadhyaya
David N. Cooper
University of Wales College of Medicine, Cardiff, U.K.

INTRODUCTION

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant, inherited disorder characterized by progressive muscle weakness, including atrophy of the facial muscles, upper arm, and shoulder girdle. Disease progression may eventually involve weakness and atrophy of the pelvic girdle and the foot extensor. FSHD is the third most common form of inherited neuromuscular disorder, after Duchenne and myotonic muscular dystrophies.[1] It is unusual for the disease to become clinically apparent before the age of 10 years. However, when it does occur in fewer than 5% of patients, it is associated with significant facial weakness. The common course of the disease is for symptoms to develop during the second decade of life. Both retinal vasculopathy and high-tone deafness may be seen as part of the clinical spectrum of FSHD.

GENE MAPPING STUDIES

Southern analysis was used to map the FSHD locus to chromosome 4q35[2,3] by using probe p13E-11 derived from the complex locus D4F104S1.[3] Indeed, the FSHD locus is closely linked to the locus D4F104S1 (Fig. 1). However, there are some evidence of genetic heterogeneity in FSHD because about 5% of families manifest an inherited pattern that is unlinked to 4q35. A provisional linkage to chromosome 15 has been suggested, but the gene still remains to be identified.

DNA REARRANGEMENTS DETECTED BY D4F104S1 AND D4Z4 REPEATS

When probe p13E-11 (D4F104S1) is hybridized against genomic DNA digested with the restriction enzyme *Eco*RI, it identifies a 3.3-kb tandem repeat sequence termed D4Z4 (Fig. 1).[4] The variability in the *Eco*RI fragment size is because of the deletion of an integral number of D4Z4 repeats. The D4F104S1 *Eco*RI polymorphism is complex and represents contributions from two separate homologous *Eco*RI polymorphic loci: one located at 4q35, and the other at 10q26. Both polymorphic elements are composed of a variable number of multiple integral copies of the 3.3-kb *Kpn*I repeat unit (Fig. 2). There have been no reports of internal deletions within the body of the repeat itself.[5] There is size overlap between the *Eco*RI D4F104S1 alleles from 4q35 and 10q26. Subsequently, it was established that each of the 10q26-located repeat contains a *Bln*I restriction site (Fig. 2) that is not present on the 4q35-derived repeats.[6] Therefore a complete distinction between 4q35-derived and 10q26-derived fragments can be obtained by double digestion of the genomic DNA with *Eco*RI and *Bln*I; this effectively removes all the 10q-derived repeats. Recently, a *Xap*I restriction site present in only 4q35-derived D4Z4 repeat was identified, and its use complements the *Eco*RI/*Bln*I digests.

In most affected FSHD patients, disease-associated polymorphic alleles range in size from 7 to 38 kb (Fig. 3), which represents the presence of 1–11 D4Z4 repeats compared with the normal allele range of 50–300 kb, representing a D4Z4 copy number greater than 12 repeats.[3,5]

Several 4q35-derived and 10q26-derived D4Z4 3.3-kb repeat units from normal individuals have been cloned and sequenced,[7] and it has been found that the sequence of each repeat unit, whether from the 4q35 or the 10q26 tandem array, is virtually identical and is defined by flanking *Kpn*I restriction sites. Each D4Z4 repeat contains a number of known repeat sequence motifs, including *LSau* and *hhspm*3, a highly GC-rich low-copy repeat. Analysis of the sequence has revealed the presence of a large open reading frame (ORF), which possesses the potential to encode two homeobox-like sequences that have been the subject of much speculation, although no such transcripts have ever been identified.

GENOTYPE/PHENOTYPE RELATIONSHIP

There is an association between the size of the deleted *Eco*RI fragment and the age at disease onset. It has been shown that smaller *Eco*RI fragments are always associated with the most severe form of the disease—a finding not specific to a single ethnic group. Thus the D4F104S1

DOI: 10.1081/E-EDGP 120025800

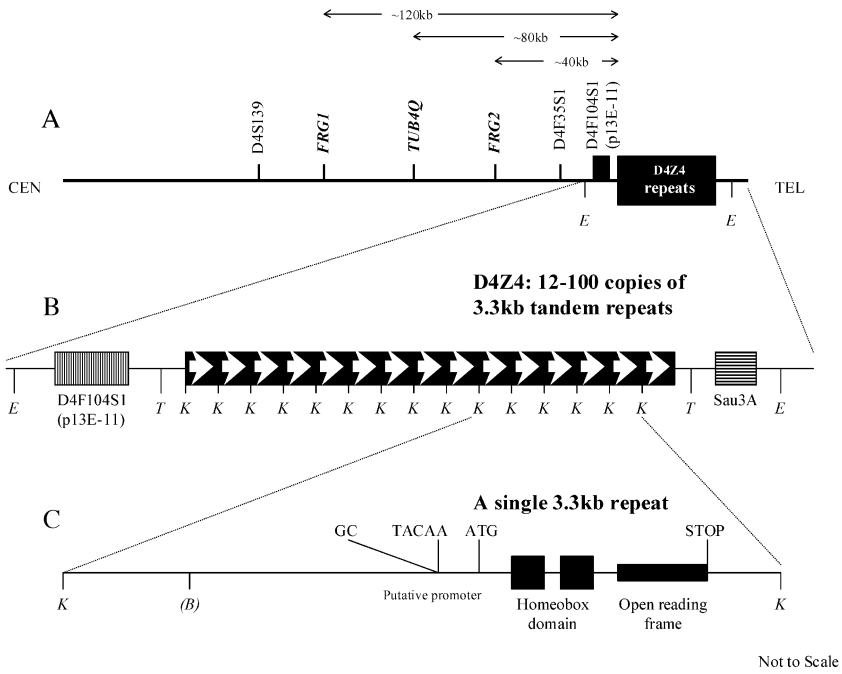

Fig. 1 (A) Restriction map of the 4q35 region. Relative positions of *FRG1*, *TUB4Q*, *FRG2*, D4F104S1 (p13E11), and D4Z4. (B) *Eco*RI fragment detected by probe p13E11 predominantly comprises an array of 3.3-kb tandem repeats, which have a copy number of 12–100 in normal controls and usually 11 or less in FSHD patients. (C) Each 3.3-kb repeat comprises two homeodomains (shaded boxes) encompassing an ORF with an in-frame start codon (ATG) and a stop codon. It encodes the *DUX4* gene. The position of the GC and TACAA boxes in the promoter-like sequence of *DUX4* gene is indicated.

*Eco*RI fragment size range noted in severe childhood cases of FSHD is 10–18 kb; in typical teenage-onset cases, between 18 and 34 kb; and in the oldest late-onset patients, larger than 30 kb.[8] However, it is still impossible to accurately predict the likely severity of disease expression based on repeat number alone. This is because of the high degree of interfamilial and intrafamilial variability of disease expression observed in this disorder, despite the fact that all affected members of a family exhibit the same-sized D4F104S1 allele.

MONOSOMY OF FSHD CANDIDATE REGION

Cytogenetic data indicate that monosomy of the distal 4q35 region, resulting in complete haploinsufficiency of the D4Z4 locus, is not associated with FSHD.[9]

SEQUENCE HOMOLOGY AND GENETIC RECOMBINATION BETWEEN 4Q35 AND 10Q26

There is a high level of sequence homology (98–100%) between D4Z4 repeats from the 4q35 and the 10q26 D4F104S1 loci. DNA sequencing was successful in identifying a unique *Bln*I restriction site present only in each copy of the 10q26-derived repeat units[10] and a *Xap*I site in all 4q35-derived repeats.

The high degree of homology between the 4q35 and the 10q26 D4F104S1 region is thought to have been responsible for interchromosomal exchanges between these two regions. In fact, complete repeat arrays (either of 4q35-derived *Bln*I-resistant D4Z4 repeats, or 10q26-derived *Bln*I-sensitive repeats) may be exchanged between these chromosomal locations. These interchromosomal exchange events are best visualized by pulsed-field gel electrophoresis (PFGE) owing to the large size of the genomic fragments involved; such studies have shown that entire repeat arrays are ''translocated'' in the majority of cases[11] (Fig. 4). It is likely that the sequence exchange is mediated by gene conversion, rather than actual physical translocation. Regardless of the precise mechanism involved, subtelomeric sequence exchanges may also lead to the formation of hybrid arrays containing interspersed 4q-derived and 10q-derived repeat units.

Perhaps surprisingly, these dynamic subtelomeric interchanges do not appear to be associated with the expression of the FSHD phenotype, as these 4q35$\leftrightarrow$10q26 exchanges are evident in about 20% of normal individuals (Fig. 4).[11] It should be emphasized that FSHD only occurs when the greatly deleted D4Z4 repeats (whether

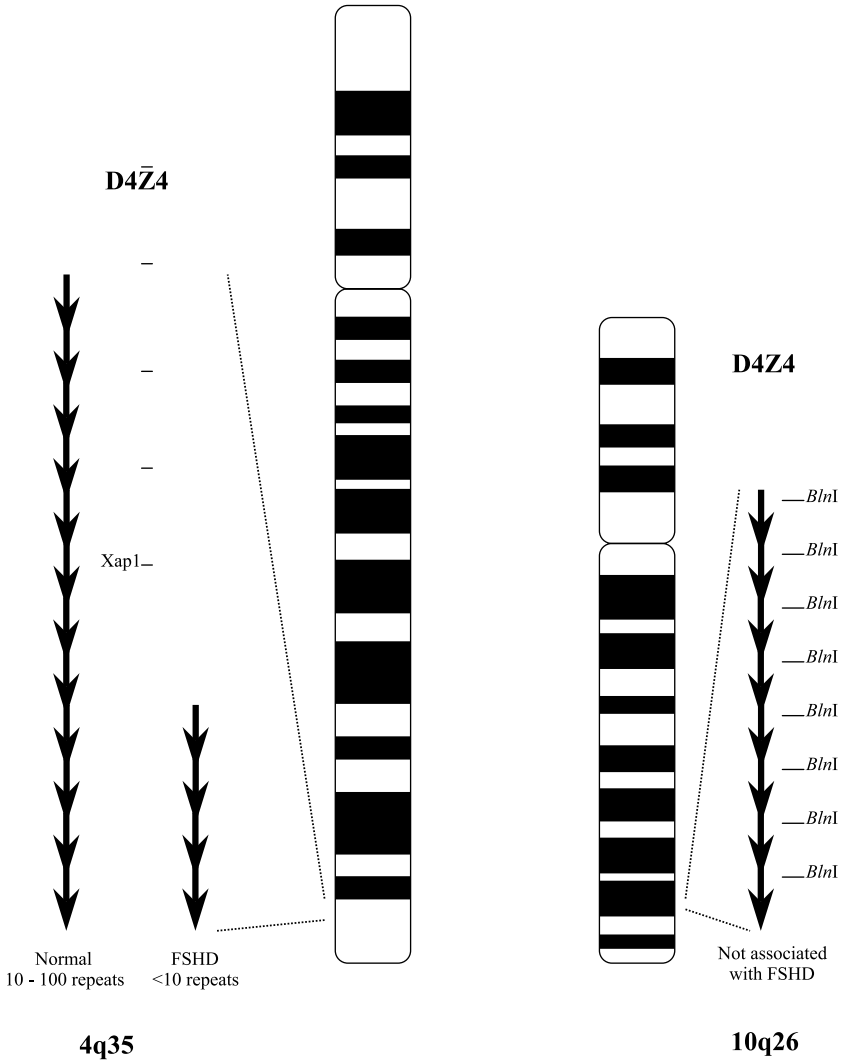

Fig. 2 Location of D4Z4 repeats at 4q35 and 10q26. The 10q-derived D4Z4 repeats differ from the 4q-derived repeats in having an internal restriction site for *Bln*I. Deletion of D4Z4 repeats at 4q35 is associated with FSHD, whereas reduction in the copy number of 10q-derived D4Z4 repeats does not result in any specific phenotype.

they are 4q35-derived or 10q26-derived) are located on chromosome 4.

SOMATIC MOSAICISM

Somatic mutations can occur early in embryonic life and may involve both somatic cells and germ cells. These individuals (gonosomal mosaics) may then be at risk of having affected children. A new mutation often first appears in a mosaic form, usually in a clinically normal person, who then has a constitutionally affected child. Van der Maarel et al.[12] detected somatic mosaicism in 40% of their de novo FSHD families (14% in an unaffected parent and 26% of the de novo FSHD patients themselves). Interestingly, an excess of mosaic-affected males was found in this dataset.

MONOZYGOTIC TWINS

Several studies have reported considerable variation in the clinical expression of FSHD in pairs of affected monozygotic twins.

GENDER BIAS

There appears to be a gender-specific influence on the degree and rate of disease progression in FSHD. The

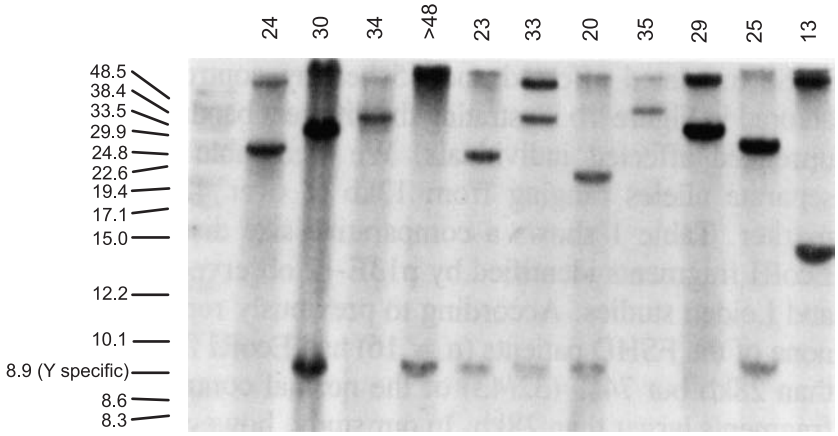

Fig. 3 The length of the smallest *Eco*RI fragment associated with the disease in unrelated FSHD individuals. Ten micrograms of DNA was digested with *Eco*RI, fractionated on a 0.5% agarose gel for 48 hr at 0.5 V/cm, and Southern-blotted onto HybondN (Amersham). The DNA on the membrane was hybridized with radiolabeled DNA probe p13E-11. Lane 1 contains high-molecular-weight markers. Lanes 2–12 contain DNA samples from unrelated FSHD patients. The corresponding smallest *Eco*RI fragment size is written on the top of each lane. The 8.9-kb fragment represents a Y-specific sequence.

age of disease onset is invariably later in female FSHD gene carriers, who are also more likely to exhibit a less severe form of the disease.[13] It has been suggested that female hormonal status somehow confers a mild protective effect. Consistent with this view, disease progression is markedly accelerated in female patients following menopause, which is often associated with a general decline in muscle strength.

MOLECULAR DIAGNOSIS OF FSHD

FSHD is associated with large deletions of the polymorphic D4Z4 repeat array when located at 4q35. The introduction of differential *Eco*RI/*Bln*I double digest has led to a dramatic improvement in molecular diagnostics for FSHD.[14,15] The specificity and sensitivity of this *Eco*RI–*Bln*I double-digest technique for accurate FSHD diagnosis have been well assessed and demonstrated to be high. However, an additional diagnostic complication is created by subtelomeric chromosomal exchanges between the two highly homologous 4q35 and 10q26 D4Z4 repeat loci, which are present in about 20% of the normal population.[11] Diagnostic complexity has been further increased by the recent observation that these subtelomeric exchanges may also result in the formation of hybrid arrays, containing an admixture of 4q35-derived and 10q26-derived D4Z4 repeat units. In addition, the complete loss of the D4F104S1 locus (probe p13E-11) has been reported in FSHD patients. Subtelomeric exchanges may lead to problems during the molecular diagnosis of FSHD in 5% of cases.[11,15] Recent findings using *Xap*I, an additional restriction enzyme, have increased the accuracy of molecular diagnosis for FSHD to 98%.[16]

THE SEARCH FOR THE *FSHD* GENE

Although D4F104S1-associated deletions are closely associated with FSHD in disease expression, the exact nature and location of the *FSHD* gene(s) remain elusive, as does the pathological basis of this association. However, although a number of functional genes have been identified within the FSHD candidate region, including *FRG1*, *FRG2*, and *DUX4*,[17] none of these genes has yet been proven to be the *FSHD* gene.

EXPRESSION STUDIES IN THE FSHD CANDIDATE REGION

Expression studies suggest that a number of genes are dysregulated in FSHD.[18] Genes that are abnormally expressed in FSHD muscles are those involved in myogenesis, cell differentiation, cell cycle control, and response to oxidative stress.

TRANSCRIPTIONAL DEREPRESSION

A 27-bp element within each D4Z4 repeat that specifically binds a multiprotein complex, consisting of YY1, HMGB2, and nucleolin, both in vitro and in vivo, has been shown to mediate the transcriptional repression

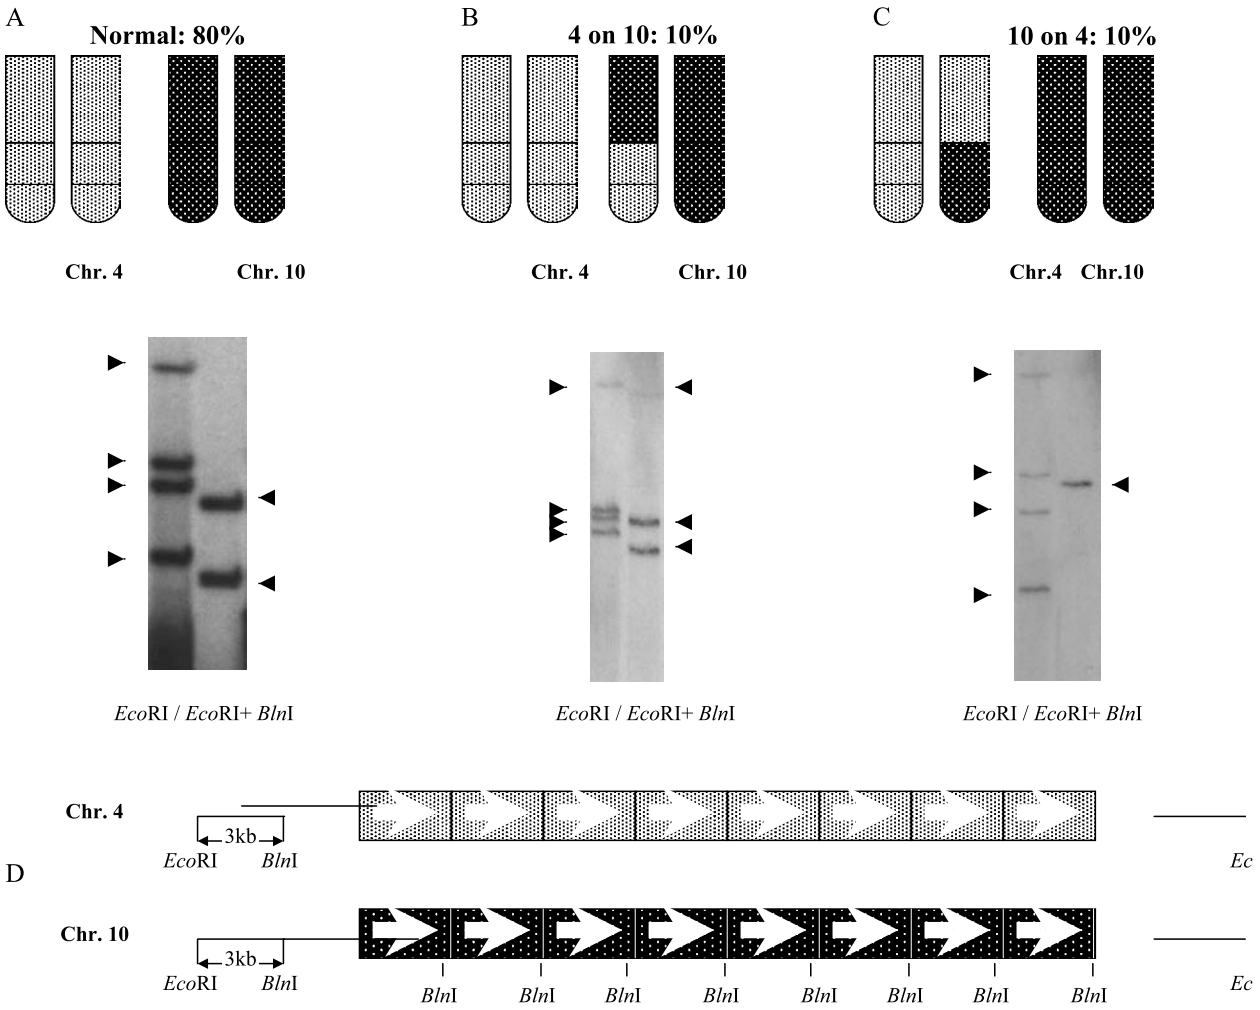

Fig. 4 Subtelomeric sequence exchange between 4q35 and 10q26 in 20% of the normal population. (From Ref. [11].) In the control population, 80% of individuals carry a standard configuration, with 4-type repeats on chromosome 4, and 10-type repeats on chromosome 10. In 10% of individuals, 4-derived repeats are also present on one of their chromosomes 10. Likewise, 10% of the control population carries 10-derived repeats on one of their chromosomes 4. (A) Five microliters of high-molecular-weight DNA digested sequentially with *Eco*RI and *Eco*RI/*Bln*I and hybridized with probe p13E11. In an informative situation, four different-sized *Eco*RI fragments are produced following a single digest: two derived from chromosome 4 and two from 10q. Digestion with enzyme *Bln*I will cleave two chromosome 10-specific fragments. Chromosome 4-specific fragments will be reduced by 3 kb, owing to the presence of a *Bln*I site proximal to the first repeat but distal to the *Eco*RI site (D). However, in 10% of individuals (B), 4-type repeats (*Bln*I-resistant) are translocated to chromosome 10; therefore with *Eco*RI/*Bln*I digestion, three alleles are seen instead of the expected two fragments. Similarly, 10% of control individuals (C) carry *Bln*I-sensitive repeats on one of their chromosomes 4; therefore with *Eco*RI/*Bln*I double digest, one allele (monosomy) is observed.

of genes at 4q35.[19] YY1 is involved in repressing and activating a number of gene promoters. HMGB2 is a member of the family of high-mobility group (HMG) proteins. Nucleolin is involved in chromatin structure formation.

In FSHD patients who possess fewer D4Z4 repeats, the amount of suppressor is greatly reduced; therefore the disease may be seen as being caused by the derepression of the transcription of genes proximal to the repeats. The deletion of repeated 27-bp elements from the subtelomeric region of 4q may act in cis on neighboring tissue-specific genes by derepressing their transcriptional activity, thereby initiating a cascade of events that eventually leads to FSHD. This finding would account for the observation that monosomy of 4q35 does not result in FSHD expression.[9] This elegant study is helping to unravel a new molecular mechanism for FSHD, which may well be found to underlie other genetic conditions.

However, in a recent study, the overexpression of genes in the FSHD candidate region was not reproduced.[20] It is possible that there is overexpression of a 4q35 gene in a small percentage of nuclei in the FSHD muscle fibers.

A polymorphism in the β-satellite repeats located distal to the D4Z4 repeat has recently been identified. This polymorphism, comprising alleles 4qA and 4qB, occurs with nearly equal frequencies in the normal population. FSHD is uniquely associated with 4qA allele.[22,23] Allele 4qA may have additional features that give rise to FSHD either by facilitating the derepression consequent to D4Z4 deletion, or, conceivably, by promoting D4Z4 deletion mutagenesis directly. It remains to be defined how allele 4qA relates to the complex that controls the expression of genes on 4q35. This finding may lead to a better understanding of the instability identified in the FSHD region.

DNA METHYLATION

D4Z4 repeats are hypomethylated not only in FSHD patients with contracted D4Z4 but also in FSHD patients without the contraction of D4Z4 copies.[23]

THERAPY

There is no current treatment specific for FSHD. Surgical intervention may involve scapular fixation and tendon transfers. Albuterol, a β_2-agonist known to increase muscle mass and to cause proliferation of muscle satellite cells, has provided some encouraging evidence of improvements to both muscle strength and mass.[24]

CONCLUSION

Many of the unique and puzzling FSHD disease-associated features need to be taken into consideration when one attempts to deduce the underlying pathological mechanism:

Monosomy of the 4q35 region, which does not produce an FSHD phenotype

High sequence complexity of this region, with its highly repetitive nature and its sequence homologies to loci on other autosomes

Absence of discernible disease phenotype associated with large deletions of the 10q26-located D4Z4 repeat arrays, despite the almost identical sequence of the 4q35-located and 10q26-located ORF

Inverse correlation, which is evident only between chromosome 4-located D4Z4 repeat copy number and clinical severity

Marked variable clinical expression of the disorder and asymmetrical progression of the disease

Discordance in clinical phenotype observed between monozygotic twins

Significant levels of somatic mosaicism observed in both asymptomatic parents and affected individuals

Abnormalities of gene expression in FSHD muscles

Derepression of the transcriptional activity of a number of genes in FSHD muscles

Complete association of the 4qA polymorphic allele with FSHD D4Z4 deletion

Significant hypomethylation of D4Z4 CpG methylation-sensitive restriction sites in FSHD.

The identification of the *FSHD* gene and the characterization of the *FSHD* gene product should enable us not only to offer accurate molecular diagnosis for this disorder and other related conditions, but also to help resolve some of the apparent complexities of the 4q35 FSHD region.

Factor IX Deficiency

Marian Hill
Gerry Dolan
Nottingham Haemophilia Comprehensive Care Centre, Nottingham, U.K.

INTRODUCTION

Factor IX plays an important role in blood coagulation. Hereditary deficiency of factor IX leads to the bleeding disorder hemophilia B, which is clinically indistinguishable from the more common hemophilia A (Factor VIII deficiency). Hemophilia B is a recessively inherited X-linked disorder with a world-wide incidence of 1/30,000–50,000. Advances in our knowledge of the factor IX protein and its functional activity and in the factor IX gene and the genetic defects associated with hemophilia B have led to major diagnostic and therapeutic advances in this disorder.

FUNCTION OF FACTOR IX

Factor IX circulates in plasma as an inactive zymogen that is activated during coagulation to factor IXa—a vitamin K-dependent serine protease. Activation results from cleavage of factor IX by either factor XIa or factor VIIa/tissue factor in the presence of Ca^{2+}. Factor IXa then forms a complex with factor VIIIa on the cell membrane surface which is responsible for the activation of factor X. This forms part of the series of reactions constituting the blood coagulation cascade that ultimately leads to the formation of a fibrin clot.[1]

CLINICAL FEATURES

Although clinical descriptions consistent with hemophilia have been found in ancient texts, the term hemophilia was not used until 1928, and factor IX deficiency was not described as a cause of hemophilia until the 1950s by Aggler et al.[2] (using the term PTC deficiency) and Biggs et al., who used the term Christmas Factor deficiency after the surname of their index patient.[3] This disorder is now commonly known as hemophilia B. The clinical severity of hemophilia B can largely be predicted from the circulating procoagulant plasma level of factor IX (FIX:C) and these levels remain constant through generations of affected individuals in each family. The severity of hemophilia B can be classified by comparing plasma factor IX levels against a standard that has a value of 1.0 u/mL (100%) (Fig. 1).

Individuals with severe hemophilia B usually have a serious, life-threatening bleeding tendency characterized by spontaneous hemorrhage, excessive bruising/bleeding after trauma, and a requirement for regular replacement therapy. In those with moderate and mild hemophilia, spontaneous bleeding is rare, sequelae of trauma are less serious, and the need for replacement therapy is reduced.

In children with severe hemophilia, the bleeding tendency may first manifest as excessive bruising and hematoma formation when crawling or attempting to walk. When there has been no preexisting history of hemophilia in the family (around 30% of cases), the diagnosis may be made during assessment of the child for nonaccidental injury or after trauma such as circumcision.

The hallmark of severe hemophilia is hemorrhage into large joints (hemarthrosis). The ankles, knees, and elbows are most often affected, and when this occurs, patients may experience premonitory symptoms such as tingling followed by painful swelling of the joint leading to impaired movement. Recurrent hemathroses lead to inflammatory changes in the synovium and destructive changes in cartilage. This may result in total destruction of the joint, marked deformity, and disability. Muscle bleeding may also be an important cause of morbidity such as the classic iliopsoas muscle hematoma, which may cause painful flexion of the hip and compression of the femoral nerve. Bleeding may occur in any part of the body; gastrointestinal, intracranial, and genitourinary bleeds are well-recognized features of hemophilia.

DIAGNOSIS

The initial approach to diagnosis is the laboratory assessment of the coagulation system.

The screening test, activated partial thromboplastin time (APTT), will be prolonged depending on the degree of FIX deficiency and the sensitivity of the reagents used. In those with a prolonged APTT and a family history of hemophilia B, FIX:C is directly assayed using a one-stage

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021389

SEVERITY	PLASMA FIX:C (I.U./mL)	PLASMA FIX:C (%)
Severe	<0.01	<1
Moderate	0.01 – 0.05	1 – 5
Mild	0.05 – 0.4	5 – 40

Fig. 1 Classification of hemophilia B.

or chromogenic assay and the diagnosis is confirmed. In those without a previous history, the deficiency of factor IX must be distinguished from deficiencies of FVIII and XI, all of which may also give a prolonged APTT. When the diagnosis is confirmed, identification of the molecular abnormality of the factor IX gene will facilitate carrier screening in other family members.

MANAGEMENT

Replacement of factor IX is essential for the prevention and treatment of hemorrhage in hemophilia B. Earlier forms of replacement therapy were crude preparations of donated plasma that were often only partially effective. The production of highly concentrated factor IX preparations had a major impact in the management of hemophilia B, facilitating home therapy, early treatment of bleeds, amelioration of joint damage, and a marked improvement in quality of life. However, their use was associated with serious complications:

1. Transfusion-transmitted infection (TTI)

   The use of donated plasma in the management of hemophilia led to the transmission of infectious agents to recipients. Hepatitis B and non-A–non-B hepatitis (later recognized as hepatitis C) were shown to be very common in individuals with hemophilia. In the early 1980s, the catastrophe of HIV transmission through blood products emerged in the hemophilic population, and 60–80% of severe hemophiliacs in Europe and the United States were infected. The risk of TTI was highest with concentrates prepared from larger donor pools. The concentrates that had led to a major improvement in the quality of life of these individuals had also caused the tragedy of transfusion-transmitted infection, which had become the leading cause of death in this population. The risks of TTI have been greatly reduced by measures such as blood donor exclusion policies and virucidal treatment of concentrates.
2. Inhibitor development

   The use of FIX replacement therapy may lead to the development of neutralizing antibodies (inhibitors) against FIX and may render the individual refractory to further treatment. Inhibitors may appear transiently in children with hemophilia but persist in approximately 1.5–3% of severely affected hemophilia B patients. In such cases, hemorrhage may be life threatening or may lead to more severe musculoskeletal complications. There is a strong association between inhibitor development and underlying genetic defect (discussed later). The inhibitors may disappear with immune tolerance strategies and bleeding episodes in inhibitor patients may respond to treatment with recombinant FVIIa.
3. Thrombosis

   Earlier FIX concentrates also contained large amounts of the other vitamin K-dependent coagulation factors: II, VII, and X; the intravenous infusion of these factors: which patients with hemophilia B are not deficient in, led to high plasma levels and thrombotic complications. With the development of high-purity FIX concentrates, thrombosis became far less common.

Recent Developments in Therapy

Recombinant factor IX

The cloning and expression of the factor IX gene led to the development of recombinant factor IX concentrate, which has no exposure to human protein and minimal exposure to animal protein. Pharmacokinetic and efficacy studies have demonstrated satisfactory in vivo recovery although substantially lower than for plasma-derived factor IX concentrate probably because of minor posttranslational differences. Recombinant factor IX concentrate is now widely used.

Prophylaxis

The availability of safer products has also led to a change in therapeutic strategy in that prophylaxis of bleeding is now widely used, particularly in children. This necessitates the intravenous administration of factor IX in doses of 25–40 u/kg twice weekly and leads to a marked reduction in spontaneous bleeding episodes and an improvement in quality of life.[4]

Gene therapy

Hemophilia B (and A) is well suited for gene therapy because it is entirely due to a single gene defect, the therapeutic window is broad, and there are good animal models. Clinical studies on hemophilia B have been

performed using autologous skin fibroblasts transduced with FIX retroviral vector and adenovirus-associated gene transfer by intramuscular and hepatic artery infusion. Results of such studies are moderately encouraging, but major challenges remain particularly in improving and maintaining expression of factor IX and ensuring safety. Several new approaches to gene therapy are in development and promise to make a major contribution to the treatment of hemophilia.[5]

FACTOR IX PROTEIN STRUCTURE

The factor IX gene is primarily expressed in the liver and the factor IX gene product has a multidomain structure (Fig. 2). The first and second domains are a signal peptide and propeptide, respectively. These are cleaved to produce the mature protein that is secreted as a 415 amino acid single-chain peptide. Factor IX undergoes extensive posttranslational modification and the N-terminal domain of mature factor IX contains 12 γ-carboxyglutamic residues; this ''Gla'' domain is important for phospholipid binding. This is followed by two EGF-like domains and an activation peptide (a 36-amino acid region that includes two cleavage sites required for activation of factor IX). The C-terminal catalytic domain is responsible for the proteolysis of factor X to factor Xa, and has substantial sequence homology to other vitamin K-dependent serine proteases. During activation, factor IX cleavage results in a light chain and a heavy chain, held together by disulfide bonds. Structural data is available for factor IX and some of its interactions[6] and this has been extended by molecular modeling studies.[7]

GENETIC DEFECTS IN HEMOPHILIA B

The factor IX gene is located at Xq27.1–q27.2 and the gene was fully cloned and sequenced in 1985.[8] The gene is approximately 35 kb in length and consists of eight exons (a–h), producing a 2.8-kb mRNA encoding a mature protein of 415 amino acids (Fig. 2). The putative promoter region is under the control of a number of regulatory elements.[9] Exon a codes for most of the signal peptide, exon b for the propeptide and most of the Gla domain, and exon c codes the remainder of the Gla domain. Exons d and e code for the two EGF-like domains. Exon f codes for the activation peptide, and exons g and h code for the catalytic domain. The stop codon is followed by a 3′ untranslated region of 1.4 kb with a polyadenylation recognition sequence.

Many different mutations have been associated with hemophilia B and these are found throughout the factor IX gene. They are mainly point mutations, and no common recurrent mutations have been identified. Missense mutations account for approximately 80% of cases of severe hemophilia B; the remaining 20% of cases are due to gross gene deletions, frameshifts, splice junction changes, and nonsense mutations. Almost all cases of nonsevere hemophilia B are caused by missense mutations.[10]

An international factor IX mutation database is available.[10] Over 800 different mutations are reported in the database in association with hemophilia B. In addition to information on point mutations and short additions and deletions, the database also lists tables of gross gene defects and known polymorphisms.

One-third of point mutations occur at CpG dinucleotides, and involve a CG→TG or CA change. The recurrence of some of these mutations in different families supports their role as ''mutation hot spots.'' However, founder effects have also been shown to be responsible for a number of reoccurring mutations in this disorder.[10]

The distribution of mutations between regions of the gene reflects their relative functional importance. Up to half of reported point mutations are in exon h, which codes for the catalytic domain. Similarly, many mutations are found in exon d, which codes for the calcium-binding EGF domain. Hemophilia B has also been associated with changes to 9 of the 12 gamma-carboxyglutamyl residues within the Gla domain, confirming their critical functional role. In addition, substitutions at each of the 22 cysteine residues in factor IX confirm the structural importance of their disulfide linkages.

The risk of development of inhibitors in response to factor IX replacement therapy is determined by the causative mutation and by variations in the immune system of individual patients.

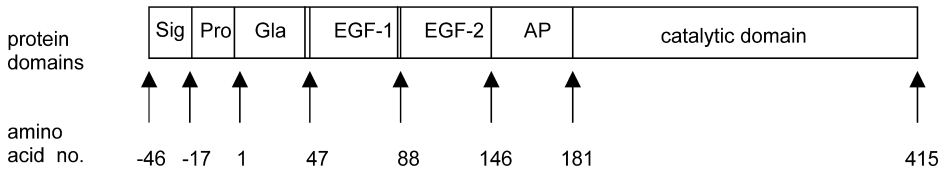

Fig. 2 Illustration of factor IX protein domains. Abbreviations: Sig = signal peptide; Pro = propeptide; AP = activation peptide.

Patients who develop inhibitors are more likely to have null mutations such as deletions and nonsense mutations that prevent synthesis of the factor IX protein. Inhibitors are more rarely found in patients where the mutation causes a loss of function, but not complete absence of the factor IX protein.[11]

Hemophilia B Leyden is a rare form of factor IX deficiency that is characterized by a gradual increase in factor IX levels that begins at puberty. This variant has been associated with a number of different point mutations within an androgen-sensitive region of the factor IX promoter (nucleotide −23 through +13) and several theories have been proposed to explain the recovery seen in such cases.[12,13]

MOLECULAR GENETIC TESTING

Genetic analysis for hemophilia B should be carried out in specialist laboratories and in the context of comprehensive genetic counseling.[14,15] The reasons for referral for genetic testing are:

1. *Assessment of the genetic basis for hemophilia B*

   Nucleotide sequencing can identify a mutation in over 99% of patients tested. In addition to direct nucleotide sequencing, mutation-screening methods have also been used in factor IX analysis.[16] Partial or complete deletions may be further investigated by Southern blotting.

   Although hemophilia B can be diagnosed by measurement of factor IX coagulant activity (FIX:C), genetic analysis confirms hereditary hemophilia and may provide information on the risk of inhibitor development. Knowledge of the genetic cause of hemophilia also facilitates accurate carrier analysis for female relatives.

   Figure 3 illustrates the oligonucleotide primers and conditions used in this laboratory for the amplification of the eight exons of the FIX gene, including splice junctions.

2. *Carrier testing*

   Carrier testing should only be carried out after relevant genetic counseling. Family history may be sufficient to identify some women as obligate carriers (e.g., the daughters of affected males or women with an affected son in addition to maternal relative with hemophilia B). However, for other female relatives, or in cases of sporadic hemophilia with no previous family history (approximately 30% of cases), carrier analysis is required.

   All potential carriers should have their factor IX clotting activity (FIX:C) determined as in a small percentage; this may be low enough to cause a mild bleeding disorder. However, many carriers have normal FIX:C levels. Therefore, genetic analysis is necessary to determine female carrier status and to provide appropriate genetic counseling.

   Carrier analysis is generally carried out by nucleotide sequencing after identification of the causative mutation in an affected relative, although this approach is not suitable for the detection of large deletions.

Where there is a family history of the disorder, linkage analysis using intragenic polymorphisms may be used to

Recommended PCR conditions: 2 mM mixed dNTP; 2.5 U Amplitaq Gold DNA polymerase; 1 × Amplitaq Gold buffer including 2.5 mM $MgCl_2$, 20 pmol/μL each primer, 100-ng template DNA, all amplified using a 35-cycle PCR (30 sec each step) and annealed using a stepdown protocol (five cycles each of 62°C, 60°C, 58°C, 54°C, 52°C, and 50°C).

track a disease-causing allele through a family. There are a number of polymorphisms throughout the factor IX gene that are used for linkage analysis. Intron 1 contains a complex polymorphic region (DdeI polymorphism) with two common variants and several rarer alleles.[17] In addition, there are 11 diallelic polymorphisms that can be used for linkage analysis.[15] All polymorphic sites are in linkage disequilibrium with each other although the frequencies considerably vary with ethnic origin.

Linkage studies are dependent on the availability of samples from family members, and may not be informative in all cases. Carrier analysis by linkage may not be suitable where there is no previous family history.

Prenatal Diagnosis

Prenatal diagnostic testing can be provided for carriers of hemophilia B where a causative mutation has been identified or informative linkage markers determined. Fetal cells are generally obtained by chorionic villus sampling at 10–13 weeks of gestation or from amniocentesis at 16–18 weeks.[14,15]

CONCLUSION

Our knowledge of the key role of factor IX in hemostasis and the structure and function of the FIX gene and protein has greatly expanded. The cloning and expression of the factor IX gene has yielded important advances in both the diagnosis and treatment of hemophilia B. Genetic analysis in this disorder has increased our understanding of the function of the factor IX protein and facilitated accurate carrier analysis. In addition, the production of recombinant factor IX concentrate has greatly improved safety of therapy, and gene replacement therapy has the potential to cure or ameliorate this congenital bleeding disorder.

Factor X Deficiency

Fabrizio Vianello
University of Padua, Padova, Italy

INTRODUCTION

Factor X (FX) is one of the vitamin K-dependent (VKD) coagulation factors. Factor X occupies a central position in the coagulation cascade and represents the point of convergence between the intrinsic and extrinsic pathways of blood coagulation. Congenital FX deficiency is a rare autosomal recessive disorder which is heterogeneous for both laboratory and clinical expression. Because of the central role of FX in the coagulation cascade, mutations are rare. To date, about 70 missense mutations as well as 12 others including deletions and one nonsense mutation have also been described. The interpretation of the functional effect of missense mutations is facilitated by the availability of crystal structures, sequence alignments, and molecular modeling, and this is effective in identifying structural perturbations in active sites.

FACTOR X FUNCTION

Factor X, the zymogen of the serine protease factor Xa, occupies a pivotal position in coagulation by virtue of the fact that it can be activated through either the contact-activated (intrinsic) pathway or the tissue-factor (extrinsic) pathway. Factor Xa associates with its cofactor, factor Va, on a membrane surface in the presence of Ca^{2+}, to form the prothrombinase complex which activates prothrombin to thrombin[1,2] (Fig. 1). Factor X was identified in 1950 by two groups of researchers, independently, and the name of the two patients affected led to its original designation as ''Stuart–Prower'' factor.[3,4] The characteristics of FX deficiency are a prolonged PT and PTT, a serum abnormality in the thromboplastin generation, and a prolonged Russell's viper venom time.

PREVALENCE

Factor X is one of the rarest of the inherited coagulation disorders. It is transmitted as an autosomal recessive disorder (Fig. 2). The estimated prevalence of homozygous FX deficiency is about 1:500,000, but clinically asymptomatic heterozygotes are likely to be as frequent as 1:500.[5]

CLINICAL DESCRIPTION

Among patients with rare coagulation defects, FX deficiency can be one of the most severe.[6] The onset of hemorrhagic manifestations in profound deficiency is typically seen early in age. In less severe deficiency, patients may experience bleeding at any age. The most frequent sites of bleeding are the mucosal, soft tissue, and central nervous system. Among mucosal bleeding, epistaxis is the most frequent, followed by menorrhagia and gastrointestinal episodes. Soft tissue bleeding such as hemarthroses and muscle hematomas may mimic classic hemophilia. Central nervous system hemorrhages represent life-threatening manifestations of severe FX deficiency. Individuals with mild FX deficiencies may only experience bleeding after trauma or surgery.[7]

MOLECULAR GENETICS

The human FX gene is 22 kb long and is located at 13q34-ter, less than 3 kb from FVII.[8] The sequence of human FX gene is highly homologous to other VKD blood coagulation factors such as FVII, FIX, and protein C, suggesting its origin from a common ancestral gene. The coding region of FX is divided into eight exons, each encoding for a particular domain within protein (Fig. 3). Exon I encodes the signal peptide, exon II the propeptide and Gla domain, and exon III a short linking segment of aromatic amino acids. Exons IV and V encode the two EGF domains, exon VI encodes the activation peptide at the N-terminus of the heavy chain, and exons VII and VIII encode the serine protease domain with the catalytic triad His236, Asp228, and Ser379.[9] Factor X is synthesized in the liver as a single-chain precursor. In plasma, FX circulates as a two-chain glycoprotein of about 59 kDa. The light chain is cleaved from the heavy chain during or after secretion into the circulation. Factor X is composed of a 306-residue heavy chain that is covalently linked by a disulfide bond to a 139-residue light chain. The light chain

DOI: 10.1081/E-EDGP 120021393

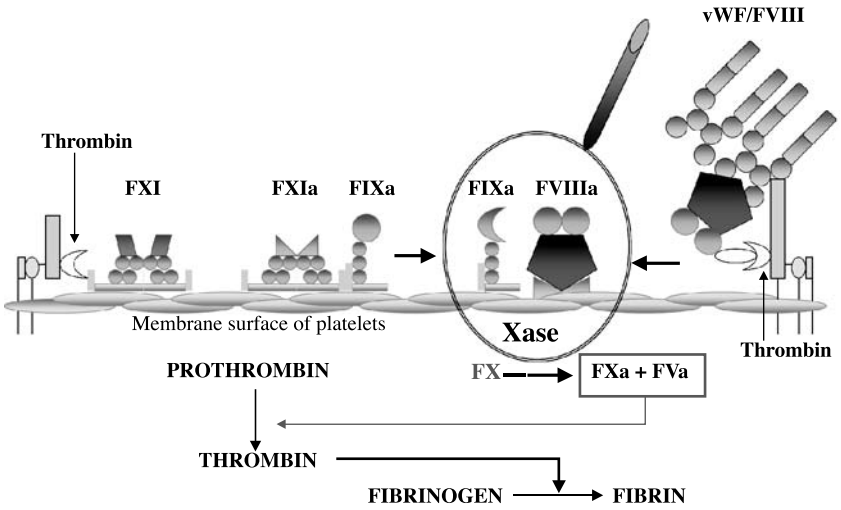

Fig. 1 After binding of thrombin to the platelet surface, FVIII and FXI are cleaved. When FIXa binds to the platelet surface, it forms the ''Xase'' complex together with FVIIIa. The ''Xase'' complex catalyzes the activation of FX. FXa/Va complexes can now produce the burst of thrombin necessary to form a hemostatic clot. (From Hoffmann et al. Thromb. Haemost. **2001**, *85*, 958.) (*View this art in color at www.dekker.com.*)

of zymogenic FX contains three structural domains, each of which possesses distinct functional properties. The heavy chain contains the serine protease domain of 254 amino acids which forms the catalytic triad of the active site.[1,2]

GENOTYPE–PHENOTYPE CORRELATION

Three main groups of FX deficiency can be identified:[9,10] the cross-reacting material (CRM)-negative group in which both antigen and activity are similarly decreased (''hypo'' or type I), while prothrombin time, activated partial thromboplastin time, as well as Russell viper venom time-based assays are prolonged; the CRM-positive group which has normal or near normal antigen levels but factor X activity is decreased (''dys'' or type II); thirdly, the CRM-reduced group in which both activity and antigen levels are reduced but antigen is markedly higher than activity (''hypo–dys'').

Clinical manifestations of FX deficiency are highly variable and usually only develop in homozygotes or double heterozygotes. Factor X levels between 10% and 40% of normal are considered sufficient to prevent

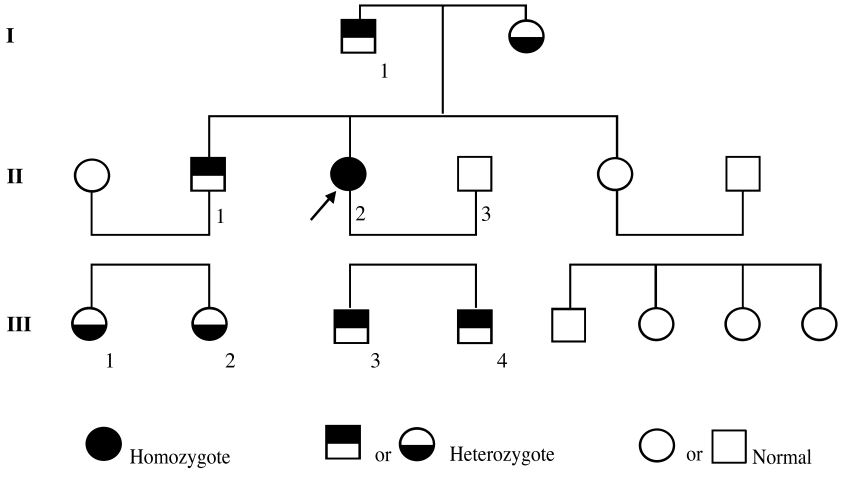

Fig. 2 Family pedigree in a case of FX deficiency. The proband (arrow) showed abnormal PT and PTT values, low FX activity, and normal FX antigen levels. The clinical history was unremarkable. (Original data.)

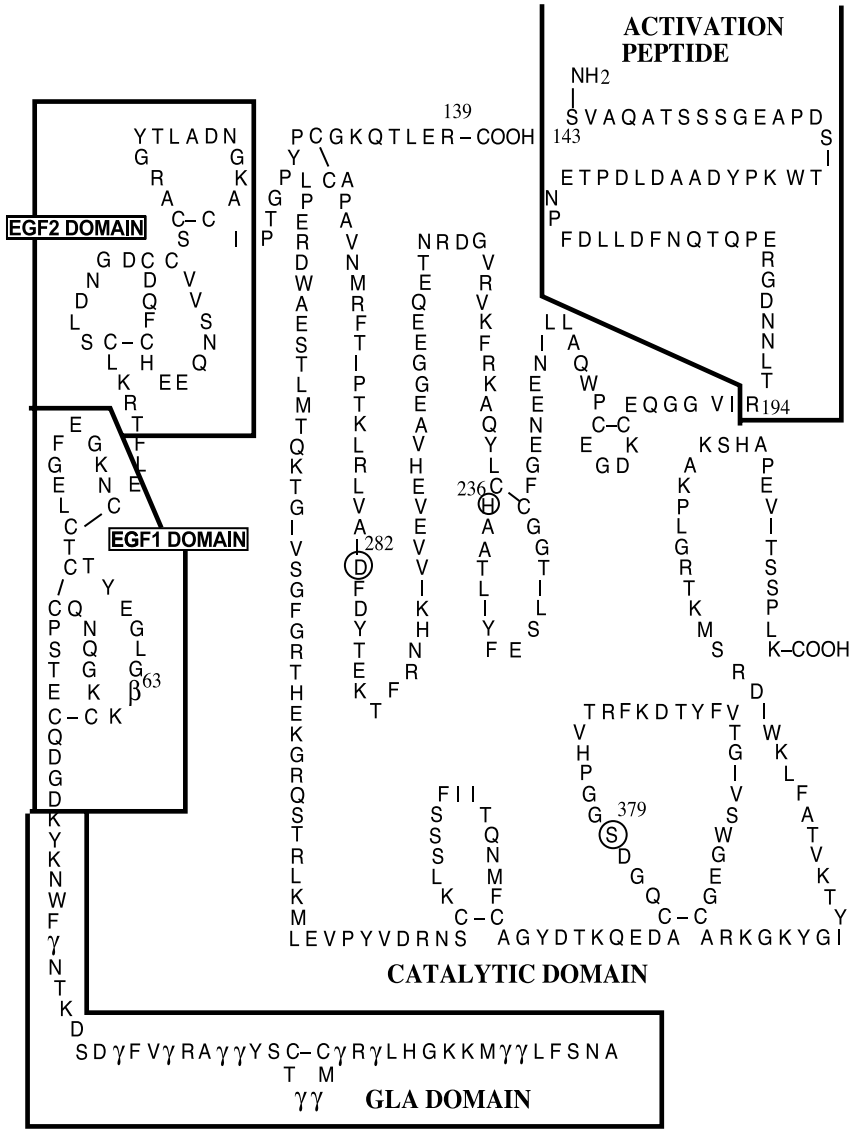

Fig. 3 Schematic representation of the primary amino acid sequence of the two-chain human FX. The form in circulating blood plasma lacking the tripeptide connecting the light chain to the activation peptide is shown. (From Leytus et al. Biochem. **1986**, *25*, 5098.)

bleeding manifestations, and homozygotes may exhibit higher than 10% activity. Thus many individuals carrying a FX mutation may remain undiagnosed or develop hemorrhagic complications only when challenged or because of an additional insult to the coagulation cascade. Although the clinical presentation of FX deficiency correlates poorly with laboratory phenotype, genetic analysis usually provides a plausible explanation for the factor X activity and antigen levels measured in the laboratory. As in other congenital coagulation disorders, FX deficiency usually arises from missense mutations. Amino acid substitutions can significantly change any number of steps in protein formation. Mutations severely impairing the protein structure are frequently associated with a reduction of the antigen as well as the activity level. In these cases, abnormal protein folding may be responsible for an impairment of protein secretion and/or a reduction in protein half-life. Missense mutations responsible for minor structural changes are often associated with an impairment in FX activity in the setting of a normal antigen level. Nonsense mutations and large gene deletions have been reported and are invariably associated with a symptomatic pattern when found in compound heterozygosis with a missense mutation impairing the FX

protein structure.[11] Interestingly, FX knockout mice with a total deficiency in blood coagulation FX present with partial embryonic lethality and fatal neonatal bleeding suggesting the crucial role of FX function.[12] It is likely that genetic mutations that cause total FX deficiency in humans may be incompatible with life as well. Very few symptomatic individuals with total or severe deficiency in the components of prothrombinase have been identified to date.

Missense mutations have been described affecting the different FX protein domains. Mutations in the preprosequence and prosequence, as FX Nice and FX Santo Domingo, have been shown by molecular modeling and expression studies to be responsible for secretion and cleavage problems explaining the type I phenotype.[13,14]

A missense mutation affecting the calcium-binding region of the Gla domain characterize the low activity and normal antigen level in the FX St. Louis.[15]

Mutations affecting the correct formation of disulfide bridges in EGF-1 and -2 domain have been reported, affecting both the function and antigen level of FX-associated mutations.[11] Missense mutations affecting the release of the activation peptide, such as FX Wenatchee I and II, have been shown to be associated with low catalytic activity and reduced FX half-life.[16]

FX Friuli is one of the most well-characterized mutations of the catalytic domain.[17] This variant consists of a $Pro^{343} \rightarrow Ser$ substitution within the heavy chain of FX. Homozygous FX Friuli patients present with a normal antigen level and a normal or near-normal activity by means of RVV assay but a severely reduced (4–9%) function in the intrinsic and extrinsic pathways. Due to the formation of a new hydrogen bond, the tertiary structure of the catalytic domain has been shown to be affected.

A good genotype–phenotype correlation has been demonstrated in an Italian family with FX deficiency, named FX S. Giovanni Rotondo.[18] In this well-characterized variant, one deletion in the region encoding for the activation peptide was described in compound heterozygosis with a missense mutation in the catalytic domain, respectively responsible for the lack of synthesis and/or secretion of FX and for a dysfunctional FX.

The loss of a disulfide bond in the catalytic domain has been shown to be associated with a type I phenotype in FX Padua 4.[19] Interestingly, mutations in this highly conserved residue among other serine proteases, factor VII and protein C, are responsible for a very similar phenotype, suggesting the critical role of this disulfide bond in FX function and secretion.

These few examples of a consistent genotype–phenotype relationship further suggest that the laboratory phenotype is largely a function of the FX gene lesion segregating in the family. Some interindividual variability, even in the presence of identical pathological FX genotypes, is common, which is likely due to the variation between laboratory assays, the contribution of polymorphisms, and possibly also the influence of variation at nonallelic loci.

DIFFERENTIAL DIAGNOSIS

Clinical history in the presence of laboratory prolongation of PT and PTT usually suggests FX deficiency. Specific diagnosis relies on the quantification of FX activity and antigen levels and on the levels of other coagulation factors. Concomitant disease may mimic congenital FX deficiency. Liver disease and vitamin K deficiency can be responsible for acquired FX deficiency, but they more commonly determine abnormalities of other VKD clotting factors. Acquired FX inhibitors have been reported and can be suspected when sample plasma added to normal plasma causes prolongation of PT and PTT. Amyloidosis has been shown to determine FX deficiency by amyloid protein binding to circulating FX.

MANAGEMENT

As FX levels do not correlate with clinical phenotype, therapy of FX deficiency is based on the presence of bleeding manifestations. Transfusion with fresh frozen plasma may be used to treat symptomatic patients. A level of 10–20% U/dL is usually sufficient for adequate hemostasis. The half-life of FX is approximately 40 hr. Plasma is administered with an initial dose of 15 mL/kg, followed by 3–6 mL/kg every 24 hr.

Prothrombin complex concentrates, i.e., FIX, contain a small quantity of FX (about 1 U FX per unit of FIX). Although these concentrates have been shown to be effective in the treatment of bleeding episodes in patients with FX and FVII deficiency, their use has been associated with significant thrombogenicity.

GENETIC COUNSELING

As for other recessive coagulation disorders, consanguineous marriage often explains the presence of homozygous mutations in symptomatic patients. In some cases, compound heterozygotes have been reported. Patients who are severely deficient in FX are severe bleeders and require frequent FX replacement therapy.[8] Therefore, prenatal diagnosis should be performed in pregnant women with at least one family member affected by this coagulation disorder. Knowledge of the underlying mutation is therefore essential to achieve this goal.

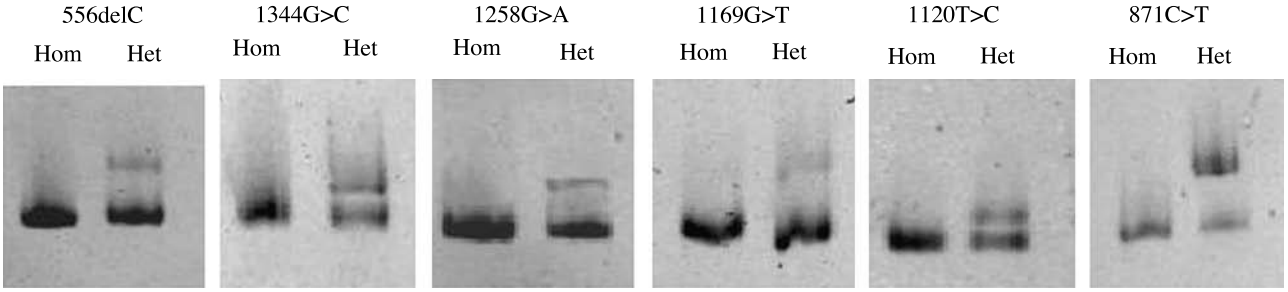

Fig. 4 Conformation sensitive gel electrophoresis of PCR amplification of FX exons 6 and 8. Each picture shows a FX mutation confirmed by gene sequencing. Hom = homoduplex; Het = heteroduplex. (From Ref. [20].)

MOLECULAR GENETIC TESTING

Molecular diagnosis of congenital FX deficiency relies on the detection of gene mutation and on the possible genotype–phenotype correlation. This can be achieved by amplifying the entire coding region of the gene by PCR and then proceeding to sequence the PCR products using the following primers:[17]

Exon 1	5′-GACAACAGCCATCCAAGCTTGGGCGTGGAC-3′
	5′-CTGCCGCCCCTCCAAGCTTCCTGGCGCTGC-3′
Exon 2	5′-GCCTGGGTGAGGGTGACCAG-3′
	5′-AGCGAGGGCGCTGTGGCCTG-3′
Exon 3	5′-AAATCTCTTTTTTCCTTTTAG-3′
	5′-AAATTAGAACAAAAGCAGAAAG-3′
Exon 4	5′-TGATGCCGGAAACAGCTTGCAG-3′
	5′-TGCCACTCTTCAGGGGCATCTG-3′
Exon 5	5′-AGCCTCCATTTCTCCAGCTG-3′
	5′-GTGTCACTGTTACCTGCCAG-3′
Exon 6	5′-TGTGCAGGCTATGGGGAGCCTCTC-3′
	5′-ACAGGTGGTCTCTCCAGCAG-3′
Exon 7	5′-AGTCAGGCAACACCTGTCCACCTG-3′
	5′-TGAAAAGCAGACAGTGACGGTGC-3′
Exon 8a	5′-AACGGATGTGCGAGAGCATGCC-3
	5′-GGCAGGCATCCTCCTGCTTG-3′
Exon 8b	5′-ACCGCAACAGCTGCAAGCTG-3′
	5′-AATCGAGAGACAAACCAGGC-3′

Even with the introduction of automated sequencing system, some intermediate steps can be useful for scanning PCR products with the aim to identify the gene fragment potentially mutated and then confirm the mutation by sequencing. The scanning techniques most commonly used for PCR products are single-strand conformation polymorphism (SSPC), enzymatic or chemical cleavage of mismatched base pairs, and differential unfolding of homoduplexes and heteroduplexes by denaturing gradient gel electrophoresis (DGGE). Recently, conformation-sensitive gel electrophoresis (CSGE) has been successfully used as a simple, inexpensive, and highly reliable method for localizing FX mutations[20] (Fig. 4). The combination of PCR–CSGE–sequencing could be useful in family studies where, after complete characterization of the mutation in a family member by sequencing the entire FX gene, the other relatives are screened by means of CSGE only. Although expression studies are invaluable to detect subtle functional differences in the cases where the mutations are antigen positive (i.e., normal antigen levels), they are less useful where the mutations are antigen negative (as is reflected in the low in vivo plasma levels), as the mutant proteins are likely to be unstable or may not be expressed. With the availability of FX crystal structures, sequence alignments and molecular modeling are effective methods in identifying structural perturbations in active sites.[21] Molecular modeling in combination with energy refinements can be an invaluable tool in the assessment of cases in which protein misfolding is the most likely outcome of a given mutation.

CONCLUSION

With the recent and more accurate studies of the genotype–phenotype relationship, it is now clear that the laboratory phenotype of congenital FX deficiency is largely a function of the FX gene lesion segregating in the family. However, some interesting cases have been reported that suggest more intricate mechanisms as responsible for congenital FX deficiency. In particular, symptomatic patients with autosomal dominant pattern of inheritance have been reported, leading to the hypothesis that the presence of a circulating abnormal FX protein can compete and exert a dominant negative effect by denying the access of the product of the wild-type factor X allele to receptor sites. Larger-scale studies of patients and their immediate relatives will provide more insight into the pathophysiology of congenital FX deficiency.

Factor XI Deficiency

Pierre Hopmeier
Hospital Rudolfstiftung, Vienna, Austria

INTRODUCTION

In general, factor XI deficiency is regarded as a rare disorder restricted to isolated cases and families. However, it is common in people of Jewish descent, particularly in individuals of Ashkenazi origin. Recently, factor XI deficiency has also been reported in the French Basques population, and the condition may also be very common in persons of African ancestry.

Although factor XI is essential for normal hemostasis, a deficiency state is not always associated with bleeding and may remain without clinical symptoms. If there is a bleeding tendency, it is often differently pronounced between individuals with the same factor XI level.

Compared to hemophilia A or B, the prevalence of spontaneous bleeding, formation of hematoma or hemarthroses is much lower even in severely deficient patients. Also, the association between plasma levels of factor XI and the frequency and severity of bleeding symptoms is much poorer than for a deficiency of factor VIII or factor IX.

BACKGROUND

Plasma factor XI circulates as a homodimer linked by a disulfide bond complexed to high molecular weight kininogen (HK) in noncovalent form at a molar ratio of 1:2.[1] Each monomer is composed of 607 amino acids and has an apparent MW of 80,000. Most, if not all, of factor XI is synthesized by the liver, although mRNA was also demonstrated in platelets and cell lines with megakaryocyte features.[2] Factor XI can be activated by factor XIIa, factor XIa, thrombin, or by autocatalysis through cleavage of a single peptide bond (Arg 369–Ile 370).[3,4]

There is a large body of evidence that under normal conditions, blood coagulation is initiated via the extrinsic pathway. The minute amounts of thrombin formed as a result of exposure of tissue factor will then activate factor XI in a feedback manner, leading to the formation of an amplification loop with continued thrombin generation. Platelets seem to play a central role. They are activated by trace amounts of thrombin, and on the activated platelet surface, thrombin-mediated activation of factor XI is more effective than activation by factor XIa or factor XIIa and directly reflects the occupancy of F XI-binding sites.[3] Furthermore, on the surface of activated platelets, fibrinogen does not inhibit thrombin-mediated factor XI activation, possibly because of colocalization of thrombin and factor XI on a high-affinity binding site.[3] Also, platelet-bound factor XIa, but not factor XIa in solution, is protected from inhibition by protease nexin 2, which is likely to be the most relevant inhibitor of factor XI within the activated platelet environment.[1,3,4]

Because thrombin, particularly in the presence of thrombomodulin, activates thrombin activatable fibrinolysis inhibitor (TAFI), feedback generation of factor XIa is also regarded to be important for the downregulation of fibrinolysis.[5]

In the laboratory, the diagnosis of factor XI deficiency is usually based on the finding of a prolonged activated partial thromboplastin time (APTT). However, common clotting tests for measurement of factor XI generally rely on factor XI activation via the intrinsic pathway and reflect the contribution of factor XIa for initial fibrin clot formation. Several aspects of factor XI activation and function, in particular the interaction with platelets and the effects of maintained thrombin-mediated factor XI generation, are not adequately measured.

GENOTYPE–PHENOTYPE CORRELATION

The lower limit of the normal range for factor XI is commonly given at about 70%. Individuals with levels up to 15–20% are regarded as partially deficient, while individuals with lower levels are severely deficient and represent homozygotes or compound heterozygotes.[6,7] In general, bleeding is negatively correlated with factor XI level.[7] However, only at a very low factor XI level is the risk for excessive bleeding clearly increased, probably because the quantity of factor XI necessary for normal thrombin generation after initiation of coagulation by minute amounts of tissue factor is very small.[7,8] For instance, patients with a factor XI of only about 9% (homozygotes for the type III mutation) still bleed less severely than patients with a factor XI level of about 1% (homozygotes for the type II mutation).[8] On the other hand, it is well established that individuals with a severe deficiency do not always have an increased pro-

DOI: 10.1081/E-EDGP 120020582

pensity to bleed, whereas some heterozygotes may bleed excessively.[6] Basically, bleeding tendency is unpredictable and may also vary in the same patient.[6,9] Consequently, the inheritance pattern of factor XI deficiency cannot be generally defined as being autosomal dominant or autosomal recessive.

CLINICAL DESCRIPTION

In symptomatic individuals, certain clinical manifestations are common. In women, menorrhagia is frequently reported and there is an increased risk of bleeding after childbirth.[9] Epistaxis may occur, whereas petechiae and bruising are rather unusual.[9] Bleeding can be excessive and frequently manifests postoperatively, in particular after surgical procedures involving tissues with high fibrinolytic activity such as dental extractions, tonsillectomies, prostatectomies, or urinary tract operations. For other surgical interventions such as appendectomies, orthopedic operations, cholecystectomies, or hysterectomies, the risk of severe bleeding is less pronounced.[10] Sometimes the first bleeding episode is observed after circumcision.[9] Bleeding can be immediate,[9] but typically, it is protracted or presents as persistent oozing after surgery.[10]

Antibodies to factor XI are rare and have mostly been described in nondeficient patients as a complication of autoimmune disease.[6] Recently, however, a number of patients who were given plasma replacement therapy were diagnosed with acquired inhibitors to factor XI. They had a mean factor XI activity level of about 1% and were all homozygous for the Glu117stop (type II) mutation, indicating that mutations associated with a very low factor XI level may be risk factors for development of an inhibitor after plasma replacement.[11]

PREVALENCE

F XI deficiency is common in the Jewish population where two mutations, the so-called type II (Glu117stop) and type III mutation (Phe283Leu), prevail. Haplotype analysis indicates that both mutations date back to ancestral founders.[12] In a study performed in Israel, the type II mutation was identified only in Iraqi Jews (allele frequency: 0.0167), which are regarded to represent the original Jewish gene pool in the Middle East. In contrast, both mutations were observed with similar allele frequencies in Ashkenazi Jews (0.0217 and 0.0254, respectively), a main segment of Jews that diverged from the original gene pool and began to migrate to Europe at the time of the Roman Empire.[12] Correspondingly, age estimates based on distribution of allelic variants at a flanking microsatellite marker suggest that the type II mutation dates back more than 120 generations, and that the type III mutation appeared later in history.[13] Recently, in French Basques, a novel mutation (Cys38Arg) with an allele frequency of about 0.005 was reported. Haplotype analysis was consistent with an ancestral founder.[14] Two substitutions, Gln226Arg and Ser248Asn, were identified in an African–American family and subsequently also in population-screening studies indicating that these two variants may be very common in individuals of African origin.[15,16] At present, about 80 mutations have been described in different ethnic groups, the majority being reported in single families or as sporadic cases with unknown allele frequency.

Apart from the Jewish population, inherited factor XI deficiency is generally regarded as a rare condition. However, in a study from the U.K., about 5% of patients with bleeding disorders had factor XI deficiency, many with no known Jewish ancestry.[6,7] Moreover, in our experience, the condition is underdiagnosed. Possible reasons include the fact that factor XI deficiency often remains asymptomatic or is only revealed after hemostatic challenge, and that in APTT assays, results for heterozygote patients may be borderline or within the normal range.[10]

MANAGEMENT

Without hemostatic challenge, patients with factor XI deficiency do not need treatment. In case of dental extractions or surgical intervention, fresh frozen plasma replacement therapy may be required. This can be combined with the application of antifibrinolytic agents. The half-life of factor XI in plasma is about 40–80 hr, and factor XI function is well preserved.[9] For dental extractions, only antifibrinolytic therapy using tranexamic acid from 12 hr before until 7 days after the procedure has also proven to be effective.[6,9] Other products such as fibrin glue or desmopressin have been used in a limited number of patients as well.[9] In general, it is recommended to continue therapy for several days. Factor XI concentrates have been developed but are presently not licensed for use in the United States.

In patients with factor XI inhibitors, the uses of prothrombin complex concentrates and recombinant factor VIIa were successful.[6]

MOLECULAR GENETICS

The gene for factor XI is located on the distal end of chromosome 4 (4q35).[17] It is 23 kb in size and consists of 15 exons (numbered 1–15) and 14 introns (named A–N).

Exon 1 is not translated and exon 2 codes for a signal peptide of 18-amino acids length, which is not integrated into the final protein.[18] Plasma factor XI is the gene product of exon 3–15 and contains a heavy chain of 369 amino acids and a light chain 238 amino acids in length.[5] Platelet factor XI mRNA was reported to be an alternative splicing product lacking exon 5; however, this was not confirmed by other research groups.[2,19] The heavy chain harbors four tandem repeats of 90–91 amino acids, named apple domains (A1–A4). Each one is encoded by two successive exons starting from exon 3.[5,18] Several binding sites are located within these domains. To a large extent, the implicated amino acids have been elucidated.[20–24] The A1 domain carries a binding site for prothrombin as well as binding sites for HK and thrombin.[3] Binding of prothrombin or HK to the A1 domain results in exposure of a platelet-binding site on the A3 domain.[1,24] The interaction of the A3 domain with activated platelets is mediated through binding to GPIb–IX–V complexes within lipid rafts in the platelet membrane.[25] Moreover, a binding site for unfractionated heparin was localized on the A3 domain.[22] Both the A2[20] and the A3 domain[21] were reported to mediate factor IX activation. On the A4 domain, a binding site for factor XIIa was localized.[23] The A4 domain is also essential for factor XI dimer formation because it mediates initial noncovalent dimerization of two factor XI subunits and harbors the Cys321 residue responsible for subsequent dimer stabilization by a single disulfide bond.[26] The light chain is encoded by exon 11–15.[5,18] It contains the active site formed by the catalytic triad (His413, Asp462, and Ser557)[5] typical for most serine proteases, as well as a high-affinity heparin-binding site.[27]

With the exception of three deletions and three insertions,[14,17,28–30] all published mutations associated with factor XI deficiency involving exon 3–15 are single-base substitutions, which are mostly missense mutations. Many are located within binding sites. Therefore one may expect aberrant factor XI molecules to circulate and interfere with normal factor XI function. However, in most instances when factor XI activity and antigen were determined, both were simultaneously reduced.[7] In fact, a defect in secretion was demonstrated for a number of factor XI variants expressed in cell lines, indicating that, in general, circulating factor XI in deficient individuals will be composed of normal monomers.[14,31] However, a few cases of circulating dysfunctional factor XI protein have been reported.[6] Recently, two novel variants with normal expression in cell culture systems were described in several patients. One individual with reduced but appreciable factor XI activity and antigen was compound heterozygous for these mutations. Consequently, all circulating factor XI of this individual must only consist of abnormal monomers. Furthermore, in individuals heterozygous for such mutations, the variant molecules may participate in circulating factor XI forming either homodimers or combine to heterodimers together with normal factor XI molecules.[15,16]

LABORATORY DIAGNOSIS

In clinical practice, e.g., for the planning of operations, diagnosis of congenital F XI deficiency is usually established by APTT-based assays, whereas molecular techniques are mostly restricted to scientific studies. However, there are conditions, such as consumption reactions or the presence of a high titer of lupus anticoagulant, where APTT-based tests may not be suitable and molecular methods are needed to identify a congenital deficiency state. For mutation analysis, genomic DNA is extracted and usually amplified by PCR with primers covering all 15 exons and the intron–exon boundaries. Frequently, primers are designed in such a way that a section of DNA encompassing a number of exons in close proximity to each other is amplified.[31,32] PCR may be directly followed by determination of nucleotide sequences of all PCR products, but frequently a mutation-screening technique such as single-stranded conformation polymorphism (SSCP) analysis is subsequently applied to avoid unnecessary sequencing.[17,33] Restriction fragment-length polymorphism (RFLP)[32] analysis and dideoxyfingerprinting (ddF)[15] have also been used for this purpose. The disadvantage of all of these methods is that the mutation-detection rate may be incomplete. For example, with Fluorescent-SSCP, the detection rate is 80–85% in routine use.[34] Recently, considerable improvement with denaturing high-performance liquid chromatography (dHPLC) has been reported. In one study, the detection rate using this technique was 100%.[34]

CONCLUSION

Congenital factor XI deficiency is probably underdiagnosed, partly because affected individuals often remain without symptoms and because in conventional APTT tests, the results for heterozygotes frequently overlap with the normal range. In general, APTT-based tests are of limited value to assess the risk of bleeding in affected individuals because the association between bleeding propensity and measured factor XI level is poor.[7,16]

Increasing numbers of mutations causing factor XI deficiency are being identified. However, there has been no comprehensive study that focus on whether genetic variants participate in the formation of circulating factor XI only in exceptional cases, or whether this is more

common, and to what extent different factor XI functions are thereby affected. Modified activity tests which better reflect the functional spectrum of factor XI and possibly, mutational analysis, may render factor XI measurement clinically more informative.

Familial Adenomatous Polyposis (FAP) Syndrome

Nader Hanna
Shaun McKenzie
Heather Pierce
University of Kentucky Medical Center, Lexington, Kentucky, U.S.A.

INTRODUCTION

Familial adenomatous polyposis (FAP) represents the classic paradigm for the hereditary cancer syndromes. It is a highly penetrant autosomal dominant disorder with classic Mendelian inheritance of mutations in the adenomatous polyposis coli (*APC*) gene and characteristic genotype–phenotype correlation. Familiarity with the natural history of the syndrome, inheritance pattern, and the colonic and extracolonic clinical manifestations is essential for early identification of families at risk. A combination of genetic counseling, genetic testing, and aggressive endoscopic surveillance is paramount to management. Surgical management is the cornerstone of therapy as chemopreventive measures continue to be developed.

FAMILIAL ADENOMATOUS POLYPOSIS SYNDROME

Familial adenomatous polyposis syndrome is characterized by accelerated tumorigenesis from normal mucosa to polyps. It occurs in 1:8000 to 1:13,000 live births and shows no racial, gender, or geographical predilection. It has autosomal dominant inheritance with 100% penetrance, and if left untreated, patients affected with FAP will inevitably develop colorectal cancer, typically by the age of 35–40 (mean age 39 years).[1] It accounts for about 1% of all colorectal cancers. Approximately 15%, 75%, and 90% of patients will develop 100 polyps or more (mostly in the left colon) by ages 10, 20, and 30, respectively. These polyps follow the typical adenoma to carcinoma progression seen in sporadic colorectal cancer, with a 5- to 10-year gap seen between diagnosis of polyposis and cancer. Unfortunately, despite the fact that this syndrome is a well-described entity, 59% of patients still succumb to metastatic colon cancer.[2] Of those who do undergo timely colonic resection, upper gastrointestinal malignancy and desmoid formation are the leading causes of death.[3] Patients with FAP are at risk of developing extracolonic tumors, including premalignant periampullary adenomas, desmoid tumors, papillary thyroid cancer, hepatoblastoma, epidermoid cysts, and congenital hypertrophy of the retinal pigment epithelium (CHRPE). The periampullary polyps appear white, smaller, and more sessile than colorectal polyps and usually concentrate in the second part of the duodenum. They are often asymptomatic, and the presence of symptoms suggests malignancy. Periampullary and duodenal lesions tend to occur 10 years after colorectal polyposis, and the average age of onset of periampullary or duodenal carcinoma is 46 years old.[4]

Attenuated flat adenoma polyposis syndrome (AFAP), Gardner syndrome, and Turcot (glioma-polyposis) syndrome are phenotypical variants of the FAP syndrome. They have the same molecular genetic basis as the FAP syndrome. Gardner syndrome is characterized by colonic polyposis along with sebaceous cysts, lipomas, desmoid tumors, fibromas, facial bone osteomas, and impacted or supernumerary teeth.[5] Turcot's syndrome is a genetically heterogeneous condition characterized by CNS tumor formation along with colonic polyposis. Turcot's syndrome usually occurs due to mutations in the *APC* gene or one of the genes associated with hereditary nonpolyposis colon cancer syndrome (HNPCC). Turcot's syndrome due to mutations in the *APC* gene is typically associated with occurrence of medulloblastoma, whereas glioblastoma is the CNS tumor type that is most frequently observed in Turcot's syndrome that occurs due to mutations in HNPCC-associated genes.[6] More recently, an attenuated form of FAP, now known as AFAP, has been described. These patients typically present with less than 100 colorectal polyps developing, on average, 10 to 15 years after those seen with FAP and usually proximal to the splenic flexure.[7] The risk of colorectal cancer is still significantly elevated, with 70% of these patients developing colorectal cancer by the age of 65 if left untreated.[1] Extracolonic manifestations can also occur, most notably gastric polyposis. Moreover, diffuse gastric polyposis can occur prior to the development of colonic lesions, and its presence at endoscopy should prompt exploration into the possibility of this syndrome.[7] Other extracolonic manifestations typical of classic FAP, such as cutaneous lesions, desmoids, and CHRPE, are rare in AFAP.[7]

GENETIC ALTERATIONS IN FAP

Familial adenomatous polyposis is caused by inheritance of germline mutation in the *APC* gene (chromosomal locus 5q21–q22). Familial adenomatous polyposis is an autosomal dominant disease with extremely high penetrance, as 95% of individuals with FAP have polyps by age 35. Approximately 20–25% of individuals with FAP have the altered gene as a result of a de novo gene mutation[8] and therefore will not have an affected parent. The *APC* gene is a ''gatekeeper'' tumor suppressor gene encoding a large protein which is involved in chromosome segregation, cell adhesion, cell migration, signal transduction, and apoptosis.[9,10] Most FAP-associated mutations in the *APC* gene cause premature truncation of the *APC* protein. Individuals with FAP only have one functional copy of the *APC* gene in each colonic epithelial cell, therefore accelerated tumorigenesis from normal mucosa to polyps and carcinoma occur. The *APC* gene contains 15 exons and 2843 codons. The colonic (including the density of colonic polyposis) and extracolonic phenotypical manifestations of FAP, as well as development of desmoid tumors (10–15% of cases), are related to the location and type (frameshifts and point mutations) of the *APC* gene mutation.[11] A great deal of research has been devoted to the apparent genotype–phenotype correlations for the disease, although due to the variation that occurs among individuals and families with identical mutations in the *APC* gene,[12] these associations are not routinely used as a basis for clinical management strategies.[13] The most common mutation in *APC* is located at codon 1309, and patients with this mutation develop a high number of adenomas at an early age, with an average age at presentation of 20 years. Individuals with mutations in codons 1250–1464 often exhibit profuse polyposis (an average of 5000 polyps).[14] In terms of age at onset of colonic symptoms, individuals with mutations between codon 168 and 1580 present at an average age of 30 years, and individuals with mutations proximal to codon 168 and distal to codon 1580 present at an average age of 52 years.[13] Attenuated familial adenomatous polyposis is most commonly associated with *APC* mutations proximal to codon 168, although germline mutations in exons 6 and 9 as well as in the distal 3′ region of the gene have also been identified in AFAP families.[15] The extracolonic manifestations of FAP also show genotype–phenotype correlations. Desmoid tumors are often associated with mutations at codons 1444 and 1578.[16] Congenital hypertrophy of the retinal pigment epithelium is associated with mutations in codons 463–1387,[17] whereas mutations distal to codon 1444 or before exon 9 are associated with the absence of CHRPE.[16] Mutations downstream from codon 1051 are associated with increased risk of malignant transformation of periampullary adenomas. A retrospective study of 190 patients with FAP showed that the ''Gardner'' phenotype, which includes desmoid tumors, osteomas, and epidermoid cysts, is most often associated with mutations in codons 1395–1493, and that hepatoblastoma and brain cancer were seen only in patients with mutations in codons 457–1309.[18] With recent advances in molecular genetics, these genotype–phenotype correlations may eventually influence the accuracy and effectiveness of genetic testing, screening recommendations, and treatment.

CLINICAL DIAGNOSIS AND GENETIC TESTING

Although the diagnosis of FAP relies primarily upon clinical findings in symptomatic individuals, genetic testing is most often used in the early diagnosis of at-risk family members and in the confirmation of the diagnosis of FAP in patients with equivocal findings. Genetic testing is typically run on DNA extracted from white blood cells obtained from a blood sample. Several DNA-based techniques are available for the detection of *APC* mutations in FAP families (Table 1),[19] including full gene sequencing, mutation scanning by conformation-sensitive gel electrophoresis (CGSE) of exons 1–14 combined with protein truncation testing (PTT) of exon 15, PTT alone, and linkage analysis. Full gene sequencing has the highest estimated mutation detection rate of approximately 95%. Sequence confirmation of familial mutations identified by any technique other than full gene sequencing is highly recommended if the result will be used for predictive testing of at-risk family members. If germline testing reveals a mutation in an individual affected with FAP, the clinical diagnosis is confirmed, and genetic testing of at-risk family members will provide true

Table 1 Molecular genetic testing for FAP

Direct full gene sequencing: Detects APC sequence alteration. Most precise method for mutation detection (~95% sensitivity). Time consuming and expensive
Single-strand conformational polymorphism (SSCP) and denaturing gradient gel electrophoresis (DGGE): Rely on difference in the movement of a mutated DNA compared with normal DNA during electrophoresis
The in vitro synthesized protein assay (IVSP), also called protein truncation test (PTT): Detects premature truncation of the APC protein. It is the main test for FAP (~80% sensitive)
Confirmation sensitive gel electrophoresis (CSGE) combined with protein truncation testing (PTT): Detects APC sequence alteration and premature truncation of the APC protein (~80–90% sensitive)

positive or negative results. Ultimately, if a mutation cannot be identified, further testing of at-risk relatives should not be pursued, because testing will not be conclusive; a negative result could be a false negative because current testing may not be capable of detecting a mutation even if present. Although it is possible to initiate germline testing with an at-risk family member when an affected family member is not available for testing, this strategy can only yield positive or inconclusive results. In this situation, only the identification of a mutation in a family member can enable a true negative result. Genetic testing should always be done in the setting of pre- and post-test genetic counseling, as endorsed by the American Society of Clinical Oncology in its position statement on genetic testing for hereditary cancer.[20] The process of genetic counseling includes providing risk assessment, educating patients about testing options, discussing the implications for medical management, and providing supportive counseling to the individual and their family. Genetic counseling for FAP should be offered to any patient that has personal or family history features suggestive of FAP, and genetic testing should be offered when results could influence the medical management of that patient or the patient's family members.

As colon screening for those at risk for classic FAP begins as early as age 10, genetic testing is offered to children in FAP families as early as age 8. In AFAP families, colon screening for at risk individuals begins at age 18 years, so genetic testing is generally offered at around 18 years of age. Age-appropriate education should be provided to at-risk children during the genetic counseling process, and children should be involved in the decision whether to undergo genetic testing.

SURVEILLANCE

Examination of the funds at birth to detect CHRPE can identify susceptible family members at young age. In family members of a FAP-positive patient, sigmoidoscopy is recommended annually starting at age 10–12 years to age 24 years, every 2 years until age 34 years, every 3 years until age 44 years and every 3–5 years thereafter. While a true negative genetic test is considered conclusive, some centers recommend interval flexible sigmoidoscopy around the ages of 18, 25, 35, and then per standard American Cancer Society guidelines, if an at-risk individual tests negative.[21] If the genetic test was indeterminate, at-risk individuals should undergo screening sigmoidoscopy every year from 10 to 25 years of age, biannually from 26 to 35, and every 3 years from 36 to 50, and then per ACS guidelines.[21] After colectomy has been performed most authors recommend screening the retained rectum every 6 months or the intestinal pouch every 1–3 years.[22] Screening for AFAP falls under similar guidelines, although screening is usually initiated at a later date, includes upper endoscopy for the gastric polyposis, and requires total colonoscopy because of the predilection for proximal lesions.[1,7]

Screening for extracolonic malignancy has proven less fruitful. Unlike colorectal cancer screening, there has been no reported evidence that early screening or therapy has improved the prognosis of duodenal and periampullary adenomatous disease.[23] Nevertheless, screening for ampullary tumors is also recommended with upper endoscopy every 1–3 years, beginning at age 20–25 years. Screening should be performed with both forward and side viewing scopes with random biopsies taken. In regard to other common extracolonic tumors, annual physical exam is recommended for thyroid disease.[21] Hepatoblastoma screening includes annual liver ultrasound with alpha-fetoprotein level until the age of 6 in patients diagnosed with FAP in infancy.[1]

CHEMOPREVENTION

The discovery of cyclooxygenase enzyme (COX1, COX2) overexpression in colorectal polyps and cancer has led to numerous studies evaluating nonsteroidal anti-inflammatory drugs (NSAiDs) in the treatment of FAP. Numerous studies involving *Sulindac* have shown a decrease in size and number of colorectal polyps (65% and 56%, respectively) in patients with FAP after several months of therapy.[24] Nevertheless, growth resumes as soon as therapy is stopped and there have been no studies to determine the safety of long-term *Sulindac* therapy. There have also been reported cases of colorectal cancer occurring while on *Sulindac* therapy. Studies are now underway to determine whether *Sulindac sulfone*, a metabolite of *Sulindac* without significant COX inhibition, will provide chemoprevention without significant side effects. In 1999, the Food and Drug Administration granted accelerated approval of *Celecoxib* for treatment of colorectal polyposis in FAP based on a 6-month trial that showed reduction in the number of polyps by 28% and the sum of poly diameter by 30.7% from baseline.[25] While these studies are encouraging there remain no long-term prospective studies showing improved prognosis with NSAiD therapy. Furthermore, there have been no studies that suggest that periampulary and duodenal disease responds to either of these two medications.[24]

SURGICAL MANAGEMENT

Once colorectal polyps are found, the only effective management is total proctocolectomy in FAP. Because

colorectal cancer is diagnosed in 5% of FAP patients by 20 years of age, surgery should be recommended at the time of diagnosis. Surgical options for colonic disease include total colectomy with ileorectal anastomosis (IRA), proctocolectomy with ileal pouch-anal anastomosis (IPAA), total proctocolectomy with Brook ileostomy, and total proctocolectomy and continent ileostomy (Koch). It should be noted that for patients with AFAP, IRA is an appropriate therapy.[7]

Duodenal and periampullary disease poses a much more challenging therapeutic dilemma. Endoscopic ablation via snare, argon plasma coagulation therapy, and laser photodynamic therapy are being attempted for mild to moderate disease; however, they also carry significant opportunity for morbidity and are often difficult to tolerate. As only a small proportion of these patients develop carcinoma, it becomes difficult to justify prophylactic resection. This decision is further complicated by the associated significant morbidity of pancreaticoduodenectomy with questionable improvement on prognosis.[23] Consequently, these options are reserved for diagnosed cancer or severe dysplasia.

CONCLUSION

Familial adenomatous polyposis exemplifies the classic hereditary cancer syndrome with Mendelian distribution. Its epidemiology reveals a rare disorder with high cancer-related mortality. Its clinical features are hallmarked by synchronous and metachronous tumor growth at an early age. Understanding the epidemiology, clinical characteristics, and genetics of FAP affords not only evidence-based preventive measures, but also allows for a better appreciation of the behavior of all hereditary cancer syndromes. Screening protocols are available, but not standardized and imperfect. As timely surgery on the primary organ has impacted mortality, the cancer-related deaths associated with extra primary sites continue to pose therapeutic dilemmas. Recent advances in molecular genetics and continued research in its genetic profile exposed an increased genotype–phenotype correlation, which may eventually influence the choice, accuracy, and effectiveness of genetic testing, screening recommendations, and chemoprevention strategies.

Fanconi Anemia

F

INTRODUCTION

Fanconi anemia (FA) is a cancer-prone chromosomal instability disorder with autosomal recessive inheritance. Cells derived from FA patients are hypersensitive to chromosomal breakage by DNA cross-linking agents such as mitomycin C or diepoxybutane, which is used to confirm a clinical suspicion of FA. At least eleven genetic subtypes are distinguished. Eight of these have been connected to distinct disease genes, including the breast cancer susceptibility gene, *BRCA2*. Most FA genes encode orphan proteins with no known molecular function. They are supposed to act in an integrated pathway with BRCA1 and BRCA2 to maintain the integrity of the genome. Molecular diagnosis is feasible in >95% of all cytogenetically confirmed FA patients.

FA: CLINICAL ASPECTS

Fanconi anemia is a rare syndrome (ca. 10 per million newborns) with autosomal recessive inheritance. Clinical symptoms include multiple developmental abnormalities, bone marrow failure, and a high risk of malignancies (Table 1). Clinical suspicion of FA is mostly based on growth delay, skeletal abnormalities (aplastic or hypoplastic thumbs and radii), in combination with bone marrow failure (pancytopenia), which usually starts between 5 and 10 years of age.[1,2] However, the symptoms are highly variable. Therefore, the diagnosis should always be verified using cytogenetic or molecular techniques. Hematopoietic mosaicism occurs in a proportion of patients because of genetic reversion at the disease locus in certain primitive progenitor cells, which may (partially) correct the bone marrow defect and in some cases may lead to an incorrect diagnosis.[3] The bone marrow failure is usually progressive. Most patients die prematurely from the consequences of aplastic anemia, leukemia, or solid tumors.

Some aplastic FA patients may respond to treatment with androgens or steroids. Transplantation with bone marrow stem cells from a related or unrelated donor is currently the only way to correct the marrow failure and reduce the risk of leukemia. Because of their hypersensitivity to cyclophosphamide, which is used in the conditioning regimen for transplants, transplantation centers follow an attenuated protocol for FA patients. Gene therapy trials aimed at correcting the genetic defect in hematopoietic stem cells are ongoing. Like bone marrow transplantation, this treatment could only repair the bone marrow defect and is not expected to change the risk of solid tumors.

GENETIC AND MOLECULAR BASIS OF FA

Fanconi anemia is highly heterogeneous, not only at the clinical level, but also at the genetic level. Laboratory studies using cell lines from 241 unrelated FA patients have revealed as many as 11 distinct ''complementation groups'' or genetic subtypes.[4] For 8 of these groups the disease gene has been identified (Table 2). *FANCC*,

Table 1 Clinical symptoms associated with FA

Congenital abnormalities[a]
Skeleton: Aplastic or hypoplastic radii and thumbs, short stature, small head.
Kidneys: Ectopic, horseshoe.
Other: Heart abnormalities, intestinal atresia, microphthalmia, hypogonadism, abnormal shape of the ears, deafness, skin pigmentation abnormalities.
Hematopoiesis
Bone marrow failure or aplastic anemia occurs typically at 5–10 years.
Cancer risk
Increased risk of AML, mostly occurring at age 5–15 years. At older ages, there is an increased risk of head and neck or esophageal cancer, as well as, in females, cancer of the vulva and vagina.
FA-D1 patients (with biallelic mutations in *BRCA2*) develop malignancies at a much earlier age (15–17 years).
Other symptoms
Endocrinopathy affecting the pancreas (diabetes mellitus) and thyroid; reduced fertility and early menopause.

[a]Congenital anomalies may be absent altogether.

I	1.6	*FANCI*[c]	?	?	?
J[d]	1.6	*FANCJ*[c]	?	?	?
L	0.4	*FANCL*	2p16.1	375	PHD-type zinc finger motif[9,12]

[a]Based on Ref. [4].
[b]For nomenclature rules of FA gene symbols, see http://www.gene.ucl.ac.uk/nomenclature/genefamily/fanconi.html.
[c]These genes remain to be identified.
[d]The proteins defective in these groups act downstream of the monoubiquitination of FANCD2; all the other FA proteins listed act upstream.

-A, *-G*, *-F* and *-E* were identified by complementation cloning;[2,5] *FANCA* was independently found by linkage analysis and positional cloning[6] *FANCD2* by microcell-mediated chromosome transfer,[7] and *BRCA2* by a candidate-gene approach.[8] *FANCL* was recently found through protein association studies.[9]

Most FA proteins assemble into a nuclear multiprotein ''core complex,'' which is required to catalyze a key reaction in the FA pathway: the activation of FANCD2 by monoubiquitination at position K561.[10] An important role for the assembly and/or stabilization of this complex has been assigned to FANCG, which belongs to the family of TPR-containing proteins.[11] FANCL, which carries a plant homology domain (PHD), is a candidate for acting as the ubiquitin E3 ligase in the monoubiquitination of FANCD2.[9,12] Monoubiquitination of FANCD2 is essential for the entire FA pathway because it allows FANCD2 to move into areas of damaged chromatin and to interact with BRCA1, resulting in repair of the damage.[10] BRCA2 and FANCJ are so far the only components of the pathway that act downstream (or independent) of the FANCD2 activation step.[4] The exact nature of the DNA damage response, which when defective causes FA, remains to be defined.

GENETIC COUNSELING

The recurrence risk is as for other autosomal recessive diseases, i.e., 25%. DNA diagnosis is feasible in >95% of the patients (Table 1), allowing early prenatal diagnosis as well as preimplantation genetic screening. As outlined below, prognosis may vary depending on the disease gene and mutations.

GENOTYPE–PHENOTYPE CORRELATIONS

There is wide variability of clinical symptoms, even within complementation groups. The type of mutation in a given FA gene seems to be of more importance for the clinical outcome than the complementation group itself.[13,14] An exception is group D1 (mutated in *BRCA2*, Ref. [8]), which as a group seems to be more severely affected than the non-D1 groups.[15–17] Within group C, the splice site mutation IVS4 + 4A > T, which accounts for over 80% of all FA in Ashkenazi Jewish people,[18] is much more severe than the exon 1 frame-shift mutation 322delG, which is relatively prevalent in the Netherlands.[19] Within group A, null mutations are significantly more severe than missense mutations or microdeletions/insertions that still allow near full-length protein to be made.[13] Group G patients seem to be more severely affected than group A/C patients.[13] There is as yet no definite evidence for any health effects for heterozygous FA gene mutation carriers.

THE DIAGNOSIS ''FANCONI ANEMIA''

Clinical suspicion of FA always needs to be confirmed by a chromosomal breakage test[20] to exclude syndromes

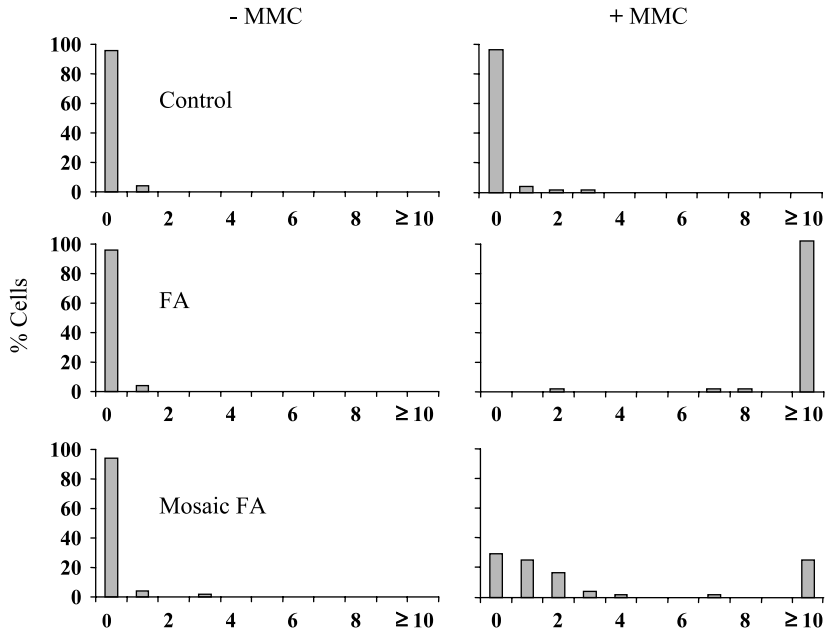

Fig. 1 Mitomycin C (MMC)-induced chromosomal breakage in phytohemagglutinin-stimulated T-lymphocyte cultures distinguishes FA (middle) from non-FA individuals (upper chart). The lower chart represents a mosaic FA patient, showing two types of lymphocytes, one responding as FA and one responding as the healthy control. (*View this art in color at www.dekker.com.*)

with overlapping clinical symptoms. In this test, T lymphocytes in a peripheral blood sample are stimulated to divide and cultured for 3 days in the presence of various concentrations of a cross-linking agent (mitomycin C or diepoxybutane), after which chromosomal aberrations (chromatid breaks and chromosomal interchange figures) are quantified in metaphase spreads. Figure 1 shows results obtained for three individuals, a healthy control, an FA patient, and an FA patient with lymphocyte mosaicism. The latter patient has two populations of T lymphocytes in roughly equal proportions: cells that respond as FA next to cells that respond as healthy control cells. The latter cells, which have originated by spontaneous reversion of one pathogenic allele at the disease locus, tend to increase with time. Therefore, some mosaic FA patients may score negative for the FA diagnosis in this test. Such patients may still be diagnosed by using skin fibroblasts, in which mosaicism has thus far not been noted.[3]

The chromosomal breakage test, originally developed by Auerbach et al.,[20] has been used for both postnatal and prenatal diagnoses and is still considered the standard test for diagnosing all genetic subtypes of FA. However, the test does not seem to distinguish FA from Nijmegen breakage syndrome,[21] which is why further testing is recommended by mutation screening (see below).

Alternative Tests

An alternative way to confirm FA is based on cell cycle analysis using flow cytometry. This test is based on the observation that FA cells (T lymphocytes or skin fibroblasts) tend to become arrested in the G2 phase of the cell cycle.[22] However, this test may fail to diagnose cases with overt leukemia or high levels of lymphocyte mosaicism.

Recently, FANCD2 western blotting has been reported as an alternative procedure to diagnose FA.[23] In this case, growth-stimulated T lymphocytes are tested for the occurrence of the ubiquitinated isoform of FANCD2, which readily reveals FA in cases where this isoform is not detected. This is a very convenient alternative for diagnosing 90% of all FA patients. However, the subtypes FA-D1 and -J, which are defective downstream of FANCD2 ubiquitination, are not diagnosed. In addition, true FA cases with a significant level of lymphocyte mosaicism may not be diagnosed as FA. In negative but still highly suspicious cases, the diagnostic workup may be extended to include additional tests, such as chromosomal breakage analysis in lymphocytes or fibroblasts.[20,24]

MOLECULAR DIAGNOSIS OF FA PATIENTS

Once the diagnosis FA has been established cytogenetically, molecular testing should demonstrate pathogenic mutations in a FA gene. This can be a laborious task, because most of the mutations are private. The following strategy has been developed at our DNA diagnostics laboratory to provide a clinically certified molecular diagnosis of FA. It is recognized that mutations in *FANCA*

account for almost 70% of all FA cases and that about 40% of the mutations in this gene are large deletions; therefore, the search usually starts with a screen for deletions in *FANCA*. However, depending on the circumstances, strategies may differ from case to case, as outlined below.

1. If information is available about the origin or ancestry of the patient a direct test for the following relatively common mutations may provide a shortcut for the classification of the patient:
   FANCA: 1263delF occurs in about 5% of all FA-A cases, whereas Exon11–17del and Exon12–31del occur relatively frequently in Afrikaans-speaking people in South Africa (cited in Ref. [2]).
   FANCC: IVS4 + 4A > T occurs homozygously in 80% of FA patients of Ashkenazi Jewish ancestry[18] and is associated with a severe phenotype. The exon 1 frameshift 322delG, associated with a relatively mild phenotype, is homozygously present in about 50% of FA cases in the Netherlands.[13,19]
   FANCG: L105X is relatively common in FA-G cases in Germany.[25]
2. In the absence of any clue, systematic mutation screening should start with a search for deletions in *FANCA*, because this gene is most often mutated, 40% of all mutations being large deletions. The quantitative multiplex ligation-dependent probe amplification (MLPA) method[26] is used for this initial screen.
3. If negative by MLPA, HPLC under denaturing conditions, followed by direct sequencing of aberrant fragments, is used to screen for mutations in *FANCA*, *-C*, *-E*, *-F*, *-G*, and *-L* simultaneously. Minor sequence variations, such as missense mutations or in-frame microdeletions or -insertions, should be tested for pathogenicity in a cellular transfection assay to check the capacity of the variant gene product for complementing activity (e.g., Ref. [27]).
4. If negative again, *FANCD2* is sequenced. This is done at the level of cDNA, because pseudogenes complicate the interpretation of genome-derived sequences. Seemingly minor alterations should be tested for pathogenicity in a transfection assay.
5. If again negative, *BRCA2* is screened by denaturing gradient gel electrophoresis (DGGE) and sequencing. Minor alterations should be tested for pathogenicity by a complementation test.
6. If negative again, cells from the patient should be tested for their ability to carry out FANCD2 monoubiquitination.[23] If negative, the patient might be defective in *FANCB* or *FANCI*. If positive, the patient may belong to group FA-J or to a new complementation group that is defective downstream of FANCD2 ubiquitination. However, before the latter conclusion can be drawn, *NBS1* should be screened for mutations to rule out Nijmegen breakage syndrome.[21]
7. If the patient has been excluded from all groups for which the disease gene is known, further work to assign the patient to a complementation group (B, I, J, or a new group) is undertaken on a research basis.

CONCLUSION

The genetic basis of FA has been largely resolved. Over 95% of all FA patients have biallelic mutations in one of at least eight disease genes, including *BRCA2*. These genes control a molecular pathway that serves to maintain the integrity of the genome. At least three additional FA genes remain to be identified. The challenge for the immediate future is to clone the missing FA genes and to further define the FA pathway in molecular terms.

FISH—An Overview

Yao-Shan Fan
University of Miami School of Medicine, Miami, Florida, U.S.A.

INTRODUCTION

Many new techniques of fluorescence in situ hybridization (FISH) have been developed in the past two decades and they are now widely utilized for clinical diagnosis.

FISH TECHNIQUES

The detailed protocols and their applications of the FISH techniques have been described in a recently published book entitled ''Molecular Cytogenetics: Protocols and Applications.''[1]

FISH with Unique DNA Sequences

FISH with unique DNA sequences represents the most basic technique. The DNA segment used as a probe may represent a functional gene or a particular chromosome region or locus. The basic steps of FISH procedure include labeling of DNA probes, preparing interphase or metaphase chromosome slides, in situ hybridization, and visualization with a fluorescent microscope.[2]

Chromosome Painting

Chromosome painting refers to a FISH procedure using probes generated from specific chromosome libraries, Alu and L1 PCR or chromosome microdissection.[3] When the probe contains unique and repetitive sequences from an entire chromosome, whole chromosomes of a homologous pair in metaphases are illuminated with fluorescence (painted). The short or long arm of a particular chromosome can be painted with an arm-specific probe. Using a device containing a 3×8 array, all 24 chromosomes can be painted simultaneously and detected sequentially on a single slide using a standard fluorescent microscope.

Spectral Karyotyping

Spectral karyotyping (SKY) is an automated chromosome painting procedure using a probe mixture containing representative DNA for each of the 24 human chromosomes.[4] The probes are directly labeled with the combinations of five fluorochromes. Through computer classification of the spectra, all 24 human chromosomes can be simultaneously visualized in different colors. SKY has been proven to be a powerful tool for the characterization of complex chromosomal rearrangements in cancer cells and de novo constitutional structural abnormalities. The sensitivity of SKY to visualize DNA alterations is about 1–2 Mb in size.[5]

Multiple Color FISH

Multiple color FISH (M-FISH) is also called multifluor FISH and multiplex FISH.[6] Similar to SKY, the probes are labeled with the combinations of multiple fluorochromes. In contrast to spectral analysis, 24 chromosomes in unique colors are detected by a series of fluorochrome-specific filters with the assistance of computer software.

FISH Following Microdissection (MicroFISH)

To perform MicroFISH, a whole chromosome, a marker, or a particular chromosome band is scraped from metaphase spreads using a micromanipulator.[7] The scraped DNA is amplified by polymerase chain reaction (PCR) and labeled as probes. FISH of such probes with normal reference metaphase chromosomes reveals the composition of chromosomes or the chromosome regions in question. This technique is useful for characterizing structural rearrangements and marker chromosomes. It is also a tool to produce specific painting probes for individual chromosomes, chromosomal arms, or regions.

Comparative Genomic Hybridization

Comparative genomic hybridization (CGH) compares test DNA with normal reference DNA.[8] The test DNA is traditionally labeled with a green color and the reference DNA with a red color. The DNA mixture is then hybridized to normal metaphase chromosomes prepared from a blood culture. By measuring the ratio of green to red color, gains or losses of chromosomes or chromosomal regions in the test DNA can be detected. The size of DNA segments that CGH can detect was estimated to be in the range of 10–20 Mb. CGH has been widely used in the investigations of solid tumors. CGH is also

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020726

useful in the characterization of de novo unbalanced structural abnormalities.

Primed In Situ Labeling

Primed in situ labeling (PRINS) refers to a process of reannealing the short oligonucleotide primers to target sequences in situ, and followed by elongation of the sequences with a *Taq* polymerase and simultaneous labeling of the target sequences with a fluorochrome.[9] PRINS primarily targets short stretches of α-satellite DNA unique to each chromosome. This technique has been used as an efficient alternative tool to detect aneuploidies.

Fiber FISH

This is a procedure of hybridization of DNA probes to extended chromatin fibers (i.e., free chromatin released from lysed cells) on a microscope slide.[10] A modified method is to hybridize probes to unfixed DNA fibers prepared from cells embedded in pulsed-field gel electrophoresis (PFGE) blocks. Fiber FISH has been used for high-resolution gene mapping, and for direct visualization of gene duplication and chromosome breakpoints involved in translocations.

Color Banding

This technique is also called cross-species FISH (Rx FISH) because it utilizes DNA obtained from flow-sorted gibbon chromosomes by PCR amplification.[11] The genome of gibbons has a high degree of homology with human DNA but with extensively rearranged chromosomes. When hybridized with a set of gibbon DNA probes labeled with a combination of FITC, Cy3, and Cy5, human metaphase chromosomes show a distinctive color banding pattern. A high-resolution multicolor banding can also be achieved by using the microdissection-based probes.[12]

Multitelomere FISH

The technique of multitelomere FISH utilizes a device containing 41 subtelomeric probes for all 24 different chromosomes (not including the short arms of acrocentrics).[13] The probes for the short arms and the long arms are dual-labeled with a green and a red fluorochrome, respectively. This allows the detection of submicroscopic deletions or translocations in all subtelomeric regions with a single hybridization.

Simultaneous Immunophenotyping and FISH

This is a simultaneous analysis of cell surface immunologic markers and interphase FISH. The strategy of combining immunophenotyping with FISH enables correlation of chromosome aberrations of interest with cell lineage and differentiation stages of tumor cells, and therefore provides a useful tool for studies of leukemia and lymphomas.[14]

APPLICATIONS

Interphase FISH for Prenatal Diagnosis

Aneuploidies of chromosomes 13, 18, 21, X, and Y account for about 95% of the chromosomal aberrations causing live-born birth defects. The currently used AneuVysion assay kit (Vysis, Downers Grove, IL) includes two sets of multicolor probe mixtures, one for chromosomes 13 and 21, and the other for chromosomes 18, X, and Y. The standardized probes and protocols have been proven to be accurate and very sensitive for prenatal diagnosis of the most common aneuploidies. This technique is particularly valuable for high-risk pregnancies, as indicated by ultrasonography or maternal serum screening.[15]

Prenatal Diagnosis Using Maternal Blood

Fetal nucleated red blood cells passing into the maternal circulation during pregnancy provide a cell source for noninvasive prenatal genetic diagnosis. Analysis of fetal cells by FISH requires relatively pure samples of fetal cells isolated from maternal blood.[16] Many methods including density gradient centrifugation, magnetic activated cell sorting, fetal cell culture, and immunocytochemical staining have been developed for the isolation, enrichment, and identification of fetal cells. An approach of combined cell sorting, immunophenotyping, and FISH appears to improve the sensitivity and specificity of the methods, and thus offers new promise to the future of noninvasive prenatal genetic testing.

Preimplantation Diagnosis of the Common Aneuploidies

A large proportion of patients undergoing in vitro fertilization (IVF) are at the age of 35 years. It was estimated in this group that about 50% of embryos are chromosomally abnormal with aneuploidy being the major contributor. The aneuploidies can be detected by FISH analysis on the first and/or second polar bodies removed from oocytes following their maturation and fertilization. DNA probes for chromosomes 13, 18, and 21 have been used most commonly for FISH studies on polar bodies. Preimplantation diagnosis of aneuploidies

has provided an accurate and reliable approach for the prevention of age-related aneuploidies in IVF patients with an advanced maternal age.[17] Selecting embryos with a normal chromosome complement can also improve the implantation rate in patients with advanced age and in carriers of an altered karyotype.

Studies of Mosaicism

Constitutional mosaicism is the result of postfertilization mitotic error, i.e., a somatic event. Two types of mosaicism, i.e., meiotic vs. somatic, have been defined by molecular studies in determining the origin of the extra chromosome in the trisomic cell line. While meiotic mosaicism refers to the occurrence of a mitotic error producing a diploid cell line in a trisomic conception, somatic mosaicism means a trisomic cell line occurred in a conception that was initially diploid. A generalized mosaicism involves all cell lineages of the conceptus including both the placenta and the embryonic/fetal tissues. A mosaicism occurring only in the placenta is called confined placenta mosaicism. Studies using FISH, CGH, and other molecular techniques have facilitated our understanding of the biological and clinical significance of chromosomal mosaicism in early embryonic/fetal development.[18]

Diagnosis of Microdeletion Syndromes

More than 30 microdeletion syndromes have been described in the past two decades.[19] 22q11.2 deletion, Williams, and Prader-Willi/Angelman are the most common microdeletion syndromes. These syndromes are usually caused by a deletion of a 2- to 4-Mb DNA sequence. The overall incidence of microdeletion syndromes is likely in the range of 1/1000–2000 newborns. FISH using probes for the genes involved in the deletions is necessary for diagnosis of these syndromes. Studies of microdeletion syndromes have led to the understanding of uniparental disomy and genomic imprinting. A combined diagnostic approach has been used for Prader-Willi and Angelman syndromes, i.e., conventional karyotyping to exclude structural abnormalities, FISH to detect microdeletion, and DNA testing for uniparental disomy and mutation.[20]

Detection of Subtelomeric Aberrations in Unexplained Mental Retardation

Genomic alterations in the subtelomeric regions appear to be an important cause of developmental disabilities. In recent studies, subtelomeric aberrations have been detected in 4–6% of the patients with unexplained mental retardation and dysmorphic features or multiple malformations.[21] The technique of multitelomere FISH is considered to be a valuable tool for a definitive diagnosis for such patients.

Identification of Structural Chromosomal Abnormalities

The incidence of constitutional structural abnormalities is approximately 1/200 at birth when chromosomes are analyzed at the level of resolution of 400 bands. Unbalanced de novo abnormalities are present in 1/1000 live birth children, and FISH analysis is necessary for most of these abnormalities.[22] Numerous acquired aberrations leading to gains or losses of chromosomal material have been described in human cancer. It is important to know whether or not a particular chromosomal region or a particular gene is involved in a chromosomal aberration so that a correct clinical diagnosis can be made. Chromosome painting, microdissection, SKY, M-FISH, CGH, and color banding have all been utilized in the studies of structural abnormalities in conjunction with G-banding analysis.

Detection of Specific Gene Rearrangements in Cancer

Over 100 recurrent chromosomal translocations have been identified in human malignant disorders, and many of these translocations involve specific gene rearrangements. The identification of a specific gene rearrangement is not only diagnostic but also important for determining a therapy plan, monitoring treatment, and predicting prognosis. Interphase FISH is highly sensitive in detecting specific gene rearrangements in leukemia and lymphoma, and has shown many advantages over the standard PCR method. Specific gene rearrangements in tumors can be detected by dual color interphase FISH in paraffin-embedded tumor tissues.[23]

Analysis of Gains and Losses of Chromosomal Regions in Tumor

With the interphase FISH approach, chromosomal aneuploidies can be detected in virtually any given tissue or cell source such as touch preparations, sections of frozen tumor, and paraffin-embedded tissue. Similarly, almost all types of clinical specimens can be used for CGH studies of tumors. Many reports have shown gains or losses of

individual chromosomes or chromosome regions correlating with particular tumors, different stages of the tumor, and the prognosis of patients. These studies have yielded extremely important information for our understanding of the biological behavior of tumors.

Detection of Gene Deletion and Amplifications in Tumor Cells

Deletion of tumor suppressor genes such as p53 and RB-1 and amplification of oncogenes such as N-*myc*, C-*myc*, and HER-2/neu can be detected by FISH or CGH studies of tumor tissues. FISH has advantages over Southern blot analysis in terms of speed, technical simplicity, ability to discern heterogeneous gene amplification among tumor cells in the same specimen, and capacity to determine the source of the amplified gene signals. Amplification of C-*myc* has been detected by FISH in many different types of tumors, including medulloblastoma, malignant melanoma, lung cancer, nasopharyngeal carcinoma, ovarian cancer, and prostate cancer. Testing of the HER-2/neu gene in breast cancer has become very important for patient management because of its association with an aggressive disease that can be successfully treated with Herceptin. A combined immunohistochemistry and FISH approach has made the test more sensitive and cost-effective.[24]

CONCLUSION

FISH has been considered a highly accurate test for the diagnosis of microdeletions and for the identification of unknown material in the genome. Using interphase FISH, genomic alterations can be studied in virtually all types of human tissues at any stage of cell division, without the need of cell culture and chromosome preparation. FISH techniques have served as an indispensable diagnostic tool in many areas of medical practice, including medical genetics, maternal–fetal medicine, pediatrics, reproductive medicine, pathology, hematology, oncology, and psychiatrics.

FISH—Banding Methods and Clinical Applications

F

Thomas Liehr
Institut für Humangenetik und Anthropologie der FSU Jena, Jena, Germany

INTRODUCTION

Since their establishment in routine cytogenetics in the mid 1990s, multicolor fluorescence in situ hybridization (FISH) approaches have become indispensable for the identification and description of chromosomal rearrangements. The subsequent exact characterization of chromosomal breakpoints is of superior clinical impact and is the requisite condition for further molecular investigations aimed at the identification of disease-related genes. Thus, various approaches for a differentiation of chromosomal subbands based on multiplex FISH (M-FISH) assays were established. Here an overview is presented on available M-FISH banding methods including their advantages, limitations, and possible applications.

DEFINITION OF FISH BANDING METHODS

Although the G-bands by trypsin using Giemsa (GTG) banding technique is still the starting point of all (molecular) cytogenetic techniques, its technical restrictions are well-known (e.g., only chromosome morphology combined with a black and white banding pattern can be evaluated; for further details, see Ref. [1]). Nonetheless, a quick and cheap overview on eventual changes within the human whole genome can be achieved by that cytogenetic banding approach.

M-FISH methods using all 24 human whole chromosome painting probes simultaneously—such as M-FISH, spectral karyotyping (SKY), combined ratio labeling FISH (COBRA-FISH), and others (reviewed in Refs. [2-4])—reach their limits in the identification of intrachromosomal rearrangements (such as small interstitial deletions, duplications, and inversions without change of the centromeric index) and when exact characterization of breakpoints is required.

These limitations were overcome by the development of new FISH banding methods during the last decade.

FISH banding methods are defined as ''any kind of FISH technique, which provides the possibility to characterize simultaneously several chromosomal subregions smaller than a chromosome arm (excluding the short arms of the acrocentric chromosomes).''[5] In contrast to the standard cytogenetic chromosome banding techniques, giving a protein-related banding pattern, the FISH banding techniques are DNA-mediated.

OVERVIEW ON AVAILABLE FISH BANDING METHODS

Five different FISH banding methods are available at present, which differ in their probe composition as well as in their banding resolution:

1. The cross-species color banding (Rx-FISH) or Harlequin FISH probe set provides the lowest resolution of 80–90 bands per haploid human karyotype and consists of flow-sorted gibbon chromosomes.[6] A set of 110 human–hamster somatic cell hybrids (split into two pools and labeled with two fluorochromes), when hybridized to human chromosomes, leads to about 100 ''bars'' along the genome. This pattern has been called ''somatic cell hybrid-based chromosome bar code.''[7] A combination of the latter and the aforementioned Rx-FISH probe set results in 160-chromosome region-specific DNA-mediated bands in human karyotypes.[7]
2. Spectral color banding (SCAN) was described exemplarily for one chromosome up to the present. Eight microdissection libraries were created along chromosome 10 with the goal to obtain a banding pattern similar to GTG banding at the 300-band level.[8]
3. A chromosome can be characterized as well by a specific signal pattern produced by yeast artificial chromosome (YAC) clones. The first attempts to label each chromosome by subregional DNA probes in different colors were performed by Lichter et al.[9] and Lengauer et al.[10] A YAC-based chromosome bar code was created especially for chromosome 12 but not for the entire human karyotype yet (for review, see Refs. [2] and [3]). A resolution of up to 400 bands can be achieved, depending on the number of the applied probes.

DOI: 10.1081/E-EDGP 120024484

4. The Interspersed PCR multiplex FISH (IPM-FISH) approach[11] has an approximate resolution of 400 bands per haploid karyotype, mainly dependent on chromosome quality. In IPM-FISH, whole chromosome painting probes are used, which are modified by interspersed PCR, leading to a 24-color FISH painting plus an R-band-like pattern.
5. The high-resolution multicolor banding (MCB) technique is based on overlapping microdissection libraries producing fluorescence profiles along the human chromosomes, and was initially described exemplarily for chromosome 5 in 1999.[12] MCB allows the differentiation of chromosome region-specific areas at the band and subband levels at a resolution of 550 bands per haploid karyotype. As the number of pseudocolored bands per chromosome can freely be assigned using the *isis* software (MetaSystems, Altlussheim, Germany), a resolution higher than that of GTG banding of the corresponding chromosome can be achieved (e.g., up to 10 MCB bands for chromosome 22 equal 800 bands per total haploid karyotype).[2] An MCB set of approximately 140 microdissection libraries covering the entire human genome was described in 2002.[13] A DNA-specific MCB pseudocolor banding pattern on normal human chromosomes is depicted in Fig. 1. A YAC/bacterial artificial chromosome (BAC)-based MCB set turned out to be of lower quality.[14] However, a combination of microdissection-based MCB probes sets with locus-specific or breakpoint-specific probes is very promising.[15] Recently, the simultaneous use of all human MCB libraries in one hybridization step for the characterization of complex karyotypes was performed.[16]

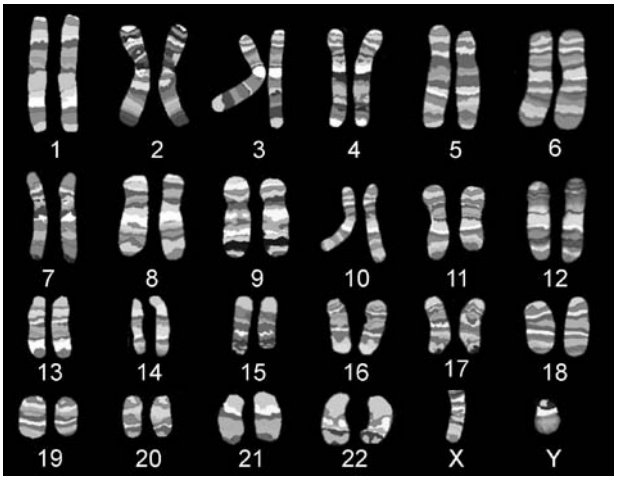

Fig. 1 MCB pseudo-color pattern for all 24 human chromosomes in a ~380-band level. Two homologue autosomes and one gonosome each are presented. The chromosomes depicted here have been put together from 24 different MCB experiments. (*View this art in color at www.dekker.com.*)

ADVANTAGES AND DISADVANTAGES OF FISH BANDING METHODS

FISH banding approaches such as the chromosome bar code technique using YACs, region-specific human–hamster somatic cell hybrids, or nonoverlapping microdissection libraries (SCAN) have, per definition, the disadvantage that unstained and noninformative gaps are left along the chromosome. Such gaps can cause problems, as breakpoints within the unstained gaps cannot exactly be described. Conversely, techniques based on locus-specific probes would theoretically provide the advantage that chromosomal breakpoints could be defined very exactly by the corresponding breakpoint-spanning or flanking clones. However, the coverage of the human genome by nonchimeric clones seems to be presently too low for such a molecular cytogenetic approach (Liehr et al., unpublished data). The IPM-FISH approach, Rx-FISH technique, Rx-FISH combined with somatic cell hybrids, and the MCB method provide the advantage of leaving no noninformative gaps.

Only FISH banding probe sets (1), (4), and (5) are finished for the whole human genome and can be applied to achieve comprehensive information in one single hybridization step. Concerning banding resolution, MCB has the highest and most flexible one. Additionally, according to the question to be studied, it can be chosen if only selected chromosomes or the whole genome shall be hybridized.

APPLICATIONS OF FISH BANDING METHODS

FISH banding methods were used successfully for research in evolution (Rx-FISH; MCB) and radiation biology (MCB), as well as for studies on the nuclear architecture (chromosome bar code; MCB). Moreover, their suitability for diagnostic purposes has been proven in prenatal, postnatal, and tumor cytogenetics (chromosome bar code; Rx-FISH; IPM-FISH, and MCB), indicating that they are an important tool with the potential to partly replace conventional banding techniques in the future (reviewed in Refs. [2], [4], and [5]). Most clinical cases were successfully analyzed by MCB followed by Rx-FISH, whereas the cases studied with the other three approaches are between 0 and <50.

CONCLUSION

The introduction of FISH banding methods was a great step forward for molecular cytogenetic diagnostics. However, none of the mentioned new methods can, for technical reasons, ever be fully informative for itself. The cytogeneticist always has to double check the results obtained in FISH banding with those achieved by other approaches, such as GTG banding, M-FISH or SKY, CGH, or others. Examples for that modus operandi can be found in the literature (e.g., FISH banding and microdissection;[17] FISH banding and CGH;[17–19] FISH banding and region-specific probes;[19–21] FISH banding and locus-specific probes.[5,14,15,22,23] Nevertheless, the goal must be to achieve fully informative cytogenetic results in a minimum of time and with a minimum of FISH experiments. Thus, further developments with respect to probe combinations (such as M-FISH/SKY with FISH banding methods) will be necessary. To perform and evaluate such complex experiments, which then will have to be based on up to nine fluorochromes, further technical developments in microscopy and computer software are necessary.

INTRODUCTION

The development of molecular hybridization techniques such as fluorescence in situ hybridization (FISH) has had a major impact in clinical research. At present, FISH is used routinely to identify recurring chromosomal abnormalities associated with hematological malignant diseases. The high sensitivity of this technique provides valuable tools not only for diagnosis, but also for follow-up and detection of minimal residual disease. The combination of G-banding, FISH, and molecular analyses has provided a powerful approach for classifying these malignant diseases into clinically and biologically relevant subgroups, allowing selecting the appropriate therapy, and monitoring the efficacy of therapeutic regimens. FISH not only provides an excellent aid for the clinical management of patients with cancer, but also constitutes a valuable tool for the characterization of chromosomal rearrangements and has been the first step to further molecular studies. Improvements of the FISH technique, including the development of multicolor FISH to detect several chromosomal changes in a single assay, and FICTION, a technique that permits to correlate phenotypic and genotypic cell features, show that FISH will continue having a major impact on efforts to characterize the genetic changes that give rise to human tumors.

OVERVIEW

In the last 30 years, information provided by cytogenetic analysis has become indispensable for the clinical management of patients with hematological malignancies. Metaphase chromosome analysis of bone marrow (BM) cells enables the entire genome to be screened for evidence of chromosomal changes, which provide the landmarks for the genes involved in leukemogenesis. Up to 80% of patients with acute lymphoblastic leukemia (ALL) and 70% of patients with acute myeloid leukemia (AML) have abnormal karyotypes. A large number of these chromosomal changes are recurrent and have been associated with specific morphological types in both myeloid and lymphoid lineages.[1] As a result, the finding of an abnormal cytogenetic clone may provide the definitive diagnosis. Besides, some chromosomal abnormalities are independent prognostic indicators. Certain karyotypes are associated with a good prognosis, whereas others indicate a poor outcome, leading to the administration of alternative therapies. One illustrative example is AML. In this leukemia, the favorable prognostic subgroup is defined by the presence of leukemic blasts with t(15;17), t(8;21), or inv(16). Unfavorable cases are those with abnormalities involving more than two chromosomes, monosomy 5/5q- or 7/7q-, or rearrangements of the long arm of chromosome 3. The survival rate of patients from this group is less than 20% at 5 years.[2] These patients represent a considerable therapeutic challenge for which no current treatment approach is satisfactory. The patients with a normal karyotype or cytogenetic abnormalities that are not included in these other categories are characterized as having an intermediate risk of relapse.

Conventional cytogenetic analysis is based on the study of metaphase chromosomes by banding techniques. Because it needs tumor metaphases to be analyzed, viable tumor cells have to be obtained from fresh material and cultured. Although highly precise, this technique requires skilled personnel and is time consuming and expensive. These factors have led investigators to seek alternative methods for identifying chromosomal abnormalities. The technique of fluorescence in situ hybridization (FISH) is one such method. At present, FISH is used largely to detect known chromosomal abnormalities using specific DNA probes. The high sensitivity and specificity of FISH, the speed with which the method can be accomplished (virtually overnight), and the ability to provide information from nondividing cells (interphase FISH) have made this molecular cytogenetic technique a powerful tool for genetic analysis.[3] The ability to examine nondividing cells or slowly cycling cells is particularly important in the analysis of some lymphoid neoplasias, in which cytogenetic analysis is often hampered by the small number or absence of mitotic cells. For instance, in chronic lymphocytic leukemia (CLL), G-banding analysis is informative in only a minority of cases, whereas FISH

DOI: 10.1081/E-EDGP 120020729

can detect chromosomal abnormalities in up to 80% of cases.[4] In a short time FISH, such as the G-banding analysis, has become a screening test to identify recurring chromosomal abnormalities associated with hematologic malignant diseases.

THE FISH TECHNIQUE

The FISH technique is based on the ability of single-stranded DNA to anneal to complementary DNA. In the case of FISH, the target DNA is the nuclear DNA of interphase cells or the DNA of metaphase chromosomes that are affixed to a glass microscope slide. FISH can be accomplished with bone marrow or peripheral blood smears, or other fixed tissue, and modifications of FISH methodology have also permitted the analysis of nuclei extracted from paraffin-embedded tissues or frozen sections from solid tumors. The test probe is labeled by enzymatic incorporation of biotin- or digoxigenin-labeled nucleotides, or directly with fluorochromes, to produce fluorescent signals at the place where the target is located within the nucleus. The use of directly labeled probes has simplified the technique eliminating the probe detection steps. These probes have proven to yield strong signals and are suitable for clinical applications. The cellular DNA and labeled probe DNA are denatured by heating in a formamide solution to form single-stranded DNA. A solution containing the probe DNA is applied to the microscope slide, the slide is covered with coverslips and sealed, and hybridization is allowed to occur by overnight incubation at 37–40°C. Thereafter, the unbound probe is removed by extensive washes, and the slides are processed for probe detection.[3] The slides are typically counter-stained with DNA-binding fluorochromes, such as propidium iodide or 4,6-diamidino-2-phenylindole (DAPI). DAPI staining induces a chromosomal banding pattern that is identical to G-banding; thus DAPI is preferred for the analysis of metaphase cells (Fig. 1).

Probes for FISH

Several types of probes can be used to detect chromosomal abnormalities by FISH. These probes are usually divided into three groups: probes that hybridize to unique sequences; probes that hybridize to satellite DNA, tandem DNA repeats that are present at the centromeres of human chromosomes; and probes that hybridize to the whole chromosome, called, for this reason, *painting* probes. An increasing number of locus-specific probes have been established for the diagnosis of leukemias and lymphomas because genetic aberrations in these neoplasias have been shown to predict clinical behavior and outcome better than morphology alone.[5] FISH assays for the detection of diagnostically relevant chromosomal changes in both myeloid and lymphoid neoplasias are commercially available from several companies (http://www.vysis.com/, http://www.cytocell.co.uk/, and http://www.qbiogene. com).

Fluorescence in situ hybridization methods have evolved dramatically during the last years leading to the development of multiple variants. Among those, single- and double-color FISH using satellite and locus-specific probes have special diagnostic applications. These probes can be applied to both metaphase and interphase cells and can detect various types of numerical or structural chromosomal aberrations. For the detection of translocations by conventional interphase FISH (I-FISH), differentially labeled probes flanking or spanning the respective breakpoints can be applied.[5]

To detect chromosomal translocations by I-FISH, there are mainly two types of probes depending on the nature of the involved genes. If both genes involved in a translocation are known, as in the t(9;22)(q34;q11) in chronic myeloid leukemia, differentially labeled probes spanning the respective genes are the most appropriate. The presence of a translocation leads to two fusion signals, one on each of the derivative chromosomes, in

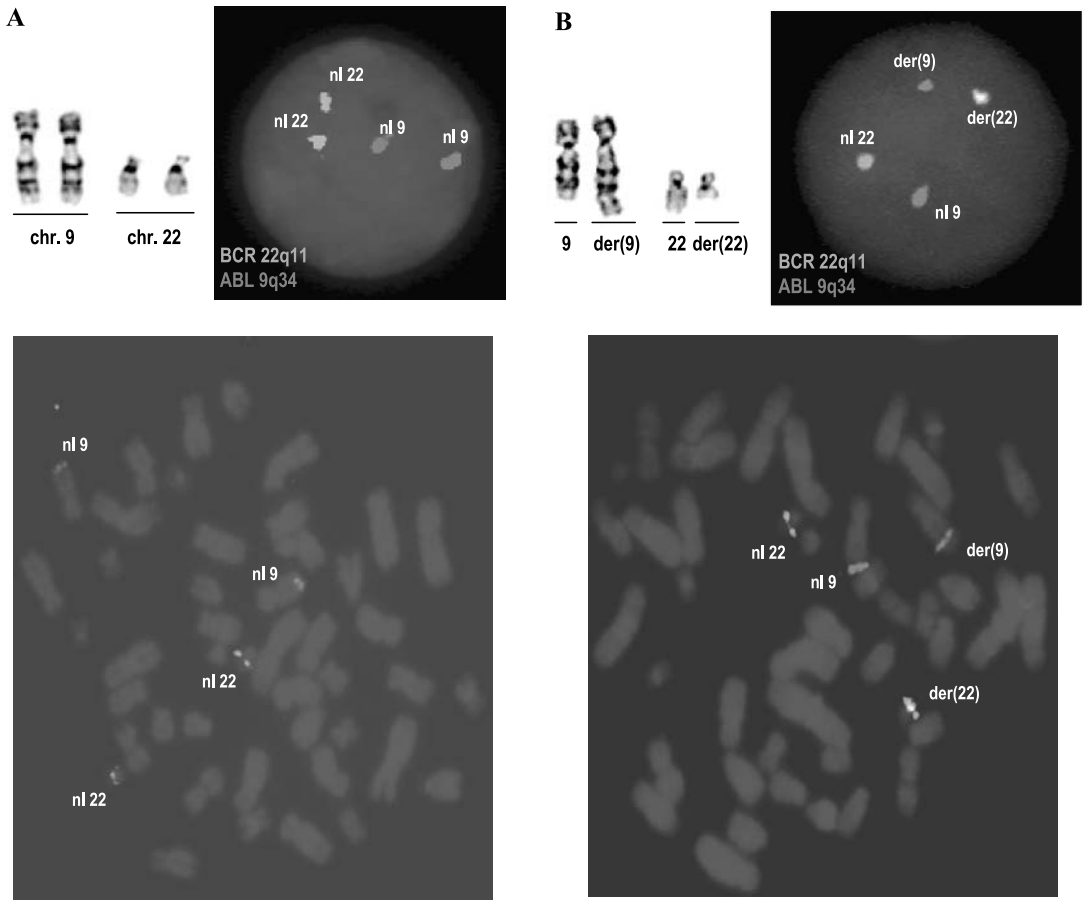

Fig. 2 FISH analysis using the LSI BCR/ABL ES Dual Color Translocation Probe (Vysis, Downer Grove, IL). This probe is a mixture of the LSI ABL probe labeled with SpectrumOrange™ and the LSI BCR probe labeled with SpectrumGreen™. The spanning ABL probe is approximately 650 kb. The SpectrumGreen BCR probe is approximately 300 kb beginning between BCR exons 13 and 14 (M-bcr exons 2 and 3) and extending well beyond the m-bcr region. The probe design allows high sensitivity on the FISH analysis. (A) Partial G-banding karyotype, nucleus, and metaphase from a healthy donor. The nucleus lacking the t(9;22) exhibits a two red, two green signal pattern. (B) Partial G-banding karyotype, nucleus, and metaphase from a patient with CML and a t(9;22)(q32;q11). In the nucleus containing the t(9;22), one green (native BCR), one large red (native ABL), one smaller red (derivative chromosome 9), and one fused red/green signal (derivative chromosome 22) are observed. In some cells, a deletion may occur 5′ at the ABL breakpoint that may reduce the pattern to a single fusion pattern. (*View this art in color at www.dekker.com.*)

addition to the single differentially labeled signals expected from the normal chromosomes (Fig. 2). When a gene locus is rearranged with a wide array of partner genes, the approach would be to use differently labeled probes flanking the recurrent breakpoint regions. In translocations, this would lead to split of the differentially labeled probes, which appear colocalized when the locus of interest is intact.[5] Such assays are, for example, applied for the detection of rearrangements involving the *IGH* locus or the promiscuous gene *MLL*.

For all probes studied, a series of positive and negative controls to establish scoring criteria and calculate the diagnostic cutoff should be established. For I-FISH probes, it is accepted that the diagnostic cutoff should be calculated in at least five healthy donors. For the signal patterns of probes leading to double split and double fusion in case of translocation, the false positive rate is virtually zero.[5]

CLINICAL APPLICATIONS

Fluorescence in situ hybridization techniques have altered the procedures used in many laboratories and promise to have a more substantial impact in the future.[6] FISH is being used increasingly, providing a means of examining the karyotypic pattern of human tumors to the many institutions that do not have access to cytogenetic

Table 1 Applications of fluorescence in situ hybridization

Analysis of tumors
- Detection of numerical and structural chromosomal abnormalities.
- Identification of marker chromosomes (rearranged chromosomes of uncertain origin).
- Detection of early relapse or minimal residual disease.
- Monitoring the effects of therapy.
- Identification of the origin of bone marrow cells following stem cell transplantation.
- Examination of the karyotypic pattern of nondividing or interphase cells.
- Identification of the lineage of neoplastic cells.

Applications in research
- Molecular analysis of chromosomal abnormalities in human tumors.
- Chromosomal localization of genes and DNA sequences.
- Preparation of cytogenetic maps (including determining the order of and distance between sequences).
- Detection of amplified genes.
- Examination of the organization of DNA/chromosomes in interphase nuclei.

laboratory services. A summary of the applications of FISH following Le Beau[3] is shown in Table 1. The application of FISH to the analysis of leukemia samples has improved the conventional cytogenetic analysis. FISH analysis provides more sensitivity and, in some cases, allows the detection of chromosomal abnormalities in samples that appeared to be normal by G-banding. FISH is most powerful when the analysis is targeted toward those abnormalities that are known to be associated with a particular disease. Cytogenetic analysis should be performed at diagnosis because it is important to obtain an overview of the chromosomal abnormalities of the patient at this time. Thereafter, FISH can be used to detect residual disease or early relapse and to assess the efficacy of therapeutic regimens. As mentioned above, FISH allows a large number of cells being analyzed in a short time with high sensitivity.

Detection of Numerical and Structural Chromosomal Abnormalities

In cancer cytogenetics, the application of FISH has resulted in the recognition of new recurring abnormalities in well-characterized diseases, such as leukemias and lymphomas, and in tumors that have been less amenable to conventional cytogenetic studies. An illustrative example is the finding of the t(12;21)(p13;q22) as the most common abnormality in childhood B-cell acute lymphoblastic leukemia, occurring in at least 25% of patients.[7] This abnormality was not detected by the analysis of banded chromosomes because the banding pattern of the involved chromosome bands and the size of the translocated material were so similar. The identification of this rearrangement has important prognostic and therapeutic implications as the translocation has been associated with a favorable clinical outcome.

Fluorescence in situ hybridization is also a sensitive and accurate means of detecting gene loss or deletion and how it has been demonstrated in the diagnosis of microdeletion syndromes. In CLL, genetic studies have identified recurring unbalanced abnormalities with prognostic significance, and FISH has become a diagnostic test to direct and monitor the treatment. Deletions of 13q14 as the sole genetic abnormality identify a group of patients with good prognosis, whereas deletions of 11q23 or 17p13 are important independent predictors of disease progression and survival.[4] However, in patients with multiple myeloma, the presence of chromosome 13 deletions has an adverse prognostic role.[8]

Fluorescence in situ hybridization has also been used to define the commonly deleted segment in recurring deletions, such as the deletions of chromosome 5 that are observed in myeloid leukemias.[9] By using FISH, several probes that fall within the critical region identified can be used to detect the deletions in interphase cells from BM samples from patients with AML, as well as to identify a putative tumor suppressor gene within the commonly deleted segment.

Monitor the Effects of Therapy and Detect Minimal Residual Disease

Posttreatment samples represent a substantial number of all cases analyzed by most clinical cancer cytogenetics laboratories. The detection of chromosomal rearrangements not only provides a diagnostic aid, but also allows the tumor clone to be quantified during follow-up, and for this, FISH provides a rapid means to detect residual leukemia cells. The monitoring should be performed either by G-banding or by FISH. G-banding only provides information about the dividing cells and FISH about both dividing and nondividing cells, so the percentages of malignant cells detected will not be the same. In general, FISH can be used to determine the proportion of normal and abnormal cells in BM and PB and to detect early relapse, although there are some interesting exceptions. An example is the monitoring of patients with chronic myeloid leukemia (CML). Almost all patients with CML carry a t(9;22)(q34;q11) reciprocal translocation that results in the formation of a *BCR-ABL* fusion gene. Treatment with imatinib (formerly STI571) induces major cytogenetic remissions or complete cytogenetic remissions (CCRs) in more than 40% of patients resistant or intolerant to interferon-alpha. Unexpectedly, it has been

reported that targeted therapy of CML with imatinib favors the manifestation of Ph- clonal disorders in some patients.[10] One immediate conclusion is that patients on imatinib should be followed with conventional cytogenetics, even after induction of CCR. Thus, despite the several advantageous features of FISH for the diagnosis of leukemias and other tumors, this technique suffers from technical limitations, being one of the most important that FISH does not provide a global view of the chromosomal aberrations.

The analysis of genetic markers is also routinely used to evaluate the results of BM transplantation. Several groups have shown the applicability of FISH using X- and Y-chromosome-specific probes in detecting host cells in sex-mismatched transplants. This method is particularly useful for samples obtained shortly after transplantation, in which there is no possible cytogenetic analysis because the cell number is very low.

IMPROVEMENTS OF THE FISH TECHNIQUE

A number of recent developments have led to improvements in FISH technology. These include the development of several multicolor fluorescence techniques as well as comparative genomic hybridization (CGH), an approach that allows tumor genomes to be tested for the presence of chromosomal unbalances without the need of metaphases and only requires small numbers of tumor cells to prepare DNA.[11]

Multicolor FISH and SKY

One of the earliest limitations of FISH was the inability to distinguish more than one or two target sequences because of the limited number of fluorochromes available. The introduction of multicolor FISH (M-FISH) and spectral karyotype (SKY) allowed detecting chromosomal abnormalities in individuals with constitutional abnormalities and in tumor samples.[12–14] Simple and complex translocations and relatively large deletions are identified with ease. However, there are some limitations of karyotyping by multiplex FISH of painting probes. This technique is not useful in the detection of paracentric inversions, some pericentric inversions, insertions involving a single chromosome arm, small duplications, and small deletions. Some of the limitations mentioned above can be addressed by using FISH probes. Therefore multiplex FISH is strongest when used in a complementary manner with both conventional cytogenetic and FISH analysis.[15]

Several studies using SKY have shown its power in resolving the full spectrum of chromosome abnormalities in tumors, especially in complex karyotypes, as well as documenting new recurring rearrangements in lymphoproliferative disorders.[16] However, SKY does not seem to be the election choice to detect hidden aberrations in normal karyotypes because only a low percentage of chromosomal abnormalities were detected by this technique. These results, and the fact that this is a laborious and expensive technique, suggest that SKY is not likely to have a clinical impact for the study of normal G-banding cases.

FICTION

An interesting approach that will have a high impact is to combine FISH with morphologic or immunohistochemical assays to examine the cytogenetic pattern of specific cell populations. This is possible because FISH does not require the destruction of the cell structure and tissue morphology. In the future, even more important than I-FISH will be a technique called fluorescence immunophenotyping and interphase cytogenetics as a tool for investigation of neoplasms (FICTION). This method allows the detection of genetic aberrations in immunologically characterized cell populations, even if they present a minority in the tissue studied.[17] Using this approach, the sensitivity of interphase FISH can be even enhanced because only certain cell subpopulations are

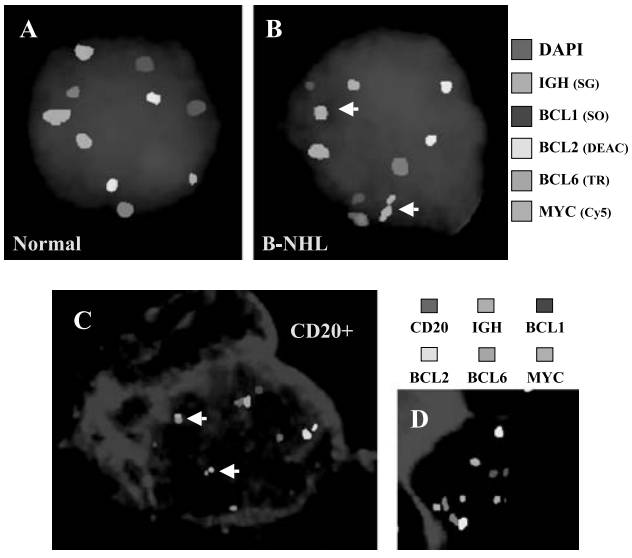

Fig. 3 Multicolor locus-specific assay for the detection of aberrations in NHL. (A) Interphase nucleus of a healthy donor. (B) Interphase nucleus of a patient with NHL with a IGH-MYC fusion due to t(8;14)(q24;q32). (C) M-FICTION assay in the same patient with NHL identified that the translocation was exclusively in the CD20+ B cells. (*View this art in color at www.dekker.com.*)

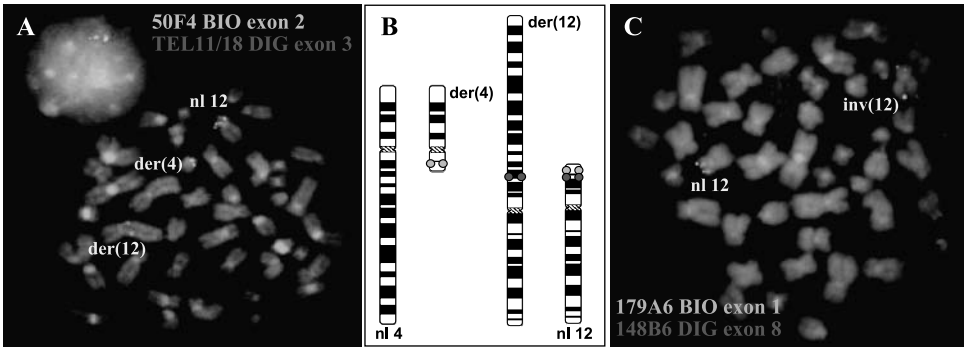

Fig. 4 Examples of FISH analysis of patients with 12p13 rearrangements showing that the gene *ETV6* is involved. (A) Patient with AML-M2 and t(4;12)(q12;p13). The red and green signals both label the normal 12p, whereas the green signal representing the telomeric probe is translocated to the der(4) and the red centromeric probe labels the der(12) chromosome. (B) Simplified representation of this case. (C) Patient with AML-M2 and inv(12)(p13q24). The red and green signals are together on the normal 12p and they are separated on the inv(12) with exon 8 remaining on 12p and exon 1 labeling 12q. (*View this art in color at www.dekker.com.*)

targeted (Fig. 3). The diagnostic importance of FICTION in leukemias and related neoplasms might take significant advantage from the achievements of high-throughput expression studies using, for example, CHIP technology, which aim to identify mRNAs and proteins differentially expressed in biologic and prognostic subgroups of hematological malignancies. By FICTION, the genetic aberrations and the discriminating proteins identified in expression studies could be detected simultaneously on a single-cell level.[17] Thus FICTION could allow a simultaneous and highly sensitive determination, and even quantification, of diagnostic and prognostic changes in leukemias and related disorders at both DNA and protein level.

FISH and Research

The Human Genome Project has stimulated other exciting applications of FISH and multicolor FISH, providing information about sequence-tagged clones placed on NCBI contigs. The BAC Resource Consortium has been working in connecting the cytogenetic and sequence maps of the human genome. This integration has been accomplished by FISH-mapping bacterial artificial chromosome (BAC) clones that contain one or more unique sequence tags. The sequence tags allow each BAC to be positioned on the emerging draft sequence of the human genome. More than 8000 clones have been mapped to date, resulting in at least one clone on average per megabase (Mb) for 23 of the 24 human chromosomes. The addition of these landmarks to the draft genome sequence has aided in the detection and molecular characterization of chromosome abnormalities that cause human disease. Each clone is available as single-colony purified bacterial stock through one of three distributors: BACPAC resources (CHORI) (http://www.chori.org/bacpac), Research Genetics (http://www.resgen.com/resources/index.php3), and the Sanger Center (http://www.sanger.ac.uk/Teams/Team63/CloneRequest).

In several studies, FISH is used in conjunction with G-banding for the accurate location of chromosomal breakpoints, which, in many instances, represents a first step toward the identification of novel tumor-related genes.[18,19] The FISH technique, together with molecular methods, has permitted the cloning of novel oncogenes involved in the pathogenesis of leukemias and lymphomas (Fig. 4). Besides, the subsequent establishment of FISH assays screening the chromosomal abnormalities in the regions of interest has revealed additional cases harboring the same or variant changes.

CONCLUSION

In conclusion, although not fully explored yet, molecular cytogenetic analysis is an invaluable tool in the clinical management of patients with hematological malignancies. Conventional cytogenetic and FISH analysis should be used in a complementary way. With the increasing number of new developments in FISH and molecular biology, it is important to understand the most appropriate techniques to apply to an individual case. RT-PCR offers an alternative to cytogenetics when the presence of the fusion gene is the only indicator required, but, in most cases, G-banding and FISH are the appropriate choice at diagnosis and provide additional important information in the follow-up of the patients. The challenge for the future is to bring these interests together.[15] The development of CHIP technology for a DNA leukemia-specific screening test may eventually replace routine cytogenetics and

molecular screening as we know them today, but until then, cytogenetic analysis remains imperative.[1] The search continues for new recurring chromosomal abnormalities with prognostic significance and the genetic changes associated with them. This is essential to increase further the understanding of the molecular mechanisms of leukemogenesis.

ACKNOWLEDGMENTS

We thank Dr. Martin-Subero (Institute of Human Genetics, University Hospital Kiel, Germany) for providing the FICTION illustrations.

FISH—Centromere-Specific Multicolor FISH

Thomas Liehr
Institut für Humangenetik und Anthropologie der FSU Jena, Jena, Germany

INTRODUCTION

It is nearly impossible to determine the origin of small supernumerary marker chromosomes (SMCs) by routine cytogenetics. However, fluorescence in situ hybridization (FISH) methods are highly suited for that purpose. Twenty-four-color FISH approaches using whole chromosome painting probes can be used successfully for the determination of such markers' chromosomal origin if the SMC is larger than 17p. Therefore smaller SMCs found in clinical cytogenetics in 0.01–0.05% of cases often could not be characterized in the past. The one-step characterization of small SMCs became possible by recently established methods such as centromere-specific multicolor FISH (cenM-FISH) and related probe sets.

SMALL SMCs

In about 50% of cases with small SMCs, the derivatives are known to originate from chromosome 15.[1] Among the remaining cases, there is: 1) a great variation in chromosomal and parental origin; 2) a possibility of genomic imprinting effects; and 3) homozygosity of autosomal recessively inherited mutations in uniparental isodisomy.[1,2] As great dissimilarities in their clinical outcomes are reported, too, the characterization of prenatally detected—particularly de novo—SMCs is of significant interest for more appropriate medical care and genetic counseling. Characterization of one or more SMCs in a patient should be followed by testing for uniparental disomy (UPD), as UPD can cause clinical signs and symptoms, as well.[3–5]

CENTROMERE-SPECIFIC FISH APPROACHES

To characterize an SMC, whole chromosome painting FISH approaches such as multiplex FISH (M-FISH) or spectral karyotyping (SKY) (overview in Refs. [6] and [7]) are well suited as long as the marker is larger than the short arm of chromosome 17. If it is smaller and including only small chromosome fragments with no euchromatin or nearly no euchromatin, then often no result may be obtained (e.g., Ref. [8]).

For the rapid characterization of such small SMCs, a multicolor FISH technique was established, allowing the unambiguous one-step identification of all human centromeric regions, excluding nos. 13 and 21. The so-called cenM-FISH[9] (Fig. 1) is based on all available centromere-specific DNA probes, labeled in five different fluorochromes. A comparable multicolor FISH, called centromeric multiplex FISH (CM-FISH) approach, was published in parallel.[10]

SMCs are initially detected during GTG banding analysis and can be characterized for the presence of an acrocentric chromosome-derived short arm by nucleolus organizing region (NOR) staining. According to the NOR staining result (NOR-negative or NOR-positive), the origin of SMCs can be determined by application of all human centromeres in one experiment (i.e., cenM-FISH,[9]) or by the acrocentric centromere-specific multicolor FISH (acro-cenM-FISH) probe set,[11] respectively. The latter consists of a probe specific for the acrocentric human p-arms, a NOR-specific probe, a probe specific for Yq12, and all centromere-specific probes for 13/21, 14/22, 15, and 22.[11] These two approaches were successfully applied in about 100 cases with SMCs up to present[9,12–15] (SMC-homepage: http://mti-n.mti.uni-jena.de/~huwww/MOL_ZYTO/sSMC.htm).

In general, neocentromeric SMCs are not stained by any of the two aforementioned approaches; in this case, other techniques for their characterization, such as M-FISH (overview in Refs. [6] and [7]), microdissection of SMCs (e.g., Ref. [16]), or micro-CGH,[16] have to be performed. About 60 cases with neocentromeres are reported in the literature (for review, see Ref. [17]).
