After determination of the origin of a small SMC with centromeric DNA, the most important question to address is if there is euchromatic material of the corresponding chromosome on it, or not. This question for partial trisomy can be studied by hybridizing whole chromosome painting or chromosome arm-specific probes (e.g., Ref. [8]). Another possibility is the use of probes, which are able to subclassify chromosomal regions such as multicolor banding (MCB) (e.g., Ref. [16]; Fig. 2). Recently, a probe set specific for the pericentric region of all human

DOI: 10.1081/E-EDGP 120020741

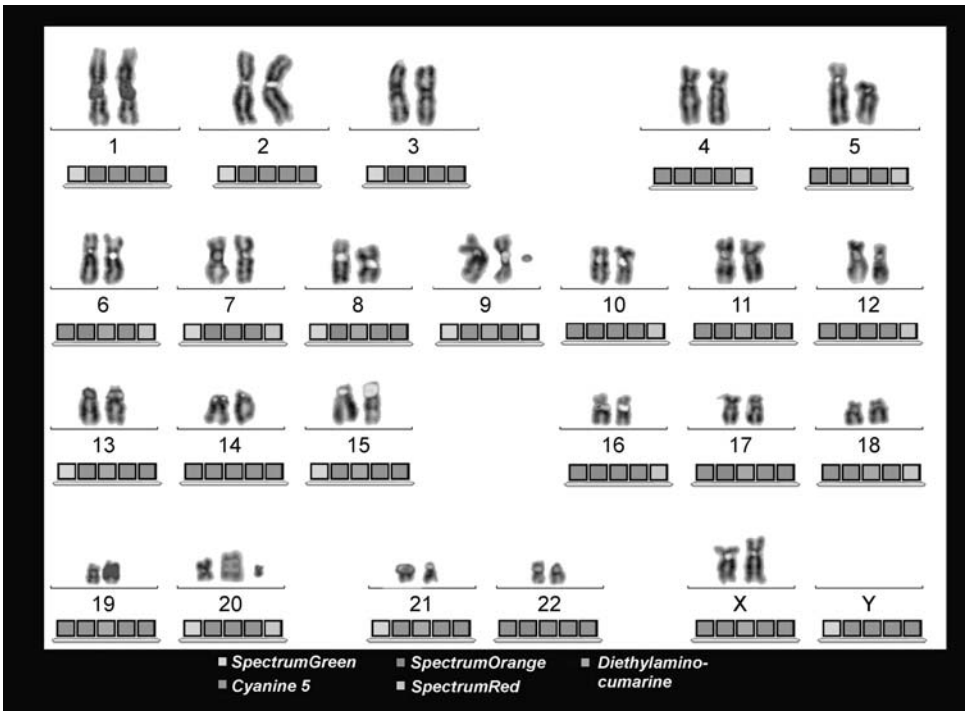

Fig. 1 CenM-FISH result of a case with two small SMCs. CenM-FISH clearly revealed that one SMC was a min(9) and one was a min(20). (*View this art in color at www.dekker.com.*)

chromosomes, the centromere-near multicolor FISH (subcenM-FISH) technique, was introduced to study this question.[18] A chromosome-specific subcenM-FISH probe set consists of a centromere-specific satellite probe, one centromere-near locus-specific probe in the long arm and the short arm (excluding the acrocentric chromosomes), and chromosome arm-specific probes.

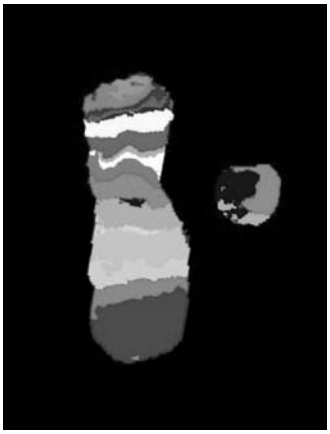

Fig. 2 MCB result of an SMC derived from the X chromosome, which turned out to be a r(X)(p11.21q13.1). (*View this art in color at www.dekker.com.*)

EXCLUSION OF UPD

Different mechanisms for the formation of small SMCs were proposed: trisomic rescue, monosomic rescue, postfertilization errors, and gamete complementation. In addition, speculations that SMCs are due to a transfection of a chromosome derived from a superfluous haploid pronucleus into the zygote are discussed.[19] UPD was reported for the majority of human chromosomes.[4,5] Therefore, in case of identification and characterization of small SMCs, an exclusion of UPD possibly present in the two normal sister chromosomes by molecular genetic methods is reasonable (e.g., Refs. [12] and [15]).

CONCLUSION

In summary, because of the new available molecular cytogenetic approaches, nowadays the detection of a small SMC does not stop after GTG banding, NOR staining, and exclusion of a chromosome 15 origin. The small SMCs can be exactly described after (acro)cenM-FISH or MCB, subcenM-FISH provides information on additional euchromatin, and molecular genetics uncovers eventually present UPD. Thus, a correlation of small SMC morphology and clinics will soon be available, which will be extremely helpful in genetic counseling.

FISH—Clinical Applications of 24-Color FISH

F

Adewale Adeyinka
Syed M. Jalal

INTRODUCTION

Identification of markers, derivative chromosomes, and analysis of complex karyotypes both for constitutional and acquired chromosome disorders is a labor- and time-intensive effort in a clinical cytogenetics laboratory. 24-Color FISH is an effective and labor-efficient screening method for the entire genome when prior knowledge of the origin of a particular chromosome aberration is not available. This, coupled with its generally high level of accuracy, has made it an important tool in the analyses of prenatal and constitutional cases as well as hematological malignancies and solid tumors.

APPLICATIONS OF 24-COLOR FISH

Multicolor FISH (fluorescent in situ hybridization or 24-color FISH) is a molecular cytogenetic technique that uses fluorescent, combinatorially labeled, chromosome-specific DNA sequences to ''paint'' chromosomes to differentiate and classify nonhomologous pairs[1,2] (Fig. 1). This technique has been successfully applied to human chromosomes as well as to chromosomes of other mammalian species.[3]

The ability to visualize specific human chromosomes using fluorescent probes has been in existence since the 1980s.[4–6] What started as the application of radioactive nucleic acid probes for labeling chromosomes in the late 1960s[7] has now emerged into the possibility to simultaneously scan all of the 24 (22 autosomes and X, Y chromosomes) human chromosomes in defined fluorescent colors. Five fluorochromes are used to assign a spectral signature to each chromosome by combinatorial labeling of one to three fluorochromes for each chromosome using fluorochrome-specific filters and computer software.[1,2] This technique at different points in time has been given different names, e.g., 24-color FISH and Multifluor FISH (M-FISH), but 24-color FISH may be more appropriate. Similar to M-FISH is spectral karyotyping (SKY), another multicolor technique that employs combinatorial labeling but uses, instead of filters, an interferometer to measure emission spectra specific for each chromosome.[1] The details of methods are provided elsewhere[8–10] and are published in this encyclopedia. Since its inception in 1996, 24-color FISH has become an important tool in clinical cytogenetics and has found a wide application in research as well.

Congenital Disorders and Prenatal Diagnosis

Chromosome aberrations substantially contribute to the genetic disease burden. For example, the prenatal frequency of de novo supernumerary marker chromosomes is around 1/2500 and it is estimated that de novo structural rearrangements occur with a frequency from 0.70/1000 rising to 2.4/1000 among mentally retarded individuals.[11,12] In addition, deletions associated with defined phenotypic anomalies have been well documented for almost all major chromosome bands.[13] Balanced reciprocal translocations occur with a frequency of 1 in 600. The risk for unbalanced translocation, which are often associated with phenotypic abnormalities, in the progeny of balanced translocation carriers vary widely from 50% to <1%.[14] Complex chromosome rearrangements, although rare, are well documented; some cases involve as many as 10 breakpoints. The use of in situ hybridization and fluorescent DNA probes for the centromeres, locus-specific probes, and whole chromosome paint probes has facilitated the description of markers, derivative chromosomes, and complex karyotypes in much greater detail for prenatal and postnatal tissues. However, in certain situations when there is no strong clinical evidence pointing to the involvement of a particular chromosome, or when a marker of unknown origin or de novo derivative chromosome is encountered, the choice of individual probes to use is often a matter of trial and error. The introduction of 24-color FISH has now largely resolved this dilemma as each nonhomologous chromosome pair can be viewed in a unique color making it possible to identify and properly classify such chromosome aberrations with ease (Fig. 2). Detailed examples of such application of M-FISH are well documented and the literature is still growing.[9,15–18] For example, translocations between the sex chromosomes, which were beyond the resolution of standard G-banding, were identified by M-FISH in a male suspected Klinefelter syndrome.[15]

DOI: 10.1081/E-EDGP 120020740

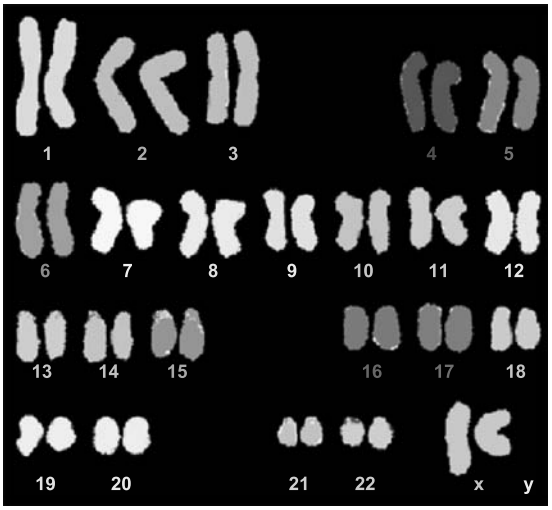

Fig. 1 Normal female karyotype obtained by 24-color FISH analysis. (*View this art in color at www.dekker.com.*)

Cytogenetics is very important for prenatal testing and the use of sensitive methods is important in this field. Another area of reproductive medicine that has created a need for sensitive genetic testing is in vitro fertilization to ensure that viable embryos are selected for this procedure. Twenty-four-color FISH appears to meet these needs. For example, in amniotic fluid specimen for prenatal diagnosis, M-FISH was used to resolve an unbalanced translocation between chromosomes 9 and 15 and subsequently confirmed by whole chromosome painting probes.[15] Also, a supernumerary ring chromosome in another amniotic fluid specimen was identified to be from chromosome 19.[15]

Hematological Malignancies

Over 150 nonrandom and recurrent chromosome abnormalities have been documented for hematological malignancies, including translocations, deletions, duplications, inversions, and aneuploidies. Some of these abnormalities occur in relatively simple karyotypes, whereas others are part of very complex karyotypes that are often beyond the resolution of routine banding techniques. Twenty-four-color FISH analysis has been used to resolve major chromosomal abnormalities in complex karyotypes from hematological disorders and of particular interest is the use of M-FISH to identify the critical anomaly that impacts on diagnosis or prognosis from a complex karyotype in hematological diseases.[17–19] For example, the G-banded karyotype in a male with acute lymphoblastic leukemia was 46,XY,add(1)(q42),add(8),add(14). M-FISH clarified that the add(1) was dup(1), the add(8) was ider(8q)(q10)t(8;22)(q24;q11), and add(14) was der(14)t(3:14). The identification of a t(8;22) was critical to the diagnosis of variant Burkitt's lymphoma involving the translocation of the oncogene c-myc adjacent to the immunoglobulin lambda light chain locus.[9] Poor morphology is another problem often encountered when analyzing chromosomes from bone marrow samples of patients with hematological malignancies. M-FISH is very useful in identifying chromosomes that otherwise would have been classified as markers because of poor morphology. For example, the G-banded karyotype from a bone marrow sample of a 9-year-old boy with unspecified hematological disorder was 45–47,XY,-6,der(9)add(9)(p13)add(9)(q34),-17,-19,-19,-22,+5mar[cp19] with poor morphology. M-FISH detected the cryptic translocation t(12;21)(p13;q21) that was confirmed by locus-specific FISH as TEL-AML1 fusion. This translocation is often missed by standard cytogenetic analysis in children with acute lymphoblastic leukemia (ALL). In addition, M-FISH identified all the remaining markers as der(6), der(9), der(15), der(20), and two normal chromosomes 19.[9]

Solid Tumors

Cytogenetic studies of solid tumors have also benefited from 24-color FISH. Most solid tumors, especially epithelial tumors, are known to be highly aberrant. Numerous marker chromosomes, cryptic translocations, chromosomal insertions, and additions have been properly characterized among the potpourri of aberrations seen in these solid tumors, and it is becoming possible to identify those that may be of pathogenetic importance.[18]

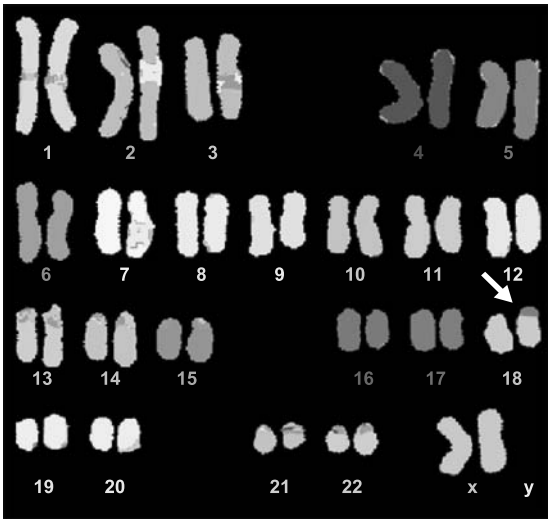

Fig. 2 Identification of a derivative chromosome, der(18)t(17;18) (arrow), using 24-color FISH. Chromosomes 2, 3, 7, and 20 were overlapped by other chromosomes. (*View this art in color at www.dekker.com.*)

CONCLUSION

Twenty-four-color FISH, although comparatively costly and labor-intensive, is an efficient and labor-effective method for scanning the entire genome especially to resolve marker-derivative chromosomes and complex karyotypes. M-FISH should be applied as an adjunct to chromosome-banding methods and other FISH techniques to obtain a comprehensive interpretation of complex and difficult karyotypes.

FISH—Detection of Individual Radiosensitivity

Alma Kuechler
Klinik für Radiologie, Abteilung Strahlentherapie des FSU Jena, Jena, Germany

Thomas Liehr
Institut für Humangenetik und Anthropologie der FSU Jena, Jena, Germany

INTRODUCTION

In radiotherapy, alongside tumor control, the prevention of severe treatment-related side effects is a major concern. Although the majority of radio-oncological patients tolerate a standard treatment protocol, toxic side effects can be detected in 0.2–10% of the cases.[1,2] The latter can be a result of an increased individual radiosensitivity, caused by a combination of exogenous and endogenous factors including genetic reasons. However, most of the exact underlying mechanisms still remain unknown. Only in few cases increased radiosensitivity is a result of an identified single gene mutation, e.g., in ataxia telangiectasia (AT) or Nijmegen breakage syndrome (NBS) patients, OMIM #208900 and #251260,[3] but in the majority, it is supposed to be modulated by a mixture of different genes.[4]

To have a chance to detect a possible overreaction prior to therapy, the availability of a predictive test system has been the aim for some decades. Although different approaches were tested (e.g., clonogenic cell survival,[5] G2-Assay[6]), there is still no reliable routine assay to identify hypersensitive or less sensitive patients to adjust their therapeutic dose. It is known that chromosomal aberrations are: 1) indicators of a previous exposure to irradiation and 2) can be used to estimate radiosensitivity. Previous studies demonstrated that molecular cytogenetic methods are superior to conventional cytogenetic analysis in detection and characterization of aberrations. At this, the frequency of breaks and the occurrence of specific aberration types reflect individual sensitivity to radiation. Especially complex chromosomal aberrations (CCR) were identified as indicators for increased individual radiosensitivity.

AVAILABLE FISH TECHNIQUES

To detect individual radiosensitivity by fluorescence in situ hybridization (FISH), three approaches are presently available: 1) painting of one up to three different chromosomes in one or different colors, 2) painting of all 24 human chromosomes in different colors (24-color FISH), and 3) FISH-based chromosome banding for the detection of intrachromosomal rearrangements.

ONE- TO THREE-COLOR FISH

Fluorescence in situ hybridization applying one up to three whole-chromosome painting (wcp) probes simultaneously was used to detect radiation-induced chromosome instability in peripheral blood lymphocytes and fibroblasts (e.g., Refs. [8,10,12]). However, in the analyses, the used chromosomes are selected by chance—although a random distribution of chromosomal rearrangements along the chromosomes is up to now still discussed controversially (e.g., Refs. [13,14]). To avoid this problem and to obtain an overview of the whole karyotype, 24-color FISH can be applied using a probe mix of the 24 different human wcp probes.[7,11,15,16]

24-COLOR FISH

This method, first described by Speicher et al.[17] and Schröck et al.,[18] allows the simultaneous visualization of all chromosomes within a metaphase in different specific colors. Nearly all chromosomal aberrations (as reciprocal and nonreciprocal translocations, complex rearrangements, ring chromosomes, acentric fragments, dicentric fragments, or insertions) can be detected and defined in more detail.

The 24-color FISH has been used, for example, for studies on normal peripheral blood lymphocytes irradiated in vitro,[11,15] on radiotherapy-induced residual chromosomal damage in peripheral lymphocytes,[7] on bone marrow cells of Chernobyl victims,[15] and for analysis of chromosomal aberrations after irradiation with ionizing alpha particles. The latter was also used for investigations on the formation of CCR.[19]

Our own studies have focused on the analysis of in vitro-induced chromosomal aberrations in NBS and AT homozygote and heterozygote individuals compared with

DOI: 10.1081/E-EDGP 120020735

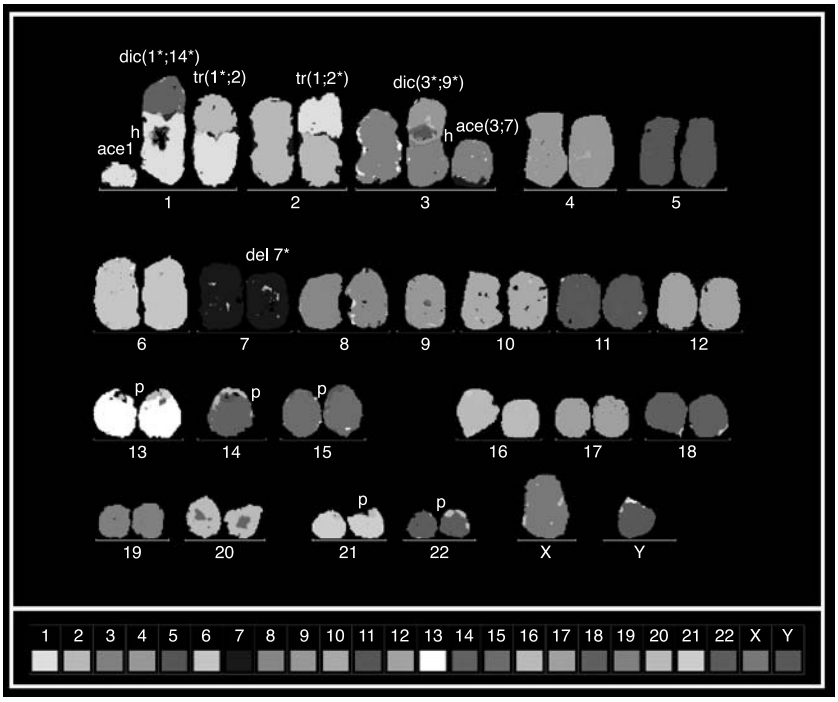

Fig. 1 Example of a 24-color FISH result: karyogram of an NBS-heterozygote person (pseudocolor representation) after in vitro irradiation with 2.0 Gy and scheme of pseudocolors for each individual chromosome. The aberration can be described (nomenclature modified according to the ISCN 1995[25]) as follows: t(1;2),dic(1;14),ace(1),dic(3;9),ace t(3;7),del(7). This result can be summarized as 7 breaks per mitosis. The translocation between chromosomes 3, 7, and 9 forms a complex chromosomal rearrangement. Abbreviations: p = short arms of the acrocentric chromosomes #13, #14, #15, #21, and #22 consisting of repetitive DNA, pseudocolored in a different paint; h = heterochromatic DNA, which is polymorphic and can be present at #1, #9, and #16. (Stars indicate centromere localization.) Images were captured with the ISIS3 digital FISH imaging system (MetaSystems, Altlussheim, Germany) using a PCO VC45 CCD camera (PCO, Kehl, Germany) on an Axioplan 2 microscope (Zeiss, Jena, Germany). (*View this art in color at www.dekker.com.*)

normal reacting controls (Figs. 1 and 2; Ref. 11 and unpublished data). The aim was to demonstrate that a difference in radiosensitivity which was already known between these individuals is also detectable using the 24-color FISH technique. Thus the increased radiosensitivity of NBS and AT patients can serve as a positive control in a predictive assay.

In the following, the criteria used in our own studies are specified to demonstrate that a reliable evaluation requires an experienced cytogeneticist. After the 24-color FISH procedure including hybridization, posthybridization washes, and detection, at least 100 metaphases per irradiation dose and patient/proband have to be acquired. This can be performed filter-based (m-FISH)[17] or spectracube-based (SKY).[18] All captured metaphases have to be karyotyped. For detailed evaluation of each metaphase, it is not enough to rely only on the pseudocolor functions of the used software, but for unambiguous results, one has to check the different fluorochrome channels or hybridization profiles. Then, aberration types and involved chromosomes have to be registered in detail. All occurring aberrations were classified into reciprocal and nonreciprocal translocations, ring chromosomes, acentric fragments, dicentric fragments, inversions, insertions, and complex rearrangements. Translocations, insertions, and complex rearrangements are visible because of a color change along a rearranged chromosome. Dicentrics and ring chromosomes can easily be identified using the inverted DAPI picture. Complex chromosomal rearrangements (CCR) consist, per definition, of at least two chromosomes with three or more breaks.[20]

For further evaluation, the frequency of break events constituting the observed aberrations was estimated as the minimal number of breaks considered to be necessary for producing the aberrations in each metaphase. The total number of break events in each patient/control and irradiation dose was summed up and divided by the number of metaphases analyzed to obtain the average rate of breaks per mitosis (B/M). The radiosensitivity of lymphocytes was expressed as number of radiation-induced B/M and CCR/M after each irradiation dose, subtracted by the 0.0-Gy control value to correct the

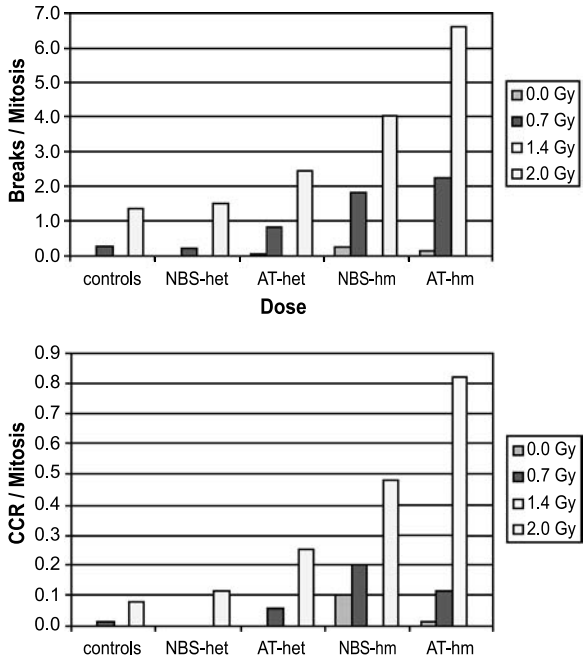

Fig. 2 For the graphic depicted here, four normal controls, two Nijmegen breakage syndrome (NBS), and two ataxia telangiectasia (AT) heterozygotes (NBS-het, AT-het) plus one NBS and one AT homozygote (NBS-hm, AT-hm) were included. The upper diagram shows the average number of breaks per mitosis, while the lower one presents the average number of CCR occurring in each mitosis for each of the five groups. Three different in vitro irradiation doses were analyzed per patient. The applied doses were 0.0, 0.7, and 2.0 Gy; in the AT-hm patient, instead of 2.0 Gy, 1.4 Gy was used. A clear differentiation was possible in both diagrams between normal controls and the homozygote patients, as well as between controls and AT-het. (*View this art in color at www.dekker.com.*)

influence of spontaneous basic aberration frequencies. For further details, see Ref. [11].

The 24-color FISH is a highly informative approach concerning the characterization of radiation-induced chromosomal rearrangements, but is based on a very sophisticated and time-consuming evaluation procedure.

MULTICOLOR BANDING

Fluorescence in situ hybridization methods using all 24 human whole-chromosome painting probes simultaneously reach their limits in identification of intrachromosomal rearrangements (such as small interstitial deletions, duplications, and inversions without change of the centromeric index) and when exact characterization of breakpoints is required. These limitations have been overcome by the development of new FISH-banding methods during the last decade.[21] In the meantime, one of these approaches—the multicolor banding (MCB) technique (or mBAND)[22]—was also used for the analysis of X-ray-induced aberrations.[23,24] However, only a probe set for chromosome 5 was applied, demonstrating that intrachromosomal aberrations are present in a considerable portion in radiation-induced changes.

CONCLUSION

In summary, genetically determined intrinsic radiosensitivity can be detected and quantified by FISH approaches. The 24-color FISH can be used as well as the three-color FISH. FISH is as reliable but more informative than conventional cytogenetic data (e.g., Refs. [8,9]). As stated before, the 24-color FISH approach requires a very sophisticated evaluation. However, the data obtainable by this technique are indispensable to decide whether there exist any hot spots for radiation-induced breakpoints. If so, such hot spots could be characterized in detail by FISH-banding methods,[21] and in the following, locus-specific breakpoint-spanning probes could be applied in the future for quick detection of individual radiosensitivity, possibly even in interphase cytogenetics.

ACKNOWLEDGMENTS

The authors thank Dr. Susann Neubauer (Erlangen, Germany) and Dr. Luitpold Distel (Erlangen, Germany) for their longstanding cooperation. Mareike Dreidax, Annett Johne, Isabell Hartmann, and Monika Ziegler are acknowledged for providing FISH data and/or for skillful technical assistance.

FISH—Human Sperm Cells

Renée H. Martin
University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

Chromosome abnormalities are amazingly common in humans, leading to infertility, pregnancy loss, and birth of children with mental and physical handicaps. Most chromosome abnormalities have their origin during meiosis; thus information on the causes of chromosome abnormalities and factors affecting their frequency is best studied in human gametes. During the past two decades, there has been an explosion of information on the chromosome complement of human spermatozoa. This has been mediated by the advent of two techniques: human sperm karyotyping using the hamster oocyte system and fluorescence in situ hybridization (FISH) analysis. Rudak et al.[1] first reported the use of hamster ova to reactivate human sperm, allowing the analysis of pronuclear chromosomes. Other laboratories followed with the first publications on the frequency and type of chromosome abnormalities in human sperm.[2–5] Human sperm karyotyping, using the hamster system, provides detailed information on each individual chromosome, permitting analysis of both numerical and structural abnormalities. However, there are significant disadvantages: sperm cells must be capable of fertilizing a hamster oocyte; the technique is very difficult, time-consuming, and expensive; and data yield is small. In fact, only 12 laboratories worldwide have had success with this technique despite many efforts. Fluorescence in situ hybridization analysis with chromosome-specific DNA probes provides a faster, cheaper, and easier alternative for detecting numerical abnormalities (aneuploidy) in human sperm. In addition, sperm cells with defects in fertilization ability and/or motility can be assessed using FISH analysis. This review will outline some of the studies that have been performed on human sperm using FISH analysis.

TECHNICAL DESCRIPTION

Our technique for FISH analysis of human sperm cells has been reported in great detail previously.[6]

IMPACT OF FISH ANALYSIS IN DIFFERENT RESEARCH AREAS

Studies on Normal Men

More than 5 million sperm cells from more than 500 normal men have been analyzed by a number of laboratories from around the world.[7] These studies have included the frequency and distribution of aneuploidy in sperm cells, and the effect of donor age, lifestyle factors, and geographical and ethnic factors.

Frequency and Distribution of Aneuploidy

The frequency and distribution of disomy in human sperm cells is of interest to determine the normal baseline values and to determine if all chromosomes have a similar frequency of nondisjunction or if some are particularly predisposed to nondisjunction.[8] The frequencies of disomic sperm for an individual chromosome are considerably different among the studies. For example, for chromosome 21, the lowest disomy frequency was 0.05%[9] and the highest was 0.95%.[10] It is unlikely that these differences arise only from interindividual variation in disomy. Rather, different approaches in the experimental design, different probes, and scoring criteria used are regarded as being responsible (for a review, see Ref. [11]). This makes it essential for each study to have controls analyzed in the same laboratory.

In a composite analysis of the distribution of disomy frequencies in studies on normal men, the mean disomy frequency for autosomes was 0.15% and 0.26% for sex chromosomes.[7] Our laboratory has determined that most autosomes have a similar frequency of nondisjunction, but chromosome 21 and the sex chromosomes have a significantly increased frequency.[8,12] These results corroborate our earlier studies in human sperm karyotypes.[13] This has also been confirmed by other groups.[14,15] Thus we see aneuploidy for all chromosomes, but chromosome 21 and the sex chromosomes appear to be particularly susceptible to nondisjunction during spermatogenesis.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020733

Effect of Donor Age

There have been a number of FISH studies addressing the possibility of a paternal age effect on nondisjunction. The great majority of studies has not found a paternal age effect for autosomes.[16–18] However, most studies have demonstrated a significant increase in the frequency of sex chromosomal aneuploidy with donor age[19–21] with approximately a doubling of disomy frequencies in the oldest donors compared to the youngest donors.

Lifestyle Factors

A small number of studies have addressed the possible effects of lifestyle factors such as smoking, air pollution, and caffeine and alcohol consumption on sperm aneuploidy frequencies. Robbins et al.[22] found a significant association between caffeine and alcohol consumption and increased disomy frequencies for some chromosomes. No significant association was noted for smoking. Two studies found a significant association between smoking and aneuploidy for some chromosomes,[23,24] but it is difficult to rule out combined lifestyle factors because smokers also consume more caffeine and alcohol than nonsmokers. Our laboratory studied over 600,000 sperm cells from heavy smokers, light smokers, and nonsmokers (all nondrinkers of alcohol) and found a significant increase of disomy only for chromosome 13, but not for chromosome 21, X, or Y.[25,26] Perreault et al.[26] studied seasonal air pollution and found an association between high levels of air pollution and YY disomy in nonsmoking men. To date, no consistent and clear association has been discovered between disomy frequency and any type of lifestyle factor. More well-controlled studies will be required to uncover any associations.

Geographical and Ethnic Factors

Two laboratories have studied the frequency of sperm aneuploidy in geographically and ethnically diverse populations using the same experimental conditions, DNA probes, and scoring criteria. We found no difference in disomy frequencies for autosomes or sex chromosomes in nonsmoking, nonalcohol drinking Chinese men compared to Canadian men.[12] However, Rubes et al.[23] detected a significant increase in the frequency of sperm disomy in nonsmoking Czech men compared to Californian men. Thus, further studies on different populations are required to determine if sperm aneuploidy frequencies differ in various groups.

POTENTIAL FUTURE APPLICATIONS

Because FISH analysis is simple and provides data on large sample sizes of sperm cells, it has been suggested as a technique for assessing the effects of potential mutagens on human sperm. We and others have studied cancer patients treated by chemotherapeutic agents and determined that these agents can cause a significant increase in the frequency of sperm chromosome abnormalities, particularly during chemotherapy and up to 2 years following treatment.[27–29]

The effects of pesticides have also been studied, as there is increasing concern about potential adverse consequences to reproduction and fertility. Two studies have not shown any association between pesticide use and sperm aneuploidy.[24,30] A third study did find an increased frequency of YY aneuploidy in pesticide factory workers exposed to higher pesticide concentrations.[31]

A number of infertility clinics have advocated the use of FISH analysis in clinical sperm samples from infertile patients. As mentioned above, infertile men certainly have an increased frequency of chromosome abnormalities in their sperm cells. Furthermore, studies have shown that specific men with an increased frequency of sperm chromosome abnormalities have fathered chromosomally abnormal pregnancies, for example, a man with a frequency of XY disomy 14 times higher than controls fathered a fetus with 47,XXY Klinefelter syndrome,[32] and men with an elevated frequency of disomy 21 sperm fathered children with Down syndrome (trisomy 21), shown to be paternally derived.[14] In addition, a number of studies have demonstrated that men with macrocephalic sperm have a very high frequency of sperm aneuploidy and diploidy.[33,34] Thus the addition of FISH analysis of sperm cells might be a useful investigation in male factor infertility, especially in cases known to have a high risk of abnormalities, such as men heterozygous for translocations or men with macrocephalic sperm cells.

CONCLUSION

Fluorescence in situ hybridization analysis of human sperm cells has been used successfully in many studies: from studies of basic mechanisms of nondisjunction, to studies of infertility and effects of mutagens on the chromosome constitution of human sperm. The technique is simple, rapid, and relatively inexpensive. However, it is important to keep in mind that there are some subjective aspects to counting fluorescent signals and each laboratory must develop stringent scoring criteria for test subjects as well as laboratory-based control donors.

FISH—Q-FISH for Telomere Length Measurement

Predrag Slijepcevic
Brunel University, Middlesex, U.K.

INTRODUCTION

Telomeres are essential structures at chromosome termini required for an accurate segregation of eukaryotic chromosomes. The structure and length of telomeres change after each cell cycle and the nature of this change depends on the cell type. In the case of human primary somatic cells, telomeres gradually shorten after each cell cycle until their structure becomes incompatible with the further progression through the cell cycle, i.e., structurally dysfunctional telomeres activate cellular DNA damage response and can lead to genomic instability. In the case of immortalized human cells or cancer cells, telomere size and structure fluctuate as a result of cell proliferation, but telomeres usually do not shorten because telomerase, an enzyme that synthesizes telomeric sequences, is active in these cells. The importance of telomeres from the clinical perspective is illustrated by at least two major observations. First, there is a correlation between telomere length on one side and either the cell senescence in vitro and possibly in vivo or individual mortality rate on the other side. Second, the enzyme telomerase, which is active in most human cancers, provides cells with the means to indefinitely maintain telomeres and as a result make them immortalized, suggesting that the inhibition of this enzyme could be an effective way to stop cancer cell growth. A major prerequisite for making the above two observations useful in the clinical practice is the capacity to measure telomere length with a high degree of accuracy. At present there are three main methods for telomere length measurement: Southern blot analysis, quantitative fluorescence in situ hybridization (Q-FISH), and flow-FISH. The most informative of these three methods is Q-FISH and this article will describe the principles of Q-FISH and discuss the advantages and disadvantages of Q-FISH in comparison with other methods.

PROBLEMS ASSOCIATED WITH TELOMERE LENGTH MEASUREMENT

The most authoritative recent review on telomere biology and papers describing the key discoveries mentioned above as well as methodological advances are listed in the reference list.[1–6] The classical method for telomere length measurement is based on Southern blot analysis. In a typical protocol, DNA is extracted from a cell sample and the resulting DNA mix is exposed to frequently cutting restriction enzymes, which will produce a series of DNA fragments, and those fragments containing telomeres are called terminal restriction fragments (TRFs). Following gel electrophoresis these fragments are transferred onto a nylon membrane, which is then hybridized with the radioactively labeled telomeric DNA probe. Following autoradiography, telomeres are detected as a smear, the size of which can be measured against appropriate molecular weight markers. This method has some major disadvantages. First, it can only measure the average telomere length and the information about the size of individual telomeres is ignored. Individual telomeres, not the average telomere length, drive genomic instability associated with telomere dysfunction,[7] thus indicating that measuring only the average telomere length may not be appropriate. Second, the presence of degenerate telomeric sequences in subtelomeric regions of chromosomes may interfere with the accuracy of Southern blot-based telomere length measurements, i.e., sequences that do not form part of functional telomeres may also be measured.[8] Third, hybridization efficiency of DNA probes is never 100% because DNA probes used for hybridization and genomic DNA have the same electrical charge and this may cause a charge repulsion between molecules resulting in inefficient hybridization. Therefore, a new method more efficient than Southern blot was required to provide more accurate information about telomere length.

DEVELOPMENT OF Q-FISH

In 1996, Lansdorp and coworkers showed that a modified DNA molecule called peptide nucleic acid (PNA) can be used for quantitative in situ hybridization.[9] The key difference between DNA and PNA is the replacement of the classical phosphate–sugar backbone in DNA by repeating *N*-(2-amynoethyl) glycine units linked by peptide bonds in PNA. Different bases (purines and pyrimidines) are linked to the PNA backbone by methylene carbonyl linkages. Because PNA backbone is not charged, the binding between PNA/DNA strands

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120030864

will be much stronger than between DNA/DNA strands, i.e., there will be no charge repulsion between PNA/DNA strands. Therefore hybridization between telomeric PNA probe and telomeric chromosomal DNA will minimize hybridization problems encountered when hybridizing molecules of the same charge, thus leading to higher hybridization efficiency. When the fluorescently labeled telomeric PNA probe is hybridized with metaphase chromosomes then all telomeres are visualized and by using appropriate software, the fluorescence intensity of each individual telomere can be accurately calculated.[8,9] This is a big advantage in comparison with Southern blot, which can only measure the average telomere length. Finally, because of its higher hybridization efficiency relative to DNA, PNA telomeric probe does not bind to degenerate telomeric sequences in subtelomeric chromosome regions.[8] Therefore all three major problems associated with the classical telomere length measurement based on Southern blot analysis (see above) are eliminated by the new Q-FISH protocol, suggesting that this is the most sensitive method for measuring telomere length.

PRINCIPLES OF Q-FISH

As stated above, Q-FISH requires the use of fluorescently labeled telomeric PNA probes. The most commonly used probe is Cy3-labeled $(CCCTAA)_3$. Following hybridization of this probe with the metaphase chromosome preparations, high stringency washes are performed to eliminate background fluorescence that may interfere with the quantitation of telomere fluorescence. Separate images of metaphase chromosomes and telomeres are then acquired using appropriate image-acquisition software packages and the resulting files can be used for the analysis of telomere fluorescence (Fig. 1). The most common software for the analysis of telomere fluorescence is TFL-TELO developed by Lansdorp's group[10] and this software is available free of charge. The software simply combines images of chromosomes and telomeres, and generates a table with the values of telomere fluorescence for each chromosome, i.e., four telomeres/chromosome. In this software each telomere is assigned a different color and, also, p-arm and q-arm telomeres can easily be distinguished. The final product is the set of data containing 184 individual telomere fluorescence values (46 chromosomes $\times$ 4 telomeres). The files generated by TFL-TELO can be exported to any standard software for statistical analysis. Software packages other than TFL-TELO may be available for Q-FISH on a commercial basis.

To ensure reproducibility of measurements by Q-FISH, it is important to minimize sources of variation associated with digital fluorescence microscopy. The first potential source of variation is the length of exposure time required to acquire optimal images of telomeres. Software packages used for image acquisition usually have two options: auto-exposure and manual exposure. In the case of auto-exposure, the exposure time is determined automatically by the image-acquisition software based on the signal strength. In the case of manual exposure desired fixed-time exposure may be selected. Our experience is that if TFL-TELO is used for telomere fluorescence analysis then the appropriate fixed-time exposure selected

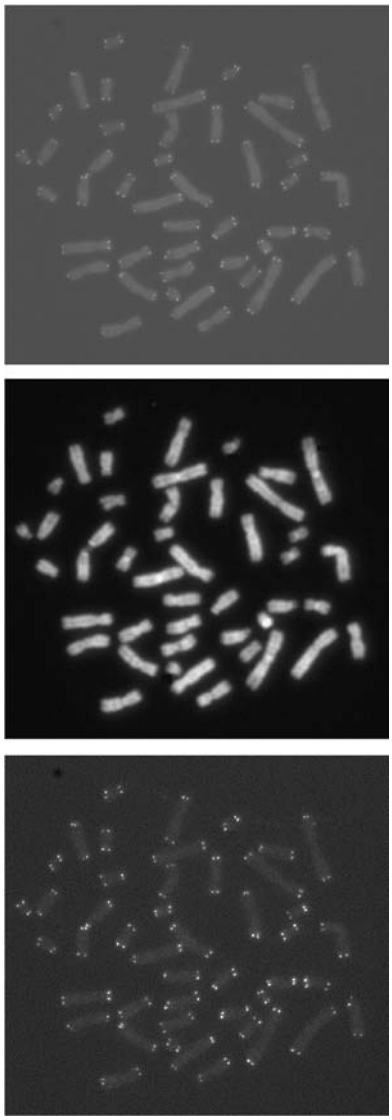

Fig. 1 A human metaphase cell. The top panel shows two-color images in which chromosomes are stained in blue (DAPI) and telomeres in red (Cy3 telomeric probe). The middle and bottom images are separate images of chromosomes and telomeres. (*View this art in color at www.dekker.com.*)

on the basis of trial and error should be used in all experiments. The second source of variation is associated with variability in microscope fluorescence lamp intensity. To avoid inaccuracies due to lamp intensity variations appropriate internal controls must be used. One option is to use fluorescence beads of defined size (i.e., 1 μm) and acquire images of these beads each time a new sample is analyzed. The values of bead fluorescence will then be used to correct the telomere fluorescence intensities of the samples under investigation. In the original Q-FISH protocol another calibration component was used, plasmids containing a defined number of telomeric sequence repeats.[8] This approach allowed for the direct conversion of telomere fluorescence into units of DNA length. Another appropriate internal control is the use of cell lines with known telomere length. In this case multiple images of metaphase chromosomes and telomeres from two cell lines with differing telomere lengths are acquired each time a new sample is analyzed, and these values are then used to generate two telomere fluorescence reference points.[11] The telomere fluorescence of the samples under investigation is then expressed relative to these two reference points.

Numerous studies demonstrated the value of Q-FISH. For example, Q-FISH was instrumental in demonstrating telomere dysfunction in mice lacking the RNA component of telomerase. These mice showed progressive telomere shortening which could only be detected by Q-FISH.[12] In addition, Q-FISH was instrumental in demonstrating 1) the heterogeneity of telomere length in individual human and mouse chromosomes;[8,13] and 2) that the shortest telomeres in the cell, not the average telomere length, drive genomic instability due to telomere dysfunction.[7] Finally, the Q-FISH procedure was recently adapted for telomere fluorescence analysis by flow cytometry and this new protocol was named flow-FISH.[14] Flow-FISH analyses the average telomere fluorescence in interphase cells and the advantage of this technique is that it can identify the average telomere length in a large number of cells with higher accuracy than Southern blot. In addition, flow-FISH is useful in identifying subpopulations of cells with differing telomere lengths, i.e., different subsets of peripheral blood lymphocytes. The most recent modification of flow-FISH is the use of multicolor flow-FISH in which different subsets of lymphocytes are detected by appropriate antibodies which must be attached to fluorochromes different from fluorochromes attached to the telomeric probe.[15] It is important to stress that Southern blot cannot reliably identify subpopulations of cells with differing telomere lengths in a given cell population. Although Q-FISH theoretically can identify subpopulations of cells with differing telomere lengths in a cell population of interest, in reality this technique is limited for this purpose because it relies on the information from only 10 to 15 cells. In contrast, flow-FISH can analyze thousands of cells in a short period of time.

CONCLUSION

Quantitative fluorescence in situ hybridization is the most sensitive method currently available for telomere length measurement. In contrast to the classical telomere length measurement based on Southern blot analysis, Q-FISH 1) identifies telomere length in each individual chromosome; 2) identifies the shortest telomere in the cell; and 3) does not take account of degenerate telomeric sequences present in subtelomeric regions of chromosomes which do not form a functional part of telomeres. The only disadvantage of Q-FISH is that it cannot reliably identify subpopulations of cells with differing telomere lengths and for that purpose it should ideally be combined with flow-FISH.

INTRODUCTION

Analysis of the complex mechanisms that initiate neoplastic changes and drive the progression of precursor lesions to cancer is a cornerstone of cancer research. These mechanisms in general consist of a spiral of (epi)genetic alterations followed by altered gene expression patterns, which cause biological changes at the cell and tissue level. Ultimately, these changes lead to clonal outgrowths of cells that, because of genomic instability, are prone to further genetic alterations. In many types of cancer, most of these genomic alterations occur at the chromosomal level, either as numerical changes or as structural rearrangements, making chromosomal instability one of the key factors in tumor progression.

Analysis of *numerical* chromosomal aberrations has proven to be very informative, as can be deduced from the multitude of published studies based on heterozygosity (LOH), comparative genomic hybridization (CGH), and fluorescence in situ hybridization (FISH). However, to fully appreciate the role of chromosomal instability in tumor progression, *structural* aberrations also need to be taken into account.

OVERVIEW

Currently, structural chromosomal aberrations such as exchanges, deletions, and insertions are routinely assayed by G-band analysis because this technique remains the most efficient and cost-effective method for cytogenetic diagnostic purposes. There is a disparity, however, in how informative this type of analysis is according to the tissue of origin of the metaphase cells being studied. In particular, the complexity of structural aberrations in tumor cells coupled with poor quality in terms of chromosome length, morphology, and mitotic index has contributed to the fact that many recurrent and on-going cytogenetic rearrangements in tumor cells remain poorly defined. One approach taken to improve this is the painting of individual chromosomes using FISH-based methodologies, where the chromosomes selected for ''painting'' are determined based on the initial banding assessment. This strategy is practical and affordable for many cytogenetic services, but has the major disadvantage of only being informative for those chromosomes in the rearrangement that were selected for painting.

Major developments over recent years have changed this. In particular, advances in strategies for combinatorial fluorescent probe labeling and technology for the detection of multiple fluorescent dyes in single experiments have made the high-resolution genome-wide analysis of structural aberrations possible.[1] Below, two hybridization techniques are described which ''paint'' all 22 human autosomes and 2 sex chromosomes as unique identifiable colors: multiplex FISH (m-FISH)[2] and spectral karyotyping (SKY).[3] Both techniques are capable of resolving previously unidentified ''marker'' chromosomes (>10 Mb in size) and also subtle cryptic rearrangements. Importantly, compared with PCR and multiple-color FISH, m-FISH and SKY can be used to screen genome wide and do not require prior knowledge of chromosomal breakpoints.

The detailed analysis of structural chromosomal aberrations is therefore no longer restricted to constitutional anomalies, hematological malignancies, and soft tissue tumors, but is now also feasible for the much larger group of epithelial tumors. Preliminary experiments have

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020744

revealed a high number of structural chromosomal aberrations in different types of solid tumors, indicating that such changes could play a much more important role in solid tumor carcinogenesis than thus far assumed.

MULTIPLEX FLUORESCENCE IN SITU HYBRIDIZATION

Multiplex fluorescence in situ hybridization was first described by Speicher et al.[2] and, like SKY, exploits combinatorial probe labeling to uniquely identify each of the human chromosome pairs. Where the two techniques differ is in the mode of fluorescence detection. For m-FISH, this is achieved using single band-pass filters that are specific for each fluorophore employed. Currently, the majority of commercially available probe sets contain five spectrally distinct fluorophores such that each chromosome is labeled down its whole length with one, two, or three different fluorophores. Consequently, only a proportion of the chromosomes is positively hybridized and therefore visible in any one fluorescence channel. Each channel is digitally captured in turn, with modifications to the excitation/emission filters, focal plane, and exposure times necessary between each fluorophore. Cells are also counterstained with DAPI and an image of this is captured to allow the visualization of the whole metaphase enabling the automated delineation of all the chromosomal material in the cell. Once this raw capture sequence has been completed, m-FISH dedicated software processes all six ''raw'' images by registering each image on top of each other (Fig. 1). It is this that produces the final merged or composite pseudo-color m-FISH image, where the color and therefore origin of chromosome represented is determined by the presence or absence of each of the five distinct fluorophores detected on a pixel-by-pixel basis. A combination of optimal FISH biology, hardware, focus, registration of raw images, and signal-to-noise ratio of each of the individual fluorophores used determined the quality of image produced. Therefore standard of analysis is tightly linked to the quality of each of the six raw images initially captured.

There are problems associated with the direct analysis of the final pseudocolor m-FISH image however. A chromosome is determined to be apparently normal if no color junctions are observed down its entire length, thus excluding the chance of detecting inversions, deletions, or homologous pair interactions, unless of course there are

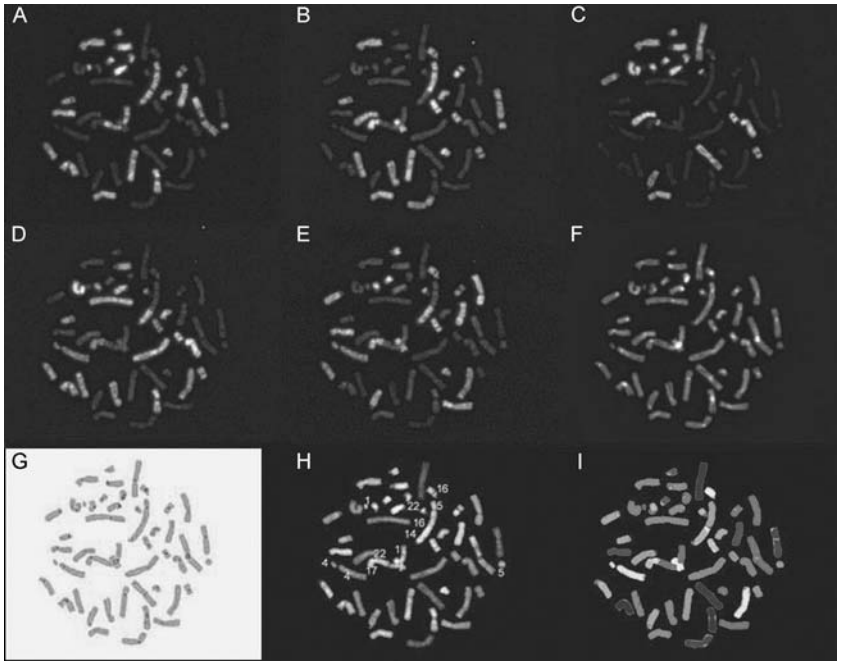

Fig. 1 M-FISH capture and analysis. Each fluorescent channel (A–E) and DAPI (F) is captured separately. Dedicated software processes each of these raw images to produce both a merged (H) and pseudo-color (I) composite. Each cell can be analyzed in detail by exploiting the individual images (A–J). This example shows a complex exchange in a human bone marrow CD34+ cell exposed in vitro to α-particle irradiation ($\sim$1 α-particle/cell). Chromosomes 1;5;14;16;17;22 have repaired as a single complex exchange, plus a deletion in 4p and a frag(4) can be seen. (*View this art in color at www.dekker.com.*)

obvious changes in centromere position or size of chromosome. In addition, depending on the fluorophore combination of chromosomes involved in an exchange, false colors can be produced at the junction as a consequence of flaring, resulting in the suggestion of an additional insertion. Technically though, it is possible to minimize such misclassification through the virtue that m-FISH compiles its pseudoimage via multiple captures. Before describing this in more detail, it is relevant to note that m-FISH is currently being applied for the successful analysis of radiation-induced chromosome aberrations where each of the damaged cells analyzed contains a unique abnormality.[4] Importantly, a number of different laboratories have verified the complexity of chromosome aberrations that can be detected at a single cell level using m-FISH, typically using cells of a similar quality and chromosome length to that seen in tumors.

The procedure of detailed (single-cell) m-FISH analysis is as follows: the DAPI raw image is examined allowing centromere and/or chromosome number to be counted and chromatid-type aberrations (relevant in ongoing genomic instability) to be scored. The chromosomes are karyotyped as enhanced DAPI, and obvious changes in banding pattern, especially involving intrachromosomal or homologous events, are noted. Each fluorescent channel is then assessed in turn looking for discontinuities in color down the length of the chromosomes, before, finally, the composite m-FISH image is assessed. Consequently, because the relative position of observed color junction breakpoints for each fluor is determined separately, the chance of bias from information displayed in the final pseudoimage is limited.

At a minimum, hardware consisting of a fluorescence microscope capable of holding six different epifluorescence filter cubes, camera, and a computer platform that supports dedicated software is required. Overall therefore, irrespective of whether the m-FISH multiplex probe sets are developed locally or obtained commercially, the establishment of an m-FISH facility does represent a significant investment.

SPECTRAL KARYOTYPING

Spectral karyotyping was first described in 1996 by Schröck et al.[3] Metaphase chromosomes are hybridized with the commercially available SKY probe mixture, consisting of 24 chromosome-specific probes. Each probe is differentially labeled with up to four different fluorophores. In contrast to m-FISH, only one image is captured. A fluorescence microscope, using a camera coupled to a spectral color analysis system, analyzes the spectrum from 450 to 750 nm for each pixel in the image. In this way, each (part of a) chromosome can be recognized by its own distinct color spectrum. With dedicated image analysis software, a final karyogram image is created showing all chromosomes with their unique spectral color (or false color if preferred), allowing easy identification of structural changes such as insertions and translocations. In addition, a DAPI image is captured to assess the band position of possible breakpoints (Fig. 2).

Because in SKY analysis the direct spectral image is used, the problem of flaring in the false color image, resulting in the suggestion of additional insertions, can be overcome. Similar to m-FISH, SKY does not detect inversions or duplications (unless there are obvious changes in centromere position or chromosome size) because these do not lead to a translocated color. In addition, small translocated chromosome parts (less than 1–3 Mbp) may be difficult to determine. Notwithstanding these limitations, several spectral karyotyping studies have shown its superior possibilities over conventional cytogenetic analyses. Comparisons showed up to 50% false interpretations with conventional cytogenetic analysis.[5,6] With the help of data from numerical chromosomal analyses, e.g., with array CGH,[7] the interpretation

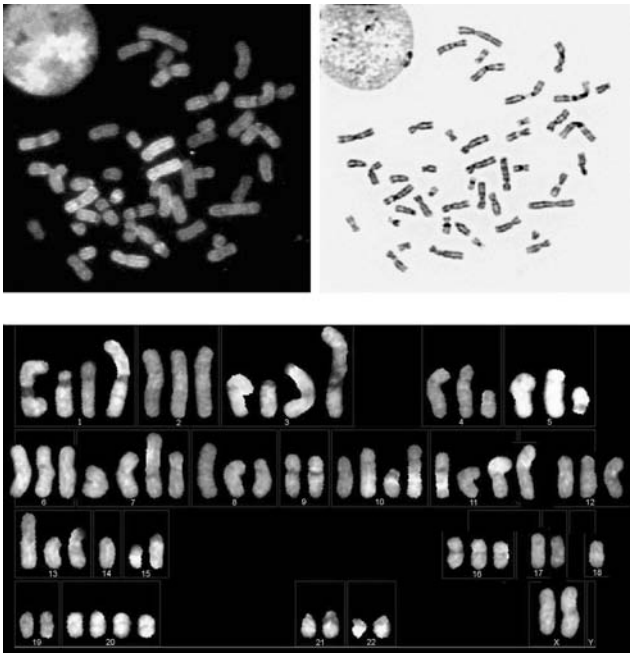

Fig. 2 Spectral and DAPI image of a normal human metaphase (top left and top right, respectively), and a spectral image showing the analyzed karyogram of scc078, an oral squamous cell carcinoma cell line (bottom). The karyogram shows a multitude of unbalanced translocated chromosomes. (*View this art in color at www.dekker.com.*)

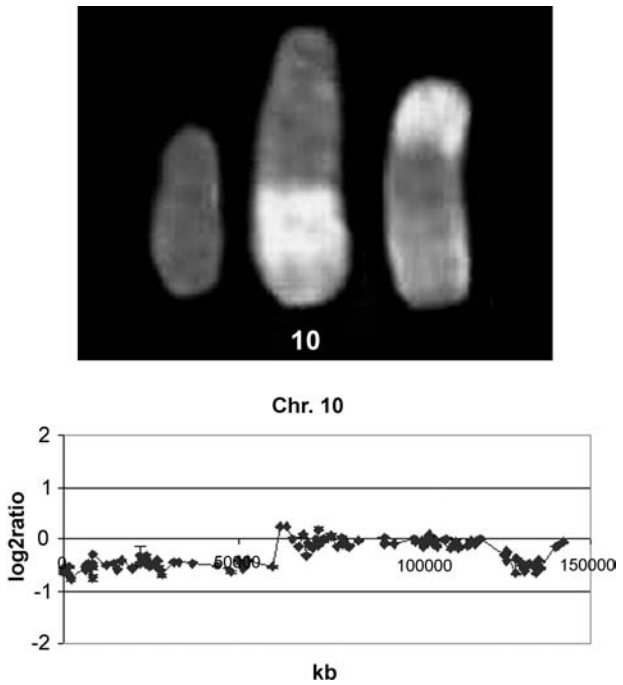

Fig. 3 Complementary information resulting from SKY analysis (left) and array CGH analysis (right) of chromosome 10 alterations in a triploid HPV-transformed keratinocyte cell line, FK18A. The SKY image shows one normal 10 (red), one 10 with a part of chromosome 20 (white) and 11 (green) attached to the q-arm, and one 10 with another part of chromosome 11 attached to the q-arm, and a whole arm 22q replacing the 10p arm. With the help of the array CGH data, it can be confirmed that the 10p arm is only present in 2 copies (in a triploid tumor, this is a loss), that part of the 10q arm is present in 3 copies (the normal number in a triploid tumor), and that the 10qter part, but not the telomere, is again only present in 2 copies. (*View this art in color at www.dekker.com.*)

of chromosome translocations can be improved further (Fig. 3). This illustrates that the respective molecular cytogenetic techniques should be regarded as complementary, providing overlapping and also unique information on the chromosomal abnormalities of tumors.[8,9]

The analysis starts with a background subtraction procedure and contrast improvement for the DAPI image. All chromosomes are checked and joined/overlapping chromosomes can be separated by the user. Subsequent karyotyping is performed by the program, based on the color-spectrum information, which may be corrected in an interactive fashion. Translocations are immediately obvious in the spectral image and may also be visualized in a false color. Using the DAPI image, translocations may be pinpointed to a specific chromosomal band.

A spectral karyotyping system consists of a high-quality fluorescence microscope (e.g., Leica RA) with a special filter set. A high-resolution CCD camera (1280×1024 pixels) and a special device for spectral analysis (SpectraCube™) sit above this. The system is completely integrated with and controlled by a high-performance Windows NT-based computer with dedicated control, imaging, and analysis software (SpectraView Software, Applied Spectral Imaging Inc., Israel) and includes printing and storage devices.

CONCLUSION

The implication of m-FISH and SKY for clinical diagnostics is that previously uncharacterized complex karyotypes and marker chromosomes are now able to be elucidated.[10] In addition, small translocations, as in constitutional anomalies, hematological tumors, and soft tissue tumors, can be identified more easily.[6] By rigorously analyzing all of the information available per cell, the operator not only minimizes error in classification, but also produces reliable and informative data even from those cases with poor mitotic index. Overall, the information gained from m-FISH and SKY, which is relevant for research as well as diagnostics and staging of disease, outweighs the cost and labor intensiveness of this technology.

The impact for health care of studying the role of structural chromosomal changes in cancer development and progression from precursor lesions to cancer is self-evident. Apart from the suffering it causes to individual patients and their families, cancer is one of the major causes of death, whereas cancer diagnosis and treatment consumes a major part of health-care budgets. Because progression of many types of cancer is driven by changes at the chromosomal level, a better understanding of these mechanisms may have a major impact on our ability to identify high-risk patients at an earlier stage. Moreover, knowledge of critical genomic alterations that drive tumor progression may also provide leads for the development of new anticancer drugs.

Fluorescence Resonance Energy Transfer (FRET)

F

Dino A. De Angelis
Memorial Sloan-Kettering Cancer Center, New York, New York, U.S.A.

INTRODUCTION

The phenomenon of fluorescence resonance energy transfer (FRET) was first described by Theodor Förster in 1948. Since then, FRET has become an incredibly useful tool in biology for three reasons: 1) FRET is really sensitive in the range of 100 Å and below, the scale at which transactions between biological macromolecules and complexes occur; 2) the instrumentation is extremely sensitive and is readily amenable to miniaturization, high throughput, and automation; and 3) cell permeable and genetically encodable FRET probes enable the real-time quantitation of dynamic cellular processes in live cells. In this chapter, we introduce the reader to the photophysics underlying FRET and present a brief general overview of the types of biological measurements enabled by the technique. Readers are referred to other chapters in the Encyclopedia for more detailed coverage of specific diagnostic applications of FRET (see for instance ''Molecular Beacons, 5′ Nuclease Oligoprobes'').

FLUORESCENCE

When photons are absorbed by a fluorescent compound (Fig. 1A), within femtoseconds it undergoes a transition from a singlet ground state (S_0) to an excited state which can be S_1 (thick line) or a higher vibrational energy level of S_1 (denoted by the thin lines above S_1). The excitation maximum of a particular fluorescent compound is the wavelength at which this process occurs most efficiently. Within picoseconds, molecules in higher vibrational states relax to the S_1 state (thick line).

Most fluorescent molecules remain in the S_1 state for 1–10 nsec on average, after which they can return to the S_0 ground state through one of a few different relaxation pathways.[1] The radiative relaxation pathway occurs through emission of fluorescent light by the excited fluorophore as it returns to the ground state, indicated by the wavy arrow in Fig. 1A. The light emitted is always of lower energy (longer wavelength) than that of the exciting light.

Several nonradiative pathways compete with fluorescence emission for return to the ground state. These nonfluorescent pathways (labeled NF in Fig. 1A) include internal conversion (a return to S_0 accompanied by release of heat), intersystem crossing (change in the electron-spin orientation resulting in relaxation to a long-lived triplet excited state before decaying to S_0), and collisional deactivation (involving direct encounters between the dye and neighboring solvent molecules). These deactivation pathways are inherent to fluorescent dyes in solution and are present to various extents.

RESONANCE ENERGY TRANSFER

Resonance energy transfer is also a nonradiative pathway, but it requires a stringent set of conditions, unlike the nonfluorescent deactivation pathways mentioned above. In resonance energy transfer, the excited dye is a FRET donor (D) which becomes deactivated via transfer of some of its excited-state energy to a compatible acceptor (A) molecule (Fig. 1B). Because it does not involve the emission of photons from the donor, FRET is more correctly referred to as ''Förster resonance energy transfer,'' or simply RET.[2] Efficient energy transfer from excited D to A requires that 1) the fluorescence emission spectrum of D and the absorption spectrum of A be overlapping (resonant frequencies as shown in Fig. 2A); 2) the distance between D and A be within 10 to 100 Å (1–10 nm); 3) the dipole moments of D and A be approximately parallel to one another. If A is also a fluorescent molecule, FRET results in an increase in fluorescence emission from A (Fig. 1B, indicated by the wavy arrow depopulating A*) in addition to the decrease in fluorescence emission from D. If A is a nonfluorescent molecule, the net result of FRET is a decrease in fluorescence emission from D. In this case, A is a fluorescence quencher and A* becomes exclusively depopulated by nonfluorescent pathways (Fig. 1B, dashed arrow).

DISTANCE DEPENDENCE OF FRET

Fluorescence resonance energy transfer efficiency is inversely proportional to the sixth power of the distance between a donor and acceptor, and therefore is extremely

DOI: 10.1081/E-EDGP 120023536

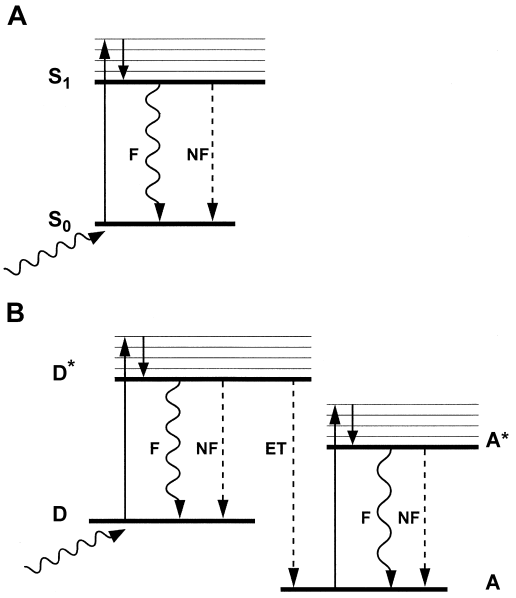

Fig. 1 A) General mechanisms of excited-state deactivation of a fluorophore. Up arrow represents transition from ground state (S_0) to an S_1 excited state (thick line) or higher (thin lines) after photon absorption (wavy upward arrow). Down arrows represent relaxation, first from higher states down to S_1 (short arrow). Relaxation from S_1 to S_0 involves either fluorescence emission (F, wavy down arrow) or nonfluorescent mechanisms (NF, dashed down arrow). B) Mechanisms of excited state deactivation of a donor fluorophore in the presence of an acceptor. Same as A except that energy transfer (ET) is also displayed (longer dashed arrow) which results in less fluorescence emission from the donor excited state (D*) and activation of acceptor molecule from ground state (A) to excited state (A*). Excited state of A can also be depopulated via fluorescent (F) or nonfluorescent (NF) mechanisms.

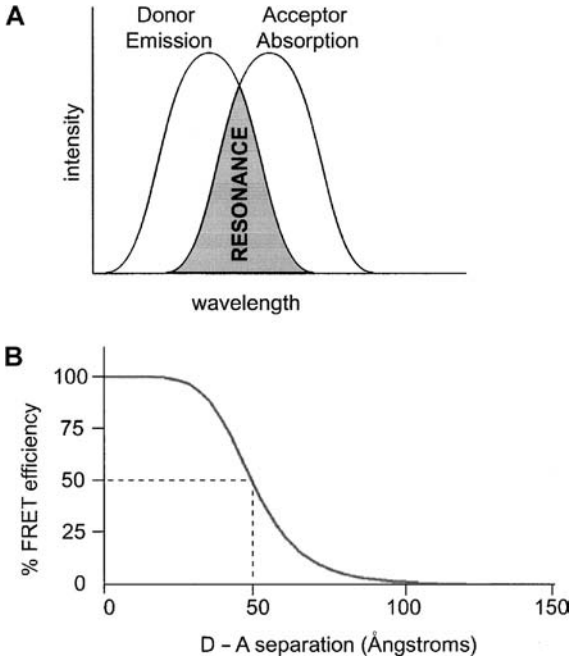

Fig. 2 A) Fluorescence intensity plotted as a function of donor emission and acceptor absorption wavelengths, displaying a spectral overlap required for resonance energy transfer. B) FRET efficiency plotted as a function of the distance between a donor and acceptor pair characterized by a R_0 of 50 Å.

sensitive to their intermolecular separation. This is illustrated in the equation:

$$E(r) = (R_0)^6/[(R_0)^6 + r^6]$$

where E is FRET efficiency, r is the distance separating D from A, and R_0 is the Förster distance. At the Förster distance, 50% of excited D is deactivated via FRET (ET in Fig. 1B), and the remainder is deactivated via fluorescence (F) and other nonfluorescent (NF) pathways. The Förster distance varies between different D–A pairs, typically ranging from 25 to 75 Å (Table 1). R_0 takes into consideration the amount of spectral overlap between the dyes and assumes that donors and acceptors are randomly oriented. For a donor–acceptor pair with an R_0 of 50 Å, doubling the intermolecular separation from 50 to 100 Å results in a 32-fold decrease in FRET efficiency (Fig. 2B).

Distance measurements obtained by monitoring FRET efficiency typically represent an average (rather than absolute) distance between D and A, because of the assumption of random orientation in the calculation of R_0, and the fact that biological macromolecules usually fluctuate between thermodynamically equivalent states. Technicalities aside, the exquisite dependence of FRET on distances of the scale of biological macromolecules (Table 2) underscores the real usefulness of the technique: detecting biological phenomena involving changes in the

proximity of two molecules (or two portions of the same molecule) respectively labeled with D and A.

DETECTION OF FRET

A wide array of phenomena can be measured using FRET, and they tend to fall into either of two main categories: 1) homogeneous in vitro assays performed in a spectrofluorimeter or microplate reader and 2) live cell FRET imaging performed by fluorescence microscopy. The basic requirements for the detection of FRET in these two domains are the same: 1) a light source for donor excitation; 2) wavelength filters to spectrally separate excitation photons (originating from the light source) from emission photons originating from both D and A; 3) detectors that can separately register emission photons from D and A as two electrical signals (spectrofluorimeter) or as two digital images (fluorescence microscopy).

IN VITRO: HOMOGENEOUS FRET

Spectrofluorimeters measure the fluorescence properties of homogeneous samples in cuvettes or in multiwell dishes. For a FRET experiment, the light source illuminates at a wavelength intended to excite the donor but not the acceptor. The detectors register photons emitted by both D and A. When D and A are much further apart than the R_0 characterizing the pair, emission from D is much higher than emission from A. The D/A emission ratio is therefore high (excited D deactivates preferentially with the fluorescence emission pathway). In contrast, when D and A are within Förster distance of one another, the D/A emission ratio decreases as D transfers a fraction of its excitation state energy to A, causing less fluorescence emission from D and more fluorescence emission from A. In cases when A is a fluorescence quencher, proximity between D and A simply results in decreased emission from D.

Binding reactions between two molecular entities (receptor–ligand; antibody–antigen; transcription factor–DNA sequence) respectively labeled with a donor and an acceptor can be quantified by FRET.[3] The labeling can be direct (via covalent modification of the molecules of interest) or indirect (i.e., via noncovalent binding of a labeled antibody or other binding moiety). Binding will result in energy transfer from the donor to the acceptor (Fig. 3A).

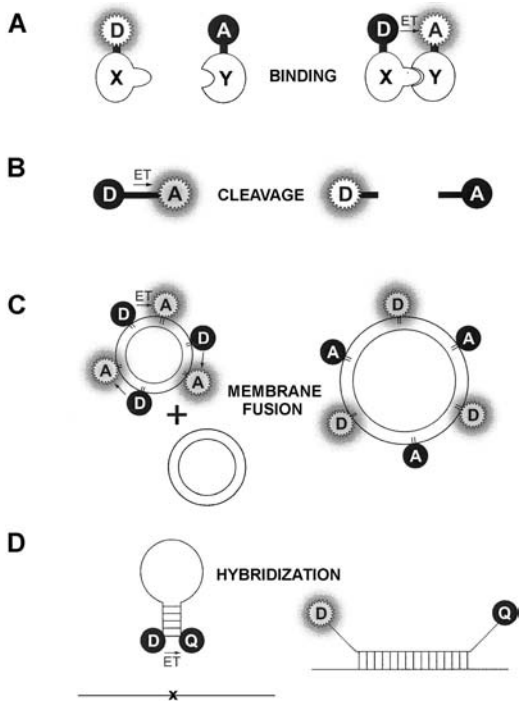

Fig. 3 Types of molecular interactions measured by FRET. A) Binding of two molecular entities X and Y, respectively labeled with donor D and acceptor A results in FRET (ET). B) Cleavage of D- and A-labeled peptide or nucleic acid sequence via protease or endonuclease results in decrease in the FRET signal. C) Fusion of liposomes containing a high concentration of D- and A-labeled phospholipids with unlabeled liposomes results in dilution of D and A and decrease of FRET in the newly fused membrane. D) Molecular beacons oligonucleotide probes adopt a stem and loop structure in the absence of a perfectly matching target DNA sequence, resulting in FRET between donor D and nonfluorescent acceptor Q (quencher). Perfect match results in hybridization of loop sequence to the target DNA and increased separation of D from Q.

Peptides containing a specific protease cleavage site, and labeled with D and A at either termini, can serve as FRET sensors.[4] Fluorescence resonance energy transfer occurs in the intact peptide but incubation with the protease separates D from A causing a decrease in the FRET signal (Fig. 3B). The activity of endonucleases can similarly be detected using a dual-labeled nucleic acid sequence.

Membrane fusion assays can also be performed using FRET, by incorporating phospholipids labeled with D and A moieties into liposomes at relatively high concentrations.[5] Because of molecular proximity, D and A undergo FRET in this liposome population. Fusion of such liposomes with unlabeled liposomes creates larger liposomes in which FRET is decreased due to the increase in average distance between labeled probes via dilution (Fig. 3C).

Molecular beacons are FRET probes that can adopt one of two very different conformations depending on the presence of specific target DNA sequences in a sample (described in more detail elsewhere in this volume, see also Refs. [6] and [7]). The technique is so sensitive that it can resolve single-base pair mismatches. In the absence of a perfectly matching sequence, the molecular beacon adopts a hairpin-like structure (Fig. 3D) which brings the donor- and acceptor-labeled ends of the molecule into close proximity. The acceptor is a quencher (Q) in these probes, therefore very little fluorescence is emitted by the probes in this conformation. In the presence of the exact match, the stem structure opens up, allowing the loop to hybridize to the perfectly matched target and increasing the distance between D and Q.

These are just a few illustrations of diagnostic in vitro assays performed using FRET probes. They are typically easy to set up and can be automated; some are known as ''walkaway'' assays because no further processing of the sample is required following the initial incubation of reagents. The extent of the reaction (whether binding, cleavage, membrane fusion, or other) can be modulated by adding competitors, agonists, antagonists, or other test compounds, either in purified form or from crude extracts, and their effect on the assay can be measured. The kinetics of any assay can be monitored by collecting the emission from D and A continuously or at timed intervals, without interrupting the reaction. In addition, because D–A pairs can be spectrally quite different from one another, several probes can be monitored simultaneously in the same reaction (multiplexing; see Ref. [7]).

In homogeneous FRET, background noise derived from sample autofluorescence can limit the sensitivity of the technique. Two related techniques extend the sensitivity range of FRET measurements by radically reducing noise in the system. Time-resolved FRET (TR-FRET) uses fluorescence donors with unusually long fluorescence lifetimes (400 nsec to 2 msec for chelates of ruthenium and lanthanides compared to 10 nsec for typical fluorescent molecules).[8] Time-resolved FRET delays the collection of light by the detector, allowing any fluorescence that is not derived from the long lifetime donors in the sample—including noise—to decay to zero. The slower decaying donor-specific fluorescence (or FRET signal) can therefore be measured in the absence of background.

Another way to reduce background fluorescence in FRET measurements is by omitting the light source altogether. Bioluminescence RET (BRET) uses a luciferase as a donor which produces light only when the substrate (coelenterazine) is added to the reaction. When bioluminescence is produced in close proximity to the acceptor, energy (not photons) is transferred resulting in an increase in the acceptor fluorescence. As there is no extrinsic illumination to activate sample autofluorescence, BRET can increase the sensitivity of donor–acceptor interactions by an order of magnitude compared to FRET.[9]

IN VIVO: LIVE-CELL FRET IMAGING

Fluorescence resonance energy transfer measurements are not limited to in vitro assays. Cell-permeable FRET

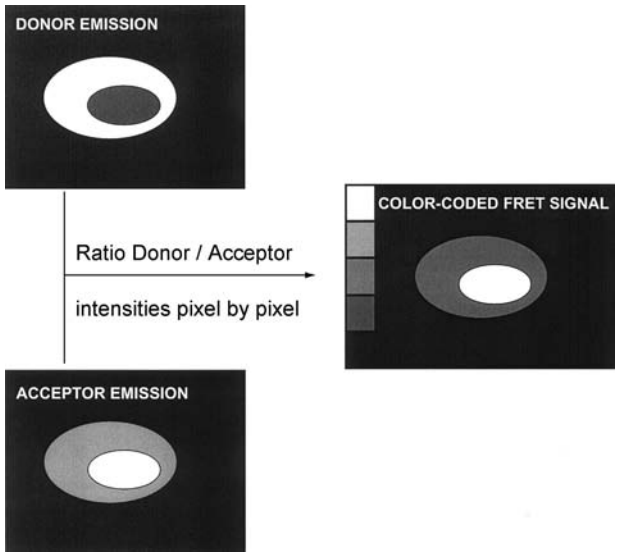

Fig. 4 Fluorescence resonance energy transfer imaging of live cells. Pair of digital images representing collection of light from the donor emission (top left image) and acceptor emission (bottom left image) following illumination of a sample at the donor excitation wavelength. The intensity of pixels from the donor emission image is divided by the intensity of pixels from the acceptor emission image via software and a color-coded map of the ratios is generated (right). In this diagram there is a high FRET signal in the nucleus (low donor intensity/high acceptor intensity).

probes as well as the green, cyan, and yellow fluorescent proteins (GFP, CFP, and YFP), introduced in cells by DNA transfection, have permitted the study of dynamic events involving changes in the proximity of macromolecules in live cells. Sensors based on GFP variants can be targeted to any compartment for which there is a known signal sequence, enabling local measurement of the activity under study. In FRET imaging, light required to excite the donor is focused by a microscope lens onto a live cell sample. Photons emitted from the donor and the acceptor are respectively collected as two digital images (Fig. 4). The intensity levels of the two images are then ratioed on a pixel-per-pixel basis, yielding a two-dimensional map of the D/A emission ratio for the particular time point. The sample can be imaged over time and thus the spatio-temporal features of the FRET signal can be analyzed. By enabling the analysis of phenomena in the range of Förster distances (1–10 nm), FRET imaging goes beyond the limits resolution of light microscopy ($\sim$200 nm).

The binding of two different proteins respectively labeled with CFP and YFP (the pair with the best spectral overlap characteristics for FRET) can be measured kinetically by measuring the amount of FRET they undergo. Protease activity can likewise be monitored in live cells by placing YFP and CFP at each extremity of a cleavable peptide. A powerful class of sensor inserts a conformationally active peptide between a CFP–YFP pair. The peptide can adopt different conformations depending on the environment, thus changing the distance and angle between the fluorescent proteins and yielding differential FRET signals. The detection of fluctuations in intracellular Ca^{2+} concentration was the first demonstrated application of this class of sensors, and the list has grown since (see Ref. [10] for a review).

For microscopy measurements, high levels of cellular autofluorescence can be compensated for by using an unlabeled region of the cell as an internal reference; this background is subtracted from the signal in the region of interest prior to calculating FRET. A more serious problem is photobleaching of the donor—basically, a destruction of the fluorophore caused by overillumination which is common in microscopy because the excitation light scans the same sample area repeatedly. Under photobleaching conditions, the efficiency of FRET undergoes an apparent decrease over time as the donor fluorophore is unable to repopulate its excited state. This is donor dependent, but can be corrected for by establishing the rate of photobleaching in a control sample, and normalizing the FRET signal obtained in the test sample to this baseline.[10] Bioluminescence RET measurements (discussed in ''In Vitro: Homogeneous FRET'') can also be performed in live cells; these experiments do not suffer from photobleaching because all of the light is generated via a bioluminescent reaction.[9]

CONCLUSION

This brief survey has only scratched the surface with respect to the breadth and power of FRET for the analysis of binding, dissociation, hybridization, and other phenomena involving changes in the proximity of biological molecules. Development of FRET-based sensors continues unabated, and so is the development of instrumentation designed to quantify FRET—with a trend toward miniaturization and high-throughput operation to enable diagnostic use of the technology on a genomic scale.

Fluoroquinolone Resistance-Associated Gene Mutations in *Streptococcus pneumoniae*

George G. Zhanel
Heather J. Smith
University of Manitoba, Winnipeg, Manitoba, Canada

INTRODUCTION

Fluoroquinolones are increasingly used in the empiric therapy of community-acquired respiratory infections likely caused by *Streptococcus pneumoniae* because of the rise in resistance to β-lactams and macrolides. However, fluoroquinolone resistance in *S. pneumoniae* has recently emerged. Fluoroquinolone resistance in *S. pneumoniae* is mediated by two main mechanisms: spontaneous point mutations in the fluoroquinolones' target enzymes (DNA gyrase and topoisomerase IV) and by active efflux. This article focuses on the chromosomal mutations associated with fluoroquinolone resistance in *S. pneumoniae*, their frequency, and the impact of these mutations on clinical outcomes. Automated DNA sequencing methods are usually used to identify fluoroquinolone resistance mutations, but new techniques such as PCR–oligonucleotide ligation assays are currently being evaluated.

HISTORY OF FLUOROQUINOLONES

A novel class of antibiotics, quinolones, originated with the discovery of nalidixic acid (actually a naphthyridine) in 1962.[1] Nalidixic acid displayed good activity against gram-negative aerobes; however, its use was limited because it displayed poor activity against gram-positive organisms, demonstrated poor pharmacokinetics, and had numerous adverse affects.[1] Structural alterations of nalidixic acid resulted in the discovery of the fluoroquinolones, norfloxacin and ciprofloxacin, in the 1980s.[1] Norfloxacin and ciprofloxacin displayed a broader spectrum of activity against both gram-negative and gram-positive organisms and were much more potent than their progenitor antibiotics.[1] Improvements have continued to be made to the fluoroquinolone class via the addition of various molecular substituents to the basic quinolone structure. The newer ''respiratory'' fluoroquinolones: gatifloxacin, gemifloxacin, levofloxacin, moxifloxacin, and the investigational des-fluoroquinolone garenoxacin, demonstrate enhanced activities against gram-positive organisms such as *S. pneumoniae* as well as improved pharmacokinetic properties.[1,2]

FLUOROQUINOLONE CELLULAR TARGETS

Fluoroquinolones function by inhibiting two type 2 topoisomerases: DNA gyrase and topoisomerase IV.[1–3] Type 2 topoisomerases cause staggered single-stranded breaks in both strands of the bacterial chromosome, pass an intact segment of the DNA strand through the break, and reseal the DNA.[1,3–5] Fluoroquinolones bind to the DNA–enzyme complex containing the broken DNA strands forming what is termed the cleavable complex.[3,5–7] DNA repair and replication are inhibited and the resulting release of double-stranded DNA breaks accounts for the bactericidal activity of the fluoroquinolones.[1,3]

DNA gyrase is an essential bacterial enzyme formed as a tetramer of two GyrA and two GyrB subunits (A_2B_2) encoded by *gyr*A and *gyr*B, respectively.[1,3–6] DNA gyrase removes superhelical twists ahead of the replication fork and introduces negative supercoils into DNA, which are necessary for replication initiation. Topoisomerase IV is a tetramer formed of two ParC and two ParE subunits (C_2E_2), encoded by *par*C and *par*E, respectively, that share significant homology with the subunits of DNA gyrase.[1,3–6] Topoisomerase IV's cellular function is the decatenation of sister chromatids during the segregation of replicated chromosomes.[1,3,5]

It was initially believed that the primary target for fluoroquinolones in all gram-negatives, such as *Escherichia coli*, was DNA gyrase, whereas the primary target in all gram-positives, such as *Staphylococcus aureus*, was topoisomerase IV.[1,4] However, it has now been demonstrated that in certain bacterial species, such as *S. pneumoniae*, the primary bacterial target is dependent on the specific fluoroquinolone structure.[1,4,7]

FLUOROQUINOLONE RESISTANCE ASSOCIATED GENE MUTATIONS

Fluoroquinolone resistance ensues from spontaneous point mutations in the quinolone-resistance determining regions (QRDRs) of DNA gyrase and topoisomerase IV. In *S. pneumoniae*, resistance mutations occur most

commonly in *gyr*A and *par*C.[1,6–10] Mutations are occasionally reported in *gyr*B and *par*E, but their contribution to resistance appears to be limited and remains controversial.[1,6–8,10]

GyrA Fluoroquinolone Resistance Mutations

The QRDR in GyrA encompasses the region from amino acid 67 to 106.[3] Resistance occurs when amino acids near GyrA's putative active site, Tyr-122, are altered.[3] The specific GyrA amino acids commonly altered in *S. pneumoniae* fluoroquinolone-resistant isolates are Ser-81 and Glu-85.[1,3,4,8,10] These amino acids are near Tyr-122 in the primary sequence.[4] The mutation of Ser-81 to a tryptophan residue reduces the binding affinity of fluoroquinolones for the gyrase complex.[4] Substitutions of phenylalanine and leucine at position 81 are also prevalent.[1,3,4,8,10] Glu-85 can be mutated to either a lysine or glycine residue.[3,4,8,10] Lysine's positive charge and the steric hindrance resulting from the bulkiness of its side chain may reduce the ability of fluoroquinolones to bind to their targets.[8] The result of all the amino acid substitutions aforementioned for Ser-81 and Glu-85 may be the alteration of the quinolone-binding site structure in the DNA gyrase–DNA complex.[4] A reduced binding affinity for the modified enzyme–DNA complex may be the cause of fluoroquinolone resistance.[4]

ParC Fluoroquinolone Resistance Mutations

Similar to GyrA, mutations in the QRDR of ParC alter the quinolone-binding site structure located at the interface of topoisomerase IV and the DNA.[4] The altered structure results in reduced fluoroquinolone binding affinity for the enzyme–DNA complex.[4] The ParC amino acids commonly associated with fluoroquinolone resistance in *S.pneumoniae* are Ser-79 and Asp-83.[1,3,4,8,10] Ser-79 can be mutated to a phenylalanine or tyrosine residue.[1,3,4,8,10] Asp-83 can be substituted by alanine, glycine, asparagine, threonine, or tyrosine.[3,8,10] Ser-52 to glycine and Lys-137 to asparagine substitutions have also been reported, although these do not appear to contribute to increased minimum inhibitory concentration (MIC) values.[8] The MIC increases resulting from the development of *gyr*A and *par*C mutations are displayed in Table 1.

FREQUENCY OF RESISTANCE

Generally in *S. pneumoniae*, *par*C mutations are observed alone in isolates with low-resistance MICs (ciprofloxacin MIC ~4 μg/mL). As the MICs increase, isolates usually have mutations in both *par*C and *gyr*A. The presence of resistance mutations (in ParC, GyrA, and ParC and GyrA) and active efflux based on ciprofloxacin MICs is demonstrated in Fig. 1. The most common mutation in ParC is Ser-79-Phe.[1,10] Of all isolates with a ParC

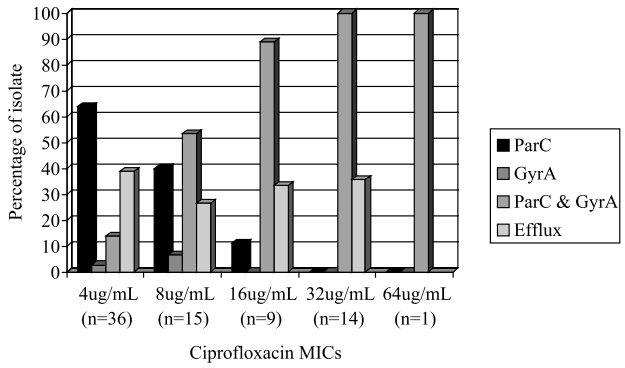

Fig. 1 Resistance mechanisms, QRDR mutations and efflux, identified in 75 ciprofloxacin-resistant *S. pneumoniae* at MICs of 4, 8, 16, 32, and 64 μg/mL (number of isolates per MIC). (From Ref. [13].)

mutation, it has been reported that 50–62.5% have the Ser-79-Phe substitution.[8,10] Likewise, Ser-81-Phe represents 69.2–78.6% of all GyrA changes.[8,10]

CLINICAL IMPLICATIONS

As the prevalence of fluoroquinolone resistance increases, clinical failures during empiric treatment are being reported. Various accounts have begun to emerge of levofloxacin failure during treatment of pneumococcal pneumonia.[6,11] Three of the depicted patients had a history of recent fluoroquinolone treatment.[6,11] The *S. pneumoniae* responsible for this fluoroquinolone failure was subsequently found to have QRDR substitutions in both ParC (Ser79Phe) and GyrA (Ser81Phe/Tyr, Glu85Lys).[6,11] These reports suggest that recent (within the last 3 months) fluoroquinolone therapy must be considered during treatment decisions.[6,11] Two other patients were described who had no history of fluoroquinolone therapy.[11] For one patient, the initial isolate had no detected substitutions in ParC or GyrA; however, following therapy, the resulting isolate had mutations in both ParC (Ser79Phe) and GyrA (Ser81Phe).[11] The other patient's initial isolate was considered susceptible but was found to have a Ser79Phe substitution in ParC.[11] After levofloxacin therapy, the isolate had mutations in both ParC (Ser79Phe) and GyrA (Ser81Phe).

The increasing use of fluoroquinolones as empiric therapy of community-acquired respiratory infections likely caused by *S. pneumoniae*, the rise in fluoroquinolone resistance, and these reports of levofloxacin therapy failure indicate that fluoroquinolone susceptibility testing should be routinely conducted. This could reduce treatment failures in cases in which the infecting isolates have high MICs resulting from mutations in ParC and GyrA. Unfortunately, it has been shown that susceptibility testing is not able to identify isolates containing only a ParC mutation.[7] These are the isolates that are most clinically disconcerting as the acquisition of a second mutation, and the resultant rise to high-level resistance MICs, occurs much more readily than a primary mutation.[7] It has recently been reported that 19% and 60% of *S. pneumoniae* isolates with levofloxacin MICs of 1 and 2 μg/mL, respectively, have ParC mutations.[12] These isolates are considered susceptible and the mutations would not be identified throughout susceptibility testing. Even with routine fluoroquinolone susceptibility testing, these isolates would be considered susceptible, treated with fluoroquinolones, and provide an opportunity for rapid development of highly fluoroquinolone resistant *S. pneumoniae* isolates. Thus, routine fluoroquinolone susceptibility testing should be conducted to reduce treatment failures resulting from *S. pneumoniae* isolates with substitutions in ParC and GyrA and additional testing methods should be developed that can rapidly identify isolates with only ParC mutations.

MOLECULAR TECHNIQUES FOR RESISTANCE DETECTION

Currently Employed Detection Method

The current method used in the detection of QRDR mutations causing fluoroquinolone resistance is automated DNA sequencing. Most studies amplify only the QRDRs of ParC and GyrA, whereas other studies also examine the QRDRs of ParE and GyrB. There are various published primer sets and amplification conditions used in these studies.[2,7,8,10] After purification and quantitation of the amplification products, the sequencing reactions are conducted.[10,12,13] DNA sequencing is performed using an ABI PRISM BigDye Terminator kit and run on an ABI PRISM sequencer.[2,7,10,12,13]

Novel Detection Methods

As previously mentioned, the utility of susceptibility studies for fluoroquinolone resistance mutation detection has been evaluated. Although this method was able to correctly identify isolates without resistance mutations and those with mutations in both ParC and GyrA, it was unable to identify isolates with only ParC mutations.[7] Susceptibility testing as a method of fluoroquinolone resistance detection is not sufficient for clinical use as *S. pneumoniae* isolates with ParC mutations are highly clinically significant.

A novel detection method for QRDR mutations has recently been developed: PCR–oligonucleotide ligation assays. Similar to sequencing studies, this method uses PCR to amplify the QRDRs of ParC and GyrA.[2] Oligonucleotide ligation assays are conducted and the specific mutations are detected colometrically.[2] This method correctly identified the majority (98%) of wild-type isolates and isolates with QRDR mutations in one or both target genes.[2] The substitutions correctly identified by this technique include the most common QRDR mutations (ParC: Ser79Phe/Tyr, Asp83Tyr/Val/Asn; GyrA: Ser81Phe/Ala/Tyr, Glu85Lys).[2] Rare mutations were also reported to be identifiable by this method.[2] The PCR–oligonucleotide ligation assay is much more rapid than DNA sequencing because it requires 12 hr for completion as opposed to 33 hr.[2] This novel, rapid, and accurate method is a good advancement in the detection of fluoroquinolone resistance mutations. However, the robustness of PCR–oligonucleotide ligation assays must be confirmed with

studies of many more isolates to become as accepted as the DNA sequencing gold standard.

CONCLUSION

Fluoroquinolone resistance in *S. pneumoniae* results from spontaneous point mutations in GyrA and ParC. The use of fluoroquinolones in the empiric treatment of community-acquired respiratory infections likely caused by *S. pneumoniae* and resistance to fluoroquinolones is increasing. Treatment failures with fluoroquinolones, such as levofloxacin, have begun to occur. Accordingly, routine fluoroquinolone susceptibility testing should be conducted to identify resistant organisms with substitutions in both ParC and GyrA so that other antimicrobials can be selected for treatment of these isolates. Most importantly, novel, rapid methods of detecting *S. pneumoniae* isolates with ParC mutations alone must be developed to limit the fluoroquinolone exposure of these isolates in hopes of reducing the development of high-level fluoroquinolone resistance.

Forensic DNA Samples—Collection and Handling

Mark Benecke
International Forensic Research & Consulting, Cologne, Germany

INTRODUCTION

Under dry and cool conditions, DNA is a relatively stable molecule. From a technical and criminalistic point of view, DNA can be collected and stored like most visible biological stains. Crucial steps are examination of evidence including photographic documentation, and storage under dry and cool conditions. Special aids such as sexual assault kits, swabs, drying devices, and filter paper treated with denaturants are available and should be used. However, DNA collection in forensic environments is not a merely technical but also a criminalistic task. Two questions are of special importance: 1) whether a stain is of relevance for the actual crime, e.g., if it could have been left at the scene some time ago by persons who are not related to the crime, and 2) if a stain should be used for extraction straight away, or stored as long as possible for morphological measurements and crime (scene) reconstruction, e.g., the form of blood stains on wallpaper, the exact location of sperm stains on clothing, or the exact location of skin cells found on furniture.

EVIDENCE EXAMINATION

Irrespective of possible chain of custody rules, examination of evidence starts with photographic and/or drawn descriptions of the items received by the forensic biologist. In every photograph, an absolute scale must be visible (millimeters/centimeters; no pennies, no matches). Resolution should be $\geq 2816 \times 2112$ pixels=4 MPixel to allow blowing up of the pictures. Flash light should be avoided because brighter parts of the objects will flash out (become white; a digital artefact).

Biological stains that were detected either by their surface properties (detection by touch: e.g., sperm stains on dark clothing), monochromatic light (e.g., saliva), or regular bright light (e.g., hair or small blood stains) are circled and numbered by use of a water-resistant pen or neon color.

COLLECTION OF BIOLOGICAL STAINS

Swabs

Practically all stains can be collected by rubbing them off with a cotton swab. Stains on fabric should be cut out first. Swabs are soaked with one drop of fresh distilled sterile water. After transfer of the stain to the swabs, they must be dried immediately. Then, they are put in paper containers. The most convenient way to dry swabs is to put them straight into a closed cardboard box at room temperature (Fig. 1). There, they can neither touch neighboring objects nor develop mold.[1]

In professional forensic environments, contamination caused by airflow during the drying process has not been reported to be a problem. Some laboratory manuals ask for drying in closed cupboards (Fig. 2) or under sterile laminar airflow. Cupboards must never tightly close to avoid building up of humidity and mold.

Swabbing is performed by *intense*, *multiple* rubbing of the stained surface to collect a maximal amount of DNA. Inside of oral cavities, the cotton swab is rubbed against the mucous membrane; saliva alone may not contain enough cells.

After complex shooting situations, used bullets can be matched to the victims by swabbing off traces of tissue that remain on the bullet once it enters the body.[2]

Early Swabbing

Swabbing of clothing items, especially of skin, should be performed as soon as possible in forensic and police investigations. For example, DNA typing was possible in the following cases where swabs had been collected early at the scene of the crime. Before swabbing, intelligent criminalistic assumptions concerning the location of the invisible yet possible stains had been made.

- Epithelial cells of an unknown suspect were swabbed off the front side of a collar of a polo-neck pullover. The victim had been stabbed; the stains had not been visible on the collar.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020544

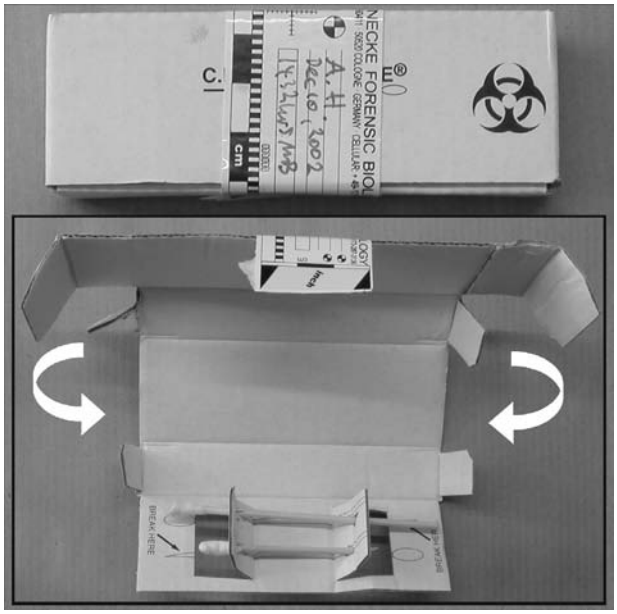

Fig. 1 Cardboard box allows simple and safe drying and storage of swabs. [Swissforensix, Switzerland (patented).] (*View this art in color at www.dekker.com.*)

- DNA contained in epithelial cells that had been transferred by saliva of an offender was swabbed off the skin of an experimental victim that had showered. Amplification of the offender's STRs was successful up to several hours after transfer of his saliva to the skin of the victim.
- In contrast to common belief, corneocytes contain DNA. Therefore, all surfaces that may have been touched by an offender (through grabbing of ropes, wearing of baseball caps, hitting a person, inside of gloves) may be swabbed successfully.[3–5]

Early swabbing is also necessary whenever cells from the top edge of bottles, beer cans, etc. are collected. Collection of the complete bottle or can frequently leads to spilling of its contents and dilution or washing off the cells. If early swabbing is not possible, the liquid must be drained out of the container by drilling a hole in its bottom.

Filter Paper

Liquid blood can be stored on filter paper that is then dried in the same way as cotton swabs. Filter paper that contains denaturants, buffer, and a free radical trap (e.g., FTA paper[6]) will lyse the blood cells and immediately deactivate bloodborne pathogens such as herpes, cytomegalovirus, and HIV.

Filter paper can also be used to store saliva and liquids from decomposed bodies. In automated laboratories, standard-sized filter paper is the preferred option. Pieces can easily be punched out of it by a machine and subsequently processed by a DNA extraction and PCR robot. The advantage of FTA paper over regular filter paper is that it can be used for multiple PCR reactions. Template DNA will stick to FTA paper after washing off the PCR products and can then be reused.

Urine and Feces

Because feces is found especially at scenes of (serial) burglaries, it should be collected irrespective of its repulsive nature. Fresh feces as well as liquid urine should be frozen below $-20^{\circ}C$ to avoid bacterial activity. DNA typing of urine is successful especially if it was excreted in the morning (when the highest number of epithelial cells are found compared to the rest of the day), and from feces after PCR inhibitors are removed. To recover the cells, urine needs to be centrifuged (cells are located in the sediment), whereas stool samples can be extracted straightaway or from swabbings with mini spin columns. The estimated number of up to 6×10^5 pg human DNA/mg stool is never reached in practice because of bacterial and digestive action; nevertheless, up to 170 pg DNA/mg stool were successfully extracted and amplified under case work conditions.[7,8]

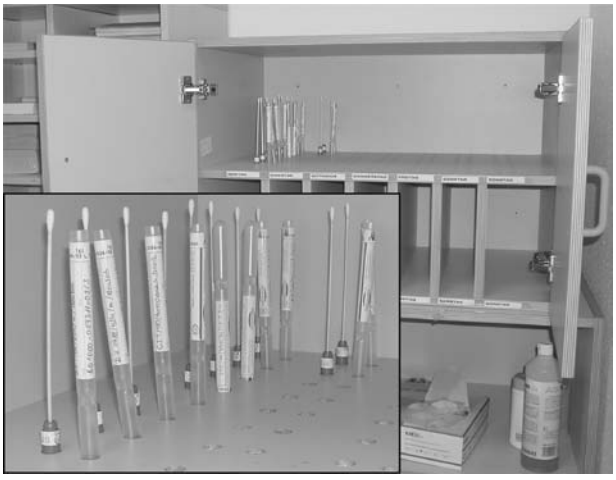

Fig. 2 Some laboratory standard procedures request cupboards to be used for drying of swabs. Sterile conditions are not necessary; contamination is not a problem as long as the swabs do not touch each other or the wall. Note that the cupboard must not be tightly closed to avoid building up of humidity. (*View this art in color at www.dekker.com.*)

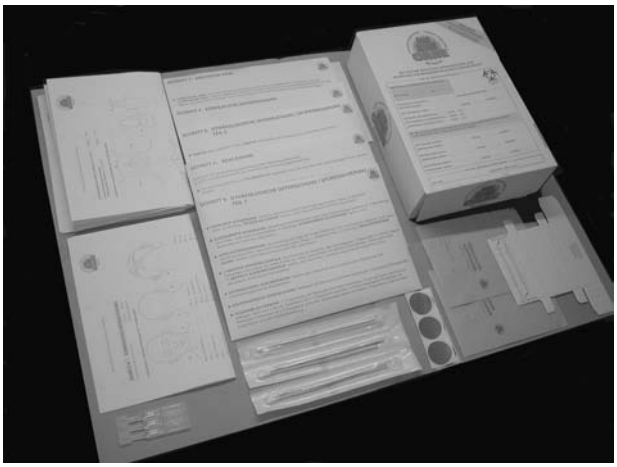

Fig. 3 Sexual assault kit (University of Bern/Swissforensix, Switzerland): Standardized descriptions and checklists are printed on the actual envelopes that contain the collection materials. (*View this art in color at www.dekker.com.*)

Sexual Assault Kits

After sexual assaults, biological stains are often collected in a hospital environment, at home, at a general practitioner's office, or at a police station. To avoid contamination of the samples and to allow full collection following a checklist, sexual assault kits are available. Their use is generally and strongly recommended to guarantee collection of all stains in the best possible way even under highly stressful conditions or in cases where lay personnel has to collect the evidence. The kits consist of prepacked envelopes in a cardboard box, which can be stored and stacked at room temperature (e.g., Sexual Assault Care Kit, University of Bern/Swissforensix, Fig. 3). The envelopes contain swabs, combs for hair (head and pubic), filter paper, sterile distilled water ampoules, large paper bags, and standardized protocol sheets.[1]

Skin Line Prints (''Fingerprints'')

DNA is resistant against many histological stains, including substances used to develop fingerprints (or other skin lines). DNA typing was successful from developed skin line prints after cyanoacrylate (super glue fume) or color reagents such as amido black, leucomalachite green, Hungarian Red, DFO, or luminol had been applied.[9,10]

Developed skin line prints should first be documented with a high-resolution camera (5–12 megapixels) or scanner (1200 dpi minimum). The original skin line prints can then be submitted to DNA storage and extraction like any other biological stain. The stronger the initial fingerprint, the more likely a DNA profile may be obtained.

STORAGE AND EXTRACTION

Dried biological samples should be stored in standardized paper bags (envelopes, brown paper bags) in a dry and cool environment. This will preserve the DNA over months to years. If dry samples need to be stored for more than 2 years, freezing below $-20^{\circ}C$ is recommended. To avoid paper layers sticking to each other in the freezer, the envelopes should be put into plastic bags. Never write on plastic surfaces that become frozen because any type of ink will easily come off. Use paper labels instead.

In temperate parts of the world, DNA was successfully extracted out of clothing and smears on slides that had been stored more than 10 years in dark environments at room temperature. In tropical countries, freezing is always necessary because of the high humidity, which allows bacteria and mold to build up.

Biological stains on glass slides, either embedded (histological tissue samples) or just regular smears (vaginal smears or blood), generally lead to good extraction results. The slides should be stored in standard cases for microscopic slides. Alternatively, they can be fixed with sticky tape inside of a paper envelope. Traces of dust generally do not affect the quality of dry stains but should obviously be avoided.

Insects collected at crime scenes or from corpses should not be dried because museum beetles will frequently destroy the samples within months. The insects should be preserved in 90% EtOH. At room temperature, DNA extraction of such material will then be possible up to several weeks after storage; at temperatures below $-20^{\circ}C$, extraction will be successful for several years.[10–12] Never use formalin to preserve samples; it will degrade the DNA.

Cigarette butts, envelopes with stamps, fingernail clippings, and dried nasal secretions should be stored dry in paper bags, envelopes, or cardboard boxes. Fingernails can be thoroughly swabbed if clipping is not an option.[13–15]

Because telogenic hair and broken-off hair shafts have been successfully used for DNA extraction, hair should be carefully stored, e.g., by attaching one end of every hair with sticky tape to the inside of an envelope or between two layers of filter paper. If hair is collected by the police using sticky tape for fiber collection, all material (fibers, lint, and hair) should remain on the tape until extraction becomes necessary.[16,17]

Extracted DNA Stored in Buffers

Depending on the applied extraction method, DNA stored in TE [10 mM Tris–HCl (pH 7.5), 1 mM EDTA] or similar buffers may be stable for weeks (after Chelex extraction) or months (phenol/chloroform extraction or use of spin columns) in the refrigerator at $+4^{\circ}C$ to $+12^{\circ}C$.

Freezing of extracted DNA in TE buffer below −20°C will preserve the sample for years. Before freezing, it is strongly recommended to distribute the DNA in small aliquots (e.g., 10 μL each) to avoid repetitive thawing and freezing of single samples.

Emergency Buffers

The standard storage buffer for extracted DNA is TE buffer. Before its use, the buffer is autoclaved or cleaned with a sterile filter. It can then be stored at room temperature. Under extreme conditions in the field, if drying of the samples is impossible (because of dust, humidity, chaotic mass disaster environments), TE can be used to collect samples by aliquoting 1 mL TE into sterile 1.5-mL plastic tubes. The collected biological stains can be put inside these emergency containers. DNA must still be extracted as soon as possible, and the samples should be stored as cool as the situation allows.

If more than a few hours are expected to pass before freezing or drying is possible, any solid biological sample in the field should be stored in centrifuge tubes containing aliquots of 95% EtOH. At room temperature, this will preserve the sample's DNA for weeks.[18]

MAIN DESTRUCTIVE INFLUENCES ON DNA

Under the influence of UV light (including sunlight) and acids, DNA contained in biological stains as well as extracted DNA breaks into pieces (degrades). Depending on the intensity of fragmentation, PCR might still be possible. Humidity does not directly affect DNA but will allow mold and bacteria to destroy the sample including the DNA within days. Frequent freezing and unfreezing of stains or extracted DNA will also lead to degradation. Household use of detergents and cleaners does not necessarily destroy DNA.[19] Sperm heads on fabric can survive machine washing at 30–40°C if no bleach was used.

CONTAMINATION

Under conditions of normal case work, contamination is only observed after careless manipulation or purposeful spraying of high (nanogram) amounts of DNA near or directly into open tubes before PCR. Secondary transfer via door handles, etc. is only a problem under extremely careless, unprofessional conditions.[20,21]

Obviously, mixtures of DNA might be present in the samples themselves. Mixtures of epithelial cells with sperm can be separated by differential lysis (separation of sperm from epithelial cells[22]). Other mixtures may show distinctively different peak heights after electrophoretic separation of the PCR products. For example, an object at a scene of crime may have been touched by Person A days before a biological stain (such as blood) of Person B is deposited on the same surface. In that case, a DNA mixture might be present later. It can often be detected by the different peak heights of the STR alleles.

Irrespective of the possible presence of mixtures, swabbing is always recommended if the items cannot be moved, are bulky, or if the stain is located on a person. Subsequent procedures like differential lysis should not be performed before DNA extraction becomes necessary. Generally, once evidence examination is completed, all biological samples should simply be stored cool and dry, and left intact as long as possible.

WITHDRAWAL OF SAMPLES OUT OF STORAGE

If parts of a stored biological sample need to be withdrawn for DNA extraction, forceps and scissors must be wiped with paper towels and 70% EtOH (or methylated spirits) every time they are used. In routine use, cross-contamination caused by wiped, smooth-surface forceps has not been observed. An exception is forceps with grooves. They must be autoclaved before every use because the groves quickly fill up with contaminants.

Still, especially during evidence examination and withdrawal, it is essential to take care of cross-contamination caused by contaminated distilled water, touching the swabs with used gloves, etc. Standard bacteriological procedures are an optimal guide.

Sample Retainment

It is recommended to always retain at least half of a stain in storage. One reason is that extracted DNA in liquid buffers is less durable than the original, dried stain. In addition, the defense should have a chance to reexamine the stain beginning with the original sample, not the extracted DNA. Only if DNA extraction and PCR seem to fail because of low amounts of DNA may stored samples be used up completely. This needs the consent of the prosecutor's (D.A.'s) office. Even in these cases, at least a minute amount of the original material should be stored so that future DNA technologies may be applied later on.

CONCLUSION

Collection of biological stains should be documented by photographs and drawings. Dry and cool storage will allow biological samples to be stored over years.

Extraction of DNA should be performed only if necessary for a current investigation; the original stains

should never be extracted completely. Contamination in the laboratory does not occur if the sampling is performed by trained personnel. Because many surfaces and even stains like fingerprints (skin lines), corneocytes on ropes, telogenic hair, the surface of skin after showering, etc. may contain material that is suitable for DNA typing, intelligent criminalistic decisions have to be made before collecting the evidence.

Intense swabbing and the use of sexual assault kits are simple yet very important procedures that guarantee maximum yield of DNA and collection of biological material even if it is not visible at the moment of collection. Even difficult stains such as feces can be extracted and should be stored frozen whenever possible. Under extreme field conditions, 90% EtOH may be used as a collection and storage liquid.

Forensic DNA Typing—Y Chromosome

F

Lluís Quintana-Murci
Institut Pasteur, Paris, France

INTRODUCTION

The human Y chromosome is one of the smallest chromosomes, representing 2–3% of a haploid genome. It is the only chromosome that has no homologue at any state or sex, in contrast to the X chromosome that has a homologue in the female sex. The majority of the Y chromosome (95%), termed nonrecombining Y (NRY), does not undergo recombination during male meiosis; however, two regions, pseudoautosomal regions (PAR1 and PAR2), located at the distal portions of the telomeres, recombine with homologous counterparts on the X chromosome. From a functional viewpoint, the Y performs specialized roles that are crucial for males, and therefore for the whole population, such as sex determination and male fertility. The haploid status of the Y and its exclusive paternal transmission make it a very useful tool in different domains as follows: 1) the estimation of historical patterns of population movements and splitting; 2) forensic applications, such as identification of male DNA in cases with male/female stain mixtures; and 3) genealogical studies and paternity testing, especially for deficiency cases, where the alleged father is deceased and his male relatives need to be tested.

Y CHROMOSOME MARKERS: HAPLOGROUPS AND HAPLOTYPES

One unique feature of Y chromosome markers is that they are inherited as a single block in linkage. Therefore Y-linked variations are largely a result of accumulation of de novo mutations over time.[1] This feature is very useful in high-resolution discrimination of individuals. Large-scale sequencing efforts and the development of rapid mutation detection techniques have accelerated the discovery of Y-chromosome variation. Today, more than 200 biallelic polymorphisms and around 30 multiallelic markers are available,[2–5] most of which are suitable for polymerase chain reaction (PCR)-based genotyping techniques. Biallelic markers mainly include single base pair variants [single nucleotide polymorphism (SNPs)] and also a reduced number of small insertions/deletions (indels), whereas multiallelic markers mainly refer to microsatellites and minisatellites. The main difference between the two sets of markers is their mutation rate: biallelic markers present lower mutation rates (about 2×10^{-8} per base per generation) than microsatellite markers ($2–3 \times 10^{-3}$ per base per generation). Biallelic variants and insertion/deletion polymorphisms almost certainly represent unique molecular events and define stable and deep-rooted branches, known as haplogroups, that can be traced back in time over thousands of years. These haplogroups present either a wide geographic distribution or, in some cases, more regionally clustered.[3,4] The multiallelic markers define the internal diversity of these haplogroups, and the combination of the allelic states of different microsatellite loci are known as haplotypes. Microsatellite haplotypes are very useful for microevolutionary studies and to distinguish subtle genetic differences between populations and/or individuals.[5] The high mutation rate of these markers, which enables a good discrimination between individuals, makes them the most suitable markers in forensic studies.[6] However, this high mutation rate has a disadvantage: the appearance of recurrent mutations. Thus, it is sometimes difficult to distinguish if two individuals are ''identical by state'' (share the same allele but not the same ancestry) or ''identical by descent'' (share the same allele and the same ancestor). This has important repercussions in population genetic studies because, at the population level, the use of these markers alone may lead to an underestimation of genetic distances among populations, thereby distorting genuine population relationships.

THE Y AND THE PAST: HUMAN ORIGINS AND POPULATION DISPERSALS

Y-chromosome studies have shown that Y-linked variation is nonrandomly distributed among human populations, showing lineage profiles that can be strikingly different among different worldwide populations.[2–4] These observations have obviously important consequences in ascertaining the origin of an individual during forensic investigations. From a human evolution viewpoint, Y-chromosome studies have given a major contribution to a better understanding of human origins and population dynamics. Y-chromosome phylogenies support the African origin of our species around 150,000 years

DOI: 10.1081/E-EDGP 120025634

ago. The most divergent branches of the trees are restricted to African populations, and non-African populations find their roots in branches of African origin.[2–4] These observations support the scenario in which modern humans can be traced back to a single African ancestral population that lived in Africa (i.e., the so-called ''Out of Africa'' model), from where it dispersed throughout the other continents replacing preexisting human species. Substantial continental and local population structure has been revealed, and hypotheses of early human migrations at different times formulated, such as the mode and tempo of the peopling of Asia and subsequent colonization of the Americas and the colonization of the Pacific.[3]

THE Y AND THE PRESENT: FORENSIC AND GENEALOGICAL STUDIES

Sex Assignment

The most obvious use of the Y chromosome in forensics is the sex assignment. The most commonly used test, the Amelogenin Sex Test (AMELY), takes advantage of the homology between the two pseudoautosomal regions of the sex chromosomes and amplifies a segment of the XY-homologous amelogenin gene pair.[7] Although this method avoids the ambiguous nature of a negative result as a result of the failure of the PCR reaction rather than to the absence of Y material, the reliability of the test depends on the assumption that the tested individuals present normal karyotypes and intact sex chromosomes. Nevertheless, individuals presenting a discordance between their sex phenotype and their karyotype (i.e., sex-reversed 46, XX males or 46, XY females) are present at appreciable frequencies in the population and can constitute a source of error in sex assignment tests based only in the AMELY test. It is suggested, therefore, to perform other sex tests in parallel, such as amplification of the *SRY* gene, which will give complementary information to the AMELY test.[8]

Identification and Discrimination of Male-Specific DNA

The analysis of Y-chromosome variation has been extensively used for forensic applications other than sex assignment. They can provide highly valuable information to resolve male–female DNA mixtures in, for example, sexual assault cases. In these cases, samples may present high amount of victims' cells, such as vaginal/anal washings, and sometimes no male autosomal profiles are identified. It has been shown that Y chromosome microsatellite analysis becomes a useful alternative because the use of specific Y-primers can improve the chances of detecting small amounts of the perpetrator's DNA in a background of heterologous female DNA.[9] Another obvious application of the Y chromosome is in paternity testing, especially for deficiency cases where the alleged father is deceased. In this case, the absence of the biological father can be resolved by the analysis of any relative sharing the same male line. However, when comparing the Y-chromosome profile in a paternity test or between a suspect and a sample, inclusion remains an important caveat. Although Y-linked microsatellites can be confidently used for exclusion purposes, nonexclusion can be problematic because 1) all the male relatives of a suspect/alleged father share presumably the same Y haplotype and 2) the Y chromosome of a suspect/alleged father may be present at high frequencies in the population under study, considerably reducing the reliability of the test. In any case, the high level of polymorphism of microsatellite markers offers a significant degree of discrimination between individuals. For example, a study of a German population using a 9-locus microsatellite haplotype, demonstrated a discriminatory capacity between Y-chromosome haplotypes of 97%.[10] However, this may not be the case in other populations with different genetic backgrounds and different population histories, where, for example, male-specific migration processes, founder effects, or genetic drift may have led to over-representation of specific haplotypes in the population.

Retracing Ethnic and Geographic Origins

Another possible information of interest for forensic investigators is that of ethnic origin. Although the highest genetic variation is observed between individuals and not between populations, Y-chromosome polymorphisms may provide the best resolution to ascertain the approximate geographic origin of a suspect.[11] Some haplogroups tend to be restricted to European populations, while others are restricted to sub-Saharan African or East Asian populations.[2–4] Geographic clustering of Y-chromosome haplogroups or haplotypes can be even more restricted. A recent Y-chromosome survey of the British Isles has shown that haplotype frequencies can differ considerably even over relatively short geographic distances.[12] Lineages of recent origin, such as haplogroup R-SRY2627, may exhibit a very limited distribution. This lineage has been observed only among Europeans and is almost restricted to Basque and Catalan populations.[13] In this case, it can be highly informative to predict the origin of the population and for exclusion purposes. However, more populations need to be tested for additional markers in order to create highly discriminative databases that will increase the power of reliability when inferring the geographic origin of a sample.

PRESIDENTS AND TSARS: THE POWER OF Y CHROMOSOMES AND MITOCHONDRIAL DNAs (MTDNAs)

The usefulness of Y chromosome data has been successfully used in some famous and controversial cases, such as U.S. President Thomas Jefferson's paternity of the children of one of his slaves. In 1802, he was accused of having fathered a child, Thomas Woodson, by Sally Hemmings. Also, Sally's last son, Eston Hemmings Jefferson, is thought to be the son of the President, although other scholars give more credence to the hypothesis that they were the sons of Jefferson's sister that fathered Eston. By analyzing several Y-polymorphisms in 14 members of the different male lines involved in the controversy (e.g., those of Thomas Woodson, Eston Hemmings, President Jefferson, and his sister's sons, the Carr's line), the authors found that President Jefferson and Eston Hemmings share the same haplotype.[14] In contrast, this haplotype was absent in Thomas Woodson and the Carr's lines, and its frequency in the general population is very low (0.1%). The authors concluded that President Jefferson fathered his slave's last child, whereas he was not the father of Sally's first child. The possibility that any other President's male-line relative could have fathered Sally's last child cannot be excluded, highlighting therefore the difficulty of being conclusive in these studies, but no historical records support this hypothesis. This study nevertheless illustrates the usefulness of Y chromosome data to disentangle complex hypothesis of alleged paternities and genealogical relationships.

In the absence of male-line comparison, a suitable partner of the Y chromosome is the mitochondrial DNA (mtDNA). This molecule can be highly informative in genealogical studies because, as the Y, it does not recombine and is transmitted through the maternal line without any modification other than naturally occurring mutations. Moreover, analyses of mtDNA in forensics can be even more powerful than Y-chromosome analyses because mtDNA is present at a higher copy number in cells and is more likely to survive prolonged periods than nuclear DNA. The most notorious example of its use in genealogical and forensic studies is the identification of the remains of Tsar Nicholas II and his family. By analyzing the amelogenin gene and autosomal STR variation in nine skeletons found in a grave in Ekaterinburg (Russia), the authors could confirm the presence of a family group, composed of two parents and three daughters and four additional unrelated bodies. To ascertain if the five related individuals corresponded to the Romanov family, mtDNA was analyzed in all bodies and in a living maternal relative of the Tsarina, Prince Philip the Duke of Edinburgh. Indeed, the mtDNA sequence of the putative Tsarina and her three daughters matched exactly that of the Duke of Edinburgh, supporting the hypothesis that their remains correspond to the Romanov family.[15] As to the putative body of the Tsar, his mtDNA sequence presented a very rare sequence heteroplasmy (presence of two alleles at a particular nucleotide position). By analyzing the body of the Tsar's brother and two living maternal relatives, the presence of this rare heteroplasmy was confirmed in the Tsar lineage, providing a powerful evidence supporting the identification of Tsar Nicholas II and his family.[16]

WHAT'S YOUR NAME? WHAT'S YOUR HAPLOTYPE?

In many societies, surnames are inherited patrilinearly, in the same manner as Y chromosomes. This parallel transmission can be used to tentatively associate surnames, or closely related human groups, and specific Y-chromosome haplotypes. For example, by using Y-chromosome microsatellites, it has been shown that half of the individuals with the English surname ''Sykes'' belong to a specific Y-chromosome haplotype, which is not present in non-Sykes samples and, in general, in other UK samples.[17] The presence of other haplotypes among the remaining Sykes samples has been attributed to historical accumulation of nonpaternity. However, further studies have shown that this lineage is present in Baltic States, although it is virtually absent in the British Isles, Scandinavia, and Iceland. This study, although preliminary, may have important forensic and genealogical applications. Increasing the number of microsatellites analyzed in individuals may eventually reach such a level of resolution that surname-specific haplotypes could be observed, with obvious important applications.

The use of Y-chromosome variation has also given insights into genealogies dealing with Jewish identity. According to Jewish tradition, males of the Levi tribe, of which Moses was a member, were assigned special religious responsibilities, and male descendants of Aaron, his brother, were selected to serve as Priests (Cohanim). Whereas in most cases Jewish identity is acquired by maternal descent, membership in the Cohen and Levi castes is determined by paternal descent. By studying a large group of Jewish individuals, which include Israelites, Cohanim, and Levites, it was shown that whereas Israelites and Levites exhibit a heterogeneous set of Y chromosomes, the Cohanim are mainly characterized by a unique haplotype that is present at high frequencies in both Ashkenazic and Sephardic Cohanim.[18] This haplotype, known as the Cohen Modal haplotype, is thought to be a potential signature of Judaic origin.

CONCLUSION

The times when the Y chromosome was considered a chromosome of ''low polymorphism'' have passed away. Today, the Y chromosome phylogeny is robust and rich in variation that has been successfully used in population genetic and forensic studies. Nevertheless, the definition of Y-chromosome variation, through a well-defined battery of markers, in global samples of different human populations remains a task to be accomplished and represents an imperative prerequisite to establish population databases of Y-chromosome haplotypes to be used in forensics. In this context, the precise knowledge of Y-haplotype frequencies in a given population becomes very important when matching the DNA profile of a suspect with the corresponding population database, because this will give the probability of finding this haplotype by chance in the population. The creation of these high-resolution population databases will also increase the probability to deduce the geographic origin of a DNA sample and will shed light on the preliminary associations between certain surnames, or lineages, and Y-chromosome haplotypes with the consequent important forensic and legal applications.

Forensic Identification—An Overview on Molecular Diagnostic Technology

F

Adrian Linacre
Yvonne E. Cruickshank
University of Strathclyde, Glasgow, U.K.

INTRODUCTION

DNA profiling has greatly changed the way in which human identification is performed for the purpose of a forensic investigation. Since the first case in 1985 through to the most recent technological advances, DNA profiling has adapted techniques used in medical and diagnostic research. The use of microarrays and nanotechnology is now becoming part of diagnostic technology, so these same methods will be adapted to forensic science. This chapter outlines the current situation regarding forensic science and diagnostic techniques.

FORENSIC DNA PROFILING

Forensic science, being the application of science to law, has applied many scientific techniques used in other fields of the analytical sciences to address questions raised in a legal context. The application of DNA technology, and in particular the use of the polymerase chain reaction (PCR), has revolutionized the field of human identification. The first use of DNA in forensic science was to help solve a sexual assault in England. Professor Sir Alec Jeffreys coined the term ''DNA fingerprinting''[1] when he was able to link two sexual assaults as committed by the same perpetrator and then to link the crime scene sample to the suspect, Colin Pitchfork. Previous examination of biological evidence used genetic polymorphisms producing different proteins; however, as the human genome is approximately 3 billion base pairs in size and that less than 3% is gene related, greater polymorphism lay in the non-gene-related regions. It was always considered that the DNA from each individual was unique, with the exception of monozygotic twins. Professor Sir Alec Jeffreys noted that there were regions of DNA where the same sequence of DNA was repeated many times. The number by which this repeat motif was found along the chromosome of different people was found to differ. These regions, termed variable number tandem repeats (minisatellites), were exploited in DNA fingerprinting. The field of DNA profiling has now moved to the analysis of hypervariable short tandem repeats (STRs). Short tandem repeats are short regions of DNA, typically 2–8 DNA bases in length, that are repeated polymorphically along the chromosome. The first use of STRs was in 1994 when four separate DNA loci were amplified in one reaction.[2] Within 1 year the multiplex PCR had increased to six independent STR DNA loci.[3] Short tandem repeats are regions of DNA found close to genes, often within introns, in which a sequence of DNA is repeated. The repeat motif is frequently 4 bp in length with the number of repeats varying from 6 to over 30. The number of repeats is known to be highly variable, producing size variations at the loci. The flanking DNA on either side of the STR loci is known to be highly conserved allowing amplification of the locus by PCR using primers made to the flanking DNA. Primers have been designed that will work on all the major ethnic populations.

With increased knowledge of the PCR process the number of loci that could be successfully and routinely amplified increased to a point where currently 10 STR loci form the basis for the National DNA Database (NDNAD) in the United Kingdom. In the United States 13 loci form the Combined DNA Index System, or CODIS. Short tandem repeats are highly abundant in the human genome and are known to be polymorphic.[4,5]

While one STR locus provides little power of discrimination, it is common to analyze 10 STR loci in a single multiplex reaction. Each of the loci examined is independently inherited producing an overall power of discrimination of greater than a billion. This equates to close to identity and meets the current needs of the forensic community.

MITOCHONDRIAL DNA AND FORENSIC SCIENCE

The current situation in forensic science is that there are a number of autosomal STR loci that can be analyzed leading to possible links between a crime scene sample and that taken from a suspect. Mitochondrial DNA has been used in forensic science for human identification and

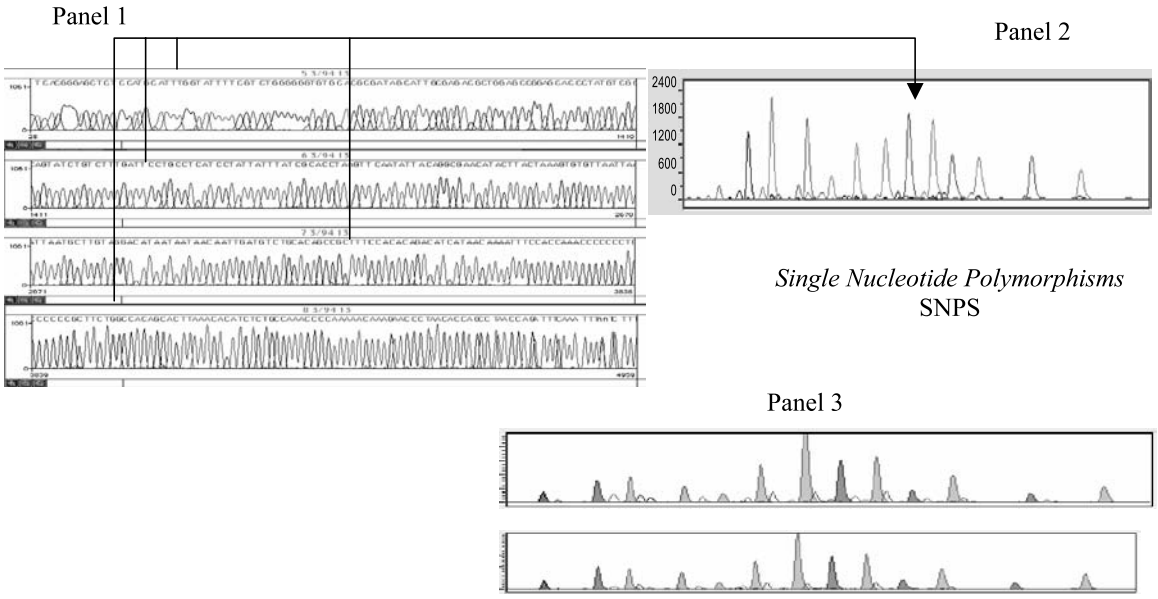

Fig. 1 Example of minisequencing of 12 SNP sites on the human mitochondrial genome. Panel 1 shows a DNA sequence trace from four samples of mitochondrial DNA and highlights single-base changes between one of the samples and the other three. Panel 2 shows the resulting minisequence trace. Panel 3 shows a casework example where the top trace is from a hair found on clothing and the bottom trace is from an alleged victim of a crime. In this case there is a match between the DNA extracted from the hair and the reference sample from the victim. (From work provided by Dr. Gillian Tully for publication purposes and based upon an illustration used in Ref. [10].) (*View this art in color at www.dekker.com.*)

for population studies.[6–8] Within each mitochondrion there is a circular loop of DNA being 16,569 bases in length in humans. There are no STR loci on the mitochondrial DNA, rather, DNA sequence polymorphisms are detected on either side of the point of replication. It is common practice to amplify this fragment of the mitochondrial genome and directly sequence the PCR product.

SINGLE NUCLEOTIDE POLYMORPHISMS

The sequence polymorphisms found within the mitochondrial DNA are termed single nucleotide polymorphisms (SNPs). Single nucleotide polymorphisms are positions within the genome where there is a difference between people at one single base. It may be that at a particular position the nucleotide ''A'' is normally found, but in a minority of people the base ''G'' is present. In such an instance most people will have the base pair A/T with a minority being G/C at the same position. There are a number of SNP sites on the mitochondrial DNA within the loci examined. Single nucleotide polymorphisms were first used in forensic science by the U.K. Forensic Science Service to examine mitochondrial DNA from suspects and from crime scenes.[9] This method examined 12-point mutations known to be variable within the mitochondrial DNA by a technique termed minisequencing. Minisequencing of the mitochondrial DNA polymorphic sites allows rapid screening of the variable DNA bases. In forensic investigations this process is used to exclude all the samples in a case that do not match at the 12 points. An example of an SNP of mitochondrial DNA is shown in Fig. 1.

Detection of SNP by minisequencing requires separation of DNA fragments by either gel or capillary electrophoresis. Much SNP testing for forensic and diagnostic purposes can now be performed using oligonucleotide microarrays.[10] Microarrays (also covered in Chapter 10 of this encyclopaedia) allow the single-base difference to be detected on a silicone chip. The two different versions, either A or G in the case example, are placed on the chip. If A is present then a DNA sequence with T will bind. If G is present a DNA sequence with C will bind. It is possible to detect SNP polymorphic sites on the mitochondrial DNA. An example is shown in Fig. 2.

SNP ANALYSIS IN CODING AND NONCODING DNA REGIONS

Within the chromosomal DNA, SNPs are highly abundant occurring on average 1 base in every 1000.[11,12] As the human genome is now known to be around 3 billion bases

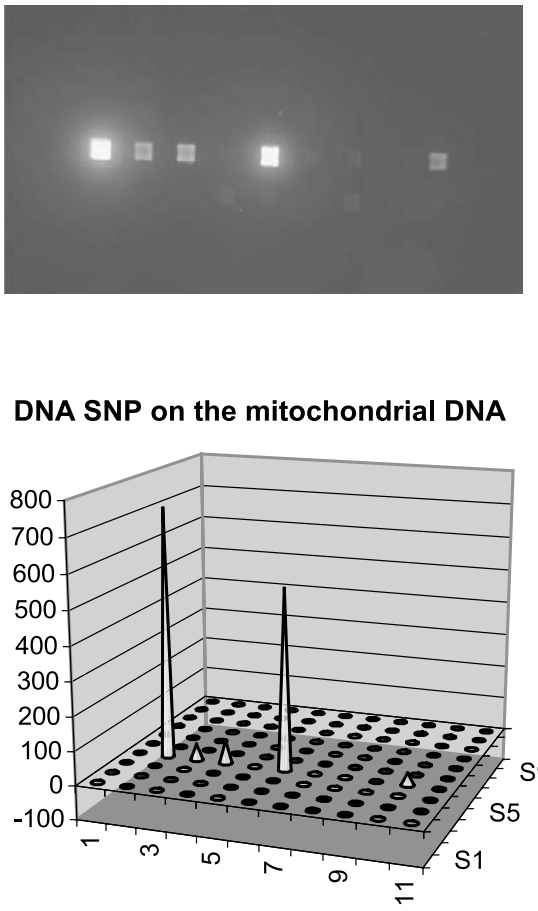

Fig. 2 Analysis of two SNP loci on the human mitochondrial genome. (Taken from research work by Dr. Barbara Llewellyn at the University of Strathclyde.) The top panel shows the results of hybridization of a segment of DNA mitochondrial DNA to oligonucleotide sequences on a silicone chip. The position on the chip where the DNA binds to a complimentary sequence is detected by fluorescence. The bottom panel shows the amount of fluorescence at the two sites. (*View this art in color at www.dekker.com.*)

in size, there are therefore approximately 3 million SNPs within the human genome. To date, the International SNP Map Working Group has identified 1.42 million SNPs distributed throughout the human genome.[13] The SNP loci examined in forensic science are within the 97% of the human genome that is noncoding. Single nucleotide polymorphisms that are present within coding regions of the DNA may have an effect on the protein transcribed by the gene and result in a genetic disorder. As such, SNPs that cause a genetic disorder are of key interest to the medical community. These SNPs may be dominant or recessive and are responsible for a number of key genetic disorders. Additionally, SNPs within the regulator region of genes, such as in promoter sequences, may influence the susceptibility of individuals to particular disorders. The majority of SNPs are considered to have no known effect on the fitness of the organism; however, those SNP loci that affect the fitness of the organism have been the focus of interest to the medical community. The field of medical genetics has recently started to develop a number of diagnostic tests based upon single base-pair mutations in the human genome. A number of genetic diseases are the result of such single base-pair mutations, such as cystic fibrosis and beta thalassaemia.[14,15] In parallel to the investment made in STRs by the forensic community, genetic diagnostics has focused on many such single point mutations. When the mutation becomes a common type, with the rarer allele at more than 1% of the frequency of the common allele, such loci are termed SNPs.[16]

Forensic science reacts to developments in other areas of science, frequently adapting techniques developed for nonforensic purposes. While DNA profiling is no exception, the analysis of STR loci has been highly successful. Tiny bloodstains can be examined and a DNA profile can be produced that has a match probability greater than 1 in a billion to a suspect. There has been much investment in the STR loci, particularly in the formation of DNA databases of felons. However, SNP analysis offers many advantages in the field of diagnostic analysis.

FORENSIC TOXICOLOGY

Forensic toxicology is defined as the study of the adverse effects of poisons on living organisms in relation to the law. Indeed, the most common poisons in today's society are drugs of abuse, controlled under different countries legislations, and the majority of forensic toxicology is concerned with the detection of such drugs within the blood or urine of a person. The analysis determines whether a controlled substance is present, and if so how much is present. In fatalities the quantity of a controlled substance must be known before a conclusion can be made as to the cause of death. To obtain the amount of drug present in the person at the time of death, a backtracking calculation is carried out. In such a calculation there are issues with the interpretation of the toxicology results. This is because one dose may be at a level that is therapeutic to one person but lethal to another. The interindividual differences in response to a drug are due to interindividual differences in drug metabolism, which in turn is a result of genetic polymorphisms in the production of drug receptors and drug transporters. A well-characterized genetic polymorphism occurs within the cytochrome–p450 system where there are subfamilies

of isoenzymes including CYP2C9, CYP2D6, and CYP3A4.[17] Slow, medium and fast metabolizers are the result of the production of different isoenzymes, which is under a genetic control. Single nucleotide polymorphisms to the gene system for the different metabolic systems would allow determination of whether the person had a slow metabolism, hence death resulting in a quantity of drug that would otherwise be therapeutic to a fast metabolizer.

CONCLUSION

One of the greatest advances in forensic science has been the introduction of DNA profiling. To date DNA profiling is performed using microsatellite amplicons (STRs) where hypervariability exists within the number of repeats of a short DNA sequence motif. Greater than 3 million samples have been analyzed by this method on the U.K. National DNA database alone, with currently an increasing number of samples on the U.S. CODIS and similar DNA databases throughout Europe. Due to the great investment in the science of DNA profiling using STR loci there would need to be a great advantage in a new technology. Single nucleotide polymorphisms offer many advantages, particularly in the speed of throughput and option for automation. Approximately 50 SNP loci are required to have the same discrimination power as 10 STR loci, but 50 SNPs can be detected readily and therefore this level of DNA detection can be overcome. One major reason for microarrays not being more common in forensic science is that crime-scene samples are frequently mixed, containing cellular material from more than one person. In such cases, a mix of a person with SNP of type A only and a person who is type G only could not be differentiated from a person who is A and G. Mixtures occur routinely in forensic science thereby adversely affecting the introduction of SNP typing in human identification.

In forensic toxicology the samples are normally from one person only and it may be in application such as this that SNP typing will find a role.

Fragile X Syndrome

James N. Macpherson
Salisbury District Hospital, Salisbury, Wiltshire, U.K.

INTRODUCTION

Fragile X Syndrome and Fragile Sites

Fragile X syndrome is a relatively common, yet—until recently—poorly understood inherited condition characterized by variable degrees of learning and social disability. First discovered in 1943 (when it was known as the Martin–Bell syndrome), it derives its name from its frequent association with a rare folate-sensitive fragile site (FRAXA) localized near the distal tip of the long arm of the X chromosome (Fig. 1) at Xq27.3, later also confirmed as the site of the gene locus.[1] In fact, there are two distinct conditions associated with expressed site fragility in this chromosomal segment: the FRAXE site is difficult to distinguish from FRAXA by conventional cytogenetics, but high-resolution methods map it slightly distal at Xq28. Some, but not all, properties of the FRAXA locus also apply to FRAXE; the primary discussion in this article will be of FRAXA, but the distinctive characteristics of the FRAXE locus will be pointed out wherever relevant.

FEATURES OF FRAXA AND FRAXE

Clinical Phenotype, Genetics, and Biochemistry

The fragile X syndrome affects males to a greater extent than females: in males, learning and social deficits are moderate to severe, with social impairments usually preventing them from fathering offspring although sperm production is thought to be unaffected. In adult males, visible signs of the condition often include a large head, long face, large ears, and macroorchidism; however, in children, the phenotype is likely to be restricted to developmental delay with perhaps some autistic-like features such as gaze avoidance or hand-flapping.[2] Females with fragile X syndrome vary from apparently normal phenotypes to moderate learning disability, often with heightened anxiety, social withdrawal, or depression.[3] The appearance of fragile X phenotypes in women may be simply a consequence of nonrandom X inactivation, although this has not been proven.

In 1991, the gene responsible for fragile X syndrome was isolated by several independent research groups[4,5] and designated *FMR1* (fragile X mental retardation 1). Most surprising was the discovery of the novel mutational mechanism—the progressive expansion of a tract of trinucleotide (CGG) repeats in the 5′ untranslated region of the gene—culminating in the shutdown of transcription and hypermethylation of the promoter for repeat numbers in excess of around 200. Repeat numbers between around 60 and 200 show pronounced instability at meiosis, with a heavy bias toward expansion; therefore, these behave as ''premutations.'' This process of progressive repeat expansion has been termed *dynamic mutation*[6] and provides an explanation for the unusual inheritance pattern of fragile X syndrome with many nonpenetrant ''transmitting'' males observed in pedigrees. A far greater instability is observed during maternal transmission; although minor instability of premutations may be observed in paternal meiosis, a paternally transmitted premutation rarely, if ever, expands into a full mutation. Rare cases of fragile X syndrome are found to have a point mutation or deletion in *FMR1* instead of a trinucleotide expansion, confirming the loss of gene product as a cause of fragile X pathology.

In addition, in 1991, the existence of the distinct condition of FRAXE was established when it became clear that several ''fragile X'' families (i.e., showing expressed site fragility in Xq27–28 and learning disability) did not have expansions in the CGG repeat tract in the *FMR1* gene. Shortly afterward, these families were found to be segregating an expansion mutation in a GCC repeat tract in exon 1 of another gene, designated *FMR2*.[7] Pedigrees of FRAXE families differ notably from those of FRAXA families in that affected males frequently have children, with the degree of intellectual and behavioral impairment being much less pronounced than for FRAXA. Males with FRAXE mutations do not show the syndromic features typical of FRAXA, and FRAXE is now considered as a nonspecific X-linked mental retardation condition with a much lower incidence than FRAXA. The FRAXE repeat shows a dynamic mutation behavior similar to that of FRAXA, with unstable premutations

DOI: 10.1081/E-EDGP 120020585

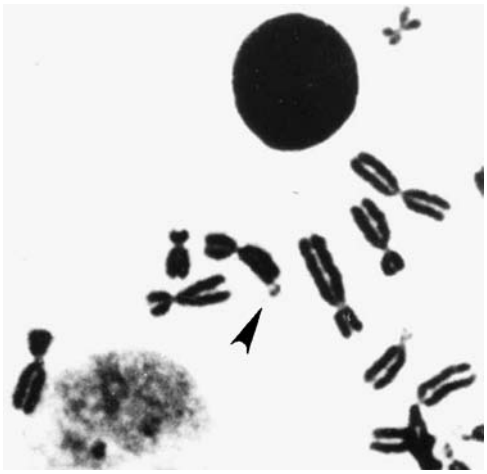

Fig. 1 Fragile X chromosome. (Courtesy of Prof. Pat Jacobs.)

expanding progressively to become full mutations. However, rather surprisingly, there is no obvious homology between *FMR1* and *FMR2* apart from the repeat tract.

The *FMR1* gene responsible for fragile X syndrome comprises 17 exons, is alternatively spliced, and codes for a protein-designated FMRP,[8] expressed in various tissues but especially strongly in neurones and spermatogonia. Although not yet fully understood, the function of FMRP is becoming rapidly elucidated in recent years. It is an RNA-binding protein whose domains also include a nuclear localization signal and a nuclear export signal. It shows affinity for a number of partner proteins in the cytoplasm, where it associates closely with ribosomes. FMRP appears to shuttle in and out of the nucleus, binding a variety of mRNA including that of *FMR1* itself, forming a ribonuclear particle that is transported along neurones to dendrites, where some local protein synthesis appears to take place. One of the key processes influenced by FMRP seems to be the maturation of dendritic spines; these fine protuberances are the principal determinants of synaptic plasticity, which in turn affects learning, memory, and cognition. Abnormal or immature dendritic spines have been demonstrated in both genetically and environmentally induced mental retardation syndromes. Knockout mice deficient in FMRP have been shown to exhibit learning deficits and immature and overabundant dendritic spines.[9]

Population Genetics

The dynamic mutation process creates a situation where new mutations are rarely observed, with all cases of premutations and full mutations in the population having been derived from parents with smaller expansion mutations. It is presumed that the smallest premutations arise from within the size range of 6–59 repeats, which exhibits a stable polymorphism within the general population. In the upper part of this ''normal'' size range, from about 45 repeats upward, the probability of unstable meiotic transmission becomes slightly elevated, but this tendency seems to be greater in some families than others, which creates a broad region of overlap in size between the ''normal'' and ''premutation'' allelic states.[10] This range of sizes, approximately 45–60 repeats for FRAXA and possibly lower for FRAXE, has been termed the ''intermediate range'' or ''grey zone.'' There are substantial difficulties in the genetic counseling of patients found to carry an intermediate-sized allele, especially where the genetic family history is incomplete. The risk of expansion to a full mutation increases progressively with the size of premutation in the mother; the smallest premutation, to date, found to expand to a full mutation in one generation has been 59 repeats.

The main factor believed to differentiate stable intermediate alleles from unstable potential premutations is the presence of interspersed AGG motifs at regular intervals, typically every 9th or 10th trinucleotide, within the CGG repeat tract.[11] These are thought to anchor the repeat sequence and prevent major unequal exchanges leading to expansion. Most normal, stably transmitted alleles are found to contain at least two interspersed AGGs, whereas almost all unstable premutations have pure CGG tracts or a single AGG. Where an AGG is retained, it is almost invariably the most proximal one in the sequence, implying that loss of interspersions and consequent expansion are effected at the distal (3′) end. The evidence is circumstantial because the loss of an AGG leading to acquired instability within a pedigree has yet to be reported. However, the GCC repeat tract at the FRAXE locus appears to be devoid of interspersions even among normal alleles; hence, the presence of interspersed motifs is clearly not the sole mechanism for restricting the mutability of trinucleotide repeat sequences.

Diagnostic Testing

Full mutations at both the FRAXA and FRAXE loci may be readily identified by a Southern blot of a genomic DNA digest followed by hybridization with a specific labeled probe (Fig. 2). Use of a double digest employing one restriction enzyme sensitive to methylation enables the observation of hypermethylation associated with full mutations, thereby providing a more sensitive resolution of full mutations and premutations based on both size and methylation status.[12] Occasionally, mosaics for a full mutation and a premutation are observed; these constitute up to 20% of FRAXA full-mutation patients and may be less severely affected with fragile X syndrome. Care should be taken when interpreting the FRAXE blots using

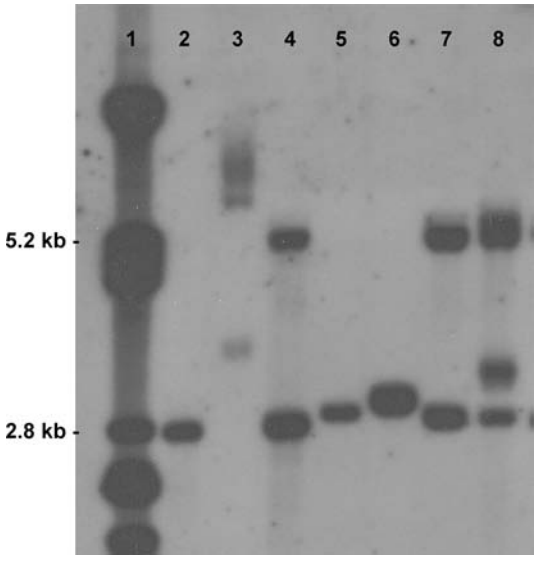

Fig. 2 Southern blot of *FMR1* gene. Digest with *Bst*ZI/*Eco*RI hybridized to probe StB12.3. (From Ref. [12].) Lane 1: Size marker λ*Pst*I digest; lane 2: normal male; lane 3: full mutation/premutation mosaic male; lane 4: normal female (note methylated upper fragment corresponding to inactive X chromosome); lane 5: male with intermediate allele; lane 6: premutation male; lane 7: normal female; lane 8: premutation female.

*Hin*dIII digests because there is a restriction site polymorphism that can mimic full mutations;[13] if this is suspected, a different enzyme digest should be used to confirm the diagnosis. Southern blot analysis is generally performed on samples of peripheral blood but may also be carried out on chorionic villus samples, facilitating reliable prenatal diagnosis of fragile X syndrome.

The high demand for fragile X testing creates a need for a high-throughput exclusion technique, and polymerase chain reaction (PCR) analysis of the repeat sequence using either a radioactive nucleotide incorporation (Fig. 3A) or a fluorescently labeled primer (Fig. 3B) provides rapid and convenient detection of males with a normal-sized allele and of females with two normal-sized alleles.[14] This technique also detects the smaller-sized premutations up to approximately 70 repeats, and enables fairly accurate estimates of repeat size to be made. However, it will not detect the larger premutations or full mutations due to the sharp reduction in efficiency of PCR for long CG-rich repeat sequences. Hence, males who show no PCR product, or females who show just a single allele require further analysis by Southern blot to determine their genotype. It should also be noted that the exclusion of fragile X by this method depends on the assumption that mosaicism for a normal allele and a full mutation is absent or very rare. If there is not enough DNA for conventional Southern blot analysis, it is possible to detect large premutations or full mutations by electrophoresing PCR products, transferring them to a membrane by electroblotting and hybridizing to a $(CGG)_n$ oligonucleotide probe.[15]

An alternative way of diagnosing fragile X syndrome is by in situ FMRP detection using an anti-FMRP antibody, which is detected as a red stain in the presence of FMRP.[16] The technique may be employed using blood cells, but has met with most success using hair root tissues. Clearly, as it is the absence of staining due to lack of FMRP that is indicative of fragile X syndrome, this diagnostic strategy is highly reliant on the efficiency of staining and must, in any case, be followed up by genetic testing of any suspected patients. Furthermore, it will not identify premutation carriers. However, it does have the advantage of detecting the minority of fragile X patients with a null mutation in the coding sequence of the gene rather than a trinucleotide repeat expansion.

Screening and Prevalence

Estimates of the prevalence of fragile X mutations have shown wide variation. Early screening studies employing cytogenetic fragile-site expression as a diagnostic criterion were subject to errors resulting from nonpenetrance of cytogenetic expression, low-level ''background'' expression leading to false positives, and the pooling of FRAXA and FRAXE site expression—these errors created probable overestimates of the prevalence of *FMR1* mutations. More recent screening studies using molecular testing to identify mutations have arrived at a consensus of 1/4000 to 1/6000 as a prevalence for the FRAXA full mutation;[17,18] although lower than previous estimates, this would still make fragile X syndrome the single most common inherited cause of intellectual disability. There is some evidence of ethnic variation: a few isolated populations have a significantly higher prevalence of FRAXA mutations.[19] The only recorded estimate of FRAXE full mutation prevalence is 1/23,000,[18] but this needs to be corroborated by further studies.

Other *FMR1* Phenotypes

Until recently, it was thought that premutations had no adverse phenotypic consequences. However, two conditions have now been found to be associated with *FMR1* premutation alleles: premature ovarian failure (POF) and fragile X-associated tremor and ataxia syndrome (FXTAS).

POF, defined as the onset of menopause before the age of 40 years, affects some 20% of female *FMR1* premutation carriers.[20] As there is no evidence of POF among full-mutation carriers, it seems likely that this is a causal effect of the premutation rather than any mutation

in an adjacent gene in linkage disequilibrium with *FMR1*. The pathological mechanism by which *FMR1* premutations cause POF is unknown, but a possible biochemical basis for this and other premutation phenotypes has been established by the discovery of elevated *FMR1* mRNA levels and reduced FMRP levels in premutation carriers.[21]

FXTAS is a more recently discovered condition than POF and its properties are still being characterized.[22] However, preliminary studies suggest that it may have a penetrance similar (20–30% of male premutation carriers) to POF, and again no comparable condition has been found in full mutation carriers. It appears that FXTAS may be restricted to male carriers, although studies continue to look for possible equivalent effects in female carriers.

CONCLUSION

The identification of the *FMR1* and *FMR2* genes has immeasurably enhanced the quality of care and counseling available to fragile X families. Many previously unidentified families have been diagnosed, and prenatal diagnosis is routinely available. Although no cure for fragile X is imminent, rapid progress in identifying the pathology of fragile X syndrome and the role of FMRP should be invaluable in the development of appropriate drug therapies and interventions. The mouse model may be a useful vehicle in such an endeavor; however, the gap in physiology between mice and humans should not be underestimated. There remains a pressing need for more accurate risk prediction for alleles in the intermediate and premutation size ranges, which may be possible using advanced sequencing techniques to establish the pattern of AGG interspersions within the repeat tract. Finally, the spectrum of conditions associated with premutations and the etiology of such effects remain to be fully elucidated.

The discovery of the *FMR1* gene and its novel mutational mechanism provided the catalyst for the identification of an abundant class of genes harboring trinucleotide repeats, including those responsible for common genetic conditions such as Huntington disease, myotonic dystrophy, and Friedreich ataxia. Although the first trinucleotide repeat disease to be discovered, FRAXA has not proved to be typical of the genre of such loci: peculiar features include association with fragile sites and loss of gene function due to methylation, extreme parent-of-origin bias in repeat expansion, and pleiotropic phenotypes attributed to premutations. Fragile X syndrome, despite a wealth of intensive study and many significant advances, continues to rank among the most intriguing and enigmatic of all human genetic diseases.

Gaucher Disease

Deborah Elstein
Ari Zimran
Shaare Zedek Medical Centre, Jerusalem, Israel

INTRODUCTION

Gaucher disease, the most common lysosomal storage disorder, is caused by deficient β-glucocerebrosidase activity and results in progressive accumulation of the substrate in macrophages, leading to hepatosplenomegaly, anemia, thrombocytopenia, skeletal lesions, lung disease, and sometimes neurological involvement. Enzyme replacement therapy (ERT) has proven to be safe and effective. Other strategies including bone marrow transplantation, substrate reduction, enzyme chaperones, and gene therapy have been variously attempted.

BACKGROUND

Gaucher disease was first described in 1882 by a French medical student, Philippe Gaucher, who assumed that the large splenic cells, which today bear his name, were a manifestation of a primary neoplasm of the spleen. More than a century later, Gaucher disease is known as the most prevalent lysosomal storage disorder, caused by an inherited enzymatic defect with consequent accumulation of undegraded glucocerebroside in monocyte–macrophage cells—the ''Gaucher cells.''[1] Nonetheless, neither quantity of residual activity nor genotype can accurately predict the type or degree of severity of the phenotype except in a broad sense. Thus the clinical heterogeneity that marks all forms of Gaucher disease is attributable only in part to the more than 200 mutations within the β-glucocerebrosidase gene;[2] other genetic and/or environmental factors undoubtedly also influence phenotype.

TYPES OF GAUCHER DISEASE

Gaucher disease has classically been divided into three clinical types based on the absence or presence of neurological involvement.

Type I is defined by the absence of neurological involvement and, usually, the presence of the N370S (1226G) mutation on at least one allele. Although pan-ethnic, it is especially prevalent among Ashkenazi Jews (1:850 live births). There is tremendous heterogeneity in the severity of clinical manifestations, ranging from asymptomatic to severely debilitating disease [often defined by the Zimran Severity Score Index (SSI), which awards up to 30 points based on disease features].

Types II and III, both relatively rare and pan-ethnic, are marked by the involvement of the central nervous system.[3] Horizontal supranuclear gaze palsy is pathognomonic for neuronopathic forms.

Type II, the infantile (acute) form, is characterized by several neurological features, including hypertonic posturing, strabismus, trismus, and retroflexion of the head, in addition to massive organomegaly. The onset of symptoms is usually during the first 6 months of life, with progressive deterioration of neurological function until death, usually before the second year.

Type III Gaucher disease has been further subclassified: type IIIa patients exhibit mild to moderate hepatosplenomegaly and slowly progressive neurological deterioration, frequently associated with recurrent myoclonic seizures. Patients with type IIIb exhibit massive hepatosplenomegaly, frequently accompanied by lung involvement, but with minimal neurological signs, usually only the horizontal supranuclear gaze palsy.

Although cardiac involvement is rare in all forms, a unique variant, type IIIc, has been described in Japanese, Spanish, and Arab children, all homozygous for the D409H (1342C) mutation, who evince progressive calcification of aortic and/or mitral valves of the heart that is life-threatening.[4] Homozygosity for this mutation is the single instance of relatively tight genotype–phenotype correlation in Gaucher disease.

MOLECULAR, GENETIC, AND ENZYMOLOGICAL ASPECTS

The genomic area near the β-glucocerebrosidase locus on human chromosome 1q21 includes its pseudogene and several other gene loci. Enzyme and mRNA activities vary among species and tissues, the import of which is unclear. Before the advent of a biochemical assay of β-glucocerebrosidase activity, demonstration of Gaucher

DOI: 10.1081/E-EDGP 120025757

cells in the bone marrow was used for diagnosis. Since 1970, routine enzymatic assay (pH 4) of leukocytes that hydrolyze 4-methylumbelliferyl-β-glucocerebrosidase to <15% of normal is the gold standard for diagnosis.[1] A limitation of the test is the overlap of activity of heterozygotes with normal values, and the inability of the enzyme level to predict neuronopathic involvement.

Therefore, mutation analysis based on routine polymerase chain reaction (PCR)-based technology has been added as an adjunct for diagnosis because some mutations have been associated with mild, severe, or lethal disease. Primers target the gene fraction of interest and amplify it (but not the pseudogene). Restriction digestion reveals mutations by gel electrophoresis; alternative approaches include allele-specific oligonucleotide hybridization,[2] and mismatched PCR methods by amplification refractory mutation systems[1] or by direct sequencing, if necessary. A new kit assay, the PRONTO™ procedure (Savyon Diagnostics, Israel), detects single-nucleotide polymorphisms in DNA sequences via multistep reactions using biotin-labeled primers, and the final results are read either visually (substrate remains clear or turns blue) or colorimetrically using enzyme-linked immunosorbent assay (ELISA).

Whereas the majority of disease alleles are single-base substitutions resulting in missense mutations, there are also nonsense mutations and rearrangements. Of the more than 200 disease-associated alleles (most of which cluster toward the 3′ end of the gene), fewer than 10 have significant frequencies in various populations, among them N370S (1226G), 84GG, L444P (1448C), IVS 2+1, D409H (1342C), R486H (1604A), and F213I (754T), and the two recombinant alleles, RecNciI and RecTL.[2]

Allele distribution reveals that the common N370S mutation is detected in 71.8% of Ashkenazi Jews (which, in homozygosity, is invariably associated with mild disease), but only in 43.6% of non-Jews;[2] indeed, among non-Jews, the prognostic information of large numbers of private/rare mutations also decreases the usefulness of mutation analysis. Thus genotype–phenotype correlations and genetic and/or environmental modifiers are areas of intense research for improved genetic counseling and open avenues of therapeutic intervention. Currently, chorionic villous sampling and amniocentesis are available for prenatal diagnosis. As a rule of thumb for broad outlines for prediction of phenotype: null/null mutations are incompatible with life, whereas mild/mild mutations generally result in mild type I disease; mild/severe or mild/null mutations often result in symptomatic, nonneuronopathic disease; and combinations of severe/severe or severe/null mutations result in neuronopathic forms.

Mutation analysis for detection of carrier status among Ashkenazi Jews is robust, being nearly 98% reliable.[1]

MALIGNANCY

An increased incidence of monoclonal gammopathies and multiple myeloma has been reported. In a recently completed study of patients in a large referral clinic and from the international registry (ICGG), approximately 4–5% of all patients developed a malignancy.

PREGNANCY

Fertility of both sexes is generally unaffected by the disease; however, pregnancy per se may affect the patient, and, in turn, Gaucher disease may affect the pregnancy. Although many patients experience a rather benign course during pregnancy, delivery, and the postpartum period, patients with more severe manifestations or with a bleeding tendency may not enjoy this outcome; hence, close hematological monitoring is recommended during pregnancy.[5]

VISCERAL SIGNS AND SYMPTOMS

Splenomegaly exists in all patients, and is typically associated with hypersplenism, early satiety, and, in children, growth (height) retardation. Anemia and thrombocytopenia, resulting in fatigue and bleeding tendency, respectively, are among the earliest presenting signs and most prominent features of Gaucher disease. In almost all symptomatic patients, there is some degree of hepatomegaly but only rarely are liver function tests abnormal.

Bone involvement is among the more variable and probably the most debilitating features, particularly the recurrent attacks of ''bone crises'' experienced primarily in childhood. The incidence of these episodes abates with age. The occurrence of pathological fractures, avascular necrosis of the heads of femur and humeri, and compression fractures of the spine are well-documented complications of severe skeletal involvement. Osteopenia and osteoporosis may be important findings even among young adults.

Pulmonary involvement is recognized as an uncommon finding in type I disease; among the neuronopathic forms, it is generally the penultimate cause of death.

THE NEUROLOGICAL CONTINUUM

Although type I is, by definition, nonneuronopathic, and the presence of the N370S allele obviates neurological involvement, nonetheless, recent data are suggestive of a

phenotypical continuum that includes some neurological signs even in patients with type I. Among the earliest anecdotal reports were those of parkinsonism that is marked by early onset, aggressive progression, and refractoriness to conventional anti-Parkinson therapy in patients with very mild type I Gaucher disease.[6]

Similarly, the very-early-onset type II or the ''neonatal form'' has been proposed wherein onset of signs is in the neonatal period, and is in conjunction with other overt abnormalities including ichthyosis, hydrops fetalis, and/or collodion baby.[7]

BIOCHEMICAL AND SEROLOGICAL MARKERS

There is no single biochemical marker for Gaucher disease that correlates perfectly with severity and/or is affected in a predictable manner with therapy. Although acid phosphatase and angiotensin-converting enzyme have long been known to be elevated in most patients, there is a preference to measure chitotriosidase levels,[8] which have been used as a measure of disease severity, to assess the success of therapeutic modalities and to compare treatment regimens.

SYMPTOMATIC MANAGEMENT

Whereas in the past, splenectomy was frequently performed for the management of severe thrombocytopenia and/or for relief of mechanical compression by the greatly enlarged spleen, by removing the main reservoir for Gaucher cells, splenectomy may induce or aggravate liver and bone involvement. Today, splenectomy is rarely indicated.

Total joint replacement is the most important orthopedic intervention, both in the past and in the present, for patients with avascular necrosis of the joints who suffer from severe pain and disability.

A rare but severe manifestation is spinal cord compression caused by the collapse of one or more adjacent vertebral bodies; options of conservative management and surgical decompression have been employed to reduce pain, ameliorate neurological deficit, and correct gibbus formation. Conversely, among children with type III disease where the gibbous develops without destruction of vertebral bodies and with no impingement on the spinal cord, the main concern is compromised diaphragmatic excursion and secondary restrictive lung disease. In these latter cases, a brace may be required, although kyphosis may not be reversible.

BONE MARROW TRANSPLANTATION

Bone marrow transplantation, albeit in limited cases, has resulted in growth spurt in children, reduction of hepatomegaly, and normalization of plasma glucocerebroside levels.[9] Unfortunately, morbidity and mortality of the procedure are high and neurological/cognitive benefit is equivocal. Nevertheless, its success has set precedents for gene therapy and nonmyeloablative stem cells transplantation as potential options.

ERT

ERT[10] with placental-derived enzyme, alglucerase (Ceredase®; Genzyme Therapeutics Inc.), or the recombinant form, imiglucerase (Cerezyme®, Genzyme Therapeutics Inc., MA), has proven to be safe and effective in more than 3000 patients worldwide. Reduction in organ volumes and improvement in hematological parameters have dramatically improved quality of life.

In a recent summary by the International Gaucher Registry, efficacy and safety profiles of ERT in over 1000 patients with 2–5 years of treatment were recorded.[11] For anemic patients, hemoglobin concentration increased to normal or near-normal within a year with sustained response through 5 years. Hepatomegaly decreased by 30–40% over 2–5 years. Splenomegaly decreased by 50–60% over 2–5 years. In patients with bone pain/crises, 52% were pain-free after 2 years and 94% reported no additional crises.

The greatest advantages of ERT may prove to be early administration to children at risk for severe disease, thereby precluding significant visceral and bone involvement.[12]

The effect on bone density is preliminary and complicated by the impact of other genetic and environmental factors. Another option for clinical management of both bone loss and secondary bone pain is biphosphonates, administered in conjunction with ERT, but which may be problematical for children and teenagers.

Infiltrative lung disease secondary to severe Gaucher disease in both children and adults may benefit from ERT. Nonetheless, pulmonary hypertension has been noted in some patients on ERT. Although a causal relationship with ERT has been difficult to prove, treatment withdrawal may be considered in patients who develop progressive primary-like pulmonary hypertension.[13]

Good clinical results have been axiomatic despite a wide range of ERT dosages and frequencies. However, ERT poses significant hardships to patients as it involves repeated intravenous infusions, usually once every 2 weeks, for life. In addition, the high cost limits the number of patients who can avail of this treatment, particularly in

developing countries. Finally, the current formulation is incapable of crossing the blood–brain barrier, thereby circumscribing its value in patients with significant neurological manifestations.

MAINTENANCE REGIMENS

Despite the success of ERT for symptomatic patients, one must ask whether dose adjustments and/or circumscribed ''drug vacations'' may be suggested in individual patients who have had up to 10 years of therapy, particularly those who have achieved near-normalization of major disease parameters. This argument is particularly cogent in light of a report that documents the continuation of the beneficial effects of enzyme on disease parameters after varying periods of withdrawal, with no deterioration among adults.[14] Drug vacations should not be considered for children.

SUBSTRATE REDUCTION THERAPY

Oral substrate reduction therapy (SRT) involves attenuation of the rate of synthesis to achieve a balance with reduced endogenous glucocerebrosidase.

A pivotal trial of SRT was carried out in 28 adult patients (from four centers: Cambridge, UK; Amsterdam; Prague; and Jerusalem) naïve to enzyme therapy, with mild to moderate type I Gaucher disease, who were unable or unwilling to receive enzyme treatment. There was significant reduction in spleen and liver, although amelioration of anemia and thrombocytopenia lagged behind. There were side effects, including diarrhea, abdominal pains, weight loss, tremor, and peripheral neuropathy, which were reversible with dose reduction or withdrawal.[15] A low-dose trial showed dose dependency for clinical improvement but no reduction in severity or frequency of side effects. Finally, using SRT as a maintenance regimen (i.e., switching from ERT or in combination with ERT), at 6 months, there were no clinically significant differences among groups.

SRT, commercially available as Zavesca™ (Actelion Pharmaceuticals, Allschwil, Switzerland; Teva Pharmaceuticals Israel, Netanya, Israel), has received European, Israeli, and American approval for patients with mild to moderate Gaucher disease, for whom ERT is unsuitable or not a therapeutic option, respectively. Because it is a small molecule capable of crossing the blood–brain barrier, this drug may potentially improve neurological features in Gaucher disease and other lysosomal storage disorders, in whom benefits may outweigh risks and discomforts of the drug in its current formulation.

FUTURE IMPROVEMENT OF ERT

Poor delivery of the current formulation of enzyme therapy to the lungs, bones, and brain, and increased convenience call for the development of new generations of enzyme. In this context, the discovery of the three-dimensional structure may provide this possibility and may be used for designing structure-based drugs to restore the activity of defective enzymes.

CHEMICAL CHAPERONES TO INCREASE ENZYME ACTIVITY

The addition of subinhibitory concentrations of *N*-(*n*-nonyl)deoxynojirimycin (NN-DNJ) in fibroblast culture led to increased N370S β-glucocerebrosidase activity that persisted after withdrawal of the putative chaperone, suggesting that NN-DNJ chaperones the folding of mutated protein, stabilizing it for transport to the Golgi apparatus and hence proper trafficking to lysosomes. This modest increase in glucocerebrosidase activity may be sufficient to achieve a therapeutic effect.[16]

GENE THERAPY

Gene therapy is a theoretically curative approach for enzyme disorders and, in fact, Gaucher disease has been among the first targeted by this modality.[17] However, despite the considerable efforts brought to bear, gene therapy is apparently not on the immediate horizon.

ETHICAL AND SOCIETAL CONSIDERATIONS

Although to date only symptomatic management can be recommended for type II disease, ethical issues relating to ERT that are neither life-prolonging nor appreciably improve the quality of life of these babies need to be addressed. Indeed, ethical arguments apply to the emotional outlay in neuronopathic forms, but also to the financial outlay for orphan drugs for nonsevere, non-neuronopathic patients. No evidence-based consensus has been documented to support the extraordinary expense of superhigh doses of ERT for children with neuronopathic forms, and no maintenance trials have been initiated to provide guidelines for tapering/withdrawing therapy once near-normal parameters have been achieved. These cases need to be addressed equitably and ethically.

CONCLUSION

Gaucher disease is caused by an enzymatic defect with consequent accumulation of glucocerebroside. Type I, the nonneuronopathic form, is rather common, with a predilection among Ashkenazi Jews. There is tremendous variability in age of onset, severity, and phenotypical expression in this type. Symptomatic presentation may include hepatosplenomegaly, anemia, thrombocytopenia, and skeletal or lung involvement. Life expectancy is unimpaired. The neuronopathic forms are pan-ethnic with a continuum of neurological and visceral signs and symptoms, and with decreased life expectancy. Diagnosis is performed by assay of β-glucocerebrosidase activity, and molecular analysis of mutations may broadly define genotype–phenotype correlations. ERT has proven to be safe and effective in ameliorating disease symptoms and signs; however, it involves life-long intravenous therapy, is costly, and is incapable of crossing the blood–brain barrier. Thus, other forms of treatment, including bone marrow transplantation and oral SRT, are attractive.

Gene Dosage—Multiplex Probe Ligation and Amplification

Anders O. H. Nygren
Jan P. Schouten
MRC-Holland, Ltd., Amsterdam, The Netherlands

INTRODUCTION

The multiplex ligation-dependent probe amplification (MLPA) technique provides the means for the quantitative analysis of various changes in gene structure and gene copy number of a large number (40–50) of DNA target sequences in a single reaction. Conventional PCR-based methods for mutation detection such as denaturing high-performance liquid chromatography (dHPLC) and sequencing are not able to detect most exon deletions and duplications because the normal allele that is present is also exponentially amplified. MLPA requires a minimum of only 20 ng human chromosomal DNA and can discriminate sequences differing by a single nucleotide. In MLPA, binary probes containing a sequence-specific part and a universal part are hybridized to their DNA targets and ligated. Each ligated probe is then PCR amplified with a universal primer pair and gives rise to an amplification product of unique size. The relative amount of each amplification product reflects the amount of the target sequence that is present in the nucleic acid sample. As the sequence detected by the probe is only around 60 nt, MLPA is able to detect copy number changes of single exons. The necessary equipment used in MLPA, a thermocycler with a heated lid and a high-resolution electrophoresis apparatus with fluorescent detection, is available in most molecular biology laboratories.

APPLICATIONS OF MLPA

Current applications of MLPA are the following:

1. Detection of unusual copy numbers of single chromosomes (Fig. 1; e.g., Down's syndrome) either from patient material or from small samples (<1 mL) of amniotic fluid, according to Slater et al.[1]
2. Detection of unusual copy numbers of one or more subtelomeric regions. Presence and copy number detection of all chromosome ends can be tested in a single MLPA reaction.[2]
3. Detection of unusual copy numbers of chromosomal regions such as the 22q11 region in DiGeorge syndrome, the ELN gene region in Williams syndrome, and different 17p11.2 region in Smith–Magenis syndrome and CMT1A/HNPP.
4. Detection of unusual copy numbers of specific genes such as the *PLP1*,[3] gene in Pelizaeus–Merzbacher disease (PMD) and the copy number of the *SMN1*,[4] and *SMN2*,[5] genes involved in spinal muscular atrophy.
5. Detection of unusual copy numbers of single exons (Fig. 2). More than 60% of all cases of Duchenne muscular dystrophy are caused by deletion or duplication of one or more exons of the 2.5-Mbp-long DMD gene. All 79 exons of this gene can be screened by performing two MLPA reactions. Depending on the presence of founder mutations in certain populations, deletion of one or more exons of the BRCA1 gene are the cause of 4–30% of all cases of BRCA1-related hereditary breast cancer.[6,7]
6. Detection of gains (e.g., Her2-neu and Myc) and losses (e.g., TP53/p16) of specific genes or chromosomal regions in tumor samples (Nederlof et al., in preparation).
7. With a variation on the ordinary MLPA protocol, both copy number changes as well as methylation status of the Prader–Willy/Angelman region can be determined (Errami et al., in preparation).

A list of commercially available MLPA kits can be found on the www.mrc-holland.com website.

TECHNICAL DESCRIPTION

The MLPA technique permits relative quantification of up to 45 different target sequences in an easy to perform reaction. In MLPA, specially designed oligonucleotide probes are hybridized to their specific DNA sequences in the DNA sample, ligated, and then amplified in a multiplex PCR. Each gene-specific probe consists of two oligonucleotides and each oligonucleotide has a gene-specific part and a universal sequence part used for amplification. The concentrations of oligonucleotide probes and the extended hybridization

Encyclopedia of Diagnostic Genomics and Proteomics

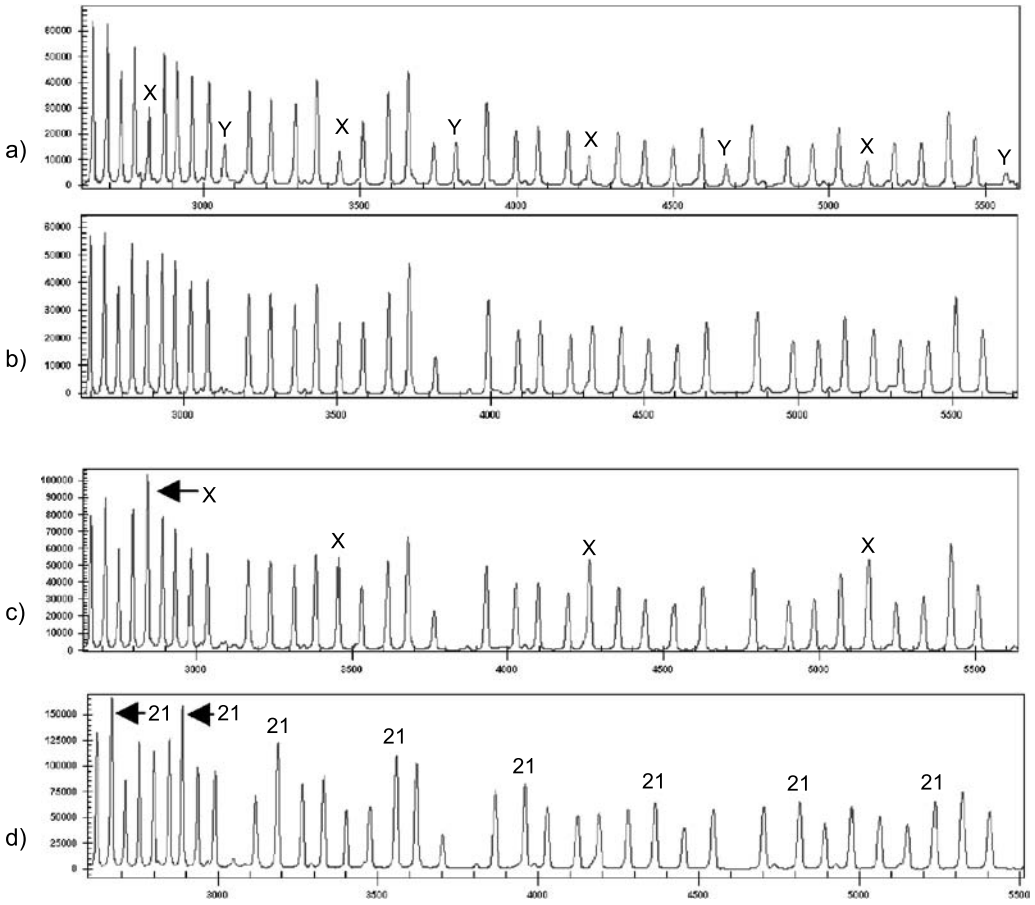

Fig. 1 Detection of trisomies by MLPA. One hundred nanograms of DNA samples were analyzed by MLPA using probe mix P001 (MRC-Holland). A detailed description of the P001 probe mix can be obtained at www.mrc-holland.com. PCR products were analyzed by capillary electrophoresis (Beckman CEQ2000). CE patterns from male (a), female (b), and DNA from a female triple chromosome X (c) and a female with triple chromosome 21 (d). (*View this art in color at www.dekker.com.*)

times are sufficient to ensure practically complete hybridization of target sequences and their corresponding probe oligonucleotides. Only probes hybridized to a perfectly matched target DNA are ligated and then exponentially amplified in the following PCR (Fig. 3). MLPA probes that do not find a target sequence cannot be ligated and consequently will not be amplified in the PCR. Probes that are hybridized to a target but have a mismatch close to the ligation point are not ligated because of the high sensitivity of the thermostable Ligase-65. This allows for the discrimination of closely related sequences such as the *SMN1* and *SMN2* genes both involved in spinal muscular atrophy. Because the relative peak area of each amplification product reflects the relative copy number of the target sequence in the DNA sample, comparison of gel patterns with patterns obtained on a control sample allows absolute copy number quantification. To obtain reproducible results, MLPA currently needs at least 20 ng human DNA, corresponding to approximately 3000 cells or 6000 single-copy target sequences.

Specificity of the Probes

When 40 probes, each consisting of two oligonucleotides, are present in one tube with genomic DNA, not 40 but 1600 different target sequences are theoretically able to hybridize with two oligonucleotides and make them a substrate for ligation. However, the specificity of MLPA is very high and no nonspecific products are generated during the PCR.[8] Control experiments showed that no product was generated when the short synthetic oligonucleotides were omitted or replaced by an identical oligonucleotide with a mismatch at the 3′ end.[5] Several factors contribute to exquisite specificity of MLPA: 1) the need for the two oligonucleotides to anneal in juxtamposition on a target nucleic acid;

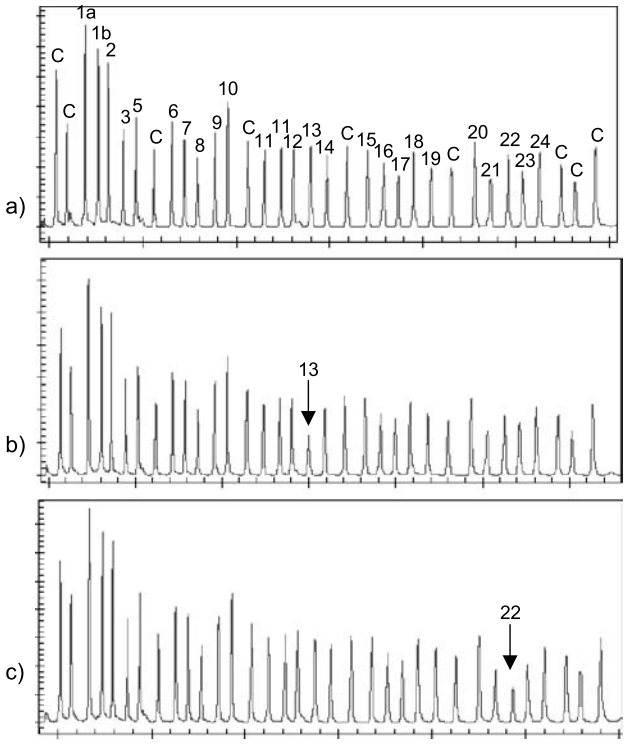

Fig. 2 Detection of exon deletions in the BRCA1 gene with MLPA. One hundred nanograms of DNAs from individuals from diagnosed breast- and/or ovarian-cancer-prone families were analyzed by MLPA using probe mix P002. The P002 mix contains one probe for each of the 24 BRCA1 exons (1–24), one extra each for the exon 1 and the large exon 11 as well as several controls probes (C) specific for different genes on different chromosomes were also designed and used in a single MPLA assay together with BRCA1 probes. A detailed description of the P002 probe mix can be obtained at www.mrc-holland.com. (a) A CE pattern obtained from a control DNA sample containing two copies of the normal BRCA1 gene. (b) A CE pattern obtained from DNA with a heterozygous BRCA1 exon 13 deletion. (c) A CE pattern obtained from DNA with a heterozygous BRCA1 exon 22 deletion. (*View this art in color at www.dekker.com.*)

2) hybridization and ligation are performed at 54–60°C, which reduces unspecific binding and increases specificity; 3) the use of thermophilic ligases requiring NAD (e.g., Ligase-65) that are very sensitive to mismatches next to the ligation site.

Probe Signal and Reproducibility

Twenty-eight probes specific for sequences on chromosomes X, 21, 18, and 13 generated, on average, a 1.44-fold higher signal on the respective trisomy DNA samples as compared with control DNA.[8] This is close to the theoretical 1.5-fold increase. Reproducibility of results in MLPA depends on several factors: 1) the purity of DNA samples, the method of PCR product analysis with capillary electrophoresis being superior to fluorescent detection on slab gels; 2) the software used for peak detection and the method used for normalization of data. Whereas DNA degradation hardly influences the results, the presence of PCR inhibitors, e.g., traces of phenol, does. In general, the standard deviation of results obtained in MLPA varies between 4% and 10% for each probe.

In MLPA the relative signal strength depends on the relative amount of the target sequences present in the sample. In model experiments, it was shown that an almost linear increase of the signal could be obtained when up to fivefold increase of synthetic targets was added to a DNA sample.[8] Addition of higher amounts of synthetic target resulted in an additional nonlinear increase in signal of that probe.

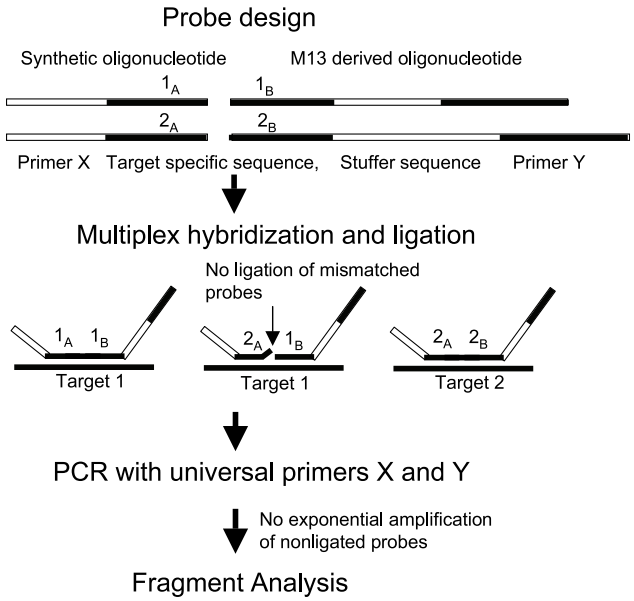

Fig. 3 Outline of MLPA. 1. Probe design: Each MLPA probe consists of two oligonucleotides, one short synthetic and one long M13 derived. The short synthetic oligonucleotide consists of a 5′ universal primer sequence X and a target-specific 3′ sequence. The M13-derived oligonucleotide consists of a 5′ target-specific sequence designed to hybridize in juxtaposition to the synthetic probe, a 3′ universal primer sequence Y and a stuffer sequence that has a different length for each probe. 2. Multiplex hybridization and ligation: One femtomole of each probe oligonucleotide is hybridized to the denatured target DNA. Only perfectly matched probes oligonucleotides are ligated by the thermostable Ligase-65. 3. PCR: Only ligated probes are exponentially amplified by the single primer pair X and Y. 4. Fragment analysis: The amplified fragments are separated and analyzed by capillary electrophoresis.

ADVANTAGES WITH MLPA

1. One technique can be used for many applications. The only difference between different assays is the probe mix used. Hybridization, ligation, and PCR reagents and conditions are identical for the various applications.
2. Multiplex: One reaction provides information on up to 45 targets. For most applications, this is sufficient to answer the specific question asked by the physician.
3. Easy to perform. Large numbers of samples, e.g., 96, can be tested simultaneously.
4. Sensitive. Only 20 ng of human DNA is required. Results do not depend on the amount of sample DNA used.
5. Reproducible. MLPA can detect small differences in copy number such as three vs. two copies of a gene sequence in a complex mixture like the human genome.
6. Requires a target sequence of only 60 nucleotides. Can therefore be used to detect deletions or duplications of a single exon and permits use of DNA of poor quality such as DNA extracted from formaldehyde-treated, paraffin-embedded tissues.
7. Sequences that differ in only a single nucleotide can be distinguished.
8. Low investment. The equipment necessary for MLPA, a thermocycler and DNA sequencing electrophoresis equipment, is present in most molecular biology laboratories. Capillary electrophoresis is preferred but MLPA has also been successfully performed on the older ABI 373 and 377 slab gels.

DISADVANTAGES WITH MLPA

1. DNA samples should be of equal purity. MLPA reactions are more sensitive to contaminants (PCR inhibitors such as small remnants of phenol) than ordinary PCR reactions. Results on DNA extracted from formaldehyde-treated, paraffin-embedded tissues can be good, but requires a DNA sample from healthy tissue that was treated identically for comparison.
2. It is time-consuming and difficult to develop your own probe mix. Each probe requires the design and preparation of an M13 clone, the purification of single-stranded DNA of that clone, and the digestion of that DNA with expensive enzymes. At this moment, MLPA kits are available only from MRC-Holland. It is possible to design a small number of completely synthetic probes, resulting in amplification products with a length between 100 and 130 nt, and to add these to the MRC-Holland probe mixes. Rules and sequences of the PCR primers are available from info@mrc-holland.com.
3. In contrast to Flourescence in situ hybridization (FISH), MLPA as it is performed today cannot be used to investigate single cells. MLPA analysis of DNA samples from cell mixtures will give the average copy number per cell. It will be difficult to detect deletions of a certain gene if the sample from which the DNA was derived contained less than 60% cancer cells.
4. MLPA is not suitable to detect new mutations, although probes can be made to detect specific known mutations. Mutations or polymorphisms exactly at the ligation site will, in most cases, result in a similar decrease in signal as a deletion of the complete target sequence of that probe. Point mutations and polymorphisms within 4 nucleotides of the ligation site will often affect the signal strength. Point mutations as well as small deletions/insertions within approximately 20 nucleotides of the ligation site may affect the probe signal.

PROTOCOL FOR DNA ANALYSIS

The use of a thermal cycler with heated lid (105°C) is essential. The use of 0.2-mL PCR tubes is recommended.

Materials and Methods

Dilute 50–500 ng of target DNA to a final volume of 5 μL with 10 mM Tris–HCl (pH 8.5), –0.1 mM EDTA and denature the DNA for 5 min at 98°C in a thermocycler with heated lid. Mix 1.5 μL probe mix (1 fmol of each probe) and 1.5 μL MLPA buffer (1.5 M KCl, 300 mM Tris–HCl pH 8.5, and 1 mM EDTA) and add to the denatured DNA. Heat the mix for 1 min at 95°C before incubating overnight (16 h) at 60°C. After hybridization dilute the sample to 40 μL with ligase mix (2.6 mM $MgCl_2$, 5 mM Tris–HCl pH 8.5, 0.013% nonionic detergents, 0.2 mM NAD) containing 1U Ligase-65 (MRC-Holland) and perform ligation reaction of the annealed probes at 54°C for 15 min. After ligation inactivate the Ligase-65 by incubating the sample 5 min at 98°C. Mix 10 μL of the ligation mix with 30 μL of PCR buffer (20 mM Tris–HCl pH 8.5, 50 mM KCl, 1.6 mM $MgCl_2$, and 0.01% nonionic detergents). While at 60°C, add 10 μL of a solution containing 10 pmol PCR primers, 2.5 nmol dNTPs, and 2.5 U SALSA polymerase (MRC-Holland) to the mix and perform 33 cycles of PCR (30 sec, 95°C; 30 sec, 60°C; and 1 min, 72°C) followed by a 20-min incubation at 72°C. Finally, a part of this PCR is denatured in 100% formamide, mixed with molecular

weight marker, and run on a sequence-type electrophoresis system.

CONCLUSION

In conclusion, the MLPA method has proved to be very sensitive, reproducible, and capable of simultaneous quantitative analysis of up to 45 genes. Its exquisite specificity overweighs difficulties in probe preparations and holds promise to be a widely used technique in quantitative studies of multiple genes.

Giardia lamblia

Enedina Jiménez-Cardoso
Hospital Infantil de México Federico Gómez, D.F., Mexico

INTRODUCTION

Giardia intestinalis is the most prevalent parasite in the world; it is acquired through ingestion of food or water that has been contaminated with cysts of *Giardia*. Children are more commonly infected and generally present with diarrhea. Individuals with giardiasis can be asymptomatic or suffer from diarrhea, abdominal pain, anorexia, and emesis. *G. intestinalis* is a peculiar microorganism with genetic characteristics of a primitive eukaryote. In developed countries, *Giardia* is regarded as a reemerging infectious agent because of its increasing role in outbreaks of diarrhea in day care centers. About 200 million people in Asia, Africa, and Latin America have symptomatic giardiasis and there are some 500,000 new cases per year. In Mexico, *G. intestinalis* can be isolated by fecal analysis from 7% to 68% of patients with diarrhea. Reported frequencies of infection in other countries are as follows: United States 1–6%; Panama 10%; Venezuela 9%; Brazil 4–11%; Egypt 4–15%; China 10%; Germany 3–27%; Italy 9%; and Spain 24%. *Giardia* is also one of the most common enteric parasites found in dogs and cats. The presence of human *Giardia* in domestic and farm animals suggests a zoonotic potential for giardiasis. However, at present, it cannot be determined whether cysts isolated from both humans and dogs originate primarily from the human *Giardia* group.

CLINICAL MANIFESTATIONS

Trophozoites of these parasites are located in the duodenum, jejunum, and upper ileum. When symptoms occur, they vary from mild to severe abdominal discomfort, diarrhea, cramping, and bloating.[1,2] Infants may have anorexia, weight loss, or a malabsorption syndrome that resembles sprue.[3,4] When a child is evaluated because of failure to thrive or is immunocompromised, the presence of *Giardia* should be considered.[5] Lactose intolerance may develop in these children and persist after elimination of the parasite.

IMMUNE RESPONSE

Abnormal humoral immune response and hypogammaglobulinemia were demonstrated in patients with severe and prolonged symptomatic giardiasis. The latter condition demonstrates the presence of circulating IgG antibodies. Human serum anti-*Giardia*, confirmed by indirect fluorescent antibody (titer 1:128), was able to kill 98% of the trophozoites in vitro. This immunoactivity was dependent on the classic complement pathway. Using a filter paper assay, serological testing of 135 samples with specific IgG anti-*Giardia* demonstrated a sensitivity of 91% to 95%. The presence of intestinal IgA against *Giardia* was associated with the resolution of infection.[6]

Lymphocyte proliferation was demonstrated by the total number of T cells in the Peyer patches. An increase in T cells was associated with resolution of infection, although the CD4-to-CD8 ratio remained unchanged. Spontaneous macrophage cytotoxicity suggested the importance of these cells in the immune response to *Giardia* infection, because monocytes–macrophages and granulocytes participate in the killing of parasites.

MECHANISMS OF DRUG RESISTANCE IN *GIARDIA*

Many effective drugs are available for treatment, as shown in Table 1. Albendazole has been reported to be as efficacious as metronidazole. Chromosome mapping of a gene expressed in drug-resistant lines revealed that chromosomes could rearrange and that segments could be lost. Further mapping studies indicated that the minor chromosomes observed earlier were partial duplications of major chromosomes with loss of substantial subtelomeric regions from different chromosomal termini. The extensive duplication and rearrangement undergone by the *Giardia* genome includes whole and partial chromosomal duplication, subtelomeric loss followed by duplication, partial duplication under stress, and extensive internal duplication among different chromosomes.

DOI: 10.1081/E-EDGP 120020851

Table 1 Drugs for treatment of giardiasis

Drugs	Dosage
Adults (nonpregnant women)	
Albendazole	400 mg by mouth once a day for 5 days
Furazolidone	100 mg by mouth 4 times a day for 7–10 days
Metronidazole	250 mg by mouth 3 times a day for 5–7 days
Paromomycin	500 mg (30 mg/kg/day) by mouth 3 times a day for 7 days
Quinacrine	100 mg by mouth 3 times a day for 5 days
Tinidazole	2 g by mouth once
Pregnant women	
Paromomycin	500 mg (30 mg/kg/day) by mouth 3–4 times a day for 7 days
Children	
Albendazole	400 mg by mouth once a day for 5 days
Furazolidone	6–8 mg/kg/day by mouth divided 3–4 times a day for 7–10 days
Metronidazole	15 mg/kg/day by mouth divided 3 times a day for 5 days (maximum=300 mg/day)
Paromomycin	30 mg/kg/day by mouth divided 3 times a day for 7 days
Quinacrine	6 mg/kg/day divided 3 times a day for 5 days (maximim=300)
Tinidazole	50 mg/kg by mouth once (maximum=2 g)
Refractory cases	
Metronidazole	750 mg by mouth 3 times a day for 14 days
Quinacrine	100 mg by mouth 3 times a day for 14 days

Source: Refs. [7,8].

Giardia resistant to metronidazole and furozolidone have been reported. Such resistance can develop via biochemical mechanisms or by abnormalities in the electron transport system within the *Giardia*. In vitro, metronidazole reduced production of toxic radicals by decreased activity of ferredoxin. *Giardia* resistant to furozolidone showed an increase in thiol cycling.

These anaerobic protozoa appear to support novel detoxification mechanisms. In studies on the genetic mechanism of drug resistance, a gene associated with a protein membrane was shown to be deleted from one chromosome.[9]

Albendazole resistance in *Giardia* is associated with cytoskeletal change, rather than with a mutation of amino acid 200 in beta-tubulin. Major chromosomal rearrangements were evident in trophozoites resistant to albendazole, as demonstrated by IFA antitubulin antibodies. These antibodies indicate differences in the cytoskeleton. Using albendazole-resistant *Giardia*, PCR primers were designed to study the sequence of the beta-tubulin gene. Results showed that the beta-tubulin gene did not carry a mutation from the Phe.[10]

DIAGNOSIS OF GIARDIASIS

Common laboratory methods for diagnosis of giardiasis are designed for stool specimens. Samples are collected and preserved in 10% formalin, although fresh stools may be examined with light microscopy. Parasites are observed via wet mount, with trichrome or iron hematoxylin staining. Cysts can also be detected by immunofluorescent antibody labeling. The sensitivity of routine examination of a single stool specimen for cysts is approximately 50% to 70%. Sensitivity increases to 100% when two or three samples are analyzed. The antigen-capture enzyme-linked immunosorbent assay for the detection of *Giardia lamblia*, with monoclonal antibody directed to 66-kDa specific antigen, correctly identifies cases of giardiasis from 67% of stool specimens from affected patients. If the antibody is targeted against the whole antigen, sensitivity increases to 95%.

A capture enzyme-linked immunosorbent assay (CELISA) and counterimmunoelectrophoresis (CIE) were evaluated for their ability to detect human *Giardia* using antibody against the whole trophozoite. The sensitivity and specificity were 100% for both. A complementary study can be performed through a microscopic examination of trophozoites obtained from duodenal material. This test requires a special gelatin capsule that remains in the intestine for several hours.[11]

MOLECULAR METHODS

Molecular methods for the diagnosis of *Giardia* have been described. Polymerase chain reaction (PCR) technology offers alternatives to conventional diagnosis for both clinical and environmental purposes with 98.9% specificity. The PCR using the JW1 forward primer 5′GCGCACCAGGAATGTCTTGT 3′ and the JW2 reverse primer 5′ TCACCTACGGATACCTTGTT 3′ DNA for amplification of 183pb showed a specificity of 100% when used to test samples from children who were immunocompromised or who lacked the usual symptomatology. This is in contrast to 87% specificity when diagnoses were made by common laboratory methods.[12,13] Classification of subgroups of *Giardia* based on ribosomal RNA gene sequence using PCR, and genotype by conventional and real-time PCR/RFPL as well as ribosomal RNA gene sequence using PCR analysis, may facilitate studies of virulence, infectivity, and epidemiology of Giardian infection. Classification of subgroups of *Giardia* based on ribosomal RNA gene sequence using PCR analysis, and on genotype by conventional and real-time PCR/RFPL, may facilitate studies of virulence, infectivity and epidemiology Giardian of infection.

MOLECULAR EPIDEMIOLOGY

The ability to amplify a specific region of the genome has been an important tool in the characterization of different sources of giardiasis and in the identification of DNA polymorphism. This tool allows the definition of a taxonomic and genetic framework for epidemiological and clinical purposes. As an example of such studies, genetic typification of *Giardia* in axenic cultures from children was useful in the characterization of the disease.[14] Epidemiological studies of infected humans and their pets have failed to demonstrate any correlation between *Giardia* infections in these animals and their owners.[15,16]

GENETIC DIVERSITY

According to certain characteristics, two groups of have been described in Europe as Polish and Belgian. In the United States, the designations are groups I and II, and in Australia the groups are called assemblages A and B or genotype A and B.[17–19] Molecular studies have also revealed the existence of genetic differences within assemblage A, named Cluster AI and AII. The latter has been isolated only from humans. Molecular analyses showed that the genetic distance partitioning these two assemblages can be used to delineate other species of protozoa. Nevertheless, at present, two important questions are posed: ''Is giardiasis a disease of animals that is transmitted to humans (zoonosis)?'' and ''What is the taxonomic status of the parasitic protozoan species isolated from humans and animals?'' because molecular analysis shows that the same *Giardia* genotype can be found in humans as well as other mammalian species.

MOLECULAR CHARACTERIZATION OF *GIARDIA* FROM CHILDREN AND ANIMALS

To characterize *Giardia* from humans and animals, fecal samples were obtained from six children with chronic recurrent diarrhea and abdominal pain, seven asymptomatic children, and three dogs. Controls were as follows: *G. intestinalis* group A Portland M54878; group B Belgian U09491; Bris/91/Hepu/1279 L29192; and dog 6 AF199449. DNA isolation was performed according to the phenol–chloroform–isoamilic alcohol method.[20] The gene 16S ribosomal RNA (ssRNA) fragment of 290pb was amplified by PCR using forward primer 5′-CATCCGGTCGATCCTGCC-3′ and the reverse primer 5′-AGTCGAACCCTEATTCTCCGCCAGG-3′, under conditions previously described.[21] The amplification products were purified using Qinquick kit (Qiagen). Double-stranded DNA sequencing was performed using the ABl Prism Big Dye Terminator Cycle Sequencing Kit (Applied Biosystems) and a set of internal primers. Sequencing alignments of 16S rDNA was performed using clustal W, and a phylogenetic tree was designed using the neighbor-joining method and the phylogenetic distance 3.6 Phillip maximum likelihood (http://www.igbmc.u-strasburg.fr/BioInfo). Analysis of the alignment of DNA sequences from symptomatic (5S, 6S, 7S, 8S, and 9S) and asymptomatic (1A, 2A, 3A, 4A, 5A, and 6A) children with giardiasis showed similarities to genotype group A DNA. However, these 11 sequences showed 37 variable sites when compared with group A (Figs. 1 and 2). Further analysis provided a phylogenetic tree with the following groups: one with samples 3A, 4A, and 5A; a second with 2A, 6A, 6S, and 9S; and a third with 1A, 5S, 7S, and 8S. Their sequences and the phylogenetic distances were very similar in samples from two symptomatic children (1S, 4S), seven axenic cultures

Fig. 2 Sequence alignment 5′ end 16s rDNA. The alignment of the 290pb of group A, P-1 (Portland M54878), group B (U09491 and Bris/91/Hepu/1279 L-29192), and dog6 (AF199449). *G. intestinalis* isolated from symptomatic children and subjected to axenic cultures: IMSS-1, IMSS-2, IMSS-3, IMSS-4, INP-1, INP-3, INP-4 and 2dog, 3dog, 5dog.

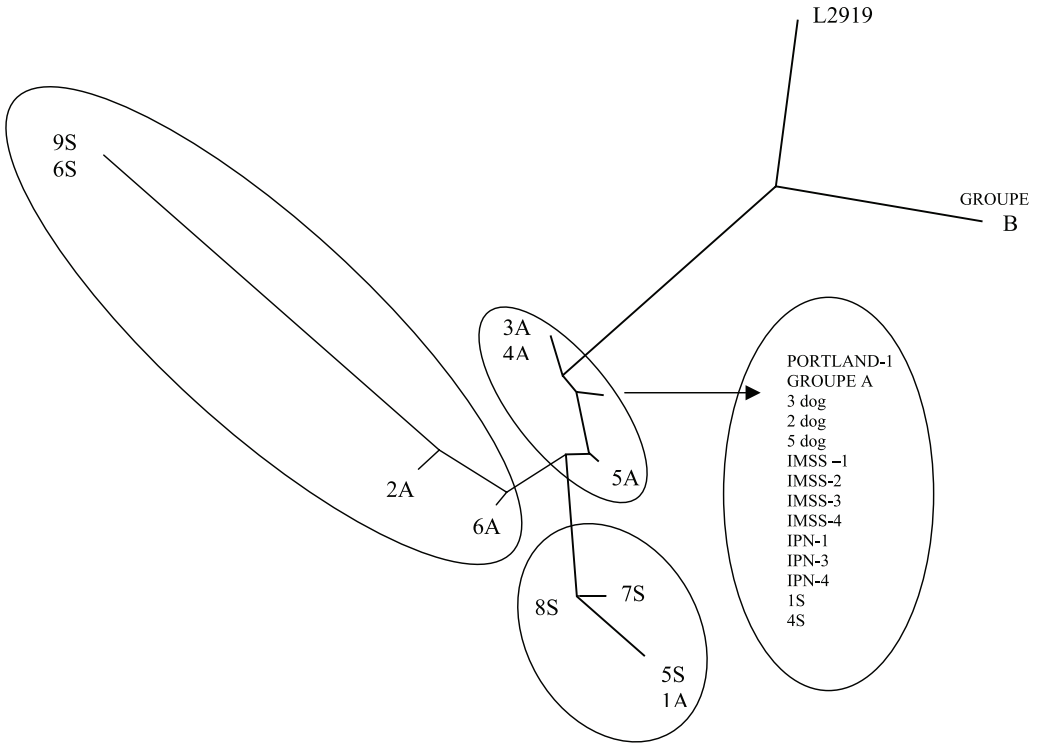

Fig. 3 The phylogenetic tree of *G. intestinalis* from symptomatic (1S, 4S, 5S, 6S, 7S, 8S, 9S) and asymptomatic children (1A, 2A, 3A, 4A, 5A, 6A); axenic cultures (IMSS-I, IMSS-2, IMSS-3, IMSS-4, IPN-1, IPN-3, IPN-4) and *Giardia* in dogs (3dog; 2dog; 5dog) including controls group A, Portland P-1, M54878 and group B (U09491 and L29192 Bris/Hepul/1279).

(IMSS-1, IMSS-2, IMSS-3, IMSS-4, IPN1, IPN2, and IPN3), and three dogs (2dog, 3dog, and 5dog), as seen in Fig. 3. Group B giardias were not found.

ZOONOTIC IMPLICATIONS OF GENOTYPIC CHARACTERIZATION

Previous results clearly indicate that *G. intestinalis* genotype A was isolated from fecal samples from humans and dogs residing in the same environment. Therefore, one can postulate a zoonotic transmission for *Giardia*. This investigation confirms the observation made in molecular epidemiological studies that *Giardia* obtained from infected humans also occurs in many mammalian species.[22] Another investigation demonstrated that 75% of giardias isolated from humans were closely related to those with a canine origin,[23,24] leaving uncertainty about whether the animals were reservoir hosts for humans or vice versa. Finally, when genotypic analysis was made from 11 isolated DNAs, 37 variables were observed that could be divided into three groups. Such differences are possibly due to the host-adapted genotypes or perhaps represent distinct species that could be associated with variable pathology.

CONCLUSION

From a public health perspective, zoonotic risk is associated with genotypes in assemblage A, particularly those in Cluster AI, and less with assemblage B. Finding similar genotypes in different hosts suggests a zoonotic transmission that per se presents important implications for the establishment of a global genetic framework. The ability to accurately identify the *Giardia* genotype is a potential and powerful predictive tool that can support direct evidence of zoonotic transmission. All results suggest that accurate molecular characterization of the parasite with phylogenetic distance should be included in order to determine zoonotic transmission. The genetic diversity only reflects that each major group contains genetically diverse isolates that are not confined to any particular host or geographic location. Giardiasis and its zoonotic potential are important for future cultural, social, and health impact in humans. Currently, no classification schemes exist that can define or detect the pathogenic potential, host range, or virulence in strains that infect man. Studies such as the one presented can determine the kind of *Giardia* transmission in any community.

The potential that giardiasis can be transmitted zoonotically has cultural, social, and health implications.

Therefore, more studies along this line of investigation are necessary to clarify the kind of transmission in every community.

Glutathione *S*-Transferase Genotype

Richard C. Strange
Anthony A. Fryer
Keele University Medical School, Staffordshire, U.K.

INTRODUCTION

The glutathione *S*-transferase (GST) supergene family is considered a key enzymic detoxicating system that protects cells from endogenous and exogenous chemicals. Indeed, GST peptides are probably expressed in all life forms, implying their importance. However, despite identification of many in vitro substrates, the biological relevance of many of these is uncertain. Indeed, accumulating evidence also suggests a noncatalytic, cell signaling function for the GST.

Although many polymorphic sites have been examined for associations with disease susceptibility there is no clear view as to biochemical consequences of most alleles. We review GST gene organization and allelic sites and consider their possible functions. This forms a basis for selecting diseases potentially influenced by polymorphism.

GST GENES

Two groups of genes encode GST peptides.[1,2] Firstly, the alpha, mu, pi, theta, sigma, zeta, and omega families that encode peptides (molecular weights 24–29 kDa) expressed in cell cytosols, and kappa family those in mitochondria,[1,2] and, secondly, the evolutionarily distinct membrane associated proteins in eicosanoid and glutathione metabolism (MAPEG).[3] The GST demonstrate widespread gene-dependent expression particularly in liver, kidney, testis, bowel, heart, ovary, and skin.

CATALYTIC FUNCTION

Xenobiotics

Much work has focused on the homo- or heterodimeric cytosolic GST enzymes that catalyze detoxication of xenobiotics via conjugation with reduced glutathione. Some substrates such as tobacco-derived carcinogenic benzo[*a*]pyrene diol epoxide result from cytochrome P450-catalyzed activation.[1,2] Importantly, not all substrates are inactivated by conjugation; theta GST utilizes dichloromethane to form reactive *S*-chloromethylglutathione.[1,2]

Response to Drug Treatment

Glutathione *S*-transferase expression has been linked with drug response, particularly resistance to anticancer agents.[2] Glutathione *S*-transferase expression is increased by exposure to various drugs including substrates thought to be inactivated by GSH-conjugation (chlorambucil, nitrogen mustards, melphalan, hydroxyalkenals) as well as nonsubstrates (bleomycin, carboplatin, cisplatin, adriamycin, mitomycin C).[2]

Oxidative Stress

Cytosolic and MAPEG GST demonstrate selenium-independent glutathione peroxidase activities toward numerous products of oxidative stress including lipid and DNA hydroperoxides and 4-hydroxynonenal.[1,3]

Eicosanoid Metabolism

Membrane associated proteins in eicosanoid and glutathione enzymes including leukotriene C_4 synthase, MGST-I, and MGST-II catalyze conversion of LTA_4 to LTC_4 (Fig. 1). Further, 5-lipoxygenase-associated protein (FLAP) with 5-lipoxygenase facilitates conversion of arachidonic acid via 5-HPETE to LTA_4.[1,3] Some cytosolic GST also demonstrate low levels of leukotriene C_4 synthase activity. MGST-II and MGST-III convert 5-HPETE to 5-HETE. Thus the proportions of FLAP to MGST-II/III determine whether 5-HPETE is converted to LTA_4 or 5-HETE. Alpha GST catalyzes the reduction of prostaglandin PGH_2 to $PGF_{2\alpha}$, whereas alpha, sigma, and MGST-I-like-I enzymes catalyze the isomerization of PGH_2 to PGD_2 and PGE_2.[1,3] Alpha, mu, and pi GST also catalyze the inactivation of PGA_2 to PGJ_2. Glutathione *S*-transferase enzymes may also indirectly affect eicosanoid synthesis via effects on the levels of lipid hydroperoxide.

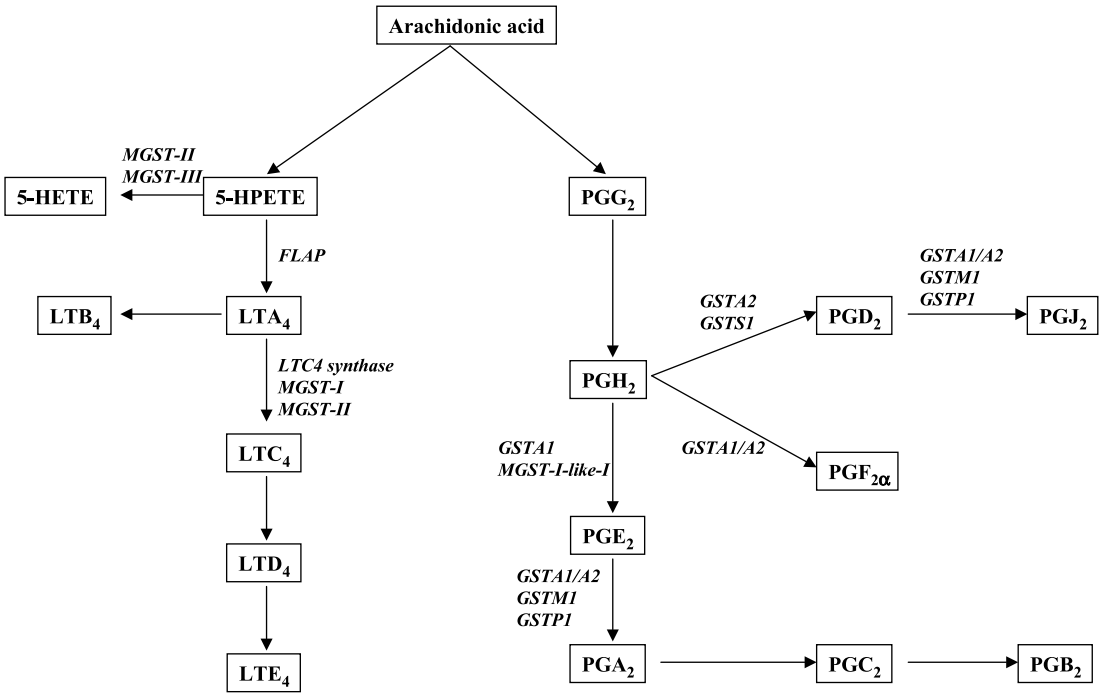

Fig. 1 The role of glutathione *S*-transferases in eicosanoid metabolism. (Based on data described in Ref. [1].)

CELL CYCLE CONTROL

Data showing interactions between GST and peptides involved in signaling pathways suggest a novel, non-catalytic role. Thus under nonstressed conditions, pi class monomers complex with Jun N-terminal kinase (JNK) preventing Jun phosphorylation.[4] Stress results in complex dissociation and restoration of kinase activity. Mu GST influences the heat shock-sensing pathway by inhibiting apoptosis signal-regulating kinase (ASK1) activity.[5] These GST may therefore regulate the mitogen-activated protein (MAP) kinase pathway. Recently, Edalat et al.[6] reported novel interactions between human GST A1-1, GST P1-1 and GST M2-2, and peptides with high sequence similarity to TRAF4-associated factor 1, G protein-coupled receptor MRGX3, tumor necrosis factor superfamily (member 9), and c-Jun N-terminal kinase 3.

REGULATION OF EXPRESSION

Regulation of expression varies between GST classes. In the promoter, response elements to transcription factors including the antioxidant response element, xenobiotic response element, glucocorticoid response element, Barbie box element, and GSTP enhancer 1 have been identified. Motifs for YY1, AP-1, MAF, Nrfl, Jun, Fos, and NK-κB have also been identified in rodents, although not all have been confirmed in human GST.[1,2] Such elements suggest an adaptive response by the GST to cellular stress.

A further mechanism for influencing GST expression is via methylation of CpG islands. In particular, GSTP1 expression appears particularly important in the protection of prostatic cells from oxidant and electrophile stress as methylation in the promoter silences expression allowing genetic damage and progression toward carcinoma.[7] Several studies have shown virtually 100% methylation of the GSTP1 CpG island in prostatic cancer cells.

POLYMORPHISM IN GST

Increasing numbers of GST polymorphisms are being identified using web-based searching although many theoretical single nucleotide polymorphisms (SNP) have not been found in humans.[8]

Alpha Class

Five alpha genes are in a cluster on chromosome 6 with several pseudogenes.[9] They show significant homology making SNP identification and genotyping assay design

problematic. The A1 promoter comprises four SNP in complete linkage disequilibrium.[9] The *B allele (T at position −69, A at position −52) alters an Sp1 binding site resulting in reduced expression. There is no evidence that two nonsynonymous substitutions in A2 (Table 1) alter GST activity. No polymorphisms have been confirmed in A3–5.

Mu Class

The mu genes are in tandem on chromosome 1 and ordered M4–M2–M1–M5–M3 with M3 in reverse orientation.[10] Complete deletion of GSTM1 is common (allele frequency 0.70 in Caucasians). A nonsynonymous substitution in exon 7 (Lys173Asp) is also identified although the differential effect of the A and B alleles on disease risk[1] is likely to result from linkage disequilibrium with a neighboring SNP. Indeed, *GSTM1*A* is in linkage disequilibrium with *GSTM3*B*, a 3-bp deletion which may generate a YY1 recognition motif.[1] The functional effect of an SNP in M4 is unknown. No significant polymorphisms have been identified in M2 or M5.

Theta Class

GSTT1 and T2 are located on chromosome 22.[11] GSTT2 is separated from a homologous pseudogene by D-dopachrome tautomerase. GSTT1*0 is deleted with an allele frequency in Caucasians of 0.40. An SNP (Thr104Pro) in GSTT1 has been described, but little studied. Both the gene deletion and the Pro104 variant demonstrate reduced activity toward haloalkanes. Although three GSTT2 SNPs have been described (Table 1), assay design is hampered by homology with pseudogene GSTT2P. Consequently, there are little data on the clinical effect of these alleles.

Pi Class

Four GSTP1 alleles have been identified: *GSTP1*A–D*[12] (Table 1). The Val^{105} variant, compared to Ile^{105}, confers higher catalytic efficiency for polycyclic aromatic hydrocarbon diol epoxides but lower efficiency for 1-chloro-2,4-dinitrobenzene. The effect of the Ala^{114}–Val^{114} substitution is unclear, although it may enhance the effect of the Ile^{105}–Val^{105} substitution.

Zeta Class

Expressed sequence tag (EST) database analysis has identified three functional substitutions in Z1 (Table 1).[1] The *A allele shows highest activity toward dichloracetic acid and lowest toward fluoroacetate.

Omega Class

Polymorphisms in O1 and O2 are described.[8] O1 is an anomaly as it shows sequence homology and functional activities with non-GST-like proteins including glutaredoxins. Its thioltransferase activity is decreased in both Asp140 (*C) and Asn217 variants, but increased in the *B allele (del115). An A–G substitution in O2 at position 424 gives rise to an asparagine to aspartic acid amino acid change in exon 4. The functional consequence of this is unknown.

MEMBRANE ASSOCIATED PROTEINS IN EICOSANOID AND GLUTATHIONE METABOLISM

Allelic MAPEG genes are candidates for inflammatory pathologies where the relative levels of pro- and anti-inflammatory eicosanoids may be influenced by polymorphism.[13] Indeed, polymorphism in the FLAP and LTC_4 synthase genes has been examined in the context of asthma, where therapeutic modulation of leukotriene synthesis has been used.

GST POLYMORPHISMS: CLINICAL IMPLICATIONS

The wide range of in vitro GST substrates has resulted in them being considered almost universal candidates for susceptibility and outcome in disease.[1]

Tobacco-Related Diseases

GSTM1 and GSTT1 have been particularly studied as risk candidates for tobacco-related cancers.[14,15] While some studies show significantly increased risk for *GSTM1*0* and *GSTT1*0* homozygotes, others have not replicated these findings prompting the use of meta-analysis. For example, analysis using 43 studies indicates that GSTM1 null is not associated with increased lung cancer risk and that there is no evidence for an interactive effect between the genotype and tobacco consumption.[15] Analysis of 31 studies of the influence of GSTM1, GSTT1, and GSTP1 polymorphisms on head/neck cancer risk found modest associations (odds ratio about 1.30) between risk and GSTM1 null and GSTT1 null with greater risk (odds ratio 2.06) associated with combinations of the genotypes.[14] Analysis of six studies also failed to identify significant associations between GSTM1 null and colorectal cancer risk.[16]

Overall, therefore, the concept that GST polymorphisms, by reflecting a detoxication-deficient phenotype,

identify individuals at increased risk of xenobiotic-related cancers is not supported by available data. However, the impact of polymorphism may be more readily observed using alternative endpoints such as formation of DNA adducts. Thus Perera et al.[17] found that in smokers, DNA adducts in white blood cells were significant predictors of lung cancer risk and that adduct levels were higher in individuals with combinations of GSTM1 and GSTP1 genotypes.

Glutathione *S*-transferase variants could mediate risk of nonmalignant diseases in which tobacco is a causative factor. However, the interactive effect of GSTM1 null and cigarette smoking was found to be insignificant in the aetiology of severe coronary artery disease in 868 patients with angiographically characterized disease.[18] Smoking is also associated with disease severity in women with rheumatoid arthritis. We found that smoking was associated with the most severe disease in patients with GSTM1 null polymorphism.[1]

Oxidative Stress-Related Disorders

Oxidative stress is implicated in the inflammatory demyelination that characterizes multiple sclerosis suggesting GST polymorphisms may be associated with disability. In 177 patients with disease duration over 10 years, GSTM3 AA (OR=2.4) and homozygosity for both GSTM1*0 and GSTP1*Ile105-encoding allele (OR=5.0) were linked with severe disability suggesting that long-term prognosis in MS is influenced by GST-mediated ability to remove toxic products of oxidative stress.[1] Exposure to ultraviolet radiation also results in local oxidative stress in skin. Response to such exposure, examined as minimal erythema dose, has been shown to be mediated by GSTM1 and GSTT1 genotype in a gene dosage-dependent manner.[19] Furthermore, nonmelanoma skin cancer has also been linked to these polymorphisms.[1]

Metabolism of Chemotherapeutic Agents

Although there are abundant data on GST expression and drug response, there are relatively little data on the effect of polymorphism on response to treatment. For example, in 148 women with epithelial ovarian cancer who were null for GSTM1 or GSTT1 there was decreased survival and reduced response to primary chemotherapy compared to those with active GSTM1 or GSTT1.[1,2]

CONCLUSION

The classic view that the GST is part of a cellular detoxication system focused on exogenous toxins remains tenable, although the failure to define precise roles for individual GST has hampered assessment of the implications of polymorphism as selection of diseases whose pathogenesis may be affected is subjective. Thus while associations between GST genotypes and clinical phenotype have been reported they cannot be predicted, and it is unclear why some, but not other, links are significant. Further, study reproducibility is a problem, probably because of variable definition of phenotypes and differences in population characteristics. Thus molecular epidemiological studies show that the impact of polymorphism on disease risk and outcome is likely to be most evident in patient subgroups.[1] Such subgroups may be defined by different sets of susceptibility genes and/or environmental exposures and identified by clinical characteristics such as tumor site, age at diagnosis, or gender. For example, the importance of exposure is shown by the chemoprotective effect of cruciferous vegetable-derived metabolites such as isothiocyanates that modulate cytochrome P450 and GST expression.[1,2] Thus GST polymorphisms may influence cancer risk through various mechanisms including interactions with diet-derived compounds. The GST effect may also be exerted via their catalysis of detoxication reactions or by interactions with peptides that mediate signaling pathways.

While most significant associations between GST genotypes and clinical phenotype have not been replicated, a minority have been independently confirmed. For example, GSTP1 Val^{105}/Val^{105} has been associated with reduced risk of airway hyperresponsiveness (odds ratio=0.23–0.38) in three studies in asthmatic adults and children.[20] This genotype is also protective against childhood respiratory illness.[21] The advent of high-throughput genotyping, availability of new SNP, and ease of deriving haplotypes should place an emphasis on large studies incorporating some assessment of reproducibility. Furthermore, assessment of further allelic GST sites associated with binding of peptides involved with cell signaling warrants further investigation.

Glycogen Storage Diseases

Yuan-Tsong Chen
Deeksha Sarihyan Bali
Duke University Medical Center, Durham, North Carolina, U.S.A.

INTRODUCTION

Glycogen storage diseases (GSDs) are inherited disorders affecting glycogen metabolism. The glycogen found in GSDs is abnormal either in quantity or quality. Liver and muscle are the most common and seriously affected tissues. The liver GSDs usually present with hepatomegaly and hypoglycemia. The GSDs primarily affecting the liver are types I, III, IV, VI, and IX. The most common features of muscle GSDs are muscle cramps, exercise intolerance, fatigue, and progressive weakness. GSDs principally affecting the muscle include GSD type II (lysosomal enzyme deficiency), V, VII, and IX (phosphorylase kinase deficiency).

The frequency of all forms of GSDs is approximately 1 in 20,000–25,000 live births. GSD types I, II, III, VI, and IX are the most common, and they account for approximately 90% of all GSDs.

GSD TYPE I (GLUCOSE-6-PHOSPHATASE OR TRANSLOCASE DEFICIENCY, VON GIERKE DISEASE)

GSD type I is caused by defect in either glucose 6-phosphatase catalytic activity[1–4] (Ia) or a defect in the glucose-6-phosphate translocase[5] (Ib). The stored materials in the liver include glycogen and fat (Table 1).

Clinical Findings

The hallmarks of the disease are hepatomegaly, hypoglycemia, lactic acidosis, hyperuricemia, hyperlipidemia, and growth retardation. Long-term complications include short stature, osteoporosis, gout, renal disease, pulmonary hypertension, and hepatic adenomas. Virtually all females have ultrasound findings consistent with polycystic ovaries.[6] Hepatic adenomas develop in a significant number of patients, and malignant transformation may occur.[7]

Type Ib has a similar clinical course with the addition of neutropenia and impaired neutrophil function resulting in recurrent bacterial infections. Oral and mucosal ulcerations are common, and in some cases, regional enteritis can also occur.[8]

Genetics

Type I GSD is autosomal recessive. The gene for glucose-6-phosphatase (G6PC; OMIM 23220) is located on chromosome 17q21, spans 12.5 kb, and has five coding exons. The gene for glucose-6-phosphate translocase (G6PT1; OMIM 23220) is located on chromosome 11q23 and consists of nine exons. Both types of GSD I are genetically heterogeneous. More than 73 disease-causing mutations are known for type Ia. Some ethnic group-specific and more frequently detected mutations for type Ia—R83C (Jewish), 130X (Hispanic), 35X, G188R, and Q347X (Caucasian), R83H (Chinese), 727 G>T (Japanese)—are responsible for about 78% of the known disease alleles.[9,10]

For GSD Ib, there are about 66 disease-causing mutations known. Two mutations, G339C and 1211delCT, appear to be more prevalent in Caucasian patients, whereas W118R appears to be common among Japanese patients.[10,11] Definitive genotype/phenotype correlation is not apparent for either subtype; however, GSD Ia mutations, 727G>A and G188R, confer specific phenotypes in affected patients when expressed in homozygous state (increased risk for hepatocellular carcinoma and recurrent infections and neutropenia, respectively). Identification of mutations allows prenatal diagnosis of both subtypes.[10,11]

GSD TYPE II (ACID MALTASE OR ACID α-GLUCOSIDASE DEFICIENCY, POMPE DISEASE)

GSD II is caused by a deficiency of lysosomal acid α-glucosidase (GAA; acid maltase), an enzyme responsible for the degradation of glycogen engulfed in autophagic lysosomal vacuoles (OMIM 232300). Three different

Table 1 Glycogen storage diseases: Distinct types and diagnosis

Disorder	Enzyme defect/deficiency	Inheritance, chromosomal localization, and gene
Type Ia (Von Gierke)	Glucose-6-phosphatase	AR[a], 17q21, Gene: *G6PC*
Type Ib	Glucose-6-phosphate translocase	AR, 11q23, Gene: *G6PT1*
Type II (Pompe) Infantile	Acid α-glucosidase (acid maltase)	AR, 17q25.2–25.3, Gene: *GAA*
Juvenile	Acid α-glucosidase (acid maltase)	AR, 17q25.2–25.3, Gene: *GAA*
Adult	Acid α-glucosidase (acid maltase)	AR, 17q25.2–25.3, Gene: *GAA*
Type IIIa (Cori or Forbes)	Liver and muscle debrancher deficiency (amylo-1,6-glucosidase)	AR, 1p21, Gene: *AGL*
Type IIIb	Liver Debrancher deficiency (amylo-1,6-glucosidase)	AR, 1p21, Gene: *AGL*
Type IV (Anderson)	Branching enzyme (BE)	AR, 3p12, Gene: *GBE1*
Type V (McArdle)	Myophosphorylase	AR, 11q13, Gene: *PYGM*
Type VI (Hers)	Liver phosphorylase	AR, 14q21–22, Gene: *PYGL*
Type VII (Tarui)	Phosphofructokinase	AR, 12q13, Gene: *PFKM*
Type IX	Phosphorylase kinase	X-linked: Xp22.2–22.1, Gene*: PHKA2*; AR, 16q12–13, Gene*: PHKB*; AR, 16p11–12, Gene: *PHKG2*
Type XI (Fanconi-Bickel syndrome)	Glucose transporter 2	AR, 3q26.1–26.3, Gene: *GLUT2*
Type GSD 0	Glycogen synthase	AR, 12p12.2, Gene: *GYS2*

[a]AR: autosomal recessive.

forms of the disease presenting with different ages of onset and clinical severity have been identified.[12,13]

Clinical Findings

The infantile form presents with progressive hypertrophic cardiomyopathy, generalized hypotonia with muscle wasting, hepatomegaly, and macroglossia, followed by a rapid, progressive course. Death usually occurs before the second year of life as a result of cardiorespiratory failure.

The juvenile form presents in early childhood, with progressive muscle weakness including the diaphragm, but no cardiac involvement. Affected patients usually die before puberty from respiratory failure.[12,13]

In the adult form, the presenting symptom may resemble the muscle weakness of limb-girdle muscular dystrophy or a respiratory insufficiency. Definitive diagnosis for GSD type II requires enzyme analysis of skin fibroblasts. In general, enzyme deficiency is more severe in the infantile form than the late-onset juvenile and adult forms.

Genetics

GSD II is autosomal recessive. The gene that encodes acid maltase (GAA) is located on chromosome 17q25.[14] Genetic and biochemical heterogeneity has been observed in GSD II without clear correlation to clinical phenotypes. More than 70 disease-causing mutations have been described,[14] and most are private family mutations. However, some common mutations exist in specific ethnic groups, including Dutch (del exon 18), Asians (C1935A), and African-Americans (C2560T), which could be used for carrier detection and diagnosis.[15]

Major clinical presentation	Enzymatic diagnosis (tissue)	Gene-based diagnosis
Hepatomegaly, hypoglycemia, elevated blood lactate, cholesterol, triglycerides and uric acid	Yes (liver)	Mutation screen
Same as Ia, with additional findings of neutropenia and neutrophil dysfunction	Yes (liver)	Mutation screen
Cardiomegaly, hypotonia, muscle weakness, macroglossia; onset birth to 6 months	Yes (blood, muscle, liver, skin fibroblasts)	Mutation screen and DNA sequencing
Myopathy, variable cardiomyopathy; onset childhood.	Yes (muscle, skin fibroblasts)	Mutation screen and DNA sequencing
Myopathy, respiratory insufficiency; onset adulthood	Yes (skin fibroblasts)	Mutation screen and DNA sequencing
Childhood hepatomegaly, growth retardation, muscle weakness, hypoglycemia, hyperlipidemia, elevated transaminases	Yes (blood, liver, muscle)	DNA Sequencing
Liver symptoms same as IIIa: no muscle symptoms	Yes (liver)	Mutation screen
Failure to thrive, hepatomegaly, splenomegaly, progressive cirrhosis, elevated transaminases	Yes (liver, muscle, skin fibroblasts)	Gene sequencing
Exercise intolerance, muscle cramps, increased fatigability	Yes (muscle)	Mutation screen
Hepatomegaly, mild hypoglycemia, hyperlipidemia, and ketosis	Yes (Liver)	Gene sequencing
Exercise intolerance, muscle cramps, myoglobinuria, hemolytic anemia	Yes (muscle)	Mutation screen and DNA sequencing
Hepatomegaly, mild hypoglycemia, hyperlipidemia, and ketosis	Yes (blood, liver)	DNA sequencing
Hepatomegaly, enlarged kidneys, rickets, renal fanconi syndrome	No	DNA sequencing
Hyperketotic hypoglycemia in infancy	Yes (liver)	DNA sequencing

GSD TYPE III (DEBRANCHER DEFICIENCY, LIMIT DEXTRINOSIS, CORI, OR FORBES DISEASE)

GSD III is caused by a deficiency of glycogen debrancher enzyme (GDE) activity.[16] GDE deficiency impairs the release of glucose from glycogen, but does not affect glucose released from gluconeogenesis (OMIM 232400). The glycogen accumulated has a structure resembling limit dextrin (glycogen with short outer chains).

Clinical Findings

Most patients with type III GSD have enzyme deficiency in liver, skeletal muscle, and heart (type IIIa). However, some patients (<15%) have debranching enzyme deficiency limited only to liver (type IIIb). During infancy and childhood, the disease may be indistinguishable from GSD I. The liver symptoms improve with age and usually disappear after puberty. Overt liver cirrhosis rarely occurs. Hepatic adenomas have been reported, but malignant transformation has not been observed.[17,18]

Definite diagnosis and subtyping requires both liver and muscle biopsies or DNA-based mutation analysis (IIIb).

Genetics

GSD III is autosomal recessive. The gene (AGL) that encodes human debranching enzyme (GDE) is a large single copy gene located on chromosome 1p21, spans 85 kb, and contains 35 exons. There is an extensive clinical and genetic heterogeneity seen in this GSD, with about 35 disease-causing mutations and 16 polymorphisms identified in AGL gene so far.[17,18]

To date, no true frequent mutations have been found except for an ethnic mutation in the Ashkenazi Jewish population (4455delT) and two mutations associated specifically with GSD-IIIb (Q6X and 17delAG).[18] Three polymorphic DNA markers within the gene have been identified. Prenatal diagnosis, carrier detection, and postnatal molecular diagnosis can be offered only to the informative families where linkage has been established or to families with known disease-causing mutation.[18]

GSD TYPE IV (BRANCHING ENZYME DEFICIENCY, AMYLOPECTINOSIS, OR ANDERSON DISEASE)

GSD IV is caused by a deficiency of glycogen branching enzyme activity (GBE1, OMIM 232500) that results in the accumulation of abnormal glycogen with unbranched, long outer chains in the tissues, having poor solubility.[19] Branching enzyme deficiency is a clinically and genetically heterogeneous multisystem disorder with symptoms ranging from classical severe infantile form, with heart, muscle, and liver involvement, to a nonprogressive neuromuscular form.

Clinical Findings

Classical branching enzyme deficiency most frequently presents during the first few months of life, with hepatosplenomegaly and failure to thrive. Progressive liver cirrhosis, with portal hypertension, ascites, esophageal varices, and death, usually occurs before 5 years of age. However, there are patients who have survived without apparent progressive liver disease. The neuromuscular system may also be involved. Severe cardiomyopathy as the predominant symptom has also been reported.[20] The diagnosis of type IV is established by demonstration of abnormal glycogen (an amylopectin-like polysaccharide) and a deficiency of glycogen branching enzyme in liver, muscle, or fibroblasts.

Genetics

GSD IV is autosomal recessive. The glycogen branching enzyme gene (GBE1) is located on chromosome 3p12. Eight disease-causing mutations are known. A point mutation, Y329S, is associated with nonprogressive hepatic form of disease, and it is also found in Ashkenazi Jewish patients with adult polyglucosan body disease. Other point mutations (R515C, F257L, R524X) or deletions are associated with severe infantile phenotype.

GSD TYPE V (MUSCLE PHOSPHORYLASE, MYOPHOSPHORYLASE DEFICIENCY, McARDLE DISEASE)

GSD type V is caused by the deficiency of muscle phosphorylase activity. A deficiency of myophosphorylase impairs the cleavage of glucosyl molecules from the straight chain of glycogen. Separately encoded, tissue-specific distinct phosphorylases are known for liver, muscle, and brain.[21]

Clinical Findings

Clinical symptoms usually appear in adulthood and are characterized by exercise intolerance with muscle cramps that can be accompanied by attacks of myoglobinuria. Serum creatine kinase is usually elevated and increases after exercise. Avoidance of strenuous exercise can prevent major episodes of rhabdomyolysis.

There have been several reports of a fatal infantile form of phosphorylase deficiency.[22] The presenting features were hypotonia, generalized muscle weakness, and progressive respiratory insufficiency.

Genetics

The gene for muscle phosphorylase (PYGM) has been mapped to chromosome 11q13. It consists of 19 exons and there is extensive genetic heterogeneity. A common nonsense mutation R49X in exon 1, which is found in 90% of Caucasians, and a deletion of a single codon in exon 17, found in 61% of Japanese patients. Other common Caucasian mutations (G204S in exon 5 and K542T in exon 14) make DNA-based testing for McArdles disease possible.[21]

GSD TYPE VI (LIVER PHOSPHORYLASE, HERS DISEASE)

The enzyme deficient in type VI GSD is liver-specific phosphorylase. It is relatively rare and a benign form of GSD with no heart and skeletal muscle involvement. Most patients with GSD VI disease present with hepatomegaly and growth retardation. Hypoglycemia, hyperlipidemia, and hyperketosis, if present, are usually mild. The hepatomegaly improves and disappears around puberty. Diagnosis rests on enzyme analysis of the liver biopsy. GSD VI is autosomal recessive. Liver phosphorylase gene (PYGL) has been mapped to chromosome 14q21 and has 20 exons.[23] A splice site mutation in intron 13 has been identified in Mennonite population.

GSD TYPE VII (PHOSPHOFRUCTOKINASE DEFICIENCY, TARUI DISEASE)

Type VII GSD is caused by the deficiency of muscle phosphofructokinase (PFK) enzyme. It is a complex isozyme consisting of three subunits variably expressed in muscle, liver, and platelet tissues.[24]

Clinical Findings

The clinical features are very similar to those in GSD V; however, hemolytic anemia can also occur. Along with glycogen accumulation, there is also an accumulation of fine fibrillar polysaccharide material resembling amylopectin, as what is seen in GSD IV.

An infantile form of phosphofructokinase deficiency has also been reported. These patients present with limb weakness, seizures, cortical blindness, and corneal clouding. Death occurs before 4 years of age from respiratory failure.

Biochemical enzyme analysis or histochemical demonstration of the enzymatic defect in the muscle is required to establish the diagnosis.

Genetics

Type VII GSD is autosomal recessive. The gene (PFKM) is located on chromosome 12q13. Eighteen mutations have been identified in *PFKM* gene. Muscle PFK deficiency seems to be prevalent in Ashkenazi Jews, and two common mutations are found in about 95% of mutant alleles.[25]

GSD TYPE IX (PHOSPHORYLASE B KINASE DEFICIENCY)

A deficiency of phosphorylase b kinase (PhK) is responsible for several forms of GSD that differ both in tissues affected and in patterns of inheritance.[26] The enzyme consists of four different subunits ($\alpha\beta\gamma\delta$), which result in multiple tissue-specific isozymes. The enzyme activates glycogen phosphorylase to enhance the breakdown of glycogen.

Clinical Findings

Patients with deficiency of liver PhK, the most common X-linked form, present in infancy with hepatomegaly, growth retardation, and delayed motor development. The symptoms improve with age, and adult patients have normal stature and minimal hepatomegaly.

Other PhK deficiency variants include an autosomal recessive form (affecting both liver and muscle), an autosomal recessive form (affecting only liver),[26] a mild myopathic form (muscle cramps and myoglobinuria), a severe myopathic form (onset in early infancy), and an isolated myocardial phosphorylase b kinase deficiency.[26,27] Clinical and genetic heterogeneity can be explained by the presence of the four subunits ($\alpha\beta\gamma\delta$) of PhK expressed in tissue-specific manner.

Definitive diagnosis of phosphorylase b kinase deficiency requires demonstration of the enzymatic defect in affected tissues.

Genetics

The genes for α, β, and γ subunits have been cloned.[28] The genes for both muscle and liver α subunit have been mapped to X chromosome (αL at Xp22.2 and αM at Xq12) and the one for β subunit to chromosome 16q12–q13. A number of mutations for different forms of phosphorylase kinase deficiency have been characterized.[26–28] The gene for muscle γ subunit (γM, PHKG1) has been localized to chromosome 7p12.[29] No mutations in this gene have been reported so far. Gene for liver/testis-specific γ subunit (γTL, PHKG2) maps to chromosome 16p12.1 and many disease-causing mutations are known for this gene.[28]

GSD TYPE XI (HEPATIC GLYCOGENOSES WITH RENAL FANCONI–BICKEL SYNDROME)

This rare GSD is caused by defects in the facilitative glucose transporter 2 (GLUT-2), which transports glucose in and out of hepatocytes, pancreatic cells, and the basolateral membranes of intestinal and renal epithelial cells.[30] The disease is characterized by proximal renal tubular dysfunction, impaired glucose and galactose utilization, and accumulation of glycogen in liver and kidney. The affected child presents in the first year of life with failure to thrive, rickets, hepato- and renomegaly, and maybe mild fasting hypoglycemia and hyperlipidemia. The gene for GLUT 2 has been cloned and is localized to chromosome 3q26.1. It comprises 10 exons and there are about 10 mutations identified.[30]

GLYCOGEN SYNTHASE DEFICIENCY

Strictly speaking, glycogen synthase deficiency (Type 0) is not a glycogen storage disease. The patients present in infancy with early-morning drowsiness, fatigue, and

sometimes convulsions associated with hypoglycemia and hyperketonemia.[31,32]

Treatment is avoidance of fasting. This autosomal recessive disease is caused by mutations in the liver glycogen synthase gene (GYS2), which is located on chromosome 12p12.2 (Table 1).

CONCLUSION

GSDs are inherited disorders caused by defects in enzymes or transport proteins involved in glycogen metabolism and glycolysis. Virtually all genes involved in GSDs have been cloned and mutations characterized. Advances in understanding the molecular basis of the various genetic deficiencies, their proteins, and regulation are being used to improve both the diagnosis and clinical outcome. Molecular studies will hopefully lead to the development of successful therapy for the more severe forms of GSD.

HAART Therapy—Antiretroviral Resistance Genotyping

Kristel Van Laethem
Anne-Mieke Vandamme
Rega Institute for Medical Research and University Hospitals, Leuven, Belgium

INTRODUCTION

Although the introduction of highly active antiretroviral therapy (HAART) in the mid-1990s has resulted in a decrease of the morbidity and mortality in the HIV-1 patient population that has access to treatment, therapy failure still occurs. The surrogate markers for therapy failure, which ultimately results into clinical progression, are CD4 cell count and viral load. As changes in viral load mostly precedes changes in CD4 count, the determination of the viral load is the most relevant laboratory procedure to monitor the short-term in vivo activity of a therapy given to an individual patient. Lack of adherence, lack of therapy potency, pharmacological reasons, drug–drug interactions, and preexisting drug resistance can be factors resulting into therapy failure and rising viral loads.

The evolution of resistance against HIV-1 inhibitors within a patient depends on the generation of genetic variation, reflected by substitutions, insertions, deletions, and recombination events, and on the selection of drug-resistant variants during antiretroviral therapy. The high HIV-1 genetic variability is caused by the error-prone nature of HIV-1 reverse transcriptase, by the absence of any enzymatic proofreading activity, and by the huge rate of HIV-1 replication in vivo. Some of the created genetic variants will result in alterations to the structure and function of the molecules targeted by the antiviral drugs (currently reverse transcriptase, protease, and glycoprotein gp41). These alterations could confer changes in susceptibility to one or more of these drugs. In the presence of therapy, the variants with some level of resistance will gradually overgrow the wild-type variants. Under the continuous selective pressure of inhibitors and with the presence of residual replication as a result of insufficient potency of the treatment, additional mutations will accumulate.

Thus, the main goal of HAART is to reduce the viral load as much as possible to prevent further clinical progression. However, its immediate goal is to reduce the viral load to prevent the formation of variants that result in antiviral resistance to the current therapy and that, because of the phenomenon of cross-resistance within drug classes, ultimately might lead to a limitation or even lack of future treatment options.

METHODOLOGY

Antiviral drug resistance can be determined at the genotypic level by the detection of resistance mutations. Alternatively, it can be determined at the phenotypic level by measuring the ability of an HIV-1 isolate to grow in the presence of a drug, or by measuring the HIV-1 reverse transcriptase or protease enzyme activity in the presence of an inhibitor.

Sequencing is the most commonly used genotypic assay for the monitoring of resistance mutations. It provides information on all nucleotides of the sequenced region. The target sequence is amplified via polymerase chain reaction, and the sequence is determined based on the incorporation of dideoxynucleotides. At the moment, most clinical laboratories perform home-brew sequencing or they use one of the two commercially available sequencing assays [ViroSeq HIV-1 Genotyping System (Abbott) and Trugene HIV-1 Genotyping Kit (Bayer)]. Another option is to send samples to service laboratories (e.g., ViroLogic and Virco).

Presently, only three companies (ViroLogic, Virco, and VIRalliance) and a few national reference laboratories routinely perform replication-based phenotypic assays. These assays start with the amplification of the patient-derived HIV-1 target sequence via polymerase chain reaction. The amplification product is subsequently incorporated into a proviral laboratory clone via ligation or homologous recombination. This generates a stock of chimeric viruses. The viruses are tested for their ability to grow in the presence of different concentrations of inhibitors. The principle of chimeric viruses for the determination of the susceptibility profile is preferred over other phenotypic assays to obtain better reproducibility and automation possibilities.[1,2]

Resistance testing has to be performed on plasma samples before starting, stopping, or changing therapy. It is highly important to monitor the active replicating viral population responsible for the therapy failure, because it is the resistance pattern of this population that can be useful in understanding the observed therapy failure.

An important limitation of current available assays is their need for plasma samples with an HIV-1 viral load exceeding 1000 copies/mL because of the lower

DOI: 10.1081/E-EDGP 120020987

sensitivity of the cDNA synthesis and amplification procedures of long templates. This is required to achieve reliable results. Otherwise, nonrepresentative variants could be picked up because of stochastic events during the experimental procedures. However, switching therapy early after viral failure, when the HIV-1 viral load is detectable but still very low, results in better chance of response to the salvage therapy. There are only few data that provide the optimal point at which therapy should be changed in terms of long-term clinical outcome, but the short-term risk of any viral replication in the presence of inhibitors is the development of resistance.

Results of the resistance assays represent only the genotypic or phenotypic profile of the majority of quasispecies present in vivo because they have difficulties in detecting minor variants that reflect less than 10–50% of the total viral population.[3] It remains uncertain what the contribution of minor viral variants is to therapy failure.

As genotypic and phenotypic assays start with an amplification procedure, the sensitivity of both tests depends on the efficient hybridization of primers, and this is strongly influenced by the variability at the primer sites. Most of the assays have originally been optimized by using subtype B HIV-1 strains because such strains were responsible for the epidemic in developed countries. However, in recent years, the prevalence of non-B subtypes has been increasing in Europe, and access to therapy has been extended to the developing world where non-B HIV-1 subtypes constitute the largest part of the epidemic.[4] Effort has been made to improve the performance of the assays on non-B HIV-1 subtypes by developing primers at more conserved sites or by the inclusion of backup primers, but no assay can guarantee to reproduce adequate results for all strains.

Both genotypic and phenotypic resistance assays have respective advantages and disadvantages (Table 1). Resistance assays have to be performed in highly specialized laboratory facilities. This particularly holds true for the phenotypic resistance assay because it requires biosafety level 2 or 3 facilities, whereas a genotypic resistance assay can be performed in a dedicated molecular biology laboratory. Because both types of assays require sophisticated technology and knowledge, a strict adherence to current laboratory standards is important; well-trained and experienced laboratory technicians are also essential.

Another practical consideration in the choice of resistance testing is the cost of the procedure. Phenotypic assays are still more expensive than genotypic assays.

Genotypic resistance assays can deliver results within a few days, whereas longer time is required to obtain

Table 1 Advantages and disadvantages of genotypic and phenotypic resistance assays

Advantages	Disadvantages
Genotypic resistance assays	
Have a wider availability, requiring biosafety level 1 facilities	Require plasma samples in general with viral load >1000 RNA copies/mL
Are less expensive	Exhibit difficulties in detecting minor variants
Display a shorter turnaround time (typically 1–2 weeks)	Exhibit a sensitivity that is strongly influenced by virus genetic variability
Detect sentinel mutations that are linked to reduced clinical response but not necessarily to reduced phenotypic susceptibility	The relevance of some mutations remains still unclear
	Some (complex) mutation patterns may be difficult to interpret
Phenotypic resistance assays	
Measure the effective susceptibility to all (also new) drugs	Require highly specialized laboratory facilities, typically biosafety level 2 or 3
Measure effects of mutational interactions	Require plasma samples in general with viral load >1000 RNA copies/mL
	Exhibit difficulties in detecting minor variants
	Exhibit a sensitivity that is strongly influenced by virus genetic variability
	Are more expensive (in general twice as much as genotyping)
	Have longer turnaround time (typically 2–4 weeks)
	The reproducibility range of the assay extends for some drugs above clinically relevant cut-offs
	The clinical relevance of drug susceptibility levels is not always clear

phenotypic resistance results. This turnaround time can be an important factor in some clinical situations, where immediate results are needed, e.g., postexposure prophylaxis and primary HIV-1 infection.

Sequencing has the advantage of detecting all known resistance-related mutations—mutations considered as markers for developing resistance patterns (e.g., K70R or Q151M in the RT gene)—or substitutions that are considered to be associated with a lower genetic barrier to resistance development (e.g., the reversal mutations T215A/C/D/S in the RT gene). Phenotypic assays measure the effective susceptibility, resulting from known, but also unknown, resistance-related mutations. However, they do not detect the presence of the latter two sets of mutations. Although these mutations are associated with reduced clinical response, they are not always linked with reduced phenotypic susceptibility.

In addition, the current phenotypic assays have difficulties in detecting resistance to some nucleoside reverse transcriptase inhibitors. These drugs compete with the natural deoxynucleoside triphosphates (dNTPs) for binding to the reverse transcriptase and incorporating into the growing DNA chain. The phenotypic assays use activated cells with high intracellular dNTP pools that do not always reflect the relevant in vivo cell conditions. The high intracellular dNTP pools lead to resistance levels that cannot be reliably measured because they are within the reproducibility range of the assays.

Another issue in the interpretation of genotypic results is whether the mutations constituting a part of a set of multiple mutations exist on a single clone or are spread across multiple clones of variants. Phenotypic resistance assays resulting in low-level resistance may be caused by a small change in susceptibility of the whole virus population or a mixture of resistant and susceptible virus. The linkage of mutations could have important clinical implications, but at the moment this issue cannot be routinely elucidated with the current resistance assays.

INTERPRETATION

The information provided by genotypic resistance assays may be difficult to interpret. Current knowledge on the correlation between the genotypic and phenotypic characteristics of an HIV-1 isolate is mainly based on in vitro studies of laboratory and clinical HIV-1 strains. The clinical relevance of mutations is also determined from linking mutation patterns with previous therapy history or from linking them with subsequent therapy response. A decade ago, when monotherapy was the standard-of-care, the direct linkage between mutations, therapy experience, and subsequently therapy response was more clear-cut than in the current HAART situation. The potency of new drugs is now investigated in ''add-on'' studies, where the new drug is added to the failing regimen. More recently, this strategy has encountered ethical problems because of the possibility that it could lead into fast resistance development against the new drug. An increasing number of efficiency studies are performed with combinations of the new drug and at least one other suspected active compound. This hampers the understanding of the impact of preexisting resistance and the subsequent viral response to the new drug.

Patients are currently treated with combination therapies that change in time and that result in complex patterns of mutations. The phenotypic effects of mutations and their interactions often cannot be reliably predicted. Some mutations that are developed under the selective pressure of a particular drug can cause resistance toward other drugs from the same class without any previous experience (cross-resistance), and others might reverse the phenotypic resistance level of certain resistance mutations. Phenotypic resistance assays give a direct measurement of susceptibility toward the tested inhibitors that includes the effect of all mutations and their interactions. However, the clinical relevance of phenotypic results can also be difficult to interpret because the threshold at which a specific inhibitor becomes ineffective in vivo has not been determined yet for all available drugs.

The investigation of the correlation between genotype and phenotype has resulted into the development of genotypic–phenotypic relational databases and rule-based algorithms.[5] These systems can be helpful in the interpretation of in vivo resistance. Large datasets containing matched genotypes and phenotypes are already used to predict phenotype from genotype. Rule-based algorithms contain lists of mutations that are: 1) known to confer phenotypic resistance toward a particular drug; 2) known to be part of a mutation pathway toward high-level resistance; 3) and, most importantly, responsible for a reduced clinical response.[6]

At the moment, several interpretation algorithms are available. They give concordant results in most cases. The observed discordances reflect the uncertainty that is still associated with particular set of mutations.[7]

These algorithms should be subject to regular updates as soon as new correlations between genotype and phenotype are established and the clinical relevance of certain genotypes and phenotypes become evident.

From the time antiretroviral drugs were first used in the treatment of HIV-1 infection, it was observed that in many cases therapy failure was associated with the development of resistance mutations at the genetic level and decreases in drug susceptibility at the phenotypic level. Only a few

years ago, after the effect of resistance on subsequent therapy failure was investigated in retrospective studies, the idea to prospectively use the results from genotypic and phenotypic resistance assays in the management of HIV-1 infection was incorporated into the design of clinical trials. In these trials, viral response on therapy guided by genotypic and/or phenotypic resistance results was compared to that during standard-of-care. In some of these prospective trials, access to genotypic or phenotypic drug resistance results led into a short-term, modest viral benefit. In other studies, the effect of resistance testing was attenuated as a consequence of many factors.

The absence of resistance does not always result into therapy response because success is a result of many factors besides antiviral resistance, such as adherence, potency, and pharmacological reasons. It has also been shown that the interpretation of the raw resistance data plays an important role in the successful implementation of resistance testing.[8] It is recommended that the interpretation should be left to experts. These experts can translate the data into recommendations that are useful for clinicians. Another limitation of the use of drug resistance assays in the clinical management of HIV-1 infection is the limited choice of drugs in the treatment of HIV-1 patients who have undergone extensive therapy with multiple failures.[9] Because of the existing cross-resistance within drug classes, a badly managed combination therapy could result into broad cross-resistance toward all available drugs, even if these respective drugs had not been previously used. Whether or not the choice of subsequent therapy is then guided by resistance testing has no longer any relevance, because there remains only limited or no option at all.

Nevertheless, resistance testing has demonstrated its advantages and has been implemented into guidelines.[10–12] It is recommended for primary and recent HIV-1 infection, before initiation of therapy in chronically infected patients if infected within the past 2 years, or in areas with high resistance prevalence, first or multiple therapy failure, and pregnancy.

CONCLUSION

Although resistance testing is widely used in the clinical management of HIV-1 treatment, questions remain. Up until now, the assays have shown a short-term modest viral benefit. Clinicians should value the results obtained with these assays but should, however, not overestimate their importance because there still exists some uncertainty concerning the clinical importance of certain genotypic mutations and phenotypic levels of susceptibility. The decision to use a specific combination of drugs should be made by the clinician, taking into account all clinical, immunological, viral, and pharmacological factors, as well as adherence issues and treatment history.

Haemophilus ducreyi

Sylvia M. Bruisten
GG&GD Municipal Health Service, Amsterdam, The Netherlands

INTRODUCTION

The gram-negative coccobacillus *Haemophilus ducreyi* causes chancroid in humans. Chancroid is a genital ulcer disease (GUD) that is highly prevalent in underdeveloped countries and in some urban areas of developed countries. It is a sexually transmitted infection (STI) that had an estimated global incidence of 7 million cases in 1997. As is the case with other GUDs, chancroid facilitates HIV-1 transmission. Naturally occurring chancroid is much more prevalent in men than in women and circumcision is known to greatly reduce the incidence. Chancroid manifests itself as a single painful ulcer after infection of damaged skin. Symptomatic diagnosis is complicated because the clinical picture is similar to GUD caused by other pathogens such as herpes simplex virus (HSV) and *Treponema pallidum* (syphilis). *H. ducreyi* is renowned for its problematic detection by culture. Experienced microbiologists are needed and these are mostly lacking where chancroid is highly prevalent. Microscopic diagnosis can only be performed in well-equipped laboratories and the same problem is recognized for amplification methods such as PCR. Nevertheless PCR provides the most sensitive diagnosis of chancroid and should be regarded as the gold standard. Development of new, easy-to-use serological assays is needed for on-site specific diagnosis.

CLASSIFICATION

In 1889, Ducreyi demonstrated the inoculable nature of chancroid pus of genital lesions. The present genus name *H. ducreyi* originated in 1921 from Neveu-Lemaire. *H. ducreyi* is classified in the *Actinobacillus* cluster of the Pasteurellaceae. Synonyms of *H. ducreyi* are *Bacillus ulceris cancrosi* (Kruse 1896) and *Coccobacillus ducreyi* (1921). The *H. ducreyi* genome consists of a single 1.7-Mbp chromosome with 1693 open reading frames (ORFs).[1] One of its virulent strains (35000 HP) has been sequenced completely. Genes with closest homology were found in *Haemophilus influenzae* and *Pasteurella multicoda*; however, there is little long-range conservation of the order of genes or ORFs in the chromosome when *H. ducreyi* is compared to these species.[1] The genes in *H. ducreyi* encoding toxic factors such as hemolysin and the cytolethal distending toxin (CDT) are absent in the genomes of other Pasteurellaceae.[1]

BIOLOGY

H. ducreyi preferentially infects keratinized stratified squamous epithelium. Epidermal microabrasions formed during sexual intercourse or otherwise damaged skin is the portal of entry for infection. After entry into the skin, the bacteria stimulate target cells such as keratinocytes, fibroblasts, and endothelial cells to secrete IL-6 and IL-8.[1] Polymorphonuclear cells are recruited within 24 hr to the epidermis and dermis and form small micropustules. A dermal infiltrate of T cells, macrophages, and some B cells evolves.[2] A tender erythematous papule may develop 4–7 days after initial infection, which can progress to the pustular stage. The bacteria remain extracellular through the pustular stage and resist phagocytosis.[3,4] Pustules often rupture after a further 2–3 days to form painful shallow ulcers with granulomatous bases and purulent exudates.[5] In the absence of effective antimicrobial therapy, the chancroid ulceration can take several weeks to months to resolve. Inguinal lymphadenitis occurs in up to 50% of cases and the lymph nodes may develop into buboes. If not aspirated or drained through incision, buboes can rupture spontaneously.[5]

In the rabbit model, *H. ducreyi* does not grow at temperatures above 35°C, but only in rabbits housed at 15–17°C. In culture the bacteria grow best at 33°C, which probably reflects the fact that in humans only external surfaces are susceptible to infection. Experimental animal models for *H. ducreyi* that most resemble the human in vivo growth are pig and macaque models. A mouse subcutaneous chamber model was developed for studying long-term growth.[6]

VIRULENCE FACTORS

In human experimental models, bacteria are delivered into the skin via puncture wounds using an allergy-testing device.[3] An estimated delivered dose (EDD) of 1 colony-forming unit already results in 50% papule formation.[4]

DOI: 10.1081/E-EDGP 120021475

Most bacteria localize in the dermis after 48 hr of infection. Several potential *H. ducreyi* virulence factors have been reported in the literature and their possible effects were studied using isogenic mutants by grafting both wild-type strains (i.e., 35000 HP) and mutant strains on each arm of volunteers.[3,4] Factors studied so far include lipooligosaccharide (LOS), pili, soluble cytolethal distending protein (sCDT), copper–zinc superoxide dismutase (SOD), a hemoglobin-binding outer membrane protein (OMP), a hemolysin capable of cytotoxicity, a filamentous hemagglutinin-like protein, and a zinc-binding periplasmic protein.[6]

The LOS of most *H. ducreyi* strains express an epitope that is also present in *Neisseria* strains and that is immunochemically similar to a precursor of a major blood group antigen found on human erythrocytes.[6] Pili are filamentous appendages involved in cell adhesion. The major 24-kDa pilin FtpA subunit shares no homology with other pilins present on the surface of gram-negative bacteria.[6] A gene cluster (*cdt* ABC) codes for the CDT proteins that were shown to block cell division in the G2 phase of the cell cycle. Superoxide dismutase are metalloenzymes that catalyze the conversion of superoxide radicals to oxygen and hydrogen peroxide. Periplasmic Cu–Zn SODs are thought to protect against oxidative cell damage by host immune cells.[6] The hemoglobin binding OMP (108-kDa *HgbA/HupA*) is essential for *H. ducreyi* to utilize both hemoglobin and haptoglobin as a source of heme required for growth. Hemolysins encoded by the *hhdA* and *hhdB* genes are possibly responsible for release of hemoglobin from erythrocytes. Two large genes, *IspA1* and *IspA2*, encode proteins that resemble in part the filamentous haemagglutinin (FhaB) virulence factor of *Bordetella pertussis*. The exact function of the Lsp-A1 and -A2 proteins remains to be determined.[6] Zinc is an important trace element for maintaining structural stability and for catalytic activity of enzymes. The *znuA* gene of *H. ducreyi* encodes a periplasmic protein involved in zinc transport. The isogenic *znuA* mutant exhibited reduced lesions in the rabbit model.

CLINICAL ASPECTS

H. ducreyi is a strictly human pathogen causing chancroid. Probably because initial stages of infection are not painful, patients typically do not seek medical attention until they had ulcers for 1 to 3 weeks, which is probably 3 to 6 weeks after inoculation.[1] The chancroid ulcer has a pale yellow shallow base and diffuse, irregular borders.[7] Three to 25 times more males than females are infected. In men the lesions typically occur on the prepuce and frenulum (Fig. 1), whereas in women the ulcers are usually external and involve the vulva, the labia, and perianal region.[6,7] Extragenital chancroid is rare but may occur by autoinoculation of the inner thighs, breasts, and fingers.[6] A past infection does not confer protective immunity because multiple episodes of *H. ducreyi* infections can occur.

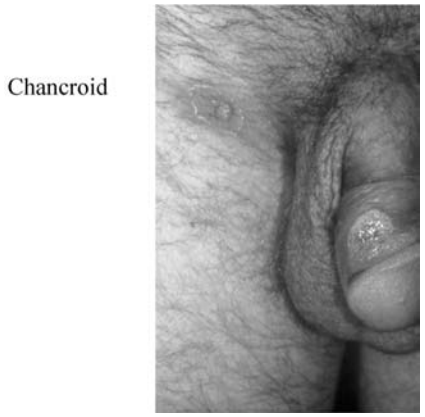

Fig. 1 Chancroid lesions on male thigh and penis shaft. (Courtesy of Han Fennema, M.D., Ph.D.) (*View this art in color at www.dekker.com.*)

Clinical diagnosis of chancroid is unreliable because of similarities of the clinical presentation of different etiologic agents of GUD, the presence of mixed infections, and atypical ulceration due to long-standing disease.[8] Next to *H. ducreyi*, causative pathogens of GUD are herpes simplex virus type 2 (HSV-2) and type 1 (HSV-1) and the bacteria *T. pallidum* (TP), which cause syphilis, and *Chlamydia trachomatis*, which cause lymphogranuloma venereum. In about 20–40% of GUD cases none of these pathogens are found despite use of the most sensitive assays.[9,10] Coinfection of *H. ducreyi* and HSV occurs commonly in the tropics.[6]

DIAGNOSIS

Diagnostic tests in use are culture tests, microscopy, PCR, serology, and antigen assays. Older studies use either culture or clinical diagnosis as the gold standard, but both are inaccurate measures of the true incidence of chancroid.[11]

H. ducreyi is a fastidious pathogen that requires complex media (containing heme) and growth conditions (33°C) for culture. *H. ducreyi* is routinely grown on 5% chocolatized horse blood agar plates, but using two specialized culture media increases the sensitivity.[11,12]

Table 1 Hybridization and amplification test formats for *H. ducreyi*

Target gene for PCR[a]	PCR test format[b]	Number of samples	Sensitivity, % (relative to)	Year of reference
16S rRNA	Nested; one tube	25	100 (culture)	1995[15]
	Colorimetric detection	83	83 (clinical)	
16S rRNA	Single, multiplex;	62	98 (culture)	1996[9]
	colorimetric detection	65	100 (HD PCR)	
16S rRNA	Nested; gel analysis	28	100 (culture)	1998[16]
16S–23S rRNA ISR[a]	Heminested; gel detection	32	96 (clinical)	1998[17]
GroEL; recD	Single; probe detection	5	60 (clinical)	2000[18]
P27 gene (=recD)	Heminested; gel detection	37	100 (culture)	2001[19]

[a]ISR: intergenic spacer region: region between the (rrs)16S and (rrl) 23S rRNA genes.
[b]Described is the type of PCR, either single, nested, seminested or mutiplex. Also the type of detection of the PCR product is given, either by (colorimetric) probe detection or by gel analysis.

Vancomycin (3 μg/mL) should be added to reduce contamination by other microorganisms. Microscopically, the colonial structures have been described as ''schools of fish,'' ''railroad tracks'' and ''fingerprints.''[11] Serological assays were developed that detect either a past infection measuring IgG anti-*H. ducreyi* levels or active infection detecting IgA and IgM levels.[10,13] IgG-based assays are mostly used to perform epidemiological studies.[11] A rapid diagnostic test based on monoclonal antibodies to the hemoglobin receptor HgbA was highly specific, but the sensitivity was too low for on-site diagnosis.[14] The first *H. ducreyi*–specific PCR assays were developed in the mid-1990s (Table 1), and DNA amplification is nowadays considered the most sensitive diagnostic method. Multiplex PCR (M-PCR) was developed in which TP, HSV, and *H. ducreyi* are simultaneously detected.[9,10,20] M-PCR is highly efficient but not commercially available. Nevertheless, PCR should be used as reference standard in evaluations of novel diagnostic techniques.[11]

TREATMENT

In developing countries with poor laboratory skills and facilities, a syndrome-based approach was developed and promoted because it was found to be inexpensive, simple, and very cost-effective. In syndromic management, patients are treated at the first visit with a combination of antimicrobials targeting the local probable etiological agents. The mainstay of chancroid treatment is 4 times daily 500 mg of oral erythromycin for 7 days (WHO website: http://www.who.int/docstore/hiv/STIManagemntguidelines/who_hiv_aids_2001.01/index.htm, accessed May 23, 2003). Other current recommended treatment regimens are single doses of either 1 g of azithromycin, 500 mg of ciprofloxacin, or 2 g of spectomycin.[5] If suspicion of infection with *Neisseria gonorrhoeae* and/or *Chlamydia trachomatis* exists, azythromycin is additionally effective against *H. ducreyi*. Although *H. ducreyi* was initially sensitive to many antibiotics, plasmid-mediated resistance has become an increasing problem worldwide since the 1970s. Resistance was documented for tetracycline, chloramphenicol, sulphonamides, aminoglycosides, and beta-lactam antimicrobial agents.[6] Chromosomally mediated resistance has lately led to decreased sensitivity for penicillin, trimethoprim, and ciprofloxacin.

EPIDEMIOLOGY

Chancroid was endemic in most parts of the world well into the 20th century. In Europe and North America, a steady decline was seen after the discovery of penicillin in 1943.[21] Reduction started, however, with changes toward reduced prostitution and improved sanitary conditions. Nowadays, the prevalence of chancroid is less than 1% in developed countries.[22] The few cases that are detected are usually imported from endemic countries or are associated with commercial sex work (CSW) and the use of crack cocaine and other illegal drugs.[7] Periodic health examinations and treatment of sex workers and other high-risk groups have largely contributed to the near-eradication of chancroid in these European countries.[21] In some cities in the United States, however, especially among high-risk communities, the *H. ducreyi* prevalence can be as high as 20%.[22,23]

Chancroid is still ubiquitous in tropical resource-poor countries located in Africa, Asia, Latin America, and the Caribbean.[6,21] In southern and eastern African countries, the *H. ducreyi* seroprevalence can be as high as 68% among CSW, but this could be overdiagnosis because in Africa the etiology of ulcers is often clinically directed.[24]

In west and central African countries the prevalence of chancroid among STI patients was significantly lower.[8,24]

HIV INFECTION

Chancroid is recognized as an important risk factor for acquiring HIV infection probably because the same type of risk behavior (prostitution, substance abuse) occurs for both diseases.[23,24] *H. ducreyi* infection enhances HIV transmission by several possible mechanisms, such as establishment of a portal of entry, promotion of viral shedding from the ulcer, and an increase in viral load in blood and semen.[25] Increased susceptibility to HIV infection is supported by the finding of recruitment of CD4 cells and macrophages in ulcers.[1] The resolution of treated chancroid lesions is prolonged in coinfected patients, and thus both HIV and *H. ducreyi* may be shed for longer periods even after antibiotic treatment for chancroid.[12] There is concern all over the world that the synergy existing between chancroid and HIV will accelerate the HIV epidemic. In southern and eastern Africa, where the levels of HIV are much higher than in West Africa, high levels of genital ulceration were noted.[24] In West and North Africa (mostly in Muslim countries) circumcision is common practice and this seems to be protective for male to female transmission of bacterially caused genital ulcers (syphilis and chancroid).[24]

PREVENTION

Annihilation of chancroid would be greatly helped by the development of an effective vaccine, but none has so far been developed.[6] Yet eradication of chancroid should be feasible, for one because the treatment of chancroid is cheap and effective.[21] *H. ducreyi* has a short duration of infectivity and can effectively be destroyed using soap and water. To survive in a population, *H. ducreyi* needs sexual networks with frequent contacts and high rates of partner exchange. Institution of preventive measures such as controlled prostitution and education to improve condom use together with regular health checks of sex workers and presumptive antibiotic treatment should all contribute to reduction of chancroid.[21] A concern regarding presumptive treatment is the possible development of antibiotic resistance and the false sense of security among those treated that could impede preventive behavior. This stresses the need for education. Targeting of uncircumcised men who are at higher risk of acquiring and transmitting chancroid may also be very effective.[24]

CONCLUSION

Diagnosis of *H. ducreyi* is performed preferably by PCR, which has the highest sensitivity and specificity. HIV and *H. ducreyi* act synergistically, explaining why there is heightened interest in the biology, immunology, and epidemiology of chancroid. *H. ducreyi* virulence factors are the subject of many studies, also with the aim to develop effective vaccines against chancroid. In addition, without vaccination chancroid may be eradicated by promoting condom use and providing education and accessible treatment facilities to those that are most at risk for recurrent *H. ducreyi* infection.

ACKNOWLEDGMENTS

Handheld Nucleic Acid Analyzer

James A. Higgins
United States Department of Agriculture–Agricultural Research Service, Beltsville, Maryland, U.S.A.

INTRODUCTION

Since the advent of the polymerase chain reaction (PCR) in the late 1980s, investigators have sought to expand the potential of this technology to that of on-site, ''bedside'' diagnostics, in which clinical parameters can be determined in real time, without the need for transport of samples to a remote testing facility. Discoveries of clandestine bioweapons programs in Iraq and the former Soviet Union in the early 1990s led the U.S. Department of Defense to sponsor development of nucleic acid-based instruments suitable for detecting a variety of pathogens at both front-line and rear-echelon locations. As we enter the mid-2000s, both of these research initiatives have begun to yield commercial handheld instruments, capable of performing PCR and RT-PCR in real time; future devices promise to offer direct detection of target nucleic acids without the need for amplification. Other instrument packages look to provide the end-user with both sample preparation/nucleic acid extraction and detection in one portable instrument. This entry reviews existing handheld nucleic acid detection instrumentation, discusses their advantages and disadvantages, and previews newer devices and platforms expected to continue to make this area of medical diagnostics particularly innovative and exciting.

THREAT AGENT DETECTION: IMPETUS FOR HANDHELD NUCLEIC ACID ANALYZER DEVELOPMENT

Successful performance of PCR obviously depends on the ability of the thermal cycling platform to maintain accurate gradations of temperature in the manifold or block containing the reaction tubes. The heating and cooling apparatus necessary to provide these temperature changes places constraints on the size and weight of the thermal cycler. ''First-generation'' thermal cyclers, such as the Perkin Elmer 480 model instrument, while reasonably light in weight and small in footprint, were not designed with field use in mind. However, during operations in the Persian Gulf in 1990–1991, field laboratories for detection of threat agents were deployed and operated by both the U.S. Army and the U.S. Navy. Polymerase chain reaction on conventional thermal cyclers, with agarose gel electrophoresis used to confirm amplification products, was used on a regular basis by these laboratories with a high degree of success, despite the trying conditions associated with performing molecular assays in a desert environment. By the mid-1990s the U.S. Army adopted PCR-based assays as a critical component of the field-deployable 520th Theatre Area Medical Laboratory (TAML), which was designed to provide rapid threat agent detection in battlefield conditions.

Just as Western defense and public health personnel were coming to grips with the disclosure of the size and scope of the Iraqi bioweapons program, it was revealed that the Soviet Union had a clandestinely operated sizeable, well-funded program of its own. Among the pathogens selected for weaponization were smallpox, plague, tularemia, and anthrax. The likelihood that U.S. and NATO troops may encounter such agents heightened the importance of on-site diagnostic techniques and, consequently, research in this area was prioritized by the Department of Defense, primarily under the auspices of the Defense Advanced Research Projects Agency (DARPA).

Research on portable nucleic acid-based detection devices was considerably aided by the discovery in 1991 that the 5′–3′ exonuclease activity of *Taq* polymerase, the enzyme mediating PCR, could be harnessed to provide real-time monitoring of the reaction via the hybridization of a fluorogenic oligonucleotide probe.[1] In 1995 researchers at Genentech, Inc., and Applied Biosystems reported the first use of a commercial probe expressly designed for real-time PCR, the ''TaqMan®'' probe.[2] With this assay system, fluorescence generated by the probe could be detected by the appropriate instrumentation and the user provided with a graphical depiction of the accumulation of the PCR amplicons over the length of the reaction. The TaqMan assay was notable for being conducted in the same reaction tube from start to finish; there was no need for postreaction manipulations. Probe design and synthesis was relatively straightforward and a TaqMan-based protocol for the detection of the foodborne bacterium *Listeria monocytogenes* was published in 1995.[3] These results gave impetus to the design and evaluation of TaqMan probes against a variety of bacterial and viral threat agents, such as orthopoxviruses.[4]

The implementation of fluorogenic probes freed the user from the need to conduct electrophoresis to determine whether or not a PCR assay was successful, and had obvious implications for reducing dependence on a laboratory infrastructure. However, the need for power sources and optics capable of monitoring the fluorescence produced by a real-time PCR assay was a major impediment to the design of portable thermal cyclers. For example, the first commercial platform dedicated to real-time PCR, the Perkin Elmer/Applied Biosystems 7700 model Prism® instrument, appeared in 1996–1997, but was too heavy (140 kg) for field use. U.S. Department of Defense-sponsored research sought to address this issue, and in 1997 researchers at the Lawrence Livermore National Laboratory (Livermore, CA) succeeded in fabricating a battery-powered, suitcase-sized real-time thermal cycler capable of using TaqMan probes: the MATCI, or Miniature Analytical Thermal Cycler Instrument.[5] Central to the operation of the device was its use of silicon ''thermalcycler'' units to mediate the heating and cooling of the associated 25-μl volume plastic reaction tube; this allowed for a one cycle per minute cycling speed. The MATCI provided sufficient temperature fidelity to allow for differentiation between sequences, with a high degree of homogeneity (such as poxvirus hemagglutinin gene), on the basis of a single nucleotide substitution.[6]

The MATCI could only accommodate one reaction tube at a time; the next iteration of the technology, the Advanced Nucleic Acid Analyzer (ANAA), which appeared in 1998, could perform 10 reactions simultaneously, and detection of as few as 500 cells of *Erwinia* was accomplished after only 7 min of thermal cycling.[7] The ANAA was a suitcase-sized instrument and researchers at the Lawrence Livermore National Laboratory were interested in advancing the miniaturization of the system to a handheld format; this led to the fabrication of the Handheld Advanced Nucleic Acid Analyzer (HANAA), arguably the world's first handheld, real-time thermal cycler instrument. The HANAA could perform four reactions simultaneously, with the use of two light emitting diodes (at 490 and 525 nm, with a combined emission of over 1 mW of power) allowing for monitoring of two dyes (e.g., FAM in one channel and JOE in the other).[8] The HANAA weighed less than 1 kg, and several sequential reactions could be performed, powered off a 12 V/3.5 A battery pack.[9] Reactions of up to 25 μl in volume were conducted in customized plastic tubes, and an improved silicon/platinum thermalcycler unit ($22 \times 6.6 \times 2$ mm) permitted ''traditional'' cycling parameters (e.g., 95°C for 0 sec, 55°C for 10 sec, and 72°C for 15 sec for 40 cycles) to be conducted in less than 20 min; strongly positive samples could generate positive results by 13 min of assay time.[10]

Prototype HANAAs were distributed to a variety of testers and feedback was favorable enough to result in licensing of the technology to Smiths Detection, Edgewood, MD; the result was production of the BioSeeq™ handheld real-time thermal cycler, available for purchase in 2003 (Figs. 1 and 2). The BioSeeq can accommodate up to six independently programmable reactions, each with a volume of 25 μL. In their evaluation of the BioSeeq during an 8-month beta testing phase, Emanuel et al.[11]

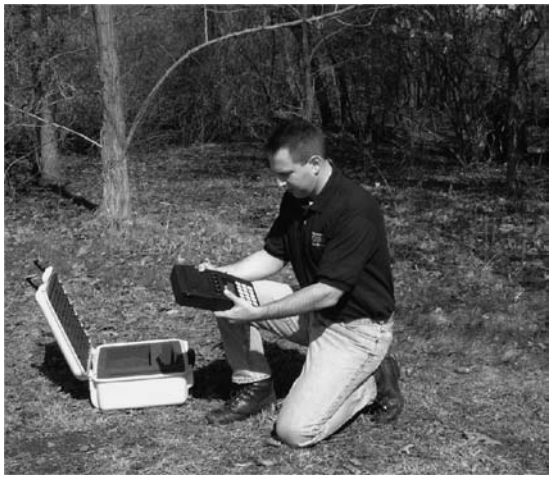

Fig. 2 Demonstration of the use of the BioSeeq™ instrument in the field. (Photo courtesy of P. Emanuel, U.S. Army, Edgewood, MD.) (*View this art in color at www.dekker.com.*)

used TaqMan probes directed against the *Francisella tularensis tul4* and *fopA* genes. Detection limits for the BioSeeq were 200 and 300 fg, respectively; these are approximately 100 and 150 genome equivalents of *F. tularensis*. In comparison, the detection limit of the assay when performed on the ABI 7900 real-time thermal cycler instrument was 50 fg, approximately 25 genome equivalents. Assay specificity, determined by testing a panel of 27 bacterial species and strains, including other possible threat agents, was the same for both targets on both instruments. When DNA extracted from tissues of mice infected with the *F. tularensis* LVS strain via aerosol exposure was assayed on the ABI 7900 and the BioSeeq, results were comparable, indicating that the handheld instrument was successful in analyzing the DNA in reaction volumes half the size of those of the ABI 7900 (which uses a volume of 50 μl). Custom reagents for a variety of threat agents are expected to be available for the BioSeeq in the Winter of 2003/2004, and the device is projected to sell for $25,000.

OTHER DOD-SPONSORED THREAT AGENT DETECTION PLATFORMS

In 2004, another real-time, handheld nucleic acid-based detection platform will become available for use by U.S. government agencies: the Razor, manufactured by Idaho Technology, Inc. (Salt Lake City, UT; Fig. 3). The Razor builds on the experience of Idaho Technology's suitcase thermal cycler, the Ruggedized Advanced Pathogen Identification System (RAPID), which was designed in collaboration with personnel from the U.S. Air Force. The RAPID is essentially a ''combat'' version of the LightCycler® (which is licensed by Roche, Inc., for sale to non-U.S.-government laboratories) and has been used extensively for the detection of threat agents in the United States, Europe, and the Middle East. The RAPID is capable of using prepackaged, freeze-dried real-time PCR and RT-PCR reagents, and this convenience has been carried over to the Razor, in which reactions are performed in plastic pouches containing the freeze-dried reagents of interest. The end-user simply uses a conventional syringe to inject sterile water into the pouch, reconstitutes the reagents, injects template, and proceeds with the assay; up to 12 reactions can be done in one pouch. The Razor, which weighs 8 lb (3.6 kg) and can analyze the entire 12-sample pouch in approximately 22 min, is designed for field use off a battery power source. The instrument's software is preloaded with thermal cycling protocols for detection of a variety of threat agents, and results are presented to the user either via plus/minus scoring on the integral LCD display (Fig. 3), or via a more comprehensive graphical display on an attached laptop computer.

Fig. 3 The Idaho Technology, Inc., Razor instrument is an 8-lb. (3.6 kg) handheld real-time thermal cycler that performs the reactions in specially formatted plastic pouches (foreground) that contain freeze-dried reagents for up to 12 samples. The reagents are reconstituted via injection of sterile water through syringe ports on either end of the pouch. Inset: results of an assay are displayed to the user as plus/minus scoring on an LCD display panel. (Photo: James Higgins; inset: Matt Scullion, Idaho Technology, Inc., Salt Lake City, UT.) HANDHELD NUCLEIC ACID ANALYZERS FOR CLINICAL USE

Simultaneously with DoD-sponsored research, a number of private companies have pursued the development and fabrication of handheld nucleic acid analyzers with an eye toward capturing what is expected to be a very lucrative and burgeoning market in ''point-of-care'' (POC) diagnostics.

Convincing physicians and clinical laboratory directors that POC nucleic acid analyzers, much less molecular methods per se, are worth embracing has traditionally been difficult.[12] Sample processing, particularly of matrices with a high concentration of PCR inhibitors (such as blood), continues to be a major hurdle. Also, firms hoping to market POC diagnostics must convince physicians and laboratory directors that the sometimes higher costs of their assays can be justified by improved sensitivity and specificity over existing methods. Nonetheless, according to *Small Times* magazine author Marlene Bourne, currently 21 companies are working on molecular diagnostic devices involving analysis of nucleic acids; at least 12 appear to be interested in the POC market (''Bantamweights vs. giants: Is a lab-on-a-chip brawl a mismatch?,'' *Small Times*, October 31, 2003).

While an exhaustive recounting of these projects is beyond the scope of this entry, some of the more interesting platforms are worthy of mention.

Clinical Microsensors (CMS), a division of Motorola, was founded in 1995 to exploit technology, developed by researchers at the California Institute of Technology, for ''bioelectronic'' detection of nucleic acid hybridization events. In late 1998 CMS had produced a prototype handheld instrument, powered by a 9-V battery, that could accommodate a ''DNA chip'' fabricated to contain 14 gold electrodes with DNA probes attached to their surface. The device promised a degree of sensitivity sufficient to detect DNA in wastewater, sludge, and blood, all very challenging sample matrices.[13] In 2000 CMS unveiled a desktop instrument, the 4800 eSensor™, which is now in commercial release; this can assay from 1 to 48 eSensor chips at one time. According to a December 2003 conversation with Motorola scientist Tim Tiemann, development of a handheld analyzer that would provide onboard sample processing and nucleic acid purification, as well as incorporating eSensor-based detection technology, is actively ongoing.

Fig. 4 Image of a prototype of Nanosphere's Verigene Mobile device, which will allow the user to perform sample processing and nucleic acid detection via hybridization assay in one handheld instrument suitable for the clinical diagnostic market. Inset: the company currently markets the portable Verigene ID system, which provides detection of nucleic acids via a proprietary, nanoparticle-mediated hybridization chemistry. (Photo courtesy of Jamie Abrams, Nanosphere, Northbrook, IL.) (*View this art in color at www.dekker.com.*)

One company has begun production (in June 2003) of a handheld nucleic acid analyzer suitable for use in a clinical diagnostic setting; this is the Verigene™ ID instrument (Fig. 4) which exploits the nanoparticle detection method developed in the laboratory of Chad Mirkin at Northwestern University, Illinois.[14] The initial Verigene ID assay is for detection of SNPs associated with coagulation disorders; future assays are planned for infectious agents and other clinical parameters.

Other firms developing POC diagnostic platforms based on array-mediated detection of nucleic acids include Nanogen, Affymetrix, and Caliper Technologies; all of which have experience in the fabrication of large, benchtop instruments. In addition to clinical tests, it is anticipated that handheld devices will also be useful for other situations in which molecular detection is particularly helpful, such as in monitoring crops and agricultural products for the presence of genetically modified organisms (GMOs); testing of environmental samples for the presence of viral, bacterial, fungal, and protozoal pathogens; and analysis of food for the presence of both pathogenic and spoilage-associated microorganisms.

For the devices mentioned above, the chemistry mediating detection of the nucleic acids of interest may or may not involve PCR and nucleic acid hybridization; for example, NuGen Technologies, Inc., (San Carlos, CA) is relying on a proprietary method called exponential single primer isothermal amplification which may allow for detection of very low quantities of target nucleic acids and can be adapted for use in microarray or microfluidic formats. Another interesting amplification chemistry is the loop-mediated isothermal amplification (LAMP), in which *Bst* DNA polymerase is used to mediate autocycling strand displacement DNA synthesis.[15]

COMBINING SAMPLE PREPARATION AND ANALYSIS IN ONE PLATFORM

The ideal handheld nucleic acid-based analysis device would incorporate both sample processing and real-time analysis and detection in one instrument. The technical challenges are formidable but some progress in fabricating such a device is underway. Nanosphere's proposed Verigene Mobile instrument (Fig. 4) promises to combine microfluidic purification of the sample and subsequent nucleic acid detection via hybridization with probe-bound nanoparticles, all in one handheld device. The Verigene Mobile will be a dedicated POC instrument suitable for use by personnel who do not have intensive training in molecular biology-based assays; the sample will be deposited into a cartridge which is in turn inserted into

the device for automated processing, with results presented to the user in real time.

CONCLUSION

By Winter of 2004 at least three handheld nucleic acid analyzers—the Smiths Detection BioSeeq, the Idaho Technology, Inc. Razor, and the Nanosphere Verigene—will be available for use. The first two instruments will rely on PCR-mediated amplification of the DNA or RNA template, whereas the Verigene relies on its proprietary nanoparticle-mediated hybridization format to detect target nucleic acids. Other devices that promise the same degree of portability may become available in 2004 and offer the end-user the ability to extract DNA or RNA from a variety of sample matrices and volumes. With continuous advances in highly active fields of research such as microfluidic systems, micro-total analysis systems (μTAS), nanotechnology-based ''lab on a chip'' devices, and microelectromechanical systems (MEMS), the future looks very exciting for the advent of novel handheld molecular biology-based devices suitable for use in the field and at the point of care.

Haploid Analysis (Monosomal Hybrid Technique)

H

Robert E. Pyatt
Emory University, Atlanta, Georgia, U.S.A.

INTRODUCTION

With the excitement and knowledge gained from the completion of the Human Genome Project, our understanding of underlying genetic determinants in monogenic and complex diseases promises to exponentially increase over the coming years. These developments should also prove to be a boon for the field of molecular diagnostics and improve our ability to diagnose and treat genetic diseases. A number of technologies, which are routinely applied toward mutation detection in the clinical laboratory setting including single-strand conformation polymorphism, denaturing gradient gel electrophoresis, denaturing high-performance liquid chromatography, and direct sequence analysis, exist today. The sensitivity of mutation detection in all of these methods is hampered by the presence of the wild-type allele, which can obscure the mutant, making it difficult to differentiate between the two. Monosomal cell hybrids can be created through the disruption of cell membranes between two cells in contact, which leads to the fusion of the membranes and the formation of a hybrid cell. When hybrids are formed between human and rodent cells, the resulting progeny will retain a random assortment of human chromosomes, which can be specifically selected for. By utilizing hybrids that are monosomal for any specific human chromosome in diagnostic testing, the sensitivity of these existing techniques can be improved by allowing each chromosome to be analyzed independently.

MONOSOMAL HYBRID TECHNIQUE

Figure 1 depicts the basic technique used for monosomal hybrid generation.[1–3] Donor cells, or human cells in which the separation of chromosomes to a haploid state is sought, are either low-density peripheral blood cells or a transformed lymphoblastoid cell line. Rodent cell lines—typically mouse[3–9] or hamster[2,10–12] cell lines—that have been engineered to allow for the selection of human–rodent fusion progeny are commonly used as recipient cells. Both cell types are initially incubated together in a low volume to promote membrane-to-membrane contact between donor and recipient cells. After a short time, an agent is introduced, such as polyethylene glycol (PEG)[1,2,6,7,10–12] or electricity,[3–5,8,9] which disrupts cell membrane integrity and promotes fusion. Cells are then washed and allowed to recover from this traumatic treatment for 1–2 days in normal culture media before selective conditions are applied.

Only a small percentage of cells will stably combine into donor–recipient progeny after fusion treatment and the remainder of unfused cells must be eliminated to prevent culture overgrowth. Although many different rodent cell lines are available as recipients, most base their methods of selection on similar biochemical principles. Nucleotides can be synthesized either from basic building blocks by the de novo pathway, or by recycling of preformed bases through the salvage pathway. In the salvage pathway, the enzyme hypoxanthine–guanine phosphoribosyl transferase (HPRT) catalyzes the addition of hypoxanthine or guanine to 5-phosphoribosyl-α-pyrophosphate, forming inosine or guanosine monophosphate, respectively. In recipient cell lines mutated for this enzyme, the salvage pathway is blocked and renders them dependent on the de novo one for growth.[2–12] Alternatively, pyrimidine salvage can also be blocked by mutating the thymidine kinase (*TK*) gene, which blocks the phosphorylation of thymidine, leading to the formation of thymidine monophosphate.[1]

After fusion, cultures are shifted to a medium containing hypoxanthine, aminopterin, and thymidine (HAT). Aminopterin is a competitive inhibitor of dihydrofolate reductase, which blocks the synthesis of tetrahydrofolate and, consequently, the de novo synthesis of purines. With both synthesis pathways blocked, unfused recipient cells are eliminated, whereas fusion daughter cells can use hypoxanthine and aminopterin in the salvage pathway if they have successfully retained the pertinent genetic material from the human donor cells. Because the gene for HPRT is located on the X chromosome and the *TK* gene is located on chromosome 17, these methods select directly for progeny containing one or more of these chromosomes, and indirectly for all other human chromosomes retained along with them. Hybrids containing chromosome 2 can be directly selected for using recipient hamster cells in which pyrimidine de novo synthesis is blocked and growth without uridine is impaired.[2] Although other strategies for selection exist, such as temperature-specific defects in protein synthesis,[2] selection systems based

DOI: 10.1081/E-EDGP 120023689

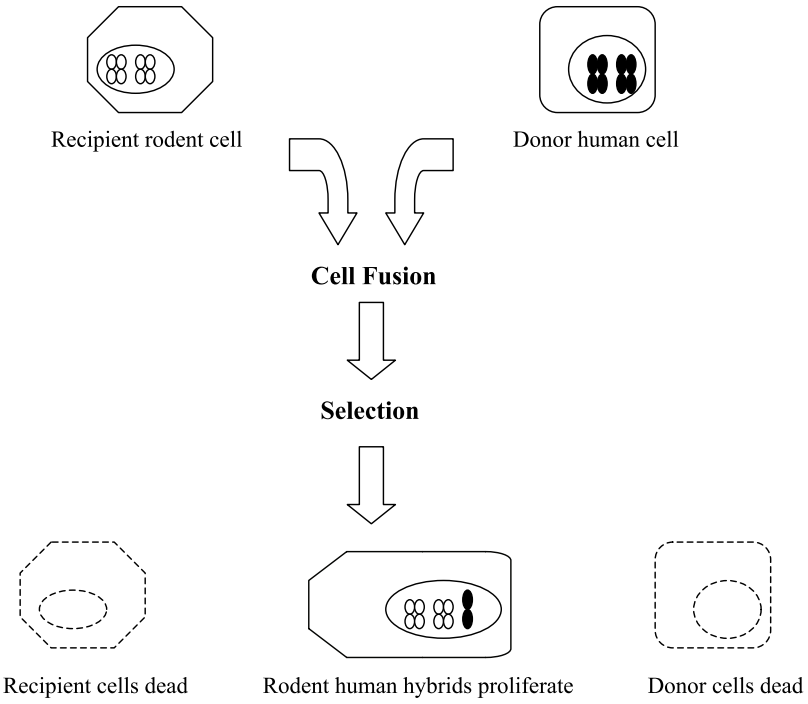

Fig. 1 Procedure for the creation of monosomal human–rodent hybrids.

on pathways of nucleotide synthesis are, by far, the most common.

Unfused human donor cells must also be removed from hybrid cultures. Chemicals such as oubain, a disruptor of sodium–potassium pumps,[1] or geneticin, an aminoglycoside related to gentamicin, can be used because human cells are sensitive to their actions.[3] However, the most common strategy exploits the adherent growth characteristics of recipient cells. Lymphoblasts and lymphoblastoid cell lines grow in suspension, but fusion progeny will retain the adherent quality of their recipient parents. Unfused donor cells can then simply be removed from cultures by repeated washes.[7,10–12]

After the specific selection criterion is applied, fusion progeny then proliferate to form colonies that are isolated and characterized for their specific human chromosomal complement. During the process of cell culture following fusion, hybrids will eliminate human chromosomes not directly required in the selection process. Over time, human chromosome retention becomes more stable and hybrids can be passaged without further losses.[2] This then has the effect of creating a series of hybrids containing the chromosome directly selected for along with a random assortment of other human chromosomes. Panels of highly polymorphic microsatellites or cytogenetic probes can be then employed to determine the number and allele of each chromosome within a particular hybrid clone. Figure 2 shows such a strategy employed for the analysis of a series of hybrids derived from the fusion of a lymphoblastoid cell line from an individual with trisomy 21 and Ade-C Chinese hamster ovary cells.[10–12] The recipient cells are deficient for the glycinamide ribonucleotide formyl transferase, an enzyme located on human chromosome 21 that blocks purine de novo synthesis. Hybrids containing human chromosome 21 can then be directly selected for by culture in purine-free media.[10–12] Multiple microsatellites are often analyzed to identify markers that are heterozygous and can, therefore, be used to distinguish each individual chromosome in a hybrid series. The original trisomic donor for the series of hybrids shown in Fig. 2 possessed three alleles of 166, 170, and 172 at the dinucleotide microsatellite D21S215 and, consequently, this marker was informative for chromosome 21 content in each hybrid. Although the direct selection methods eliminate nonfused recipient cells and any fusion progeny not containing at least one copy of the selected chromosome, hybrids can still retain more than one copy of that chromosome. In this series, fusion resulted in one hybrid clone retaining one copy of donor chromosome 21 (Fig. 2, row D), one hybrid with two copies of chromosome 21 (Fig. 2, row C), and a third hybrid retaining the complete trisomic set from the donor (Fig. 2, row B). Because the utility of fusion hybrids lies

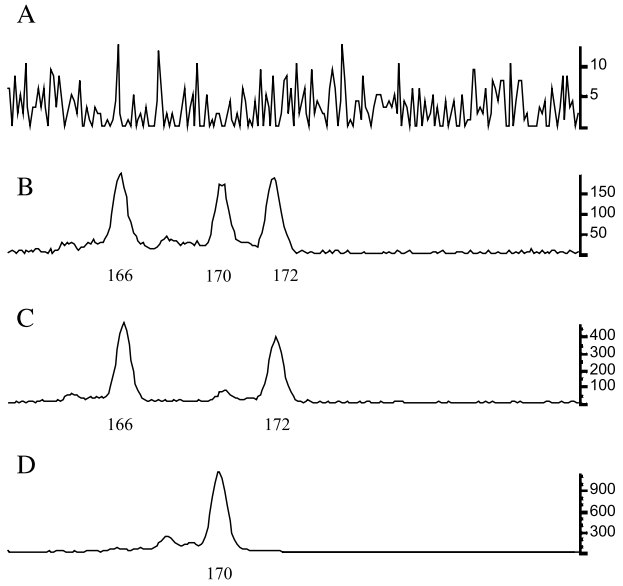

Fig. 2 Genotype analysis of hybrids at the microsatellite D21S215. DNA from a series of human–hamster hybrids (rows B–D) and the hamster recipient cell line (row A) were amplified at this dinucleotide marker using fluorescent-labeled primers to identify the human chromosome 21 content in each hybrid.

in their retention of a single copy of one human chromosome, the characterization of all hybrids must be conducted in an exhaustive manner to accurately define appropriate monosomal substrates for further genetic analysis. This is in addition to the random assortment of other human chromosomes retained along with the selected chromosome, which should also be defined.

UTILITY OF HYBRIDS IN DIAGNOSTIC TESTING

Hybrids are of greatest utility in diagnostic testing when traditional mutation detection methodologies have been ineffective or have proven inconclusive. Recently, the Molecular Pathology Laboratory at Ohio State University described the use of monosomal hybrids in the identification of large genomic alterations in individuals with hereditary nonpolyposis colorectal cancer (HNPCC).[8] Hereditary nonpolyposis colorectal cancer is an autosomal dominant cancer syndrome characterized by an increased risk for colorectal tumors and cancers at a distinct set of other anatomic sites including the stomach and endometrium.[13] The pedigree examined included two first-degree relatives—a deceased proband and her mother—with multiple instances of cancer, including colorectal cancer and many of the extracolonic tumors associated with the HNPCC cancer spectrum. The colorectal tumor from the proband exhibited microsatellite instability, which suggested an underlying defect in mismatch repair; however, direct genomic sequencing of the mismatch repair genes *MSH2*, *MLH1*, and *MSH6* failed to identify a pathologic mutation. Altered Southern blot hybridization patterns for the *MSH2* gene were observed for multiple restriction enzyme digestions of genomic DNA from both individuals compared with normal controls. This suggested the presence of a large genomic deletion in the 5′ portion of that gene, but attempts to define the deletion

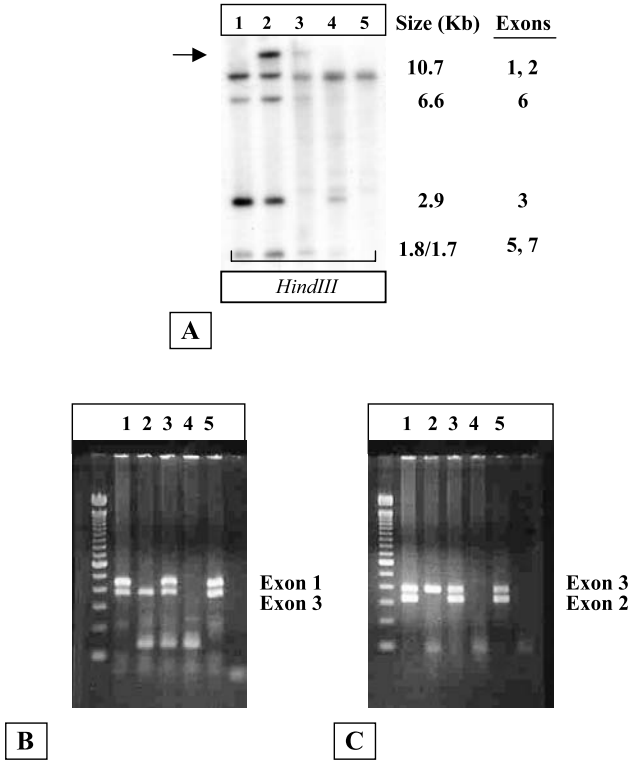

Fig. 3 Southern blot analysis and multiplex PCR reactions of mouse–human chromosome 2 monosomal cell hybrids. *Hin*dIII digests of a normal control (A; lane 1), proband (A; lane 2), two monosomal cell hybrids with one allele each of MSH2 (A; lanes 3 and 4), and the mouse fusion recipient cell line (A; lane 5) were hybridized with the same *MSH2* cDNA probe. The size of each fragment is presented in kilobases (kb) along with the corresponding exons, and the arrow illustrates a new fragment seen in digests of affected family members. Multiplex PCR reactions using primers to either exons 1 and 3 (B) or exons 2 and 3 (C) were then conducted with normal controls (B and C; lanes 1 and 5); the monosomal cell hybrid with the unique *Hin*dIII hybridization pattern (B and C; lane 2); the monosomal cell hybrid with the wild-type pattern (B and C; lane 3); and the mouse fusion recipient cell line (B and C; lane 4). (From Ref. [8]. Blackwell Publishing.)

breakpoints by long-range polymerase chain reaction (PCR) using genomic DNA proved inconclusive.

Hybrids monosomal for chromosome 2 were then created using lymphocytes from the mother of the proband to directly examine each allele of *MSH2*. Southern blots were repeated, and although one allele of *MSH2* from the donor demonstrated the wild-type hybridization pattern (Fig. 3A, lane 4) also seen in normal controls (Fig. 3A, lane 1), the second *MSH2* allele (Fig. 3A, lane 3) presented the same new fragment of approximately 11 kb as seen in the genomic DNA from the proband (Fig. 3A, lane 2). *MSH2* exon-specific PCR reactions for exons 1 and 3 (Fig. 3B) and exons 2 and 3 (Fig. 3C) showed that the allele with the altered hybridization pattern failed to amplify at exons 1 and 2 (Fig. 3B and C, lane 2), whereas the allele with the wild-type pattern amplified at both exons (Fig. 3B and C, lane 3). With the further identification of the deletion breakpoints, carrier testing could then be conducted on siblings of the proband to determine their relative risk for tumor development.

The literature contains a number of other case reports where monosomal cell hybrids were utilized as successful templates for traditional mutation detection techniques. Hybrids have also been used to identify deletions and splice site alterations in mismatch repair genes by use of PCR, reverse transcription (RT) PCR, and direct sequencing in two series of HNPCC patients in which conventional mutation detection techniques had failed using genomic DNA.[3,4] Similar methodologies were also used to confirm homozygosity for a single nucleotide substitution in the *CSA* gene in a patient with autosomal recessive Cockayne syndrome.[6] Hybrids have been used in cytogenetic cases to identify the translocation breakpoints in a patient with multiple myeloma using chromosome painting[7] and the parent of origin for a Robertsonian translocation involving chromosome 21 in an individual with Down syndrome by fluorescence in situ hybridization.[10] Finally, monosomal hybrids were used to demonstrate the presence of two SMN1 copies on one chromosome in a carrier of autosomal recessive proximal spinal muscular atrophy (SMA).[9] Molecular diagnosis of SMA carriers is typically performed through a quantitative PCR assay for SMN1 copy number,[14] and an individual with two SMN1 copies on one chromosome and none on the second chromosome would appear normal by the dosage assay but would be a carrier in reality.[9]

CONCLUSION

Although hybrids have demonstrated great potential in enhancing the sensitivity of existing mutation detection strategies, their conventional use in diagnostic laboratories has failed to fully materialize. This is due primarily to the time required for the fusion protocol to yield sufficient genetic material for use in molecular or cytogenetic assays and the high cost of the procedure. The HNPCC case described above required almost a year for the generation of sufficient DNA from hybrids for Southern blotting and PCR, which included two independent blood draws from the donor after the first fusion attempt failed. Cell culture is itself an expensive practice, and both the need to culture a large number of fusion clones to ensure the capture of each chromosome of interest and the duration of culture needed to amplify a hybrid from a single cell greatly increase the cost of this technique. The development of specific selection techniques would allow the direct capture of every human chromosome and reduce the total number of hybrids that are collected and analyzed, but this technique will always be somewhat hindered by biological limitations of cell culture.

Because the genetic material from hybrids is destined for molecular or cytogenetic analyses, there is always some concern that cross-reactivity of human PCR primers or cytogenetic probes with recipient DNA could complicate the interpretation of diagnostic results. The human *MSH2* probe hybridized to the blot in Fig. 3 demonstrates specific hybridization to a fragment of 10.7 kb from the mouse recipient cells, which corresponds to the fragment containing exons 1 and 2 in humans. Because the *MSH2* allele in lane 3 presents with a new restriction fragment due to the deletion of exons 1 and 2, the 10.7-kb fragment corresponding to those sequences should be missing, clearly confirming their deletion. However, because the human probe cross-hybridizes with the murine genomic DNA in this area, confirmation of the deletion had to be conducted using highly specific PCR primers, as shown in Fig. 3B and C.

Matsui et al.[15] have evaluated the cross-hybridization of human spectral karyotyping probes to mouse chromosomes, and although no specific hybridization was observed, they noted a weak, generalized background of staining over the mouse material. Consequently, further evaluation of cross-reactivity between cytogenetic and molecular probes and both mouse and hamster genetic materials is suggested. The use of recipient-only controls in all diagnostic assays is a must. Additionally, the possibility of interspecies chromosomal rearrangements in hybrids and the subsequent effects on results from diagnostic assays must also be considered in each case.[1]

ACKNOWLEDGMENTS

I would like to thank the Molecular Pathology Laboratory at Ohio State University for their assistance in the HNPCC

study and Dr. Jeff Mahr for his critical evaluation of this manuscript.

HBV Quantification

Annemarie Berger
J.W. Goethe University, Frankfurt, Germany

INTRODUCTION

For hepatitis B virus (HBV), which is not cultivable in vitro, serological assays permit an accurate diagnosis and follow-up of acute or chronic infection.

Qualitative serological assays for the detection of HBV antigens (HBsAg and HBeAg) and antibodies (anti-HBs, total and IgM anti-HBc, and anti-HBe) are also widely available and standardized.[1]

While active HBV infection is defined by the presence of hepatitis B virus surface antigen (HBsAg) in plasma, the secretory version of HBV core protein, HBeAg, serves as a marker for viral replication and can easily be detected by enzyme immunoassay (EIA). However, the absence of HBeAg in serum or plasma does not exclude viral replication.[2,3] Reasons may be the relatively low sensitivity of current HBeAg tests or mutations in the precore region of the HBV core gene.[4] Nevertheless, there is a strong correlation between the detection of HBeAg and the HBV DNA level.[3]

OVERVIEW

Attempts have been made to use the quantitative determination of HBeAg for the monitoring of antiviral therapy. In patients who respond to interferon-α therapy, a decline in the HBeAg concentration of more than 90% is observed by week 12 of therapy, whereas nonresponders do not demonstrate such important declines in HBeAg levels.[5] However, the clearance of HBV DNA from serum may precede the disappearance of HBeAg by several months.[6]

Hepatitis B virus DNA quantification is used for monitoring of antiviral therapy, for determination of infectiosity, and, in combination with serological markers, for the resolution of unusual profiles, i.e., isolated anti-HBc reactivity, as well as for cases in which the presence of HBV mutants is suspected.

Methods for the detection of viral genome (nucleic acid testing, NAT) have considerably extended the diagnostic repertoire of virological laboratories (VL) in recent years, proving superior to conventional techniques in many circumstances. In addition to qualitative analysis, quantitative NAT—initially used mainly for research purposes—has now firmly established itself in routine diagnostic virology.[7–9]

TEST METHODS

Molecular biology-based assays are invaluable tools for the management of chronic viral hepatitis. Assays employing target—namely, polymerase chain reaction (PCR) and nucleic acid sequence-based amplification (NASBA, TMA)—or signal amplification techniques—branched chain signal amplification (bDNA) and the hybrid capture system (HCS)—are now commercially available for the quantification of viral burden in infected patients (Table 1). Different assays have different sensitivities and ranges of linearity. More recently, ''real-time'' PCR techniques have been developed. The principle is to detect amplicon synthesis and to deduce the amount of viral genomes in the starting clinical samples during, rather than at, the end of the PCR reaction. These methods are theoretically more sensitive than classical target amplification techniques and are not prone to carryover contamination. Their dynamic range of quantification is consistently wider, making them particularly useful for quantifying the full range of viral loads observed in untreated and treated patients.

Whatever the technique used, software is used to calculate the threshold cycle (CT in ABI Prism, Cp in LightCycler) in each reaction with which there is a linear relationship with the initial amount of DNA. In each run, parallel processing of a panel of quantified standards is used to establish a standard curve for quantification (for further review, see Ref. [10]).

MANAGEMENT OF HBV-INFECTED PATIENTS

No molecular biology-based assays are necessary for the diagnosis of acute hepatitis B, which is based on serological testing. Chronic hepatitis B is defined by HBsAg persistence in serum for more than 6 months. In this setting, HBV DNA detection–quantification is necessary to determine whether or not HBV is replicating.

DOI: 10.1081/E-EDGP 120027607

Table 1 Commercially available HBV DNA quantification assays

Assay	Test principle	Quantification	Dynamic range
HBV Hybrid Capture II (Digene, Gaithersburg, MD)	Hybridization with RNA probes, detection after signal amplification with multiple conjugated antibodies	Comparison of the chemiluminescence emission with a standard curve generated simultaneously	1.4×10^5–1.7×10^9 copies/mL Ultrasensitive version: 4.7–5.7 $\times 10^7$ copies/mL
Versant HBV DNA (Bayer, Ludwigshafen, Germany)	Hybridization with capture and extender probes and preamplifier probes. Detection after signal amplification with branched DNA (bDNA) probes and conjugated probes	Comparison of the chemiluminescence emission with a standard curve generated simultaneously	Version 2.0: 7×10^5–5.7×10^9 copies/mL Version 3.0: 1.5×10^3–1×10^8 copies/mL 350–1.7 10^7 IU/mL
Cobas Amplicor HBV Monitor (Roche, Basel, Switzerland)	PCR-based target amplification, coamplification with an IS, WT, and IS-specific hybridization of the amplified products. Quantification is based on calculation of the OD values of IS and WT	Calculation of the copy amount in comparison of the OD values of WT and IS	300–200,000 copies/mL 52–3.4 $\times 10^4$ IU/mL
Cobas Taqman HBV (Roche)	Real-time PCR-based target amplification. Coamplification with an IS. Simultaneous detection of the fluorescence signals with specific labeled probes during the amplification	Comparison of the WT signal to the IS signal	Sensitivity: 6 IU/mL Range: 30–1.1 $\times 10^8$ IU/mL 35–6.4 $\times 10^8$ copies/mL
RealArt HBV TM PCR (Artus, Hamburg, Germany)	Real-time PCR-based target amplification. Coamplification with an internal control (=amplification control). Simultaneous detection of the fluorescence signals with specific labeled probes during the amplification	Comparison of the WT signal with a standard curve generated simultaneously	0.4–4 $\times 10^8$ IU/mL

IS = internal standard; WT = wild-type.

In the presence of HBeAg, the diagnosis of replicating chronic hepatitis B can be made whatever the viral load. Chronic hepatitis due to precore HBV mutants presents as hepatitis B e antigen (HBeAg)-negative chronic hepatitis B with generally lower replication levels than HBeAg-positive patients. HBeAg-negative chronic hepatitis B (CHB) represents a late phase in the natural course of chronic HBV infection that develops after HBeAg loss and seroconversion to anti-HBe. It is usually associated with mutations in the precore region of the HBV C gene inducing a stop codon that inhibits the production of HBeAg.[11] The diagnosis of HBeAg-negative CHB is based on HBsAg positivity, HBeAg negativity, and mainly on increased aminotransferases (ALT) and serum HBV DNA levels. Although the cut-off level of serum HBV DNA has not been definitely determined.[12] It has been suggested that an HBV DNA load of less than 10^5 copies/mL is associated with an ''inactive carrier state.''[13]

The inactive HBsAg carrier state is characterized by detectable HBsAg and anti-HBe in serum, undetectable HBeAg, low or undetectable levels of HBV DNA, normal ALT, and minimal or no necroinflammation; although inactive cirrhosis may be present if transition to an inactive carrier state occurred after many years of chronic hepatitis.[14,15]

Persistence of significant levels of viremia that are not detected by many hybridization assays of low sensitivity may be observed after anti-HBe seroconversion. The precise monitoring of viremia levels using more sensitive assays and the search for HBV mutant strains are warranted in patients undergoing antiviral therapy.

The correlation between HBV DNA serum levels and severity of liver disease is rather low. Therefore histological examination of liver biopsy material is still the best way of assessing the severity of chronic hepatitis B and establishing the prognosis. Nevertheless, active HBV replication is associated with a significant risk of

disease progression. This risk is low in the absence of detectable HBV DNA.[13]

The major issue is the value of serum HBV DNA quantification to assess the antiviral response to therapy and in monitoring disease progression. Serial quantitations of HBV DNA levels during antiviral therapy—although more cumbersome than HBeAg testing—permit the early identification of nonresponders, thus avoiding ineffective and expensive therapy.[6,16]

ESTIMATION OF INFECTIVITY

Another important reason for HBV viral load determination is the assessment of the infectivity of hepatitis B carriers. Without intervention, more than 90% of HBeAg-positive female chronic HBV carriers transmit the virus to their infants;[17] of these, 85–90% develop chronic HBV infection—in most cases asymptomatic—themselves, thus perpetuating the infection in high-endemicity settings. Immediate postpartum immunization of the infant can efficiently prevent transmission. It has to be considered that the level of viremia present in maternal serum can only be approximated with the HBeAg assay. Recent quantitative evaluation of sera for HBV DNA using molecular hybridization technology has shown that wide fluctuations in the concentration of virus exist in HBeAg-positive carriers. Vertical transmission is rarely documented with maternal HBV DNA levels below 10^7 geq/mL (5 pg/mL).[18,19] In a recent study, no cases of transplacental transmission of HBV were observed with maternal HBV DNA levels of 6.0×10^5 geq/mL or lower. In mothers with HBV DNA levels of $10^6/10^7$ and 10^8 geq/mL, 2% and 22% of the children, respectively, had HBsAg detected in the blood within 24 hr of birth (=transplacental transmission).[20]

HBeAg-positive physicians will not be allowed to exercise exposure-prone procedures. This is inadequate, as HBeAg-negative mutants of HBV may reach high titres. Hepatitis B virus transmission from four HBeAg negative surgeons to patients has been documented.[21] A more reliable estimate of the infectivity can be obtained by testing serum concentrations of HBV DNA.[22]

The European consensus panel[23] now proposes a maximum HBV DNA level of 10^4 geq/mL, but does not supply scientific data that provide support for proposing this level.[24]

CONCLUSION

The quantification of viral genome has, within a few years, become an integral part of the clinical management of patients suffering from infection with HBV. The modern molecular biological techniques have evolved from being elusive and research tools into widely used and, meanwhile, rather reliable virological routine diagnostic tools.

Besides providing prognostic information on individual cases, genome quantification plays a most important role during monitoring of the patient's response to antiviral treatment.

Further, hitherto less well-established uses of VL testing include the assessment of an individual's infectivity, be it in the health-care setting (transmission risk of blood-borne viruses) or in infected pregnant women.

Practical problems still waiting to be resolved are virus strain-related differences in quantitative results and a relatively low degree of intra- and interassay as well as interlaboratory reproducibility. The establishment of internationally accepted standards against which all working reagents could be calibrated, using a common standard unit of measurement, IU, would overcome this major problem.[25] Further work is required to fully standardize assays and quantification units, improve automation, and better define clinically relevant thresholds.

HCV Genotyping

Alexander C. Haushofer
General Hospital of St. Pöelten, St. Pöelten, Lower Austria, Austria

Harald H. Kessler
Medical University Graz, Graz, Austria

INTRODUCTION

Hepatitis C virus (HCV) is a small, enveloped Flavivirus with a positive strand ribonucleic acid (RNA) genome of approximately 9400 bases in length. The genome comprises one large open reading frame flanked by untranslated regions (UTRs), a highly conserved one at the 5′ end, and another one which shows high heterogeneity at the 3′ terminus. Substantial nucleotide sequence variations between various HCV isolates were found throughout the entire HCV genome. The genetic variation of HCV is thought to reflect sequence errors because of a nonproofreading RNA-dependent RNA polymerase. Many different but closely related HCV variants are thus generated within one HCV-infected individual called quasispecies.

OVERVIEW

Hepatitis C virus genotypes may differ by as much as 33% of their nucleotide sequence distributed over the entire viral genome. Different HCV isolates are distinguished based on their genetic similarity in genotypes, which further separate into subtypes. All HCV isolates fall into phylogenetically related clusters called subtypes. Subtypes can be classified into several major types (sequence similarities of 65–75%).[1] Eleven genotypes as well as more than 90 subtypes have been identified.[2,3] Despite a high degree of sequence conservation in the 5′UTRs, genotype-specific differences exist in this region. Based on sequence variations in the 5′UTR and the NS5 region, Simmonds et al.[4,5] proposed a classification of HCV types and subtypes confirmed by phylogenetic tree analysis, which is currently most often used. Therapeutical management of chronic HCV infection has been based on the HCV genotype as recommended in Consensus Statements published by the European Association of the Study of the Liver and the National Institutes of Health.[6,7]

Nucleotide sequencing of the entire HCV genome followed by composition of a phylogenetic tree has been considered as ''gold standard.''[8] This approach, however, is cumbersome and regarded as impractical for routine clinical laboratory settings.[9] The 5′UTR region has been shown to be more convenient for genotyping in routine diagnostic laboratories.[3] Moreover, this region is usually chosen as target sequence for detection of HCV RNA, thus allowing direct analysis of amplification products in a genotyping assay. The less conserved NS5B region, which contains a subtype-specific motif and which is standard for epidemiological applications, may also be chosen.[2] For serological (ELISA-based) typing methods, type-specific antigenic properties of several epitopes encoded by the NS4 and core regions are used.[10] The core and NS3 may offer additional possibilities for HCV genotyping; however, their high variability renders the respective methods less sensitive, especially if only one probe/subtype is used.[11]

METHODS FOR GENOTYPING

Hepatitis C virus genotypes can be determined in routine laboratory settings by direct methods based on molecular typing and by an indirect method based on serological typing[12–14] (Table 1).

Direct Methods

Sequencing

The TruGene™ HCV 5′NC Genotyping Kit. The TruGene™ HCV 5′NC Genotyping Kit (Bayer Healthcare Diagnostics, Berkeley, CA) is based on a semiautomated terminator cycle sequencing technique of PCR products from the 5′UTR region conveniently retrieved from the Cobas Amplicor™ HCV Test (Roche Molecular Systems, Pleasanton, CA) or the Cobas Amplicor™ HCV Monitor Test (Roche). For the sequencing procedure, the CLIP™ sequencing technique (Bayer), allowing both directions of the amplification product to be sequenced simultaneously within the same tube, is employed. Electrophoresis and data analysis are carried out with the automated

DOI: 10.1081/E-EDGP 120026360

Table 1 Methods for HCV genotyping

Test name	Manufacturer	Method	Gen. region	Routine lab
TruGene™ HCV 5′NC genotyping kit	Bayer	DM; terminator cycle sequencing	5′UTR	Yes
Celera HCV genotyping assay	Celera; distributed by Abbott	DM; real-time PCR	5′UTR	Yes
Inno-LiPA HCV II (Versant)	Innogenetics; distributed by Bayer	DM; reverse-hybridization	5′UTR	Yes
RFLP analysis	Home-brew	DM; restriction fragment length polymorphism	5′UTR	No
Gen-Eti-K DEIA	Sorin Biomedica	DM; PCR and DNA enzyme immunoassay (EIA)	Core	Yes
HTA/HMA-Heteroduplex tracking/mobility assay	Home-brew	DM; electrophoresis of hybridization products of RT-PCR products with ST-specific probes	Core/E1	No
SIA-3 or SIA-6	Murex Diagnostics	IM; serotyping	NS4	Yes
RIBA HCV SIA	Chiron Corporation	IM; serotyping	NS4 and core	Yes

Gen. region = genomic region of the HCV used for genotyping; Routine lab = suitable for routine diagnostic laboratory settings; 5′NC = 5′ noncoding region; DM = direct method based on molecular typing; 5′UTR = 5′ untranslated region; E1 = envelope 1; IM = indirect method; NS4 = nonstructural 4 region.

OpenGene™ DNA sequencing system (Bayer) that is combined with the automated Long-Read Tower™ for the separation of the sequenced fragments. Data are acquired with the GeneLibrarian™ module of the GeneObjects™ (Bayer) software.

Multiplex real-time polymerase chain reaction-based genotyping

The Celera HCV Genotyping assay (Celera Diagnostics, South San Francisco, CA; distributed by Abbott Laboratories, North Chicago, IL) is based on a multiplex real-time PCR technique. This assay is performed on the ABI Prism 7000, a real-time cycler (Applied Biosystems, Foster City, CA), and the analysis software used is SDS v1.01. Per sample, three reactions using three different fluorescent dyes for simultaneous detection are necessary: reaction 1 detects genotypes 1a and 1b; reaction 2 detects genotypes 2a, 2b, and 3; reaction 3 detects genotypes 4, 5, and 6.

Genotype-/subtype-specific hybridization

The Inno-LiPA HCV II (Versant; Innogenetics, Ghent, Belgium; distributed by Bayer) assay is based on the reverse-hybridization principle of RT-PCR products derived from the 5′UTR.[3] Biotinylated RT-PCR products (RT-PCR products from Cobas Amplicor™ HCV Test; Roche) are hybridized to a selection of 19 specific oligonucleotide probes immobilized on nitrocellulose membrane strips. The RT-PCR products hybridize to a probe matching the sequence of the isolate and allowing discrimination at the subtype level. HCV genotypes/subtypes are identified by comparing the pattern of positive (colored) lines with a special interpretation chart.

Restriction fragment length polymorphism

Sequences amplified by PCR from the 5′UTR are cleaved by restriction endonucleases for identification of different HCV genotypes/subtypes. Initially, enzymes *Hae*III–*Rsa*I and *Hin*fI–*Mva*I are employed for cutting the PCR fragments from the 5′UTR which is followed by cleavage using *Bst*U1 or *Scr*FI. HCV genotypes/subtypes 1a, 1b, 2a, 2b, 3a, 3b, 4, 5, and 6 can be identified.[15]

DNA enzyme immunoassay

The DNA enzyme immunoassay (DEIA) (Gen-Eti-K DEIA; Sorin Biomedica, Saluggia, Italy) is based on a combination of nested PCR (core region) and DNA enzyme immunoassay.[16] Amplification products are hybridized to type-specific oligonucleotides. The hybrids are detected by a standard ELISA technique which employs monoclonal antibodies reacting with double-stranded DNA.

Heteroduplex tracking assay

The heteroduplex tracking assay (HTA), also called heteroduplex mobility analysis (HMA), is based on the fact that the genetic relationship between isolates can be determined by the relative migration of the heteroduplex on gels.[17] This assay involves hybridization with probes from known HCV subtypes to RT-PCR products generated

from homologous sera or from unknown samples and agarose gel electrophoresis of hybridization products.[18,19] The formation of a heteroduplex band on a gel indicates genotype and subtype.

RT-PCR with genotype-specific primers

Okamoto et al.[20] described a polymerase chain reaction (PCR)-based assay using primers for the hepatitis C core gene. This assay is just able to identify subtypes 1a, 1b, 2a, and 2b. The primary PCR with consensus primers is followed by a second-round PCR with type-specific primers. HCV subtypes are determined by the size of the amplification products generated. The original assay has been modified by Widell et al.[21] by adding another second-round PCR for identification of genotype 3.

Indirect Method

Serotyping assay

The HCV serotyping assay (SIA-3 or SIA-6 Murex HCV Serotyping assay, Murex Diagnostics Ltd, Dartford, U.K.) is based on the detection of genotype-specific antibodies directed to epitopes encoded by the NS4 region of the HCV genome. Eight (SIA-3) or 24 (SIA-6) NS4-encoded genotype-specific branched peptides are used in a competitive way to discriminate between genotypes 1–3 and 1–6, respectively.[10] With the RIBA HCV SIA (Chiron Corporation, Emeryville, CA), eight serotype-specific HCV peptide antigens, five of which are from the NS4 region of HCV subtypes 1a, 1b, 2a, 2b, and 3, and three of which are from the core region of types 1 and 2, are immobilized. Genotyping is achieved by an algorithm.[22]

Comparison of hepatitis C virus genotyping methods

The Inno-LiPA HCV II (Innogenetics), probably the most frequently used assay, has been well characterized in earlier studies.[23,24] In comparative studies, the Inno-LiPA HCV II assay (Innogenetics) and the TruGene™ HCV 5′NC Genotyping Kit (Bayer) show concordant results on the genotype level in 100% and 99.5%, respectively.[25–28] The overall accuracy for the discrimination of subtypes, however, was found to be lower for both, the Inno-LiPA HCV II assay (Innogenetics) and the TruGene™ HCV 5′NC Genotyping Kit (Bayer) with 95.5% and 85.9%, respectively, when using the TruGene™ HCV 5′NC Genotyping Kit (Bayer) or the Inno-LiPA HCV II assay (Innogenetics) as reference test for the alternative assay.[27] As recently reported, the TruGene™ HCV 5′NC Genotyping Kit (Bayer) and the Inno-LiPA HCV II assay (Innogenetics) gave concordant results on the subtype level in 90.9% of samples.[29] Accuracies for the discrimination of subtypes were 76% and 91.9% for the TruGene™ HCV 5′NC Genotyping Kit (Bayer) and 74% and 85.8% for the Inno-LiPA HCV II assay (Innogenetics), respectively, in comparison to sequence analysis of the NS5B region.[25,26] Sandres-Sauné et al.[30] showed a concordance of 94%, regarding subtypes 1a or 1b, when comparing the TruGene™ HCV 5′NC Genotyping Kit (Bayer) and a noncommercial assay using the NS5B region. The insufficient sequence polymorphism of the 5′UTR has been suggested as the major problem preventing correct discrimination of HCV subtypes. For the discrimination of subtypes 1a and 1b, it was shown that the polymorphism at position 99 of the 5′UTR may not always be linked to subtype 1a or 1b sequences detected in the core region.[23] This was also demonstrated in two comparative studies which focused on the performance of the Inno-LiPA HCV II assay (Innogenetics) versus that of NS5B sequencing with a concordance of 80% and 94%, respectively.[30,31] This limitation is common to all HCV genotyping procedures based on the analysis of the 5′UTR.[25]

Mixed HCV infections with different HCV genotypes/subtypes may occur in patients with intravenous drug abuse, hemophilia, and those on hemodialysis. The Inno-LiPA HCV II assay (Innogenetics) shows a high sensitivity for detection of minor sequence variants[11] and may be useful for detection of mixed infections involving different HCV genotypes.[8,32] This assay was consistently able to detect as little as 1–2% of the viral population (minor genotype) compared with restriction fragment length polymorphism (RFLP) (which may detect 5–30%) in a recent study.[33]

The TruGene™ HCV 5′NC Genotyping Kit (Bayer) or sequencing of the NS5b region is only possible if the serum HCV level exceeds 600 IU/mL.[30] To ensure accurate results, especially for low HCV levels, optimal blood collection systems containing a liquid nucleic acid stabilizer capable of stabilization nucleic acids within the blood samples even at room temperature for at least 96 hr are recommended.[34] After centrifugation, aliquots should immediately be frozen at −70°C.

In a comparative study, the TruGene™ HCV 5′NC Genotyping Kit (Bayer) and the DEIA (Sorin Biomedica) showed concordant results on subtype level in 91%.[9] However, serological methods, while easier to perform, lack sensitivity and specificity in comparison to molecular assays.[10,13,14]

Restriction fragment length polymorphism analysis based on the 5′UTR may be more sensitive than HCV serotyping but less sensitive when compared with the Inno-LiPA HCV II assay (Innogenetics).[33,35]

CONCLUSION

Today, tests for HCV genotyping usually employ the 5′UTR. All of them have been more or less found to be reliable for genotyping in the routine laboratory setting. Incomplete or incorrect subtyping may be avoided by using less conserved parts of the HCV genome, such as the core or the NS5B region. Those inherent problems of the 5′UTR are, however, not crucial for clinical purposes because therapeutic implications are only based on genotype analysis.

INTRODUCTION

HCV is a small, enveloped human flavivirus with a positive-strand ribonucleic acid (RNA) genome of approximately 9400 bases in length. The genome comprises one large open reading frame flanked by untranslated regions (UTRs), a highly conserved one at the 5′ end, and another one which shows high heterogeneity at the 3′ terminus; the secondary and tertiary structures are essentially preserved and have essentially regulatory functions.

Since the discovery of the hepatitis C virus (HCV), 70–80% of former posttransfusion or sporadic chronic non-A, non-B hepatitis cases have been determined as HCV-induced hepatitis. Acute HCV infection is often asymptomatic and approximately 70–80% of cases progress to chronic hepatitis. This may lead to cirrhosis in 20% of these patients, subsequent to hepatocellular carcinoma, which has an incidence of 1–4% per year. Factors associated with disease progression following HCV infection include viral genotype, alcohol consumption, and viral load.

OVERVIEW

High viral loads are associated with decreased rates of response to interferon therapy,[1] and a decrease in the HCV load during the early phase of treatment (2–12 weeks) has been shown to predict effective treatment responses.[2]

Molecular techniques can be labor intensive and time consuming with in-house methods.[3] In this review, currently used assays for HCV virus load testing based either on target amplification [the HCV (Cobas) Amplicor Monitor 2.0 test (Roche Diagnostic Systems, Branchburg, NJ); the HCV Superquant (National Genetics Institute (NGI), Culver City, CA); nucleic acid sequence-based amplification; the NASBA-QT test (Organon Teknika, Boxtel, The Netherlands); and real-time detection polymerase chain reaction (RTD-PCR) test applying 5′-nuclease PCR/TaqMan PCR (Perkin Elmer Corp./Applied Biosystems, Foster City, CA; Cobas TaqMan HCV Test, Roche Diagnostic Systems)], or on signal amplification [branched DNA (bDNA) assays; the VERSANT HCV RNA 3.0 assay (Bayer Diagnostics, Berkeley, CA)], or on immunological detection of free HCV core antigen [the trak-C test (Ortho-Clinical Diagnostics, Inc., Raritan, NJ)] are presented (Table 1).

General Considerations

Six key performance characteristics of quantitative analytical assays can have important effects on the result, use, and interpretation of these assays: linearity, accuracy, precision, tolerance limit, sensitivity, and specificity.[4]

QUANTITATIVE HCV ASSAYS

The Amplicor HCV Monitor 2.0 and Cobas Amplicor HCV Monitor 2.0 Test (Roche Diagnostic Systems)

Based on reverse transcription polymerase chain reaction (RT-PCR), the Amplicor HCV Monitor test (Roche Diagnostic Systems) was developed.[5] Recently, an improved version 2.0 was introduced, which achieved an equivalent quantitation of each genotype over the quantitative range (5×10^2 to 5×10^5 copies of RNA/mL).[6,7] HCV RNA is extracted from plasma by chaotropic salt and is then precipitated by isopropanol. Both RT and PCR of RNA are accomplished in one tube using the recombinant thermostable DNA polymerase (*r*Tth), which offers both reverse transcriptase activity, forming a cDNA from the RNA target sequence of the 5′ UTR, and polymerase activity for amplification of the cDNA under appropriate conditions. An internal quantification standard shows the same primer-binding sites as the target but with a changed internal sequence, which allows binding to special detection probes. This allows quantification after a series of dilutions at the end of the assay. To meet the needs of routine diagnostic laboratories, PCR amplification and detection of amplified

Table 1 Commercial quantitative HCV assays

Test name	Manufacturer	Method	Linear range
(Cobas) Amplicor HCV Monitor 2.0 test	Roche Diagnostic Systems	MM; RT-PCR; Cobas Amplicor—semiautomated PCR	5×10^2 to 5×10^5 IU/mL; 6×10^2 to 7×10^5 IU/mL (with CE certification)
Superquant assay	NGI[a]	MM; multicycle RT-PCR; Southern blot	4×10 to 2.0×10^6 IU/mL
NASBA-QT test	Organon Teknika	MM; nucleic acid sequence-based amplification	5.5×10^2 to 5.5×10^6 IU/mL
Cobas TaqMan HCV Monitor	Roche Diagnostic Systems	MM; real-time homogeneous PCR, 5′–3′endonuclease activity of *Z05* polymerase; Cobas TaqMan 48 or 96	3×10 to 2×10^8 IU/mL; DL: 1×10^1 IU/mL
Versant HCV RNA 3.0 test	Bayer Diagnostics	MM; bDNA	3.2×10^3 to 40×10^6 copies/mL[b]
trak-C Test	Ortho-Clinical Diagnostics	IM: HCV core AG ELISA	DL: 50×10^4 IU/mL

MM = molecular method; IM = immunological method; IU = WHO international HCV RNA standard; DL = detection limit.
[a]Test only available through the National Genetics Institute.
[b]A total of 5.2 HCV RNA copies/IU.

products (Amplicor HCV Monitor 2.0) have been semiautomated with the Cobas Amplicor (Roche Diagnostic Systems).[8,9] AmpErase® (uracil-*N*-glycosylase, or UNG) is used, which destroys dUTP-containing amplicons from previous amplifications and provides safety from contamination of amplicons of previously amplified samples. In contrast to signal amplification techniques, the amplified target is quantified.

The Superquant Assay (NGI)

The HCV Superquant assay (NGI), which is based on a multicycle RT-PCR method with an internal control, followed by Southern blot detection for the quantification of HCV RNA, shows a relatively large dynamic range from approximately 40×10^1 to 2.0×10^6 IU/mL. A cDNA is produced from extracted HCV RNA. This cDNA is then amplified in four separate PCRs with inclining cycles. The PCR products are visualized by Southern blotting, and subsequent quantification is accomplished by densitometry, comparing the product band intensity of the wild-type HCV to the internal control product band intensity.[10] The Superquant assay utilizes robotic instruments for agarose gel electrophoresis, vacuum transfer Southern blot hybridization, and immunostaining.[11]

The NASBA-QT Test (Organon Teknika)

Like RT-PCR, in the NASBA-QT test (Organon Teknika), the target nucleic acid is first amplified and then the amplification products are quantified in comparison with three different synthetic internal standard RNA calibrators.[12] This isothermal amplification technique uses RNA, not DNA. Instead of a precipitation of RNA by alcohol used in RT-PCR, the extraction is performed by adherence of RNA to silica particles. The amplification of target RNA involves the coordinated activities of three enzymes—reverse transcriptase, RNase H, and T7 RNA polymerase—in four steps: extension, degradation, DNA synthesis, and cyclic RNA amplification. RNA calibrators are added in three concentrations to control efficiency in extraction and enzymatic amplification. Quantification results from the ratio of signals of the specimen HCV RNA divided by the signal of the appropriate internal calibrator.

The RTD-PCR Test (5′-Nuclease PCR or TaqMan PCR)

Morris et al.[13] described the application of a fluorogenic probe-based (TaqMan probes) PCR assay (TaqMan; Applied Biosystems) for the detection of HCV RNA in serum and plasma. This assay allows the direct detection of specific PCR products by monitoring the increase in fluorescence of a dye-labeled oligonucleotide probe. TaqMan PCR uses the 5′–3′ endonuclease activity of *Taq* DNA polymerase to digest a probe labeled with a fluorescent reporter and quencher dye, and inclining PCR cycles result in exponential amplification of PCR products and fluorescence activity. Takeuchi et al.[14] described the

establishment of a real-time detection system for real-time quantitative HCV PCR—the ABI PRISM 7000 instrument (Applied Biosystems). This instrument combines thermal cycling, fluorescent detection, and application-specific software in a single instrument.

Now, the Cobas TaqMan HCV test, a real-time homogenous quantitative PCR using TaqMan technology, and the Cobas TaqMan 48 or 96 analyzer are introduced for routine diagnostic laboratory. In this quantitative assay, the recombinant *Thermus* specie Z05 polymerase is used, which offers reverse transcriptase, polymerase, and endonuclease activity. Roche Diagnostic Systems states a detection limit of 10 IU/mL and a high dynamic range between 30×10^1 and 2×10^8 IU/mL.

The bDNA Test

Chiron Corporation has developed a bDNA signal amplification for viral load detection of hepatitis C.[15] The pelleted virus is lysed with proteolytic agents and detergents to release RNA and then is added to wells of a microwell plate. RNA is captured by hybridization with a set of specific synthetic oligonucleotide capture probes immobilized to the plate. A set of target probes hybridizes to both the viral RNA and the preamplifier probes (the backbone of the branched complex). The capture probes and the target probes bind to the 5′ UTR and core region of the HCV genome. The amplifier probe subsequently hybridizes to the preamplifier, forming a bDNA complex. By a series of hybridizations, multiple bDNA amplifier molecules and alkaline phosphatase-labeled probes are then hybridized to this immobilized complex. Detection is achieved by a chemiluminescent substrate. The emitted signal directly correlates to the amount of HCV RNA present.

The HCV Core Antigen ELISA—trak-C Test

Recently, as alternative to molecular quantitative detection of HCV load, a quantitative immunoassay for the measurement of total hepatitis C nucleocapsid core antigen—the trak-C test (Ortho-Clinical Diagnostics, Inc.)—in the presence or absence of antibodies to HCV in human serum or plasma was introduced.[16]

Comparison of Assays

In comparison with the HCV Superquant assay, only available through NGI and not accessible to other laboratories, quantification with the Cobas Amplicor HVC Monitor 2.0 test (Roche Diagnostic Systems), suitable for routine laboratory settings, has been shown to be linear up to viral loads of 8.5×10^5 IU/mL by appropriate dilution.[17] Results of both tests correlated significantly. Moreover, Konnick et al.[18] demonstrated a good agreement between the Cobas Amplicor HVC Monitor 2.0 (Roche Diagnostic Systems) and the Superquant (NGI) assay results.

Through some technical improvements in probe design and background reduction, bDNA Version 3.0, the Versant HCV RNA 3.0 test (Bayer Diagnostics), now shows a broader range of 5.2×10^2 to 8.3×10^6 IU/mL for quantification of HCV RNA[19] compared with the previous range of bDNA 2.0 (Chiron Corporation) of 2×10^5 to 5×10^7 copies/mL.[15] Later, the reportable range was further improved (3.2×10^3 to 40×10^6 copies/mL; conversion factor: 5.2 HCV RNA copies/IU). Beld et al.[19] found a good correlation for viral load (expressed in international units per milliliter) obtained from the Amplicor HCV Monitor 2.0 test (Roche Diagnostic Systems) and the Versant HCV RNA 3.0 test (Bayer Diagnostics).

Zanetti et al.[20] demonstrated a good correlation of the trak-C test (Ortho) with the Cobas Amplicor HCV Monitor 2.0 test (Roche Diagnostic Systems) except for HCV RNA levels $<5 \times 10^4$ IU/mL, where the trak-C test was negative due to a lower sensitivity compared to the Cobas Amplicor HCV Monitor 2.0 test (Roche Diagnostic Systems). An additional new quantitative assay based on PCR (the LC × HCV Quantitative test; Abbott, Chicago, IL) is being evaluated.

Sample preparation is currently thought to be the major weakness in the molecular detection of HCV RNA. Conventional sample preparation protocols are usually time consuming, labor intensive, and sensitive to contamination producing false-positive results. Therefore, besides ready-to-use sample preparation kits, automated specimen preparation systems such as the Cobas Ampliprep (Roche Diagnostic Systems) designed for Cobas Amplicor PCR and, in the future, for Cobas TaqMan 48 and 96 analyzer were developed and brought to the market. It could be demonstrated that quantitative test results were comparable between a combination of the Cobas Ampliprep with the Cobas Amplicor HCV Monitor 2.0 test (Roche Diagnostic Systems) and the Cobas Amplicor HCV Monitor 2.0 test (Roche Diagnostic Systems) alone within ± 0.5 $\log_{10}$.[21] Standardization for any commercially available assay or method is essential for providing reliable information for appropriate patient management, especially if, following the recommendations of EASL Consensus Panel,[22] a clinically relevant threshold of 2×10^6 copies/mL is used as a guideline for determining the outcome of treatment with interferon plus ribavirin in patients infected with genotypes 1, 4, and 5, or defining the duration of treatment. The NIH Consensus Statement[23] defined early viral response (EVR) as a minimum of 2 $\log_{10}$ decrease in viral load during the first

12 weeks of treatment, which is predictive of sustained viral response (SVR) and should be a routine part of monitoring patients with genotype 1.

CONCLUSION

Several well-documented assays are nowadays available for quantitation of HCV load. Standardization for any commercially available assay and, in the future, automated sample preparation systems are essential for providing reliable information. For an independent comparison of different assays, the World Health Organization (WHO) First International HCV RNA Standard has been introduced to permit normalization of reported viral titers in international units.[24] Shiffman et al.[25] demonstrated for the Amplicor HCV Monitor 2.0, the Superquant assay, and the Versant HCV RNA 3.0 test (Bayer Diagnostics), using the international unit standard, that approximately 90% of results was within 1 $\log_{10}$ unit. Participation in proficiency programs, such as Quality Control of Molecular Diagnostics (QCMD), should be mandatory in routine laboratory settings.[26]

Helper-Dependent Adenoviral Vectors

Philip Ng
Baylor College of Medicine, Houston, Texas, U.S.A.

INTRODUCTION

The adenovirus (Ad) has been extensively exploited as a gene therapy vector because of its ability to efficiently transduce a wide variety of cell types from many different species independent of the cell cycle to direct high-level transgene expression. First-generation Ad vectors (FGAd) typically have the viral early region 1 (E1) replaced by the therapeutic transgene. First-generation Ad vectors are replication deficient and require E1 complementing cells for propagation. However, the majority of the Ad genome remains intact leading to low-level expression of viral genes in the transduced cells. This is directly cytotoxic and also leads to an adaptive cellular immune response against the transduced cells consequently resulting in transient transgene expression and long-term toxicity, thus rendering these vectors unsuitable for many gene therapy applications where long-term transgene expression is desired. In an attempt to further attenuate Ad, vectors have been engineered with deletions or mutations in the viral E2 and E4 genes in addition to deletion of E1. Despite the potential offered by these multiply deleted Ad vectors (also called second- or third-generation Ad vectors), the majority of the viral coding sequences still remain and therefore so does the potential for their expression. The advantages of multiply deleted Ad over FGAd remain controversial as some studies show them to be superior in terms of reduced toxicity and enhanced longevity of transgene expression whereas others do not. Significant improvement in the safety and efficacy of Ad-based vectors came with the development of helper-dependent adenoviral vectors (HDAds, also referred to as gutless, gutted, mini, fully deleted, high-capacity, Δ, pseudo) which are deleted of all viral coding sequences. Helper-dependent adenoviral vectors retain the advantages of FGAd including high efficiency in vivo transduction and high-level transgene expression. However, owing to the absence of viral gene expression in transduced cells, these HDAds are able to mediate high-level, long-term transgene expression in the absence of chronic toxicity. In addition, because the vector genomes exist episomally in transduced cells, the risks of germline transmission and insertional mutagenesis leading to oncogenic transformation are negligible. Moreover, the deletion of the viral sequences permits a tremendous cloning capacity of ~37 kb allowing for the delivery of whole genomic loci, multiple transgenes, and large *cis*-acting elements. A summary of the current state of HDAd is presented here and a more comprehensive discussion can be found elsewhere.[1] Discussions regarding Ad and early-generation Ad vectors can be found elsewhere in this volume.

PRODUCTION AND CHARACTERIZATION

Because HDAds are deleted of all viral coding sequences, a helper virus is required for their propagation. The first efficient and currently most widely used method for generating HDAd is the Cre/loxP system developed by Graham and coworkers in 1996[2] (Fig. 1). In this system the HDAd genome is first constructed in a bacterial plasmid. Minimally, the HDAd genome contains the expression cassette of interest and ~500 bp of *cis*-acting Ad sequences necessary for vector DNA replication (ITRs) and packaging (Ψ). Because efficient packaging into the Ad capsid requires a genome size between ~27.7 and ~38 kb, ''stuffer'' DNA is usually included in HDAd. To rescue the HDAd (to convert the ''plasmid form'' of the HDAd genome into the ''viral form''), the plasmid is first digested with the appropriate restriction enzyme to liberate the HDAd genome from the bacterial plasmid sequences. 293 cells expressing the site-specific recombinase Cre are then transfected with the linearized HDAd genome and subsequently infected with the helper virus. The helper virus bears a packaging signal flanked by loxP sites, the target sequence for Cre, and thus following infection of 293Cre cells, the packaging signal is excised from the helper viral genome by Cre-mediated site-specific recombination between the loxP sites. This renders the helper viral genome unpackagable but still able to undergo DNA replication and thus trans-complement the replication and encapsidation of the HDAd genome. The titer of the HDAd is increased by serial coinfection of 293Cre cells with the HDAd and the helper virus and the HDAd is finally purified by CsCl ultracentrifugation. Subsequent improvements of this original system permit efficient and simple large-scale HDAd production with yields of >10,000 vector particles per coinfected producer cell and with helper virus

DOI: 10.1081/E-EDGP 120029814

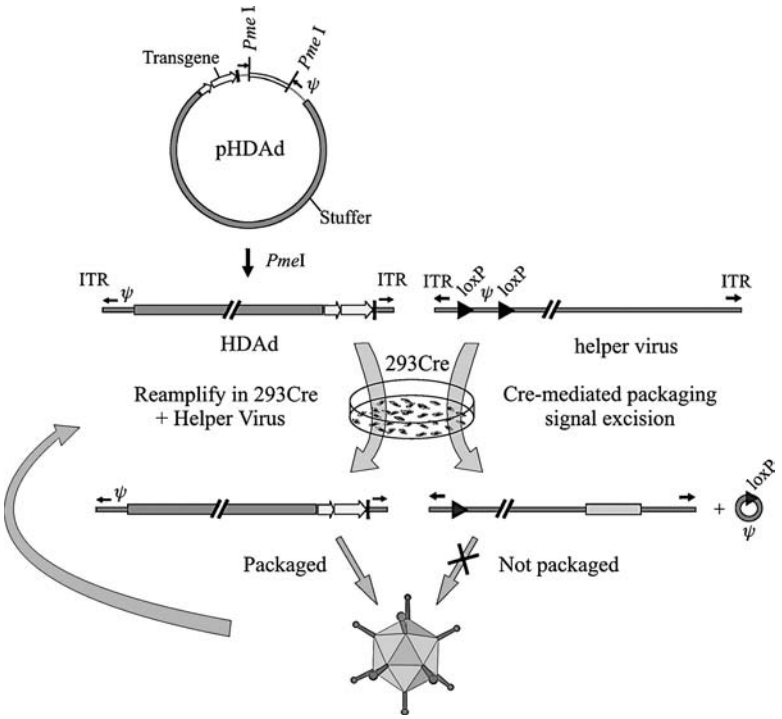

Fig. 1 The Cre/loxP system for generating HD vectors. The HDAd contains only ~500 bp of *cis*-acting Ad sequences required for DNA replication (ITRs) and packaging (ψ), the remainder of the genome consists of the desired transgene and non-Ad ''stuffer'' sequences. The HDAd genome is constructed as a bacterial plasmid (pHDAd) and is liberated by restriction enzyme digestion (e.g., *Pme*I). To rescue the HDAd, the liberated genome is transfected into 293Cre cells and infected with a helper virus bearing a packaging signal (ψ) flanked by loxP sites. Cre-mediated excision of ψ renders the helper virus genome unpackagable, but still able to replicate and provide all of the necessary *trans*-acting factors for propagation of the HDAd. The titer of the HD vector is increased by serial coinfections of 293Cre cells with the HDAd and the helper virus. (*View this art in color at www.dekker.com.*)

contamination levels of <0.02%.[3] Detailed methodologies for producing HDAd are described in detail elsewhere.[3,4]

IN VIVO APPLICATIONS

Liver Transduction

The liver is an attractive gene therapy target because the fenestrated endothelium permits exposure to intravenously delivered vector, hepatocytes are well suited for secretion of therapeutic proteins into the circulation for systemic delivery, and it is the affected organ in many genetic disorders. Helper-dependent adenoviral vectors are particularly attractive vectors for liver-directed gene therapy because of their ability to efficiency transduce hepatocytes following intravenous injection.

To evaluate the utility of liver-directed, HDAd-mediated gene therapy in a large animal model, three baboons were intravenously injected with 3.3 to 3.9×10^{11} vector particles per kilogram of a HDAd expressing human α_1-antitrypsin (hAAT).[5] Human α_1-antitrypsin antagonizes neutrophilic elastase and is abundantly expressed in hepatocytes and at a lower level in macrophages and α_1-antitrypsin-deficient patients have shortened life expectancies because of emphysema. Expression of hAAT persisted for more than 1 year in two of the three animals (Fig. 2). Maximum levels of serum hAAT of 3 to 4 μg/mL were reached 3 to 4 weeks postinjection in these two baboons and slowly declined to 8% and 19% of the highest levels after 24 and 16 months, respectively. The slow decline in hAAT expression was attributed to the fact that the baboons were young (7.5 and 9 months old) when injected, and that the decrease in hAAT concentrations was correlative to the growth of the animals. The third baboon had significantly lower levels of serum hAAT which rapidly declined to undetectable levels after 2 months. This baboon had generated anti-hAAT antibodies thus accounting for the low level and rapid loss of serum hAAT. No abnormalities in blood cell counts and chemistries were observed in these three baboons at any time, starting 3 days postinjection. In contrast, hAAT expression lasted only 3 to 5 months in all four baboons

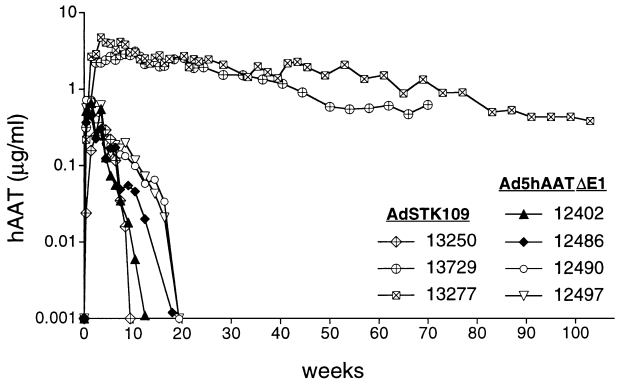

Fig. 2 Serum levels of hAAT in baboons following intravenous administration of the HDAd AdSTK109 or the FGAd AdhAATΔE1. Baboons 12402 and 12486 were injected with 6.2×10^{11} particles/kg of AdhAATΔE1. Baboons 12490 and 12497 were injected with 1.4×10^{12} particles/kg of AdhAATΔE1. Baboons 13250, 13729, and 13277 were injected with 3.3×10^{11}, 3.9×10^{11} and 3.6×10^{11} particles/kg, respectively, of AdSTK109.

injected with an FGAd expressing hAAT (Fig. 2). This was shown to be due to the generation of a cellular immune response against viral proteins expressed from the vector backbone of the FGAd resulting in the elimination of transduced hepatocytes. These experiments convincingly demonstrated that HDAds were superior to FGAd with respect to duration of transgene expression and hepatotoxicity in a nonhuman primate.

The potential of liver-directed, HDAd-mediated gene therapy was investigated for the phenotypic correction of hypercholesterolemia in the apolipoprotein E-deficient ($apoE^{-/-}$) mouse model.[6] Apolipoprotein E, a 34-kDa plasma glycoprotein, is a component of all plasma lipoproteins except low-density lipoprotein (LDL) and plays a major role in lipoprotein catabolism by acting as a ligand for the LDL-receptor (LDLR) and the LDLR-related protein for transport of excess cholesterol from the peripheral tissues to the liver for excretion. The $apoE^{-/-}$ mouse is an excellent model for cardiovascular disease because they develop severe hypercholesterolemia and atherosclerotic lesions similar to those found in humans. Chan and coworkers investigated correction of hypercholesterolemia in $apoE^{-/-}$ mice with either a FGAd or a HDAd expressing apoE.[6] Injection of $apoE^{-/-}$ mice with FGAd resulted in an immediate rise in plasma apoE levels and a concomitant drop in plasma cholesterol levels to within normal range. However, this effect was transient, as apoE levels rapidly declined to pretreatment levels by day 28 and plasma cholesterol levels increased after 28 days, returning to pretreatment levels by 112 days. In contrast, a single injection of HDAd resulted in immediate lowering of plasma cholesterol to subnormal or normal levels for the rest of the natural lifespan of the animal (2.5 years). Plasma apoE levels reached ~200% wild-type and remained at supraphysiological levels for >4 months, only to decline slowly to wild-type levels at 1 year and remained at 60–90% physiological concentrations for the lifetime of the animals (2.5 years). Analysis of total plasma cholesterol revealed normalization of the plasma lipoproteins back to a predominately HDL pattern seen in wild-type mice. Aortas in all mice, examined at 2.5 years after treatment with HDAd, were essentially free of atherosclerotic lesions in contrast to saline-injected mice whose aortas were completely covered with lesions. Significantly, this study demonstrated that a single injection of HDAd encoding apoE could confer lifetime protection against aortic atherosclerosis. Toxicity studies revealed that whereas injection of FGAd resulted in significant chronic hepatotoxicity, no such evidence of damage was observed following injection of HDAd. In summary, this study demonstrated the tremendous potential of HDAds for gene therapy; a single injection of HDAd resulted in lifelong expression of a therapeutic transgene and permanent phenotypic correction in a mouse model of a genetic disease without long-term toxicity.

Muscle Transduction

Duchenne muscular dystrophy (DMD) is a lethal, X-linked, degenerative muscle disease with a frequency of 1 in 3500 male births caused by mutations in the dystrophin gene. Dystrophin is an essential structural component of the skeletal muscle cell membrane, linking intracellular actin filaments with the dystrophin-associated proteins (DAPs) in the sarcolemma. Dystrophin deficiency results in instability of the muscle cell membrane causing muscle fiber degeneration. The length of the dystrophin cDNA (14 kb) precluded its inclusion into most gene therapy viral vectors but following the development of HDAds with large cloning capacity, gene transfer of the full-length dystrophin cDNA became feasible. Gilbert et al.[7] demonstrated that a single injection of a HDAd carrying two copies of the full-length human dystrophin cDNA resulted in transduction of 34% of the fibers of the total tibialis anterior (TA) muscle in neonatal *mdx* mice, a genetic and biochemical mouse model for DMD. The amount of dystrophin produced in these muscles was five times that in normal human muscle. However, only 7% transduction was achieved following injection into the TA muscle of adult *mdx* mice. In these transduced adult fibers, the amount of dystrophin produced was only 10% of the amount in normal humans. However, the high levels of transduction were transient and a humoral immune response was mounted against the foreign human dystrophin protein in the *mdx* mice. Importantly, such a response was not observed in immunodeficient SCID mice suggesting that sustained expression could be achieved in the absence of an immune response to the

transgene product. Indeed, injection of a HDAd expressing the full-length murine dystrophin cDNA into the tibialis anterior muscle of neonatal *mdx* mice resulted in sustained expression for at least 1 year in 52% of the muscle fibers. The treated muscle showed restored dystrophin–glycoprotein complex to the sarcolemma, significant improvement in isometric force production, resistance to high stress muscle contraction damage, and improved muscle histopathology.[8] This study demonstrates the tremendous potential of HDAd-mediated DMD gene therapy.

Brain Transduction

The brain is an attractive target for gene therapy to treat CNS structural and functional deficits such as aging-related memory loss, Parkinson's disease, Alzheimer's disease, or amyotrophic lateral sclerosis. Zou et al.[9] compared the efficiency, toxicity, and persistence of HDAd and FGAd vector-mediated gene transfer into the hippocampus or lateral ventricle of the brain in 20-month-old rats. Transgene expression peaked 6 days post-injection for both vectors. In the hippocampus, transgene expression from the FGAd decreased rapidly after day 6, being significantly lower than HDAd-injected hippocampus by day 16, and undetectable by day 183. In the ventricle, transgene expression from FGAd was significantly lower than HDAd by day 33 and undetectable by day 66. In contrast, transgene expression from the HDAd remained relatively stable with expression remaining >60% of peak levels on day 183. Overall, expression from HDAd was significantly higher than from FGAd at all time points after 6 days. First-generation Ad vectors induced substantial inflammatory and immune response which were significantly higher than those induced by HDAd at all time points after 3 hr. While both vectors induced a rapid increase in the proinflammatory cytokine that peaked at 3 hr postinjection, by 3 days, the level was significantly lower in the HDAd-treated brains than the FGAd-treated brains.

Lung Transduction

The lung is another attractive target for gene transfer primarily because of the desire to develop gene therapy for cystic fibrosis (CF). Cystic fibrosis is caused by recessive mutations in the CF transmembrane conductance regulatory (CFTR) gene which encodes a membrane chloride channel present in the epithelium of the lung and other organs. Morbidity and mortality in CF patients is due to lung disease characterized by inflammation, obstructive mucus, and persistent infection. Helper-dependent adenoviral vector efficiently transduces airway epithelial and submucosal cells in mice following intranasal administration, and in contrast to FGAd results in negligible inflammation, with transgene expression lasting for up to 15 weeks.[10] Moreover, intranasal administration of a HDAd bearing the CFTR gene resulted in expression of CFTR in the airway epithelial cells of CFTR-knockout mice and could protect the lung from bacterial challenge.[11] These studies suggest that HDAd-mediated CF gene therapy would benefit CF patients by reducing susceptibility to opportunistic pathogens.

ACUTE TOXICITY

In addition to long-term, chronic toxicity mediated by viral protein expression from the vector backbone, systemic administration of FGAd also results in acute toxicity. This acute toxicity occurs immediately following vector administration and is characterized by high-level inflammatory cytokine production, consistent with activation of an acute inflammatory response.[12–15] While the precise mechanism responsible for this acute response remains to be determined, it appears to be mediated by the viral capsid in a dose-dependent manner with potentially severe and lethal consequences. Indeed, the death of a partial OTC-deficient patient, whose clinical course was marked by systemic inflammatory response syndrome (SIRS), disseminated intravascular coagulation, and multiorgan failure, was attributed to acute toxicity from the administration of a second-generation (E1- and E4-deleted) Ad vector.[16] Because the viral capsid of early generation Ad and HDAd are identical, it has been hypothesized that HDAd would also provoke an identical acute response. Indeed, this was confirmed in nonhuman primates in which dose-dependent acute toxicity, consistent with activation of the innate inflammatory immune response, was observed following systemic administration of HDAd.[17] It is important to note that robust activation of the acute inflammatory response is also observed in mice given systemic Ad. However, unlike primates, lethal SIRS does not develop in rodents, even at high doses which are lethal to primates. This may reflect species-to-species differences in the quality of the innate immune response or sensitivities of the end organs to pathologic sequelae. This likely accounts for the plethora of studies reporting negligible toxicity in mice given high-dose HDAd and underscores the importance of safety and toxicity evaluations in larger animals for all gene therapy vectors.

CONCLUSION

Helper-dependent adenoviral vectors possess many characteristics that make them attractive vectors for gene therapy of a wide variety of genetic and acquired diseases. However, acute toxicity provoked by the viral capsid

currently hinders the clinical application of this otherwise promising technology. Clearly, studies to elucidate the mechanism(s) of Ad-mediated activation of the innate inflammatory response are needed. Perhaps with a clearer understanding of this phenomenon strategies can be developed to minimize, if not eliminate, this acute toxic response. If this can be accomplished, then HDAd should be able to provide sustained, high-level transgene expression with no further long-term toxicity.

Hemoglobinopathies, Structural

H

Lewis P. Rubin
Women & Infants Hospital and Brown Medical School, Providence, Rhode Island, U.S.A.

INTRODUCTION

The hemoglobinopathies resulting from mutations in the α- or β-globin gene clusters are the most common single-gene disorders in humans. An estimated 7% of the world population carries one or more globin gene mutations[1] and over 300,000 persons each year are born with a severe hemoglobinopathy. Although most of the more than 700 identified hemoglobin variants are clinically inconsequential, several different single nucleotide substitutions lead to critical amino acid substitutions that cause hemolytic anemia, i.e., sickle cell disease (SCD), unstable hemoglobins, or hemoglobin tetramers that have altered oxygen affinity.

These variant hemoglobins have featured prominently in the development of molecular medicine and genomic and proteomic diagnostics. Pauling's investigations on hemoglobin in sickle cell anemia were the first demonstration of a causal link between an inherited alteration in protein molecular structure and a disease. In 1985, SCD also was the first genetic disease involving a point mutation in a single-copy gene to which diagnostic Southern blotting was applied, i.e., hybridization of genomic DNA with allele-specific oligonucleotide probes.

Heterozygosity for clinically significant hemoglobin variants (e.g., HbS, HbC, and HbE), as is the case for thalassemias and glucose-6-phosphate dehydrogenase (G6PD) deficiency, confers advantage in malarial endemic regions. This hypothesis was first formulated by Haldane, and the complex interrelationships among genetics, ecology, and culture on the frequency of sickle cell disease (SCD) were later established by the anthropologist Livingstone.[2] Subsequent research on genetic drift and gene flow supports the proposition that an introduction of agriculture several thousand years ago promoted malarial endemicity and exerted evolutionary selection on hemoglobinopathies.[3] In historic malarial belt high-risk populations, different globin chain abnormalities (hemoglobin variants and thalassemias) often interact to produce marked hemolytic anemia or red blood cell (RBC) sickling. Structural hemoglobinopathies that cause anemia also complicate pregnancy by increasing risk of intrauterine growth restriction, preterm birth, low birth weight, and perinatal mortality.[4]

OVERVIEW

Tetrameric hemoglobin consists of two different globin chain pairs, each containing one heme molecule. Balanced expression of α-globin and non-α-globin chains is necessary for normal hemoglobin synthesis and RBC function. During development, three embryonic hemoglobins are produced: Hb Gower-1 (ζ_2/ε_2), Hb Gower-2 (α_2/ε_2), and Hb Portland (α_2/γ_2). By week 8, fetal hemoglobin (HbF, α_2/γ_2) comprises at least 50% of the hemoglobin present. A δ- to β-globin chain switch by 12–16 weeks after birth results in a shift to the predominant adult hemoglobin, HbA (α_2/β_2). This phenomenon of postnatal hemoglobin switching precludes clinical consequences of β-globin chain variants before or at the time of birth. Individuals with clinically significant hemoglobin variants, and those that produce disease when coinherited with α- or β-thalassemias, tend to become symptomatic only after the decline in HbF levels after the first months.

Diagnostic testing for hemoglobinopathies generally is performed for clinical evaluation and population (newborn) screening. In couples considering pregnancy, pregnant women, or conceptuses, laboratory evaluation for hemoglobinopathies can confirm a provisional diagnosis, e.g., SCD, determine the cause(s) of a hematological abnormality, e.g., anemia or microcytosis, permit genetic counseling for prospective parents, or make a fetal diagnosis.

LABORATORY METHODS (PROTEIN AND DNA ANALYSIS)

The initial step in investigation of a suspected hemoglobinopathy is to obtain a complete blood count (CBC). Inspection of the blood smear red cell morphology is particularly useful in detecting an unstable hemoglobin, SCD, or thalassemia. A reticulocyte count is indicated whenever there is hemolysis, which may occur with unstable hemoglobins or SCD.

Proteomic diagnosis using electrophoretic separations is the foundation for analysis of hemoglobin variants. Presumptive diagnosis of an abnormal hemoglobin

DOI: 10.1081/E-EDGP 120020591

frequently can be made based on characteristic electrophoretic mobility and clinical setting. Nevertheless, each electrophoretic technique has distinct pitfalls. For routine clinical laboratory diagnosis, the most widely used method is alkaline (pH 8.6) cellulose acetate electrophoresis. It is capable of separating HbA, HbF, HbS, HbC, and several less common hemoglobin variants. However, similarity of overall surface charge causes comigration of several other hemoglobins. Of practical importance, HbE, HbA_2, HbC, HbE, and HbO are not well separated and HbS cannot be distinguished from the less important HbD or HbG. Identification of these hemoglobins is assisted by acidic (pH 6.2) citrate agar electrophoresis.

Thin gel isoelectric focusing (IEF) yields better resolution and quantification of certain hemoglobins. In IEF, hemoglobins migrate in a pH gradient to a position of zero net charge (isoelectric point). Because IEF is relatively simple, fast, and adaptable for automation, it has become the most common method used in mass newborn screening programs.

Increasingly, electrophoretic methods are being replaced or supplemented by high-performance liquid chromatography (HPLC) and capillary zone electrophoresis. Cation-exchange HPLC combines advantages of mobile phase pH and ionic strength gradients for quantitative separation. It is a method of choice for quantification of HbA_2 and HbF and identification of certain variant hemoglobins.[5] Appropriate column selection permits separation of more than 45 hemoglobin variants and detection of as little as 0.1% of total hemoglobin in 0.5 μL of whole blood.[6] Capillary zone electrophoretic methods are also sensitive, rapid, and highly selective.[7] Combination with IEF permits identification and quantification of HbS, HbC, HbE, HbO-Arab, and HbD-Punjab.

Careful electrophoretic technique also permits visualization of the split HbA_2 band. This finding is helpful to distinguish α-chain variants, e.g., the clinically innocuous HbG-Philadelphia, from β-chain variants such as HbD-Punjab. HbA_2 can be quantified by cellulose acetate electrophoresis followed by elution and spectrometry, by microcolumn chromatography, or, most accurately, by HPLC.

Accurate diagnosis in complex or indeterminate phenotypes usually requires DNA analysis. Several point mutations for hemoglobin variants can be recognized by the change in susceptibility to cleavage by specific restriction endonucleases, e.g., HbO-Arab with *Eco*RI. The sickle cell (HbS) mutation eliminates sites for *Mnl*I, *Dde*I, and *Mst*II, allowing detection by restriction fragment length polymorphism (RFLP) analysis. Recently, PCR-based assays for detection of single nucleotide polymorphisms (SNPs) have offered a simple, low-cost genotyping method for diagnosing homozygous HbS and other SCD syndromes.[8] Mutation detection by gene chip (microarray) analysis has been developed for diagnosis of β-thalassemias. This high-throughput, sensitive methodology will likely be adapted for hemoglobinopathy diagnostics.

The discovery that fetal cell-free DNA can be isolated from maternal plasma[9] holds the promise in the near future for rapid, ultrasensitive, and noninvasive detection of many fetal hematological disorders. This method already has become a standard clinical laboratory technique for genotyping fetuses at risk for Rh isoimmunization and erythroblastosis fetalis (see Chapter ?).

Hardison et al.[10] have constructed a Web-accessible, updated relational database on the genomic sequence changes leading to hemoglobin variants and thalassemias called *HbVar* (http://globin.cse.psu.edu/globin/hbvar/). *HbVar* is searchable by mutation genomic location, sequence alterations, biochemical and hematological effects, pathology, population frequencies, and references.[11]

HEMOGLOBIN C

The HbC β-globin mutation (β^6 Glu → Lys) has similar consequences to those induced by the sickle cell disease (HbS) mutation (β^6 Glu → Val); that is, a (−)-charged glutamic acid is replaced by a (+)-charged residue. Homozygosity for HbC causes severe hemolytic disease. Blood smears of affected individuals show frequent target cells (because of increased RBC surface area to cell volume ratio) and polychromasia. Haplotyping studies indicate that HbC mutation had a unicentric origin in sub-Saharan Africa. Recent evidence also supports the Haldane hypothesis for a protective effect of HbC heterozygosity against severe malarial infection.[12]

The HbC band is identifiable by alkaline cellulose acetate gel electrophoresis and confirmed by acidic gel electrophoresis. Of note, HbC and HbA_2 coelute on diethylaminoethyl (DEAE) cellulose column chromatography, a common procedure for quantifying HbA_2. Homozygous HbC disease also can be differentiated from HbC/β-thalassemia by cation-exchange HPLC. HbC and HbS-Oman (see below) coelute on HPLC, but the presence of distinctive sickled ''Napoleon hat cells'' on a blood film will suggest HbS-Oman. DNA analysis will confirm the specific mutation(s).

Detection of HbC by DNA analysis has been more difficult than for HbS because no known restriction endonuclease site is abolished or created by the mutation. However, newer allele-specific PCR amplification techniques permit rapid identification of the HbC mutation.

HEMOGLOBIN CONSTANT SPRING

Hb constant spring (HbCS) is an abnormal hemoglobin characterized by a mutation of the α2-globin gene termination codon that produces an elongated α-chain. HbCS occurs in South China, Southeast Asia, and the Mediterranean region. The carrier frequency is estimated to be 5% in northeast Thailand and Laos and it is the most prevalent nondeletional α-thalassemia in Southeast Asia.

Asymptomatic heterozygous HbCS is difficult to detect by standard electrophoresis, as HbCS levels are less than 1% of total hemoglobin. In contrast, the homozygous state causes hemolytic anemia; HbCS levels are often 6–8% of total hemoglobin and Hb Bart's (see Chapter ?) is about 1–2%. The diagnosis should be suspected in individuals (especially from high-risk ethnic groups) who have mild anemia, minimal microcytosis, nucleated RBCs, marked basophilic stippling on blood smear, low (<2%) HbA_2 levels, or persistent Hb Bart's. Southern analysis (e.g., reverse dot blot format) using allele-specific probes for the α2-chain termination mutants will confirm the diagnosis. More recently, simplified PCR assays for HbCS have been developed.[13]

HEMOGLOBIN D

Hemoglobin D-Punjab (HbD-Los Angeles) is common worldwide and is the most frequent abnormal hemoglobin in the Xinjiang region of China. HbD is a β-chain variant (β^{121} Glu → Gln) resulting from a G → C substitution. The same nucleotide is altered in HbD-Punjab and HbO-Arab (see below). When HbD (or HbO-Arab) is coinherited with HbS, HbS polymerization is facilitated leading to severe sickling.

By IEF, HbD may be difficult to distinguish from other β-globin variants (e.g., HbS) that have similar electrophoretic mobility or from γ-globin variants. HbD is a slow-moving species on cation-exchange HPLC. It elutes soon after HbA_2 and may interfere with accurate integration of the HbA_2 peak. The presence of HbD can be confirmed either by PCR or direct sequencing.

HEMOGLOBIN E

The HbE mutation (β^{26} Glu → Lys; GAG → AAG) occurs almost exclusively in Southeast Asia, Bangladesh, northeast India, and Sri Lanka. It is the most common abnormal hemoglobin in this region and reaches a carrier frequency of at least 50% at the border of Thailand, Cambodia, and Laos. HbE has become more frequently encountered in Europe and North America with increased Southeast Asian and Bengali immigration. The protective effect of HbE against severe malaria may be related to an unidentified membrane abnormality that renders most of the RBC population relatively resistant to invasion by *Plasmodium falciparum*.[14]

Individuals with HbE trait or homozygous HbE have hypochromic microcytosis and a modest anemia, but HbE/β-thalassemia can cause severe, transfusion-dependent anemia.[15] In fact, globally, HbE/β-thalassemia is the most prevalent form of β-thalassemia major. In Southeast Asia, HbE may also be coinherited with one of several endemic α-globin abnormalities (including HbCS) and cause complex thalassemia syndromes.[13]

In high-risk populations, the England–Fraser discriminant function [MCV − RBC − (5 × Hb) − 3.4] may be helpful in identifying individuals carrying HbE.[16] HbE is distinguished by characteristic electrophoretic mobilities on alkaline and acid gels, properties on anion/cation-exchange HPLC, and mild insolubility. Of note, coinheritance of HbE with α-thalassemia may confound routine diagnostic investigations because the hemoglobin interactions can lead to reduced HbE levels and altered hematologic features.

Newborn screening programs need to incorporate strategies to distinguish the relatively benign homozygous HbE state from HbE/β-thalassemia. Hemoglobin quantitation by HPLC is helpful in this regard; newborn infants with HbE/β-thalassemia have lower HbE percentages and different HbF/HbE ratios compared to HbE homozygotes. DNA analysis using multiplex allele-specific PCR will confirm the presence of HbE and distinguish the homozygous HbE from HbE/β-thalassemia genotypes.

HEMOGLOBIN O

The HbO-Arab substitution is β^{121} Glu → Lys that results from a point mutation in the same codon (β^{121}) as the HbD mutation. This amino acid residue is a contact point for hemoglobin polymer formation. As the case for HbD, HbO-Arab is not clinically consequential unless coinherited with HbS. HbO-Arab occurs in North Africa, the Near East, Balkans, and Mediterranean, i.e., the historical extent of the Ottoman Empire, and gene flow may have followed Sudanese contingents in the Ottoman military.

Homozygous HbO-Arab individuals are clinically asymptomatic, but laboratory evaluation will reveal a mild compensated hemolytic anemia. HbO-Arab/HbS compound heterozygotes, often Near Eastern or African-American, have clinical and laboratory manifestations of SCD.

Accurate diagnosis of HbS/HbO-Arab individuals requires electrophoresis at both alkaline and acidic pH; HbO-Arab has similar electrophoretic mobility to HbC,

HbE, and HbA_2 on cellulose acetate at alkaline pH, and it migrates closely to HbS on citrate agar at acidic pH. With the introduction of newborn hemoglobin screening, HbO-Arab is increasingly identified at birth.

HEMOGLOBIN S

Sickle cell disease was the first human genetic disorder in which a causative mutation was identified at the molecular level, the β-globin chain substitution β^6 Glu → Val. When deoxygenated, HbS polymerizes, causing sickling and leading to anemia, acute chest syndrome, stroke, splenic and renal dysfunction, vaso-occlusive painful crises, and susceptibility to bacterial infections. SCD is the most common hemoglobinopathy in the United States, with 8–10% of African–Americans carrying the sickle hemoglobin (HbS) gene. Haplotype analysis has revealed several origins for the HbS mutation in Africa, Asia, and Southern Europe. Haplotype is correlated to some extent with disease severity: individuals with the ''Indian/Arabian haplotype'' have the mildest course, whereas those with the ''Bantu haplotype'' often exhibit severe SCD.

Neonatal screening for SCD has been driven by the demonstration that daily oral penicillin administration prevents early morbidity and mortality from pneumococcal septicemia.[17] This is the single instance where newborn screening has been prompted by evidence from a randomized, double-blind, placebo-controlled clinical trial.

In France, a combination of IEF and more sensitive, quantitative cation-exchange HPLC has confirmed the status of 99.7% of newborn infant dried blood spot hemoglobinopathy screening samples. Exceptional cases required reverse-phase HPLC for γ- or α-globin chain variants or confirmatory testing by DNA.[18]

Digestion of genomic DNA from uncultured amniocytes with *Mst*II results in fragments larger than those produced by some other enzymes and therefore has been particularly useful in prenatal diagnosis of SCD. These genotyping methods are being supplanted by PCR amplification of the relevant segment of the human β-globin gene, followed by hybridization of the amplicon with allele-specific oligonucleotide probes, and, most recently, by direct PCR amplification using allele-specific primers.

A related HbS variant, HbS-Oman, contains the classic HbS β^6 Glu → Val mutation as well as a second mutation in the same β-chain, β^{121} Glu → Lys, i.e., the HbO-Arab mutation. This HbS-Arab double mutation can produce particularly severe sickling. Deoxygenation of HbS-Oman RBCs in vitro induces polymerization and a characteristic ''yarn/knitting-needle'' cell deformation.

CONCLUSION

Hemoglobinopathies are the most common class of single-gene disorders worldwide. Structural hemoglobinopathies have been paradigms of ''molecular diseases'' in which codon and resultant amino acid changes produce a dysfunctional protein.

Familiarity with the performance characteristics of different methods of hemoglobin variant analysis is basic to accurate diagnosis. Hemoglobin electrophoresis is useful for screening a small number of samples, but the bands are relatively wide, many hemoglobin variants overlap, and quantitation by densitometry is inaccurate at low concentrations. IEF and HPLC-based methods offer specific advantages. HPLC offers excellent sensitivity and specificity plus the attribute of quantification, important for accurately discriminating phenotypes where a hemoglobin variant and β-thalassemia are coinherited.

The increasing adoption of newborn screening programs for hemoglobinopathies, initially driven by presymptomatic identification of homozygous HbS disease and other double heterozygous forms of SCD, has permitted frequency analysis of phenotypes containing hemoglobins F, A, S, C, E, O, and D. Most newborn screening programs currently perform IEF on eluates from the newborn dried blood spots. Some programs use HPLC or cellulose acetate electrophoresis as an initial screening method.

The introduction of PCR-based techniques has significantly improved accuracy, reliability, and throughput of structural hemoglobin diagnosis. In the United Kingdom, the reported total error rate for PCR-based antenatal diagnosis of hemoglobinopathies has been 0.41%, comprising a 0.10% laboratory error rate and a 0.31% nonlaboratory error rate.[19] DNA analysis is available on a clinical basis for the mutations associated with each of the hemoglobin variants discussed in this article. In light of the high prevalence of hemoglobinopathies, diagnostic genomics for hemoglobin variants is a current priority in developing countries.

Hereditary Breast and Ovarian Cancer Syndrome

Nader Hanna
Heather Pierce
University of Kentucky Medical Center, Lexington, Kentucky, U.S.A.

INTRODUCTION

Hereditary breast and ovarian cancer syndrome (HBOC) is an inherited autosomal dominant disorder because of germline mutation in *BRCA1* and *BRCA2* genes. Inheritance of *BRCA* mutations confers increased lifetime risk for breast, ovarian, and other malignancies. Individuals with suspected HBOC should undergo thorough pedigree analysis, education, and counseling in regards to genetic testing, disclosure and interpretation of the results, and determination of cancer risk. Comprehensive review of surveillance strategies, chemoprevention, surgical prophylaxis with its limitations and potential adverse effects, and the need for lifelong follow-up and screening for other malignancies is essential.

OVERVIEW

Five to ten percent of breast cancer and 7–10% of ovarian cancer demonstrate a pattern of autosomal dominant inheritance. Hereditary syndromes with breast and/or ovarian cancer are summarized in Table 1. Mutations in the *BRCA* genes account for only 2–3% of all breast cancers. A single copy of the mutated gene is inherited, and mutation of the second wild-type allele of the gene, through acquired genetic events, is required for loss of function and tumorigenesis. Accumulation of additional somatic mutations in other tumor suppressor genes or oncogenes accounts for the phenotypic differences and explains the increasing age-related penetrance of tumorigenic phenotype in HBOC syndrome. *BRCA* genes act as tumor suppressor and DNA repair genes. The *BRCA1* gene is located on long arm chromosome 17 (17q12–21) and encodes an acid nuclear phosphoprotein. It is responsible for breast cancer in 45% of families with multiple breast cancers and up to 90% of families with both breast and ovarian cancers. The *BRCA2* gene is located on the long arm of chromosome 13 (13q12–13) and accounts for breast cancer in 35% of families with multiple breast cancers. The lifetime risks for breast, ovarian, and other *BRCA1*- and *BRCA2*-associated cancers in HBOC syndrome are summarized in Table 2.

CLINICAL FEATURES IN HEREDITARY BREAST AND OVARIAN CANCER SYNDROME

BRCA mutations occur in approximately 20% of families with inherited susceptibility to breast cancer. Personal and family characteristics associated with an increased likelihood that a *BRCA* mutation will be identified are listed in Table 3. Breast cancers in *BRCA1* carriers often have medullary features, are more likely to be poorly differentiated with high mitotic rates and S-phase fraction, lack an in situ component, have low estrogen and progesterone receptors score, and node-positive. *BRCA2* tumors are more histologically heterogeneous and more likely to be estrogen–receptor-positive. For *BRCA1* carriers, breast cancer survival rates are similar to those for sporadic cancer patients when controlling for stage. The lifetime risk for second primary breast cancers in *BRCA*-mutation carriers with breast cancer is 40–60%, with 5-year risk estimates of 22–31%. The lifetime risk for male breast cancer in *BRCA2*-mutation carriers has been reported to be approximately 6.3%.[1] The average age of onset of ovarian cancer is 48–54 years in *BRCA1* carriers and 62 years in *BRCA2* carriers, similar to onset ages in sporadic cases. Ninety-four percent of *BRCA1* ovarian tumors have serous histology (60% in sporadic cases).

GENETIC TESTING AND COUNSELING IN HEREDITARY BREAST AND OVARIAN CANCER SYNDROME

Genetic testing for HBOC has become generally accepted as part of standard clinical practice and should be offered to any patient that has personal or family history features suggestive of HBOC (Table 3) and when genetic testing results could influence the medical management of that patient or the patient's family members. Clinical laboratories employ a variety of molecular techniques to detect germline mutations in *BRCA1* and *BRCA2* in a peripheral blood sample (Table 4). The sensitivity of molecular testing for *BRCA* cancer-predisposing mutations is

Encyclopedia of Diagnostic Genomics and Proteomics

Table 1 Syndromes associated with hereditary breast and/or ovarian cancer

Hereditary cancer syndrome	Associated tumor suppressor genes or oncogenes	Associated malignancies
Hereditary breast and ovarian cancer	*BRCA1*	— Breast, ovarian, colon, and prostate cancer
	BRCA2	— Breast, ovarian, prostate, pancreatic, bile duct and gall bladder, stomach cancer, and malignant melanoma
Li–Fraumeni	*P53*	— Soft-tissue sarcomas, breast cancer, brain tumors, acute leukemia, and other epithelial and mesenchymal tumors
Cowden's disease	*PTEN*	— Breast cancer, thyroid cancer, and colonic neoplasms
Peutz–Jegher	*STK11/LKP1*	— Colorectal cancer, ovarian stromal tumors, uterine and cervical cancer
		— GI tract polyposis and cancers, breast, testis, cancers
Ataxia telangiectasia	*ATM* (autosomal recessive)	— Lymphoma, leukemia, breast cancer, and other solid malignancies
Hereditary diffuse gastric cancer	*CDH1*	— Gastric cancer and lobular breast cancer in females
Hereditary nonpolyposis colorectal cancer	Mismatch repair genes (*MSH2*, *MLH1*, *PMS1*, *PMS2*, *MSH3*, *MSH5*, *MSH6*)	— Colorectal, endometrial, ovarian, stomach, uroepithelial, hepatobiliary, brain, and small bowel cancers
Gorlin (nevoid basal-cell carcinoma)	*PTCH*	— Basal-cell carcinoma, medulloblastoma, ovarian calcifications and fibroma, and leiomyosarcoma
Multiple endocrine neoplasia type 1	*RET* oncogene	— Parathyroid hyperplasia, gastrinoma, and pituitary neoplasms

dependent on the method used for analysis and the a priori risk of the person tested to have a mutation in either gene based on the person's cancer history, family history, and ethnic background. No currently available technique can guarantee the identification of all cancer-predisposing mutations in the *BRCA1* or *BRCA2* genes.[2] The molecular method with the highest level of sensitivity in situations where a familial mutation has not yet been identified is DNA sequencing. Mutation-specific clinical testing is utilized primarily for the three Ashkenazi Jewish founder mutations, which include 185delAG and 5382insC in *BRCA1* and 6174delT in *BRCA2*, as well as in families in which a mutation has previously been identified. Clinical interpretation of the results of genetic testing is divided into three categories: positive (a deleterious mutation is detected), negative (no mutation is detected), and uninformative (a variant of unknown clinical significance is detected). The only truly informative

Table 2 Estimated lifetime risks of *BRCA1*- and *BRCA2*-associated malignancies

Gene	Associated malignancy	Risk to age 70 in mutation carriers
BRCA1[1,19–21]	Female breast	56–87%
	Ovary	15–54%
	Prostate	3.33RR (95% CI 1.78–6.20)
	Colon	4.11RR (95% CI 2.36–7.15)
BRCA2[1,21–25]	Female breast	56–87%
	Ovary	10–23%
	Male breast	6.3%
	Prostate	4.65RR (95% CI 3.48–6.22)
	Pancreas	3.51RR (95% CI 1.87–6.58)
	Gall bladder/bile duct	4.97RR (95% CI 1.50–16.52)
	Stomach	2.59RR (95% CI 1.46–4.61)
	Malignant melanoma	2.58RR (95% CI 1.28–5.17)

Table 3 Personal and family history features suggestive of HBOC

Personal features	—	Breast cancer before age of 40
	—	Bilateral breast cancer
	—	History of both breast and ovarian cancer
Family features	—	Two or more family members <50 years of age with breast cancer
	—	Both breast and ovarian cancer in the family
	—	Breast cancer in one or more male family members
	—	A family member with known mutation in breast cancer susceptibility genes
	—	Ashkenazi Jewish background

genetic test results are a positive result or a negative result in a family in which a deleterious mutation has previously been identified. A variant result or a negative result in a family in which no mutation has been identified is of limited clinical value because it is unknown whether a detectable deleterious mutation is responsible for the cancer diagnoses in the family.

Adequate pretest and posttest genetic counseling should be provided to patients that undergo genetic testing to obtain full-informed consent. Assessment of an individual's risk for hereditary cancer through genetic counseling and genetic testing has been shown to improve patients' risk comprehension, facilitate more informed decisions regarding cancer prevention, and assist in the identification of at-risk family members.

Pretest genetic counseling is a complex, time-consuming, and frequently emotionally charged process. In its most basic form, pretest genetic counseling for *BRCA1* and *BRCA2* testing should include 1) basic information about breast cancer; 2) basic information about hereditary cancer; 3) information about hereditary breast cancer, including clinical management options for families with hereditary breast and ovarian cancer syndrome (HBOC); 4) possible outcomes of genetic testing for HBOC; 5) potential benefits, limitations, and risks of genetic testing for HBOC; and 6) alternatives to genetic testing for HBOC. In addition to these requirements, the session should include discussion of the potential risk for insurance or employment discrimination, confidentiality issues, and the importance of sharing test results with at-risk relatives. Adequate posttest genetic counseling should include discussion of test results and options for clinical management, plans for sharing test results with at-risk family members, and additional genetic-assessment options if the test results are uninformative.

SCREENING IN HEREDITARY BREAST AND OVARIAN CANCER SYNDROME

Although overall population screening reduces breast cancer mortality by 25–40% in women between the ages of 50 and 70 years, no data are available on the outcomes of interventions to reduce risk in HBOC syndrome. No data are available to demonstrate that surveillance for ovarian cancer in high-risk women reduces mortality[3] because transvaginal ultrasound and CA-125 lack sensitivity and specificity. However, recommended screening in *BRCA* gene mutation carriers includes monthly breast

Table 4 Molecular techniques for genetic testing of *BRCA1* and *BRCA2*

Technique	Features and limitations
DNA sequencing	— Highest overall level of sensitivity
	— May detect variants of unknown clinical significance
	— Intronic mutations, genomic rearrangements may be missed
	— Higher cost, longer turnaround time than most other techniques
Exon scanning (CSGE, SSCP, DGGE)	— Rapid, low-cost initial screening technique
	— Requires sequencing to confirm the exact nature of the mutation
Protein truncation testing (PTT)	— Useful for detecting loss-of-function mutations
	— Change-of-function mutations may be missed
	— Requires sequencing to confirm the exact nature of the mutation
Southern blot	— Can screen for large genomic rearrangements
	— Will not detect point mutations or small deletions and insertions
Allele-specific oligonucleotide (ASO)	— High level of sensitivity for mutation-specific testing
	— Rapid, low-cost technique
	— Only screens for specific known mutations
Recombination-specific PCR	— Can detect specific genomic rearrangements
	— Only screens for specific known rearrangements

self-examination starting at age 18, semiannual clinical breast examination and annual mammography starting at age 25, and starting at age 30–40, semiannual transvaginal ultrasound with color Doppler, serum CA-125, and pelvic examination. Several studies have shown that in women with germline *BRCA1* and *BRCA2* mutations, breast cancers are likely to occur as interval cancers[4] and that standard mammography is more likely to be negative than in women at low or moderate risk.[5] Recent data suggest that magnetic resonance imaging (MRI) of the breast may be much more sensitive than mammography for detecting cancer in mutation carriers.[6]

CHEMOPREVENTION IN HEREDITARY BREAST AND OVARIAN CANCER SYNDROME

Women who desire risk reduction intervention for breast cancer have the option of chemoprevention with tamoxifen therapy (20 mg/day for 5 years) or prophylactic surgery. The National Surgical Adjuvant Breast and Bowel Project prevention trial in healthy women 35 years and older with a 1.7% or greater cumulative 5-year risk for developing breast cancer demonstrated short-term reduction in risk of developing estrogen–receptor-positive breast cancer by 49%. The utility of tamoxifen for breast cancer risk reduction in women under the age of 35 years is unknown and current evidence-based data regarding tamoxifen breast cancer risk reduction in *BRCA* gene mutation carriers are insufficient. Women with *BRCA1* mutations who develop breast cancer have estrogen–receptor-negative tumors in approximately 80% of cases, whereas women with *BRCA2* mutations who develop breast cancer have estrogen–receptor-positive tumors in 80% of cases. Therefore, the use of tamoxifen for breast cancer prevention in *BRCA1*-mutation carriers cannot be routinely recommended, whereas it appears to be a reasonable choice for risk reduction in *BRCA2*-mutation carriers based on current evidence. The incidence of contralateral breast cancer in *BRCA*-mutation carriers was shown to be reduced by 50% with tamoxifen use,[7] by 60% after chemotherapeutic treatment of the first breast cancer,[7] and by 58% after bilateral oophorectomy.[7,8]

The use of oral contraceptive pills (OCP) as chemoprevention in ovarian cancer has been extensively studied. It has been estimated that there is an overall risk reduction of approximately 40%[9] and that more than half of all ovarian cancer in the United States could be prevented by the use of oral contraceptive pills for at least 4 or 5 years.[10,11] However, the role of chemoprevention against ovarian cancer in HBOC syndrome is unknown. There have been conflicting reports on the impact of OCP use on breast and ovarian cancer risk in *BRCA*-mutation carriers.[12–15]

PROPHYLACTIC SURGERY

Prophylactic surgery in HBOC syndrome includes prophylactic bilateral mastectomy and/or complete bilateral salpingo-oophorectomy (including the entire fallopian tubes and infundibulopelvic ligaments). Prophylactic bilateral mastectomy with reconstruction option is the safest measure for prevention of breast cancer. In *BRCA*-mutation carriers, prophylactic bilateral mastectomy was associated with an 85–100% risk reduction for breast cancer.

In HBOC syndrome, prophylactic oophorectomy is recommended at age 35 or after childbearing is completed.[3] Among mutation carriers, prophylactic oophorectomy has been shown to reduce the risk of breast and ovarian cancer by 53–68% and 85–96%, respectively. Ten to fifteen percent of women with *BRCA1* or *BRCA2* mutations who underwent prophylactic oophorectomy were found to have occult ovarian carcinoma.[16] A residual risk of primary peritoneal carcinoma and peritoneal carcinomatosis has been documented in 2–11% of women who undergo prophylactic oophorectomy.[17] The majority of women (86.4%) who had prophylactic oophorectomy were satisfied because surgery effectively reduced their anxiety about ovarian cancer, with the benefit of anxiety reduction outweighing the potential adverse events of surgery.[18]

CONCLUSION

Identifying HBOC syndrome has clinical implication for both the clinician and the individuals diagnosed, as they have an increased risk of several malignancies. Management strategies to address the increased cancer risk include genetic counseling and testing, targeted surveillance, chemoprevention, and prophylactic surgery. Genetic testing in high-risk family members is strongly recommended. The available current data indicate superiority of surgical prophylaxis compared with surveillance in reducing cancer risk in carriers of *BRCA* mutations. Surgery limitations and related adverse effects on morbidity and quality of life should always be discussed in extensive preoperative counseling. For evidence-based medical recommendation, more prospective data with appropriate surveillance protocol, longer follow-up, and quality-adjusted overall survival as endpoints are needed.

Hereditary Diffuse Gastric Cancer Syndrome

Nader Hanna
University of Kentucky Medical Center, Lexington, Kentucky, U.S.A.

INTRODUCTION

Hereditary diffuse gastric cancer (HDGC) syndrome is an autosomal-dominant inherited cancer susceptibility syndrome with high penetrance for gastric cancer caused by germline truncating mutation in the E-cadherin (*CDH1*) tumor-suppressor gene. Male carriers have a 67% lifetime risk for gastric cancer; female carriers have a 83% lifetime risk for gastric cancer and a 39% risk for breast cancer. The syndrome is characterized by early, diffuse, multifocal submucosal involvement, rendering endoscopy and random biopsy inaccurate. Once a carrier is identified, prophylactic total gastrectomy is the only effective treatment.

OVERVIEW

Despite a declining incidence of, and mortality from, gastric cancer worldwide, it remains the second largest cause of cancer-related death. Most gastric cancers occur sporadically without evidence of an inherited cancer predisposition. Familial clustering of gastric cancer is observed in approximately 10% of cases. However, hereditary gastric cancer caused by inheritance of germline mutations accounts for only 1–3% of all gastric cancers and is seen in HDGC, hereditary nonpolyposis colon cancer syndrome (HNPCC), Peutz–Jeghers syndrome, Cowden's syndrome, and some kindreds affected with Li–Fraumeni syndrome and familial adenomatous polyposis (FAP; Table 1). Compared with other malignancies such as colorectal cancer, the genetic events that contribute to the tumorigenicity of gastric cancer are rather undefined. However, it is believed that complex interactions between dietary factors, *Helicobacter pylori* infection, and genetic predisposition contribute to the pathogenesis of gastric cancer, account for phenotypic differences, and explain the increasing age-related penetrance of tumorigenic phenotype.

BIOLOGICAL BASIS OF HDGC SYNDROME

HDGC is an autosomal dominant disorder with high penetrance, caused by germline mutations in the *CDH1* gene encoding for E-cadherin. E-cadherin is a 120-kDa calcium-dependent transmembrane glycoprotein localized in lateral cell–cell contacts and enriched in the zonula adherens junctions.[1] The intact function of this adhesion molecule is crucial for the establishment and maintenance of epithelial tissue polarity, structural integrity, and cellular differentiation.[1,2] It has five tandemly repeated extracellular domains that mediate intercellular adhesion through homophilic cellular interactions, and a cytoplasmic domain that is responsible for the adhesive function of E-cadherin to the actin cytoskeleton through a complex with α, β, and γ catenins.[2] E-cadherin mutations have been described for breast, gastric, endometrium, ovary, and thyroid carcinomas. However, frequent somatic mutations in *CDH1* have been particularly implicated in the carcinogenesis of gastric carcinomas (in 40–83% of sporadic diffuse-type gastric cancer, but not in sporadic intestinal-type gastric cancer.[3,4]) and infiltrative lobular breast carcinomas.[5,6] In diffuse gastric carcinomas, the predominant mutations are exon skippings causing in-frame deletion, in contrast to premature stop codon mutations identified in lobular breast cancer. Germline mutation of *CDH1* gene in gastric cancer was originally discovered and reported in three Maori families in 1998.[7] The characteristics of the 18 families reported in the literature to have HDGC syndrome are summarized in Table 2. Both copies of the gene must be mutated to result in loss of function and carcinogenesis. A single copy of the mutated gene is inherited, and mutation or loss of promoter methylation of the second wild-type allele of the gene, through acquired genetic events, is required for loss of function and tumorigenesis. The accumulation of additional somatic mutations in other tumor-suppressor genes or oncogenes accounts for the phenotypic differences, and explains the increasing age-related penetrance of tumorigenic phenotype.

CLINICOPATHOLOGICAL FEATURES

HDGC was defined, during the First Workshop of the International Gastric Cancer Linkage Consortium (IGCLC) held in 1999, as any family that fits the following criteria: 1) two or more documented cases of diffuse gastric cancer in first-degree/second-degree relatives,

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120024106

Table 1 Hereditary syndromes associated with gastric cancer

Hereditary cancer syndrome	Associated genes or oncogenes	Associated malignancies and their penetrance
HDGC	*CDH1*	Gastric cancer (70%) Lobular breast cancer in females (39%)
Hereditary nonpolyposis colorectal cancer (HNCC; Lynch syndrome)	Mismatch repair genes (*MSH2*, *MLH1*, *PMS1*, *PMS2*, *MSH3*, *MSH5*, *MSH6*)	Colorectal cancer (70–85%) Endometrial cancer (40–60%) Ovarian cancer (12%) Stomach, uroepithelial, hepatobiliary, brain, small bowel cancers
Peutz–Jeghers	*STK11*, *LKP1*	Colorectal cancer Ovarian stromal tumors Uterine and cervical cancer Gastrointestinal tract polyposis and cancers, breast and testis, cancers
Cowden	*PTEN*	Thyroid cancer Breast cancer Gastric cancer
Li–Fraumeni	*p53*	Leukemia Breast cancer Gastric cancer
FAP	*APC* (adenomatous polyposis coli) *DCC/DPC/JV18* *p53* *KRAS*	Colorectal carcinoma (100%) Ampullary carcinoma (30%) Desmoid tumors (10%) Gastric cancer

with one at least diagnosed before the age of 50 years; or 2) three or more cases of documented diffuse gastric cancer in first-degree/second-degree relatives, independently of age of onset.[14] All gastric carcinomas from documented germline mutation E-cadherin carriers have been of the diffuse or linitis plastica type. The penetrance of germline *CDH1* mutations is estimated to be approximately 70%.[7] The average age of onset of gastric cancer is 38 years, with occurrence in the 20s not unusual. The lesions are multifocal, spread submucosally without forming grossly visible exophytic mass, and are not associated with precancerous morphological or pathological abnormalities, rendering screening endoscopy and early diagnosis very difficult. Clinical diagnosis was often at an advanced incurable stage. Lobular breast carcinoma,[8,10,15] colorectal cancer, and prostate carcinoma[7,9,11] have also been documented in mutant E-cadherin gene carriers and may be a part of the malignant spectrum in HDGC. The estimated cumulative risk of gastric cancer by age 80 years was 67% for men [95% confidence interval (95% CI), 39–99] and 83% for women (95% CI, 58–99). For women, the cumulative risk of breast cancer was 39% (95% CI, 12–84). The combined risk of gastric cancer and breast cancer in women was 90% by age 80 years.[15]

MANAGEMENT STRATEGIES

Individuals with suspected HDGC should undergo thorough pedigree analysis, education and counseling in regards to genetic testing, disclosure and interpretation of the results, and determination of cancer risk. A comprehensive review of surveillance strategies, chemoprevention, surgical prophylaxis with its limitations and potential adverse effects, and the need for lifelong follow-up and screening for other malignancies is essential. Genetic testing and counseling guidelines for HDGC are provisional at this time and are only provided on an investigational basis. These guidelines are likely to change to parallel the ongoing scientific discovery of the genes responsible for the syndrome. Molecular techniques employed to detect germline mutations are summarized in Table 3. No currently available technique can guarantee the identification of all cancer-predisposing mutations in the *CDH1* gene. The molecular method with the highest level of sensitivity in situations where a familial mutation has not yet been identified is DNA sequencing. Mutation-specific clinical testing is utilized primarily in families in which a mutation has previously been identified.

Table 2 Characteristics of the 18 families reported in the literature to have DHGC syndrome

Ethnic background	Mutation	Location and type of mutation	Age at diagnosis of DGC (years)
Maori[8]	G1008T	Exon 7 (splice site)	14–67
Maori[8]	C2095T (Q699X)	Exon 13 (silent)	30
Maori[8]	2382–2386insC	Exon 15 (frame shift)	16–35
Maori[9]	C190T (Q64X)	Exon 3 (nonsense)	22–28
White[9]	A(49-2) G	Exon 2 (splice site)	34–69
White[9]	G59A (W20X)	Exon 2 (nonsense)	27–50
White[8]	G70T (E24X)	Exon 2 (nonsense)	37–46
White[10]	372–377 delC	Exon 3 (frameshift)	15–58
White[11]	C187T (R63X)	Exon 3	33–69
White[8]	G586T (G196X)	Exon 5 (nonsense)	31–55
White[8]	1487del7	Exon 10 (frameshift)	31
White[8]	1588insC	Exon 11 (frameshift)	40–63
White[11]	1711insG	Exon 11 (frameshift)	30–68
White[11]	C1792T (R598X)	Exon 12 (silent)	23–43
African–American[8]	G(1137+1) A	Intron 8 (donor splice site)	29–58
Korean[12]	A731G	Codon 244 in exon 6 (missense)	30–63
Korean[12]	T1460C	Codon 487 in exon 10 (missense)	42–49
Japanese[13]	G185T	Codon 62 in Exon 3 (missense)	46–72

There are no effective screening regimens or surveillance modalities. Upper endoscopy with biopsy, endoscopic ultrasound, and/or chemoendoscopy appears to have no value in the detection of early and potentially curable multifocal submucosal gastric cancer. Surveillance endoscopy was unable to detect early cancer found in prophylactic total gastrectomy specimens. Surveillance modalities that can identify carriers who would benefit from early prophylactic gastrectomy are being evaluated. These include endoscopic surveillance with optical coherent tomography and molecular marker analysis of gastric lavage fluid.

There are no known nonsurgical prevention strategies for *CDH1* carriers at this time. However, prophylactic treatment with demethylating agents, such as 5-azadeoxycystidine, has been suggested based on the observation that some tumors demonstrated methylation of the *CDH1* promoter as the ''second hit.''[16,17] A recent report also suggests that E-cadherin methylation is an early event in gastric carcinogenesis and is initiated by *H. pylori* infection.[18] Another potential strategy is early and annual screening and complete eradication of *H. pylori* infection in *CDH1* carriers, similar to the recommendation of the Maastricht 2-2000 Consensus

Table 3 Molecular techniques for genetic testing

Technique	Features and limitations
DNA sequencing	Highest overall level of sensitivity May detect variants of unknown clinical significance Intronic mutations, genomic rearrangements may be missed Higher cost, longer turnaround time than most other techniques
Exon scanning	Rapid, low-cost initial screening technique Requires sequencing to confirm the exact nature of the mutation
Protein truncation testing (PTT)	Useful for detecting loss-of-function mutations Change-of-function mutations may be missed Requires sequencing to confirm the exact nature of the mutation
Southern blot	Can screen for large genomic rearrangements Will not detect point mutations or small deletions and insertions
Allele-specific oligonucleotide (ASO)	High level of sensitivity for mutation-specific testing Rapid, low-cost technique Only screens for specific known mutations
Recombination-specific polymerase chain reaction (PCR)	Can detect specific genomic rearrangements Only screens for specific known rearrangements

Table 4 Long-term complications after total gastrectomy

- Esophagojejunostomy anastomotic stricture (10–15%)
- Lactose intolerance: occurs in approximately 50% of patients
- Malabsorption and steatorrhea: occur in 66–100% of patients due to relative pancreatic insufficiency, bacterial overgrowth, and rapid intestinal transient time
- Postprandial fullness and dumping syndrome: occur in 20–30% of patients due to rapid emptying of hyperosmotic carbohydrates into the small bowel and the release of enteric hormones
- Iron and vitamin B_{12} deficiency
- Weight loss: approximately 10% (average of 4–7 kg) of the preoperative weight (mainly body fat) during the first year

Report, stating that patients with a family history of gastric cancer should undergo *H. pylori* eradication therapy.[19] Several analyses showed an association between *H. pylori* seropositivity (especially CagA-positive strains) and gastric cancer, particularly in younger patients and non-cardia adenocarcinoma.[20,21] The increased prevalence of *H. pylori* infection and *H. pylori*-associated precancerous changes has also been observed in first-degree relatives of sporadic gastric cancer patients.[21] In a cluster of familial gastric cancer, genetic abnormalities were found in first-degree relatives only in the presence of *H. pylori* infection.[22] Successful eradication of *H. pylori* improves the secretion of vitamin C into gastric juice, which may increase protection against gastric cancer. A randomized, placebo-controlled trial in people at high risk for developing gastric cancer showed that effective anti-*H. pylori* treatment and dietary supplementation with antioxidants were statistically significant in promoting the regression of precancerous lesions.[23]

The optimal clinical management of E-cadherin germline mutation carriers is unclear and controversial, especially in regard to the role of prophylactic gastrectomy. Prophylactic total gastrectomies in five patients (ages 37, 39, 40, 41, and 47 years) with a known E-cadherin germline mutation were first reported in 2001.[24] All five patients had negative endoscopic evaluation, yet all postgastrectomy specimens demonstrated occult microscopic foci of intramucosal signet ring cell adenocarcinoma in various regions of the stomach. Huntsman et al.[25] reported similar findings in another five subjects (ages between 22 and 40 years). At present, the International Gastric Cancer Consortium (IGCC) recommends testing for E-cadherin alterations in patients with diffuse gastric cancer and suggests prophylactic total gastrectomy in carriers of E-cadherin germline mutations.[14] Complete removal of gastric mucosa should be confirmed intraoperatively on frozen section by a demonstration of esophageal and duodenal mucosa at the proximal and distal margins, respectively. Prophylactic gastrectomy also has the potential benefit of anxiety reduction and perhaps improvement of the overall quality of life in these mutation carriers. However, there are several concerns for adopting a universal policy of prophylactic gastrectomy in *CDH1* mutation carriers. Prophylactic gastrectomy would result in a nontherapeutic surgery in 30% of these carriers. The biological behavior of these early submucosal multifocal lesions is not known. The age at which prophylactic surgery should be recommended is not clear. Although prophylactic gastrectomy at a young-enough age reduces the risk of gastric cancer development, its effect on the overall life expectancy is unknown and unproven. Carriers of the *CDH1* gene are at increased risk for developing other malignancies and require regular screening. Gastrectomies, in general, are associated with operative mortality of 5% or less and a morbidity rate of 35–40%. Significant long-term sequels (Table 4) can have a significant negative impact on quality of life. Clinical studies have shown that patients with jejunal pouch reconstruction have better food intake, fewer postprandial symptoms, less weight loss, and a chance for a better quality of life. However, it is expected that prophylactic total gastrectomy in these otherwise healthy young individuals would have lower morbidity and less negative impact on quality of life.

CONCLUSION

Identifying HDGC has clinical implications for both the clinician and the individuals diagnosed with this hereditary form of cancer, as they have an increased risk of gastric cancer and other malignancies. Management strategies to address the increased cancer risk include genetic counseling and testing, targeted surveillance, chemoprevention, and prophylactic surgery. Genetic testing in high-risk family members is strongly recommended. The available current data indicate the superiority of surgical prophylaxis compared with surveillance in reducing gastric cancer risk in carriers of *CDH1* mutations. Surgery limitations and related adverse effects on morbidity and quality of life should always be discussed in extensive preoperative counseling. For evidence-based medical recommendation, more prospective data with appropriate surveillance protocol, longer follow-up, and quality-adjusted overall survival as endpoints are needed.

Southern Iron Disorders Center, Birmingham, Alabama, U.S.A.

INTRODUCTION

Hereditary hemochromatosis (OMIM #235200) is an autosomal recessive disorder of iron metabolism that affects 1/200 to 1/400 Caucasians of central, northern, and western European descent. Some Hispanics also develop hemochromatosis that is phenotypically and genotypically similar to that in Caucasians. Other iron overload disorders in Caucasians, most of which are uncommon, share some clinical and biochemical features with ''classic'' hemochromatosis, although they are associated with mutations in other genes. Iron overload in other racial/ethnic groups also differs phenotypically and genotypically from ''classic'' Caucasian hemochromatosis.

In some persons with hemochromatosis, excessive iron accumulation in parenchymal cells can lead to hepatic cirrhosis, primary liver cancer, arthropathy, diabetes mellitus, hypogonadism, and cardiomyopathy, if untreated. Diagnosis is usually based on detection of elevated serum transferrin saturation in the absence of other demonstrable cause. Iron overload is characterized by elevation of serum ferritin concentration or hepatic iron concentration, or by quantitative phlebotomy to achieve iron depletion. Complications of hemochromatosis can be prevented by early diagnosis and simple, effective treatment to remove excess iron and maintain low normal body iron stores (therapeutic phlebotomy). Because hemochromatosis is common, easily diagnosed, and readily treatable, it has become a public health concern in a large fraction of the world's population.

GENETIC FEATURES OF HEMOCHROMATOSIS

Some features of hemochromatosis are displayed in Table 1.[1–3] Hemochromatosis is linked to human leukocyte antigen (HLA) class I genes within the major histocompatibility complex (MHC) region on Ch6p.[1] Mutations in a nonclassical MHC class I gene (*HFE*), which maps ~4 Mb telomeric to HLA-A at 6p21.3, account for most cases in Caucasians[4] (Table 2). ''Classic'' hemochromatosis is associated with homozygosity for the *HFE* C282Y mutation. C282Y often lies within an ancestral HLA haplotype A*03-B*07.[1,6] This haplotype is the predominant hemochromatosis-associated haplotype in northwestern European countries.[6] This is attributed to the origin of C282Y on an A*03-B*07 haplotype in northwestern Europe and its early dissemination by Vikings.[6] Modification of the ancestral chromosome by recombination and admixture as a result of geographic migration explains the occurrence of chromosomes bearing C282Y in association with different HLA haplotypes.[6] Thus some nonancestral haplotypes also occur with significantly increased frequencies in hemochromatosis patients in various countries in Europe and in descendants of Europeans.[6]

C282Y and H63D, the most common *HFE* mutations detected in Caucasians, occur with frequencies of 0.01–0.14 and 0.05–0.22, respectively.[7] Frequencies of these mutations vary among racial, ethnic, or national groups, and are positively correlated with the prevalence of hemochromatosis.[7] In various Caucasian populations, 60–100% of hemochromatosis cases are attributable to homozygosity for C282Y.[4,8] Some patients are compound heterozygotes for C282Y and H63D, or are H63D homozygotes.[4,8] Other persons with a hemochromatosis phenotype have ''atypical'' *HFE* genotypes, i.e., are heterozygous for C282Y or H63D, have uncommon *HFE* mutations, or do not have a detectable mutation in *HFE* coding regions (Table 2).[4,8,9] Differences in case ascertainment criteria could partly explain dissimilarities in the geographic distribution of hemochromatosis patients with ''atypical'' *HFE* genotypes.[8,9] Missense mutations in other genes that control iron absorption could also account for hemochromatosis phenotypes in some cases.

The severity of iron overload in Caucasians with hemochromatosis is variable, and is correlated with the particular *HFE* genotype; for example, persons with the genotype C282Y/C282Y usually have more stored iron at diagnosis than persons with the genotypes C282Y/H63D or H63D/H63D.[8] Persons who inherit C282Y on the ancestral haplotype characterized by HLA-A*03,-B*07 may have more severe iron overload, on the average, than those who lack this haplotype.[10] Some investigators have suggested that ''mutations at a second HLA-linked locus,

Table 1 Features of hemochromatosis

Variable	Clinical feature
Affected populations	Caucasians of European descent
Prevalence in populations	1/200–1/400
Prevalence in liver biopsy specimens	0.034, 0.046
Serum transferrin saturation with iron	Usually elevated
Serum ferritin concentration	Often elevated
Primary target organs of iron overload	Excess iron is deposited in almost all organs and tissues in severe cases, especially liver
Pattern of iron deposition	Primarily parenchymal cells
Complications of iron overload	Hepatic cirrhosis, primary liver cancer, diabetes mellitus, hypogonadotrophic hypogonadism, arthropathy, cardiomyopathy, hyperpigmentation, abnormalities of ascorbic acid (vitamin C) metabolism
Pattern of inheritance	Autosomal recessive
Associated genes	Mutations in *HFE*
Prevention or treatment of iron overload	Phlebotomy

rather than recombination between A*03 and C282Y, could explain some regional disease associations with non-A*03 haplotypes.''[11] Conversely, other investigators suggest that ''another haplotype containing HLA-B*07 and HLA-Cw*0702 contains an element affording protection against hemochromatosis.''[12] Locus heterogeneity also has been proposed as an explanation of the observations that the distribution of *HFE* genotypes in patients deviates from that expected under Hardy–Weinberg equilibrium.[4] It is possible that multiple MHC haplospecific regions contribute to the hemochromatosis phenotype.[8] For example, a modifying gene in the region of D6S105 on Ch6p may affect the severity of iron overload in hemochromatosis.[13] Among hemochromatosis patients homozygous for C282Y, those with D6S105 allele 8 homozygosity had significantly higher hepatic iron indices than those heterozygous or nullizygous for D6S105 allele 8.[13] In contrast, an analysis of microsatellites between HLA-A*03 and *HFE* in C282Y homozygotes and their siblings revealed no evidence of modifier genes in this region.[14] Polymorphisms in the promoter region of the tumor necrosis factor-alpha (TNF-α) gene, also located within the MHC region, have been implicated in the development of iron overload or expression of its complications by some[15] but not other investigators.[16]

In addition to Ch6p alleles, the expression of iron overload in individuals with hemochromatosis is associated with sex, age, intake of iron and other dietary factors, coinheritance of forms of hereditary anemia that stimulate iron absorption, and the severity of physiological and pathological iron and blood loss.[1,2,11] At present, only short-term longitudinal studies to ascertain the development of iron overload and its complications in C282Y

homozygotes have been reported.[17] Therefore debate regarding the penetrance of iron overload and associated complications in cohort analyses of C282Y homozygotes is unresolved.[18] Until long-term studies are conducted, estimates of penetrance will remain controversial.

ROLE OF *HFE* IN IRON METABOLISM

The first indication that class I MHC molecules are involved in cellular iron metabolism were observations that beta 2-microglobulin knockout mice develop iron overload.[19] Subsequently, HFE protein was observed to have sequence and structural homology with MHC class I proteins,[4] but lacks a functional peptide binding groove and interactions with T cells.[20] HFE lacks a peptide-binding groove analogous to classical class I MHC proteins because of the greater proximity of its $\alpha 1$ and $\alpha 2$ helices. Moreover, C282Y, the predominant *HFE* mutation associated with hemochromatosis, encodes a tyrosine for cysteine substitution that results in loss of the disulfide bond in the $\alpha 3$ domain.[21] Without this disulfide loop, the molecule cannot fold properly, does not associate with beta 2-microglobulin, and is not expressed on the cell surface.[21] Wild-type and H63D HFE proteins form stable complexes with the transferrin receptor (TfR), whereas the C282Y mutant protein does not associate with TfR[22] The TfR-binding site of HFE is located on the C-terminal area of the $\alpha 1$ domain helix and in an adjacent loop.[22] This region of HFE is distinct from the peptide-binding site of classical class I MHC proteins. HFE binds TfR at or near the site where diferric transferrin binds. Although HFE competes with transferrin for binding sites on TfR, it is unclear if this is the mechanism whereby HFE regulates iron metabolism. In cells expressing HFE, TfR levels are increased and ferritin levels are decreased.[23] In cultured cells, expression of HFE reduces the uptake of ferritin from transferrin, suggesting that HFE has a role in regulating transferrin-mediated iron uptake. There are other proteins known to have a role in regulating iron absorption and metabolism. The relationship of their interaction with HFE is less well understood or is unreported.

EARLY DIAGNOSIS OF HEMOCHROMATOSIS: PHENOTYPING VS. GENOTYPING

Early diagnosis of hemochromatosis permits treatment of iron overload and thereby prevents premature death due to hepatic cirrhosis (and primary liver cancer) and diabetes mellitus complications.[1,2] Preventing iron overload may also reduce the frequency or severity of arthropathy, hypogonadotrophic hypogonadism and other endocrinopathic disorders, and cardiac abnormalities.[1,2] The cornerstone of case detection in medical care and in population screening has been the measurement of serum transferrin saturation.[1] The severity of iron overload is estimated by quantification of the serum ferritin concentration, and by measurement of iron stores in liver biopsy specimens. An estimate of excess body iron stores can also be determined after the completion of iron depletion by therapeutic phlebotomy, although this does not provide data useful in prospective case ascertainment.

After the cloning of *HFE* and observations from early reports of significant associations of the mutations C282Y and H63D with hemochromatosis in Caucasians, there was hope that *HFE* genotyping could be used to identify persons at risk for developing iron overload. This would allow early intervention that could prevent or reduce the morbid conditions that often develop in persons with severe iron overload. Although genotyping is useful to detect hemochromatosis in western Caucasian ethnic groups and family members of affected individuals,[24] there are still too many unanswered questions regarding factors that affect clinical penetrance to recommend universal population genotypic screening. However, *HFE* genotyping is a useful test that can augment phenotyping with serum transferrin saturation and serum ferritin levels.

With the recent discovery of mutations in genes associated with other forms of hemochromatosis there is now the possibility that these mutations when present with *HFE* mutations can enhance or modify the risk for ''classical'' hemochromatosis (Table 3). In addition to ''classical'' hemochromatosis three other forms of hemochromatosis have been described. Juvenile hemochromatosis (OMIM #602390) is a relatively rare severe autosomal recessive disorder with an early age of onset.[25] Clinical symptoms usually appear in the second to third decade of life. There may be two forms of this disorder. Mutations in *HAMP*, a gene located on chromosome 19q13 (OMIM #606464) that codes for hepcidin, have been observed associated with one form of severe juvenile hemochromatosis in Italian families and in individuals with, ''altered indicators of iron status.''[26,27] Mutations in *HAMP* have been observed in subjects with iron overload who are also heterozygous for C282Y or S65C.[27–29] These data suggest that the onset or severity of iron overload may be ''modified'' by the presence of *HAMP* mutations in C282Y homozygous or heterozygous individuals.

The other form of juvenile hemochromatosis is linked to a gene on chromosome 1q21 (OMIM #608374). Mutations in the transcript unit *LOC148738* now referred to as *HJV* have been reported associated with juvenile hemochromatosis in several families.[30] This gene appears to modulate hepcidin expression.

Mutations in *TFR2*, which maps to 7q22 and codes for transferrin receptor 2, have also been reported associated

[a]These data do not include gene mutations that cause heritable forms of anemia associated with iron overload.

with a form of hemochromatosis (OMIM #604250) in several racial and ethnic groups.[31–36] The mutations originally reported in Sicilian families[31] were considered to be rare based on other investigators failure to observe them associated with iron overload in several racial/ethnic groups.[37,38] However, mutations in *TFR2* when present with *HFE* mutations could also modify the penetrance of an iron overload phenotype.[36]

Mutations in the ferroportin 1 gene (*FPN1*), located on chromosome 2q32, are associated with an autosomal dominant form of hemochromatosis (OMIM #606069) in several racial and ethnic groups.[39–48]

Although it is likely that there will be cases of iron overload due to various combinations of mutations in the genes just described, this possibility has not been extensively explored. The frequency in which mutations in these genes appear in various racial/ethnic groups varies. Thus, it is likely that the combination of mutations found associated with iron overload will also vary by racial/ethnic group. This will have to be considered in the selection of cohorts to assess these possibilities. Current large multiethnic screening studies in diverse geographic regions may provide answers to these questions and predict more precisely who will develop iron overload.[49]

MUTATION DETECTION

The mutations herein described have been detected by a variety of methods—all of which have been utilized to identify genes associated with other disorders. Mapping of putative genes involved in iron overload for the most part has been conducted by multipoint linkage analysis, followed by positional cloning and sequencing of the area of interest.[4,30] After a chromosome region is defined and the candidate gene sequenced, a comparison of sequences from patients and controls may reveal missense, nonsense, and splice site mutations or deletions, which results in a nonfunctional product or failure to synthesize the product. Once the sequence of the gene is known, primers of the various regions can be generated and used in PCR, followed by denaturing HPLC to detect mutations.[50] Once a given mutation has been identified, subjects can then be genotyped by use of PCR-SSP or PCR-SSCP, PCR-RFLP followed by gel or capillary electrophoresis, mutagenically separated PCR, heteroduplex analysis, PCR followed by dot blot analysis, mass spectrometry based on single nucleotide extension, and microchip arrays.[51,52] Primers specific for several mutations can often be used together in multiplex PCR, allowing for rapid comprehensive genotyping.[52] Most of these assays are robust. For example, the analytic sensitivity and specificity for detecting C282Y homozygosity are 98.4% and 99.8%, respectively.[53]

CONCLUSION

The increase in knowledge about hemochromatosis has raised the interest of health care providers and the public in this common yet frequently undiagnosed disorder. It is now clear that ''classic'' hemochromatosis is only one of many distinct iron overload disorders. However, it is possible to diagnose hemochromatosis and detect iron overload with the genotypic and phenotypic assays currently available before significant organ and tissue damage occurs. As more is learned about the genetics and environmental modifiers of hemochromatosis and iron overload, the morbidity associated with this disorder should be significantly reduced.

Hereditary Hemorrhagic Telangiectasia (Rendu–Osler–Weber Disease)

Carlo Sabbà
Anna Cirulli
Ginevra Guanti
Università di Bari, Bari, Italy

INTRODUCTION

The Rendu–Osler–Weber disease or hereditary hemorrhagic telangiectasia (HHT) is a disease characterized by epistaxis, mucocutaneous telangiectases, and visceral arteriovenous malformations (AVMs) particularly in the brain, lung, gastrointestinal tract, and liver. Hereditary hemorrhagic telangiectasia is transmitted as an autosomal-dominant disorder whose phenotypic penetrance is age-dependent and nearly complete by age 40. Mutations in two different genes identify HHT type 1 and HHT type 2, respectively: endoglin (MIM#131195; XM_055188) located on chromosome 9q33–q34 and activin-like kinase type 1 (ALK-1) or ACVRL1 (MIM#601284; Z22533) on chromosome 12q13. The existence of a third locus has been predicted. Hereditary hemorrhagic telangiectasia type 1 is considered a more severe form of the disease with an earlier onset of epistaxis and telangectasia and an occurrence of pulmonary arteriovenous malformations higher than in HHT-2 subjects.

The heterogeneous clinical setting renders the diagnosis difficult, thus explaining why HHT was once considered a rare disease. Moreover, frequent misdiagnosis has led to an underestimation of the actual prevalence of HHT which currently is 10–20/100,000. Extensive experience is necessary with both the various clinical expressions of the disease and the instrumental diagnostic possibilities for a correct diagnosis. In fact, a single biological test is not yet available and diagnosis is made following the clinical criteria: recurrent epistaxis, mucocutaneous telangiectases, autosomal-dominant inheritance, and visceral involvement. The diagnosis is considered definite if patients demonstrate at least three of the above criteria, suspected in the presence of two criteria, and excluded if only one criterion is present.

Recent progress in the field of genetics has permitted the identification of many gene mutations, thus, facilitating the characterization of the at-risk members of the same family.

PATHOPHYSIOLOGIC AND GENETIC FEATURES

The first step in the telangiectasia formation consists a focal dilatation of postcapillary venules with predominant stress fibers in pericytes along the luminal border. As the venules enlarge, they become convoluted and form excessive layers of smooth muscle cells without elastic fibers and connect directly with the dilated arterioles.[1]

The molecular basis consists of a defect of the TGF-β signaling pathway which, in normal conditions, plays an important role in vascular remodeling and maintenance of vessel wall integrity.[2] The genes responsible for HHT, endoglin and ALK-1 represent a coreceptor and a type 1 TGF-β receptor, respectively. In particular, endoglin is a homodimeric transmembrane glycoprotein expressed predominantly in endothelial cells and is composed of disulfide-linked 90-kDa subunits with large extracellular domains and serine/threonine-rich cytoplasmic regions without consensus signaling motifs. Thus far, numerous mutations of *ENG* gene have been described and these mutations tend to be unique and family specific.[3,4]

ALK-1 has the characteristics of a Type 1 serine–threonine kinase receptor; in vitro, it binds to activin or TGF-β types 1, 2, and 3, but the natural ligand in vivo is unknown. ALK-1 mutations include insertions, deletions, and nonsense mutations and, *as in endoglin*, several of these mutations give rise to an unstable protein. Both ALK-1 and endoglin have been suggested to trigger HHT according to the haploinsufficiency model.[5–7]

The exact mechanism by which mutations of endoglin and ALK-1 induce the diffuse angiodysplasia is poorly understood. The transmission of the TGF-β signals from the cell surface to the nucleus requires a complex system of receptors and cytosolic Smad proteins. Endoglin modulates this transmission, forming a complex with TGF-β1 and TGF-β2 receptors on the endothelial cells. Upon association with type 2 TGF-β, the receptor endoglin is phosphorylated. The association with TGF-β2 receptor results in an increased phosphorylation of type

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120025762

1 TGF-β receptor which, in turn, phosphorylates Smad2. This activated complex associates with Smad4 and, entering the nucleus, regulates the transcription of the target genes.

A balance model for the role of ALK and endoglin in angiogenesis has been proposed. Activation of ALK-1 leads to the endothelial cell (EC) resolution phase where angiogenic factors, such as the vascular endothelial growth factor (VEGF), are repressed; when the TGF-β1 signal is mediated by ALK-5, it transforms ECs into the activation phase of angiogenesis. The ALK-1 pathway is disrupted in HHT type 2, leading to the dominance of the ALK-5 signaling route, thus stimulating the activation phase of ECs and resulting in arteriovenous connections between dilated venules and arteries. In HHT type 1 a reduced dosage of endoglin may give a significant decrease in TGF-β1 concentration, impairing the ALK-1 and ALK-5 pathways. Therefore, having a higher sensitivity to TGF-β1 than ALK-1, ALK-5 pathway predominates and induces the arteriovenous connections.[2] According to the proposed model, the overexpression of several vascular growth factors, such as VEGF, would result from an aberrant angiogenic signal in HHT and might participate in the formation and enlargement of the vascular malformations. In fact, in our recent study, we demonstrated increased levels of VEGF in the serum of HHT patients, in agreement with the VEGF stimulation synthesis proposed in the murine model.[8]

Recently, ALK-1 signaling has been demonstrated to have a role in arterialization and remodeling of arteries so that the arterioles rather than the venules are the primary vessels affected by the loss of an ALK-1 allele. Thus, contrary to the current view of HHT as a venous disease, the arterioles rather than the venules are the primary vessels affected by the loss of an ALK-1 allele.[9]

Genetic Testing

The search for mutations is time consuming and expensive because of genetic heterogeneity and the fact that mutations in either gene tend to span the entire coding sequence and are usually family-specific. Direct sequencing, SSCP, heteroduplex analysis, Southern blotting and RT-PCR are the techniques more frequently utilized for mutation screening. Considering that any endoglin mutation will determine a reduction by half in the detection of its cell surface expression, Abdalla et al.[6] have developed a mutation detection strategy based on the flow cytometry quantification of surface endoglin on newborns' HUVECs and on adult patients' activated monocytes followed by quantitative multiplex polymerase chain reaction (QMPCR). As HHT-2 patients show no reduction of steady-state endoglin expression, this method eliminates the necessity of screening for both HHT genes and allows the detection of large deletions and duplications involving whole exons, which would not be identified by the aforementioned screening procedures. Once the mutation has been identified, screening of the ''at-risk'' members of the family is important to identify the carriers of the gene alteration in order to potentially prevent or timely treat more serious sequelae. With this regard, the report of intracranial hemorrhage in neonates with family history of HHT[10] suggests the usefulness of prenatal diagnosis in order to ensure appropriate medical care for the mutation carriers at childbirth.

CLINICAL FEATURES

Nose

Recurrent epistaxis represents the most common and, frequently, the initial symptom of the disease, affecting more than 90% of HHT patients. It begins by the age of 10–20 years and becomes more severe over time. These episodes may be so mild as to never suspect the presence of HHT, or so severe as to require iron supplementation and multiple transfusions.[1] Although nose bleeding usually does not represent the prevalent cause of death in HHT patients, it significantly compromises the quality of life of the affected persons,[16] thus justifying the multiple efforts to find a definite therapy for this symptom.

Epistaxis treatments include cauterization, septal dermatoplasty, laser ablation, and transcatheter embolotherapy, but unfortunately, results have been controversial. Medical therapy includes estrogens, inducing a metaplasia in the nasal mucosa, and antifibrinolitic drugs.[1] Antifibrinolitic drugs are administered as a nasal ointment[12] or orally, leading to less-frequent epistaxis episodes.[13]

Skin

Mucocutaneous telangiectases are usually found later in life with regard to epistaxis and affect the lips, tongue, palate, fingers, face, conjunctivas, trunk, arms, and nail beds. Bleeding from these telangiectases is possible, but rarely clinically important. The therapeutic options, usually considered for esthetic reasons, include topical agents and laser ablations.[1]

Lung

Pulmonary arteriovenous malformations (PAVMs) represent a direct connection between a branch of the

pulmonary artery and a vein through a thin-wall aneurysm. Pulmonary arteriovenous malformations occur in 20–60% of the HHT population and prevalence varies according to the type of gene mutation.[14] The direct right-to-left shunts originating in PAVMs are responsible for dyspnea, fatigue, cyanosis, and polycytemia. Paradoxical embolization occurs when emboli (thrombotic or bacterial) originating in the venous circulation bypass the normal filtering system of the pulmonary capillaries, enter the arterial circulation, and occlude arteries in the various organs. Stroke, TIA, and brain abscesses represent the most frequent complications and often the initial manifestation of PAVMs.

Pulse oximetry and chest X-rays are deemed insufficient as screening procedures, whereas the echo-bubble is considered more accurate as it demonstrates the presence of microbubbles in the left atrium after an intravenous injection of agitated saline in four to five cardiac cycles. Angiography is regarded as the gold standard and remains fundamental for those patients requiring transcatheter embolotherapy which represents the best therapeutic approach.[1,15] Recent studies have shown that the echo-bubble remains positive after embolotherapy, even in patients without residual PAVMs visualized with angiography. This may reflect the presence of residual PAVMs that are too small to visualize using angiography.[16]

Brain

Cerebral arteriovenous malformations (CAVMs) may affect about 5–10% of HHT patients. Generally, the neurological symptoms in HHT depend on PAVMs, but it is not uncommon that seizures or paraparesis masks the presence of CAVMs.[1] A subarachnoid hemorrhage is the most severe complication of CAVMs, so severe as to justify screening procedures.[7] Angio-MRI and angiography represent the main diagnostic techniques. Current therapy consists of neurovascular surgery, embolotherapy, and stereotactic radiosurgery.[1]

Digestive Tract

Telangiectases of the digestive tract are similar in size and appearance to those of the nasal and oral mucosa and may affect the esophagous, stomach, duodenum, small bowel, and colon. The actual prevalence of digestive telangiectases is still unknown because of the difficulty of performing endoscopy of the entire digestive tract and because nonsymptomatic telangiectasic lesions are probably present in a larger proportion of patients than those currently diagnosed.

Hemorrhaging from gastrointestinal (GI) telangiectases tends to appear in the fourth or fifth decade of life, affecting 13–33% of HHT patients.[18] However, this is probably an underestimation of the problem as most episodes of hemorrhaging are attributed to epistaxis rather than to a genuine GI bleeding.

While the endoscopic diagnosis of GI telangiectases in the upper digestive tract and colon is relatively uncomplicated, the investigation of the source of small bowel bleeding is more complex. Recently, the wireless-capsule endoscopy has been performed to study HHT patients with obscure and uncontrolled GI bleeding.[19]

The management of the GI bleeding in HHT patients is difficult, especially when the telangiectases are multiple and diffused throughout the entire digestive tract. Photocoagulation or laser procedures are effective in the short term, but less satisfactory over longer periods. Pharmacological therapy with estrogen and progesterone has been demonstrated to reduce the need for transfusions in HHT patients with GI bleeding, but the mechanism responsible for this effect is unknown as yet.[1]

Liver

Vascular malformations in HHT predominantly consist in shunts from the hepatic artery to the hepatic veins; direct connections between portal and hepatic veins are less frequent. The typical clinical manifestations depend on the predominance of such shunts. High-output heart failure results from an anastomosis between the hepatic artery and hepatic veins; portal hypertension is caused by shunts from the hepatic artery to the portal vein; portosystemic encefalopathy is the result of portal to hepatic vein shunting. Finally, anicteric cholestasis is probably due to a hypoperfusion of the peribiliary plexus.[20]

Recently, the abdominal CT multislice scan has been performed in a prospective study revealing that 74% of HHT patients have liver AVMs, most frequently asymptomatic. Doppler ultrasonography has been proposed as the ideal tool for the screening and follow-up of HHT patients with liver involvement. Selective angiography of the hepatic artery is considered the gold standard for diagnosis of hepatic shunting although abdominal CT multislice scan has been demonstrated to be very accurate, safer, cheaper, and better tolerated by patients.[21]

Treatment options for liver involvement in HHT are rather limited. Segmental embolotherapy of the branch hepatic arteries has led to controversial results because of severe complications, such as liver necrosis. Liver transplantation has been performed with good results.[20]

CONCLUSION

In the last few years, the understanding of HHT has expanded rapidly and several diagnostic and therapeutic protocols have been proposed. On the other hand, the management of the disease is extremely complex because multiple organs are involved. The management of HHT

patients should aim at controlling local and systemic symptoms and preventing complications. Epistaxis greatly influences the quality of life of HHT patients and it should be treated especially when the episodes begin to be very frequent and severe. Oral tranexamic acid administration and estrogen therapy in women significantly reduce the frequency of the episodes and ameliorate the quality of life of these patients. Septal dermatoplasty should be proposed when severe epistaxis leads to life-threatening anemia.

In the follow-up of affected persons, the lung and the brain are of particular concern because each may contain clinically silent lesions that can result in sudden morbidity and mortality. Echo-bubble is widely recognized as the most accurate technique to screen PAVMs. Cerebral screening by MRI should be performed at least once during the lifetime of patients, preferably in childhood. Presymptomatic intervention by embolotherapy for both PAVMs and CAVMs may positively influence outcome.

The systematic screening of liver involvement has not been generally suggested because the hepatic shunts are frequently asymptomatic, but considering the high frequency of these lesions and the possibility of severe complications, adult patients should undergo abdominal echo-color-Doppler examination before being included in a follow-up program. Lastly, the screening of the GI telangiectases should be performed in the presence of a severe anemia only partially explained by recurrent epistaxis. Endoscopy permits the diagnosis and treatment of telangiectases located in the upper digestive tract and in the colon with laser coagulation, whereas the examination of the small bowel depends on the availability of capsule endoscopy which, however, cannot be considered yet as a screening procedure because of its high cost. In conclusion, at present, HHT management requires a multidisciplinary approach and the availability of several diagnostic and therapeutic options. Multispecialistic cooperation is needed to develop a specific biological test for HHT diagnosis in addition to new therapeutic approaches for the disease, such as gene replacement.

Hereditary Nonpolyposis Colorectal Cancer (HNPCC) Syndrome

H

INTRODUCTION

Hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, also known as Lynch syndrome, is due to germline mutation in mismatch repair (MMR) genes. It represents a highly penetrant autosomal dominant disorder with classic Mendelian distribution. Although it lacks a pathognomonic phenotype characteristic often seen in some hereditary cancer syndromes, there are some fundamental clinical characteristics that should raise suspicion to the possibility of this diagnosis. A combination of genetic counseling, genetic testing, and aggressive endoscopic surveillance is paramount to management. Surgery remains the definitive therapy in HNPCC-affected patients, but the appropriate role for prophylactic resection remains to be delineated.

OVERVIEW

Sporadic colorectal cancer accounts for 75% of all cases and mostly occurs in persons over 50 years of age. Inherited genetic mutations account for 5% of cases, whereas familial colorectal cancer occurs in 20% of cases where there is no identifiable hereditary syndrome, suggesting genetic contribution and/or common exposures in these families. Hereditary nonpolyposis colorectal cancer accounts for 2–5% of all colon cancers. It has autosomal dominant inheritance pattern with gene penetrance for colon cancer of approximately 70–85%. Hereditary nonpolyposis colorectal cancer gene carriers also have increased risk for malignancy at several extracolonic sites (Lynch II or cancer family syndrome), primarily endometrial (5–10% of all endometrial cancer cases), gastric, hepatobiliary, pancreatic, renal pelvis, ovarian, brain, and small bowel carcinoma.[1] The risk of endometrial cancer is 40–60%, and the risk of all other extracolonic cancers is less than 10–15%. Furthermore, two other named familial syndromes are associated with HNPCC. The combination of HNPCC and cutaneous lesions such as adenomas, eptheliomas, carcinoma, keratoacanthomas, and epidermal cysts is known as Muir–Torre syndrome. The combination of HNPCC and CNS lesions, specifically glioblastoma multiforme, is known as Turcot's syndrome.

Hereditary nonpolyposis colorectal cancer results in accelerated tumorigenesis from polyp to cancer in 1–2 years. Males have overall increased risk, with early age of onset about 45 years. HNPCC-related colorectal cancer accounts for 15–20% of all colorectal cancers diagnosed before the age of 45. Clinicopathological features of colorectal cancers in HNPCC are summarized in Table 1. Multiple colon cancer develops both synchronously and metachronously in patients with less than total abdominal colectomy[2] (about 40% within 10 years). In patients treated with total colectomy and ileorectal anastomosis, the risk of rectal cancer is 1% per year for the first 12 years making annual endoscopic examination of the rectal stump mandatory.[3] In HNPCC syndrome, endometrial and ovarian cancers have a similar mean age at onset (during the fourth decade) to colorectal cancer and usually precede that of sporadic gynecologic malignancy by 15 years. The risk of endometrial cancer (60%) in mutation-positive women exceeds that of colorectal cancer (54%).[4] Ovarian cancer occurs 3.6–13 times more frequently than expected in the general population.[4]

GENETIC ALTERATIONS IN HNPCC

Hereditary nonpolyposis colorectal cancer occurs due to inherited germline mutations in one of at least five mismatch repair (MMR) genes including *hMLH1* at 3p21.3, *hMSH2* at 2p22–p21, *hMSH6* at 2p16, *hPMS1* at 2q31–33, and *hPMS2* at 7p22. The products of these five genes all participate in a multimeric DNA mismatch repair complex. Germline mutation of MMR genes results in the accumulation of somatic errors within the genome at an accelerated pace, leading to an increased risk and early age at onset of malignant neoplasm. A molecular hallmark of HNPCC is a high level of microsatellite instability (MSI), which is a variation in the length of short repeat

DOI: 10.1081/E-EDGP 120024109

Table 1 Clinicopathological features of HNPCC-associated colorectal cancers

Characteristic clinical features:[14]
– Early age of onset about 45 years
– 70% of tumors are proximal to splenic flexure
– Approximately one-third of all tumors occurring in the cecum
– Synchronous and metachronous lesions
– One in five patients diagnosed with HNPCC develops rectal cancer as the index colorectal lesion
– Improved survival compared with sporadic colorectal cancer
Distinct pathological (but not pathognomic) features:[14]
– High grade: mucinous and poor differentiation
– Prominent peritumoral lymphocytic infiltration
– Crohn's disease-like reaction
– Tumor infiltrating lymphocytes
– High level of microsatellite instability (MSI)

DNA sequences that results from this generalized genomic instability. High levels of MSI are found in the DNA from colorectal tumor tissue, but not in the adjacent normal colorectal mucosa, in approximately 90% of individuals with germline mutations in an HNPCC-associated gene, although high levels of MSI are also detected in about 15% of sporadic cases of colorectal cancer.[5]

Mutations in *MLH1* and *MSH2* account for the majority of cases of HNPCC.[6]

Mutations in *MSH6* are thought to account for up to 10% of HNPCC families and are associated with higher frequency of endometrial cancer. Mutations in *PMS1* and *PMS2* have been reported to be associated with only a few HNPCC families.[7] Although the majority of mutations identified in *MLH1* and *MSH2* are small genomic insertions or deletions that result in a truncated protein product, it is estimated that up to 20% of families meeting the Amsterdam criteria may have large deletions or other genomic rearrangements in *MLH1* or *MSH2* that are not detectable by conventional testing techniques.[8]

CLINICAL DIAGNOSIS AND GENETIC TESTING

Diagnosis of this syndrome requires evaluating a combination of clinical criteria including a thorough family history, histological tumor characteristics, and consideration of genetic testing. The International Collaborative group for HNPCC initially developed the Amsterdam Criteria to help identify potential HNPCC patients.[9] However, 60% of families with a known germline mutation do not meet the criteria for the disease,[10] and only 40–80% of patients meeting the criteria have an identified germline mutation.[11] The revised Amsterdam criteria were developed to include extracolonic malignancy.[12] These criteria increased sensitivity by 12%,[13] but the identified MMR mutations were found in only 5–50%.[11] Subsequently, the Bethesda guidelines (Table 2) were developed to help identify patients who should undergo microsatelite instability analysis.[15]

Strategy for molecular testing for HNPCC varies among clinical centers, but generally is performed as a multistep process. At some centers, MSI testing and immunohistochemistry for MLH1 and MSH2 proteins are performed on colorectal tumor tissue from an individual putatively affected with HNPCC prior to consideration of germline *MLH1* and *MSH2* testing, as it may help more accurately target individuals who are likely to carry germline mutations.[16] This strategy has been endorsed by the American Gastroenterological Association in its position statement on genetic testing for hereditary colorectal cancer.[17] Tumors are considered to have high MSI when two or more of a panel of two mononucleotide (Bat 25 and Bat 26) and three dinucleotide repeats (D5S346, D2S123, and D17S250) show differences between the length of the microsatellite repeat regions amplified in tumor and normal DNA. Once high level of MSI is detected in tumor DNA, germline testing (typically performed on peripheral lymphocytes) by sequencing, conformational-sensitive gel electrophoresis (CSGE), or single-strand conformation polymorphism (SSCP) analysis for mutations in *MLH1* and *MSH2* is considered. Loss of MLH1 or MSH2 protein

Table 2 Bethesda guidelines for testing of colorectal tumors for MSI

– Individuals with cancer in families that meet the Amsterdam criteria
– Individuals with two HNPCC-related cancers, including synchronous and metachronous colorectal cancers or associated extracolonic cancers
– Individuals with colorectal cancer and a first-degree relative with colorectal cancer and/or HNPCC-related extracolonic cancer and/or a colorectal adenoma; one of the cancers diagnosed at age less than 45 years, and the adenoma diagnosed at age less than 40 years
– Individuals with colorectal cancer or endometrial cancer diagnosed at age less than 45 years
– Individuals with right-sided colorectal cancer with an undifferentiated pattern (solid/cribriform) on histopathology diagnosed at age less than 45 years
– Individuals with signet-ring-cell-type colorectal cancer diagnosed at age less than 45 years
– Individuals with adenomas diagnosed at age less than 40 years

staining by immunohistochemistry may direct which gene to target for germline analysis. Individuals with low or absent levels of MSI in tumor DNA are unlikely to harbor germline MMR gene mutations, and germline testing is usually not pursued. If germline testing reveals a mutation in a putatively affected family member, the HNPCC diagnosis is confirmed, and genetic testing of at-risk family members will provide true positive or negative results. If no mutation is detected, or if a variant of unknown clinical significance is detected, further genetic studies for large genomic rearrangements may be pursued, or segregation analysis in families carrying the same variant may be initiated. Ultimately, if a mutation cannot be identified, further testing of at-risk relatives should not be pursued, because testing will not be conclusive; a negative result could be a false negative because current testing may not be capable of detecting a mutation even if present. If MSI testing is not possible in the affected individual because of the absence or condition of the tumor specimen, or if the first three conditions of the modified Bethesda criteria are met, AGA guidelines support consideration of initial germline testing in the affected individual. Although it is possible to initiate germline testing with an at-risk family member when an affected family member is not available for testing, this strategy can only yield positive or inconclusive results. In this situation, only the identification of a mutation in a family member can enable a true negative result.

Genetic testing should be offered when results could influence the medical management of that patient or the patient's family members. It should always be done in the setting of pre- and posttest genetic counseling, as endorsed by the American Society of Clinical Oncology in its position statement on genetic testing for hereditary cancer.[18] The process of genetic counseling includes providing risk assessment, educating patients about testing options, discussing the implications for medical management, and providing supportive counseling to the individual and their family.

SURVEILLANCE

Once a diagnosis of HNPCC has been made, or the diagnosis is indeterminate based on genetic analysis, aggressive screening protocols should be implemented. Although screening programs in average-risk people prevent death from colorectal cancer, no data are available regarding the effectiveness of surveillance in hereditary colorectal cancer syndromes, as people with genetic risks are excluded from colorectal screening trials and a randomized trial with a no-screening arm for patients with genetic risk is not feasible. Observational studies performed on families with HNPCC and FAP suggest a stage shift toward earlier stages and a probable reduction in colorectal cancer mortality among screen-detected cancers. In HNPCC, current recommendation for surveillance includes full colonoscopy starting at age 20–25 years (or 5 years younger than the youngest age at diagnosis in the family) and repeated every 1–2 years.[19] Annual colonoscopy should ensue at age 40. Rectal stump surveillance with annual sigmoidoscopy should continue in patients after subtotal colectomy. This level of screening has been shown to decrease the risk of colorectal cancer by greater than 50% and 65% fewer colorectal cancer deaths.[20,21] Screening for extracolonic malignancy in Lynch II syndrome has not proven as beneficial as that for colorectal cancer because of lack of sensitivity for the available screening modalities. Nevertheless, recommendations exist. For endometrial and ovarian cancer, annual transvaginal ultrasound with endometrial aspirate cytology and CA-125 is recommended starting at age 25–35 and repeated every 1–2 years.[19] While upper GI endoscopy and genitourinary ultrasound with urinalysis and cytology are not recommended in the entire HNPCC population, they may be helpful and are recommended in pedigrees that show a propensity toward malignancy at those sites.

CHEMOPREVENTION

The possibility of chemoprevention in these patients is an attractive area of research. Epidemiological studies have shown that chronic ingestion of nonsteroidal antiinflammatory agents (NSAiDs) reduces the incidence of colorectal cancer and that continued use of oral contraceptive pills (OCPs) decreases the incidence of both ovarian and endometrial cancer.[22] Three separate studies have shown no benefit of oral calcium supplementation decreasing cancer risk in HNPCC patients.[23] No studies have evaluated the role of OCPs in women with HNPCC.

SURGICAL MANAGEMENT

Once colorectal polyps are found, the only effective management is total abdominal colectomy with ileorectal anastomosis. In HNPCC, endometrial and ovarian cancers have a similar mean age at onset to colorectal cancer; therefore prophylactic total abdominal hysterectomy with bilateral salpingo-oophorectomy should be considered at time of colon surgery if the patient is postmenopausal or has completed her family. The success of polypectomy during colonoscopy and the fact that 15–30% of mutation-positive carriers may not develop colorectal cancer have fueled the debate over

prophylactic surgery vs. rigorous endoscopic surveillance and endoscopic polypectomy. Therefore, decision and timing for prophylactic subtotal colectomy should be individualized and based on the histological characteristics of the polyp(s), compliance with surveillance program, and patient's personal preferences.

CONCLUSION

Hereditary nonpolyposis colorectal cancer is the most commonly occurring familial colorectal cancer syndrome. Knowledge of the clinical and pathological characteristics of the syndrome and the possible association with extracolonic malignancies is crucial for identifying patients and families that would benefit from genetic counseling and testing. Management strategies to address the increased cancer risk in carriers include targeted surveillance and prophylactic surgery. Surgery limitations and related adverse effects on morbidity and quality of life should always be discussed in extensive preoperative counseling. Chemoprevention may prove helpful but remains in a state of discovery.

Heteroduplex Analysis (HA)

Philip L. Beales
Institute of Child Health (UCL), London, U.K.

INTRODUCTION

The Human Genome Project has now provided a reestimate of the total number of genes within the human genome, and as specific links are made between genes and disease, the need for simple and cost-effective gene mutation detection becomes increasingly important. Nonetheless, the choice of test undertaken for any given screen presents a challenge, and in doing so, a number of considerations should be taken into account: 1) the level of throughput required; 2) the sensitivity and specificity permissible; 3) the resources available; 4) the speed with which a result is needed; and 5) cost.

Direct sequencing, for long considered the gold standard of mutation detection, is still costly and time-consuming; however, in terms of simplicity, heteroduplex analysis (HA) is unsurpassed in its application and analysis. This chapter will review the technique, its applications, and the latest developments which keep HA at the forefront of scanning technologies.

HETERODUPLEX ANALYSIS

More than 90% of disease-related mutations are caused by ''microlesions'' [single-base substitutions or small insertion/deletions (indels)] rather than large lesions (such as rearrangements or large indels) (Human Gene Mutation Database[1]). Given this overrepresentation of microlesions, it is paramount that mutation detection methods are sensitive to single-base substitutions. The principle of heteroduplex analysis relies on the formation of heteroduplex species formed when there is a complementary sequence mismatch in a double-stranded DNA fragment. The electrophoretic mobility of a heteroduplex is altered relative to a homoduplex and in general tends to retard migration of the fragment. Clearly, if an alteration is homozygous no heteroduplex species will be formed and therefore it will be necessary to mix wild-type and mutant fragments together prior to the denaturation and annealing steps to generate four species: a wild-type homoduplex, a mutant homoduplex, and two heteroduplexes. The occurrence of heteroduplex fragments was, in fact, first reported as a PCR artefact.[2]

Bhattacharyya and Lilley[3] predicted the formation of two forms of heteroduplex depending on the type of underlying mutation. A small insertion or deletion produces a ''bulge'' as a result of a relatively large stretch of unmatched bases in the duplex (Fig. 1). Such ''bulges'' have been directly visualized on electron microscopy.[4] In contrast, a ''bubble'' will form at the site of a base substitution. The net effect on migration of a ''bulge'' heteroduplex is much greater relative to a homoduplex, owing to the bending of the DNA at the site of the bulge. In fact, the larger the sequence mismatch, the greater the bend and, consequently, the greater is the degree of retardation. In contrast, the ''bubble''-type heteroduplex produces only subtle perturbations of structure, owing to less bending of the DNA and hence relatively minor migration defects. Nonetheless, the migration of these species can be further influenced by factors such as the length of fragment and even the nature and position of the mismatch.[5]

Heteroduplex Analysis Matrices

At its earliest inception, the sensitivity of HA was limited by the availability of suitable gel matrices. Slab–gel systems are limited to agarose and polyacrylamide. The improved MDE gel solution (Cambrex) is a polyacrylamide-like matrix with a high sensitivity for DNA conformational changes. The gel's unique structure allows DNA separation on the basis of both size and conformation, thus increasing the probability of detecting sequence differences from as low as 15% achieved in standard polyacrylamide gels to approximately 80%.

A number of modifications to the matrix have been reported to improve the gel's ability to enhance fragment retardation. For example, the use of mild denaturants which exaggerate the effects of the mismatch forms the basis of conformation-sensitive gel electrophoresis (CSGE).[6–8] Ganguly et al.[9] have adapted the technique for use with fluorescently labeled fragments which can then be resolved using the ABI 377 (Applied Biosystems) DNA sequencer platform. They labeled PCR products with either 6-FAM, HEX, or NED prior to heteroduplex formation.

An array of matrices is now available for use with capillary electrophoresis such as cellulose derivatives and hydrophilic polymers substantially improving the resolution of HA.[10–12] One of the earliest reports to describe

the adaptation of HA to capillary electrophoresis employed an entangled polymer matrix under nondenaturing conditions.[13] Rozycka et al.[14] adapted the technique for use with a single capillary fragment analyzer (ABI 310, Applied Biosystems) and were able to achieve high sensitivity in products of <350 bp. Such systems utilize replaceable linear polyacrylamides (LPAs) offering lower viscosity, high resolution, and rapid replacement of matrix thus permitting multiple reuse of the capillary. To attain high-throughput coupled with a greater resolution, Gao and Yeung[15] described temperature-gradient capillary electrophoresis. They exploited the lower melting temperature of heteroduplexes relative to homoduplexes and applied a temperature gradient to partially denature the DNA fragments during electrophoresis. By covering the entire range of melting temperatures of duplexes, they were able to achieve a high sensitivity for single-base substitutions set in a 96-well format. Our group, in an effort to raise the level of throughput without compromising sensitivity, designed a modification called multiplex capillary heteroduplex analysis (MCHA) using the 96-capillary MegaBACE1000 DNA Analyzer platform (Amersham Biosciences).[16] We described an additional level of throughput achieved by multiplexing up to six differently labeled (6-FAM, HEX, or TET) or sized products (up to 494 bp) in a single well. This coupled with 96-sample capability per run allows up to 576 samples in 1 hr or as many as 3000 samples in a day. Multiplex capillary heteroduplex analysis is extremely effective at detecting known alterations (specific) but has proven to be a useful scanning tool for the detection of novel mutations (Fig. 2).

Sensitivity of HA

The sensitivity of heteroduplex analysis has consistently been reported to be high when utilized alone or together with another complementary technique such as single-strand conformation polymorphism (SSCP). Rosetti et al.[17] compared conventional horizontal gel HA with SSCP using known mutations from four different genes. Heteroduplex analysis detected 93% of mutations compared with 67% using SSCP; however, when combined, all mutations were revealed.

A comparison of HA, SSCP, and DGGE used for detecting apolipoprotein mutations in a large cohort of patients with hypercholesterolaemia revealed HA and DGGE to be equally as effective but superior to SSCP.[18]

Recently, Crepin et al.[19] designed an assay combining HA and an SSCP variation they called mutation detection gel analysis (MDGA) for the detection of multiple mutations in MEN1 using fluorescently labeled PCR fragments. Heteroduplexes were resolved on a 0.5 × MDE gel and for MDGA, single-stranded products on an Elliomut gel (Elliotek, Paris), both electrophoresed as a slab using an automated sequencer (ABI 377). Peaks were compared with controls and abnormal profiles subsequently sequenced to reveal the true nature of any underlying mutation. They demonstrated that each mutation cast a specific and reproducible pattern dependent on the base change. Heteroduplex analysis detected 88.5% of mutations and 100% when combined with MDGA. The authors questioned the specificity of the tests and suggested this be remedied by reducing the fragment length to less than 400 bp. They concluded that even if the positive predicted value of the combined test does not reach 100%, the negative predictive value does, a point of critical importance in genetic testing.

The study of Hoskins et al.[16] which tested 12 sequence changes (2 deletions and 10 substitutions) in four Bardet–Biedl syndrome genes concluded that HA when adapted for use on a 3% nondenaturing capillary injected matrix (LPA) gave outstanding sensitivity (100%) alone. Furthermore, they calculated the sample cost to be at least one-tenth that for direct sequencing.

Factors Influencing Sensitivity

A number of factors are now known to influence the ability to detect single-base substitutions, which include the length of the fragment, the position of the mismatch within the fragment, the GC content, and the nature of the mismatch.

Fragment length

Very short (<150 bp) or very long (>600 bp) fragments are considered unsuitable for HA. Rozycka et al.[14] showed a reduction in sensitivity as the fragment length increased above 350 bp. Hoskins et al.[16] using a capillary gel were able to detect mismatches in fragments of up to 500 bp with no deterioration in sensitivity.

scan no.

Position of mismatch

Mismatches within 50 bp of the product start and end are difficult to detect.[14] Therefore, attention to the design of amplification products is paramount.[16]

GC content

The GC content of the fragment in question and the sequence flanking the change can influence the ability of HA to detect the mismatch. This is thought to be due to the three-dimensional conformation adopted by the double-stranded DNA which in turn is dependent on the GC content. The relationship of the GC-rich sequence in the region surrounding the mismatch will also influence detection rates especially if the mismatch is buried in the heteroduplex structure compared with a more superficial location.

Nature of the mismatch

The presence of a mismatch, e.g., a C>T within a double-stranded fragment, will generate four species: a wild-type homoduplex (composed of C:G), a mutant homoduplex (T:A), and two heteroduplexes, one containing a C:A mismatch and the other a T:G. Highsmith et al.[5] designed a DNA ''toolbox,'' a set of molecules of varying length and GC content containing all possible mismatches at a particular location, to determine which factor had the greatest effect on the ability to detect a single-base substitution. They reported that the factor with the greatest effect was the nature of the nucleotide change; the order of detection being G:G/C:C>A:C/T:G>A:A/T:T. They concluded that this hierarchy of resolution was in agreement with the measured thermodynamic stability of oligonucleotides with different base-pair mismatches.[20–22] It was presumed that the larger the distortion due to several unstacked bases, the greater the differential migration in the gel compared with fully complementary strands.

In an analysis of all mutations recorded in the Human Gene Mutation Database (HGMD), Krawczak et al.[23] reported that 60% were transitions. One reason for the predilection toward transitions in any set of alterations is the relatively high incidence of CG>TG and CG>CA substitutions caused by deamination of methylcytosine. Methylated cytosines most commonly occur in CpG dinucleotides and are susceptible to deamination favoring the formation of thymine (CG>TG). CG>CA substitutions occur if, following deamination of a methyl-cytosine in the antisense strand, there is a miscorrection of G>A in the sense strand. In an update to the study of Hoskins et al.[16] (unpublished) these types of mutation accounted for 21% of substitutions and 33% of transitions consistent with Krawczak et al.'s findings. The majority of the remaining transitions were A>G substitutions, with five of seven adenines preceded by another adenine. The local DNA sequence environment may therefore influence the sensitivity of techniques such as MCHA.

ADAPTATIONS

The use of denaturing HPLC systems to resolve heteroduplexes from homoduplexes has been reported for many gene mutations and has been discussed in another chapter. Heteroduplex analysis has been adapted for the detection of specific mutations in numerous conditions including von Willebrand's disease, PKU, hemochromatosis, and rifampicin resistance in tuberculosis.[24–27] As discussed above, test samples which are heterozygous for a mutation provide for a straightforward preparation of DNA heteroduplexes without the need for annealing to a reference sample, an additional step which can be time-consuming. For single-base substitutions the conformational change is often relatively small, but to enhance this difference for specific mutations a special fragment, termed a universal heteroduplex generator (UHG), has been developed.[28] This synthetic sequence is similar to genomic sequence but contains specific substitutions or indels at nucleotide positions corresponding to and contiguous with known mutation sites within the genomic DNA. A PCR-amplified test fragment is mixed with the UHG, denatured, and then slowly cooled to form a heteroduplex which is then electrophoresed on a suitable gel (Fig. 3). If the test fragment contains a point mutation then the heteroduplex will contain both a bulge and bubble, and, consequently, will migrate much more slowly than a heteroduplex without the mutation or a homoduplex.

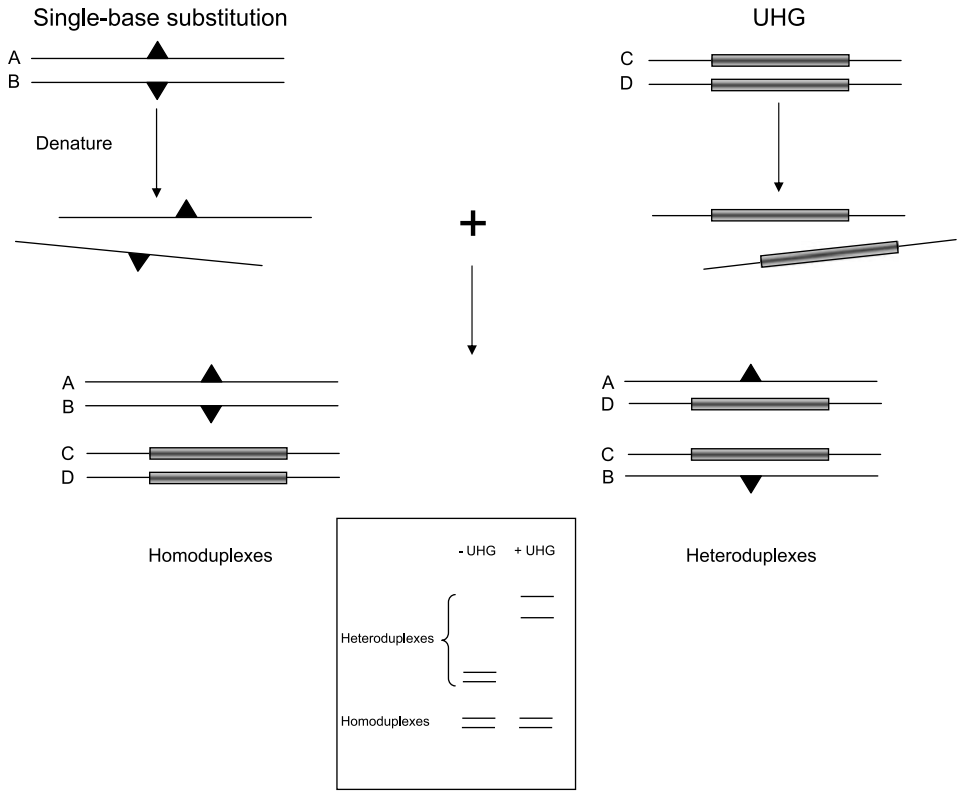

Fig. 3 Schematic of the principle of the universal heteroduplex generator (UHG). The artificial mutation enhances the bubble effect of an existing mutation resulting in greater separation on gel electrophoresis.

CONCLUSION

Despite continuing improvements to direct sequencing methodologies, SSCP and HA remain the most popular scanning techniques. Heteroduplex analysis, although similar in principle to SSCP, is considered to be the simpler and quicker of the two techniques. The relative sensitivities, although initially low, have now been substantially enhanced by the development of new gel matrices and, more recently, the adaptation to fluorescent capillary platforms (e.g., MCHA) enabling mutation detection rates close to 100%. The cost of HA compared with direct sequencing for scanning purposes is much more economical even when abnormal resulting fragments are subsequently sequenced to reveal the nature of the underlying mutation. Developments such as the universal heteroduplex generator allow the technique to be tailored to specific mutations.

Already a number of reports have considered the use of microchip-based electrophoresis in resolving heteroduplexes. Footz et al.[29] described a simple but sensitive method for specific mutation detection for *BRCA1* and *BRCA2*. They utilized a proprietary microfluidic chip (Micralyne, Edmonton, AB) consisting of a defined network of microchannels in glass, similar to conventional capillaries. The chip was filled with a commercially available sieving matrix (POP-6, Applied Biosystems) and loaded with 200–300-bp test PCR products. They experienced very high sensitivity rates for known mutations and reported rapid run times. Each run utilizes a very small quantity of PCR product (250 pL) and virtually no optimization is required. Clearly, similar efforts to increase throughput in a microchip-based system are on the horizon.

ACKNOWLEDGMENTS

I would like to thank Bethan Hoskins for her development of multiplex capillary heteroduplex analysis and for helpful comments in preparing this manuscript. This work is supported by the Wellcome Trust.

HLA Typing by PCR-Based Techniques

J. -M. Tiercy
University Hospital, Geneva, Switzerland

INTRODUCTION

Tissue compatibility is determined by genes of the major histocompatibility complex, known as the human leukocyte antigen (HLA) system in humans. The HLA region comprises 12 genes that are characterized by an extensive degree of polymorphism. Initially detected by serology, HLA diversity has been found by molecular typing techniques to be much larger than anticipated, with over 1500 HLA alleles currently known and more to be disclosed. Three major polymerase chain reaction (PCR)-based methodologies are now used routinely for HLA genotyping: PCR sequence-specific primers (SSPs), PCR sequence-specific oligonucleotide probe (SSOP) hybridization, and direct sequencing of PCR products. The multigenic system, high heterozygosity rate, intralocus and interlocus sharing of sequence motifs, and the growing number of new alleles all make unambiguous HLA allelic assignments a complex issue in molecular diagnostics. The choice of the typing method will be influenced by the clinical setting, scaling of typing samples, emergency, and level of resolution required. Laboratories are facing several challenges: different clinical transplant programs call for different resolution levels, unambiguous allele assignments may require the use of more than one molecular technique, efficient quality assurance systems must be set up to control commercially available reagents, and updates should cope with newly identified HLA alleles.

HLA POLYMORPHISM

HLAs are encoded by 12 genes located in the MHC on chromosome 6. The multigenic HLA system comprises the most polymorphic loci of the human genome, with a total of 1572 alleles currently identified in worldwide populations (Fig. 1).[1] HLA molecules are structurally homologous cell surface glycoproteins, which are classified into class I (HLA-A, HLA-B, and HLA-C) and class II (HLA-DR, HLA-DQ, and HLA-DP) antigens as a function of their structure, tissue distribution, and characteristics in peptide presentation to T-cells. The biological function of HLA molecules is to present pathogen-derived peptides to T-lymphocytes. Because of their biological role as antigen-presenting molecules,[2] HLA diversity has been maintained in human populations to allow the widest possible range of foreign peptides being presented to T-cells. Peptide–HLA complexes are recognized by clonally distributed T-cell receptors (TCRs). TCRs are also able to recognize allogeneic HLA molecules at a high frequency, so that 1–10% of the peripheral blood lymphocytes of an individual can respond to a nonself HLA antigen. Thus immune responses against incompatible HLA antigens represent a major barrier to organ and hematopoietic stem cell (HSC) transplantation.

HLA antigens were initially discriminated by serology (i.e., complement-dependent cytotoxicity assays using alloantisera from multiparous women immunized against paternal HLA antigens). However, it was soon realized that serologically defined antigens could, in fact, be split into subtypes (alleles): first, by in vitro cellular assays, and, second, by DNA sequencing analyses (Fig. 1).[1,2] For example, the 21 DR serotypes are now subdivided into 342 alleles with widely different frequencies in different populations. A centralized repository (http://www.ebi.ac.uk/imgt/hla) of the sequences of all HLA alleles named by the World Health Organization (WHO) Nomenclature Committee for Factors of the HLA System is a very useful tool for clinical laboratories. Early recognition of the limitations of serological typing led to the rapid development of DNA typing techniques combining PCR and the knowledge of sequences of the polymorphic exons of HLA genes. HLA genotyping can be viewed as a parallel analysis of multiple regions of variation (single nucleotide polymorphism, or SNP) and the complexity of the analysis resides in the high number of SNPs in coding regions and the sharing of SNPs among HLA alleles.

Major applications of HLA genotyping concern clinical transplantation programs (i.e., solid organ and HSC),[3,4] HLA–disease associations (e.g., narcolepsy, ankylosing spondylarthritis, Behçet's disease, Birdshot retinochoroidopathy, rheumatoid arthritis, insulin-dependent diabetes mellitus type I, and coeliac disease), and vaccination protocols (e.g., melanoma-specific antigens). HLA polymorphisms are also widely used as informative markers in population genetics studies.[5]

DOI: 10.1081/E-EDGP 120021009

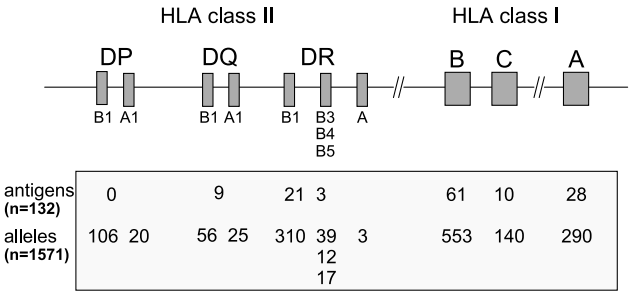

Fig. 1 Schematic representation of HLA class I and class II loci in the MHC that comprises >200 genes on the short arm of chromosome 6. The corresponding number of antigens (as defined by serology) and alleles (as defined by nucleotide sequence) is indicated for each locus. (From Ref. [1].) About 10% of the alleles assigned by the Nomenclature Committee are characterized by silent substitutions. Three HLA class I genes (A, B, and C) located at the telomeric end of the MHC encode, respectively, for the heavy chains of HLA-A, HLA-B, and HLA-C antigens that pair with β_2-microglobulin. (From Ref. [2].) Polymorphic residues are essentially located in the α_1-domains and α_2-domains encoded by exons 2 and 3, respectively, which form the peptide-binding site. HLA class II antigens (DR, DQ, and DP) are heterodimers encoded by an α-chain and a β-chain gene that colocalize at the centromeric part of the MHC. Essentially all of the polymorphisms are located in exon 2 (α_1-domain) of β-chain genes, whereas the *DRA* gene is non-polymorphic, and DQA1 and DPA1 loci exhibit a low level of polymorphism. The HLA-DR subregion presents an additional complexity level with the presence of a second *DRB* gene in most haplotypes: DRB3, DRB4, or DRB5. The nonclassical polymorphic HLA genes—*HLA-DM*, *HLA-DO*, *HLA-E*, *HLA-F*, *HLA-G*, *MICA*, and *MICB*—that code for molecules implicated in the immune response are also located in the MHC. (*View this art in color at www.dekker.com.*)

LEVELS OF RESOLUTION

Three different levels of resolution for HLA typing are usually recognized (Table 1). Low-resolution typing, also referred to as *generic* typing or *two-digit* typing, corresponds to the identification of broad families of alleles that cluster into serotypes (e.g., A*02), and is the equivalent of serological typing (A2). High-resolution typing (four-digit typing) allows the discrimination of individual alleles within each serotype (e.g., A*0201). Intermediate resolution provides information on a limited number of alleles that could be present in a given individual, excluding all other known alleles. In clinical transplantation setting, low-resolution HLA typing is required for solid-organ transplant programs, whereas high-resolution typing is required for HSC transplantation, particularly for unrelated donor matching.[3,4] For HLA–disease association studies, some diseases require low-resolution typing only (B27 for ankylosing spondylarthritis, and B51 for Behçet's disease), whereas other diseases rely on high-resolution typing (DQB1*0602 for narcolepsy).

THE TECHNIQUES

Restriction Fragment Length Polymorphism

In the early age of molecular typing, restriction fragment length polymorphism (RFLP) allowed to discriminate not only the serotypes, but also some groups of alleles subdividing serotypes, particularly for DRB and DQA1/DQB1 loci.[6] However, most polymorphic restriction sites were located in noncoding regions and the technique, although very useful in the late 1980s, was not resolutive enough to cope with the continuously growing HLA allelic polymorphism and was too cumbersome for routine clinical use.

PCR-SSOP

The combination of PCR technology and hybridization with SSOPs was first applied to HLA class II typing[7,8] because of the limitations of DR serology and of the better knowledge of allelic polymorphism at DR/DQ loci. The procedure relies on the locus-specific amplification of the genomic DNA segment comprising the polymorphic sites of HLA alleles, exon 2 for HLA class II genes, and exons 2+3 for class I genes. Amplified DNA is then immobilized on a solid support (dot blot), usually a nylon membrane, and then hybridized with a battery of SSOPs (direct hybridization). The higher the number of probes, the better is the resolution level. The method is well suited for large-scale typing, as many DNA samples can be tested in a single hybridization step, but it requires simultaneous hybridization with a large number of probes for which each melting temperature has to be optimized.

Alternatively, probes are fixed on a solid support, a membrane,[9] a microtiter tray,[10] or microbeads, and a single DNA sample can by genotyped in a single hybridization step. Ideally suited for rapid HLA typing as required for clinical transplantation, the method has now been developed by a number of commercial companies that have automatized the hybridization/washing/reading steps, thereby allowing high-throughput typing. Usually 50–100 probes per locus are used for intermediate/high-resolution typing.

PCR-SSP

The procedure relies on the specificity of primer extension that is matched or mismatched with the template at its 3′

Table 1 HLA nomenclature and levels of resolution

HLA	Definition	Resolution
A2	Refers to the A2 antigen defined by monospecific/polyspecific antisera	Low
A*02	Any of the 64 known A*02 alleles (A*0201–0264)	Low
A*0205/0208/0214	Any one of these three alleles; other A*02 alleles are excluded	Intermediate
A*0201	Allele defined	High
A*0232N	Allele with a substitution in the coding sequence that leads to a stop codon (null allele)	High
DRB1*030101 and DRB1*030102	Two DRB1*0301 alleles that differ by a silent substitution in exon 2	High
A*24020102L[a]	A*2402 allele with low expression due to a mutation in intron 2 sequence	High

[a]The first two digits refer to the serotype (A*24), the third and fourth digits define substitution(s) in the coding sequence (A*2402), the fifth and sixth digits describe synonymous substitution(s), and the seventh and eight digits refer to substitution(s) in intron or 5′ or 3′ sequences. N and L mark alleles with no or low surface expression, respectively.

end. A combination of two primers designed for each of the two polymorphic sequence motifs in cis allows the identification of an allele or a group of alleles that are characterized by these two motifs. The presence or absence of the two motifs in cis is usually detected by gel electrophoresis,[11] but other detection methods have been developed.[12] The method is rapid and ideally suited for a small number of samples. The method can be applied for low-resolution typing, using primer combinations that detect all alleles within a given serotype, as well as for high-resolution typing. Depending on the HLA phenotype, a combination of 300–400 different primer mixes is necessary to determine the HLA-A/B/C/DRB1/DRB3/DRB4/DRB5/DQB1 alleles in a given individual.

Direct Sequencing

The gold standard remains the complete sequencing information of HLA alleles. In routine practice, usually only the most polymorphic exons are sequenced: exon 2 (270 bp) for class II, and exons 2+3 (540 bp) for class I genes. A number of sequencing protocols have been published so far (e.g., Ref. [13]). These are based either on locus-specific PCR and sequencing of both alleles at once, which is faster but implies possible ambiguities in sequence interpretation, or on group-specific PCR that allows to separate the alleles, which is more time-consuming but avoids ambiguities. Protocols validated through the 13th International Histocompatibility Workshop are available at the following web site: http://www.ihwg.org/components/sbtover.htm.

Conformational Analyses

Discrimination of HLA alleles can also be achieved by analyzing variations in DNA conformation (secondary structures of PCR products) by polyacrylamide gel electrophoresis. Single-strand conformation polymorphism or heteroduplex analyses have been implemented by using a reference strand in duplex formation, which increases the resolution power of the technique.[14] The reference strand conformation-mediated analysis (RSCA) method, as a high-resolution technique, can be applied for donor selection in the HSC transplantation setting.

Microarrays

A few pilot studies, based on known polymorphisms, have demonstrated the feasibility of genotyping HLA-B alleles by SSOP hybridization with 137 probes[15] immobilized on glass supports, or five HLA-A exon 2 polymorphic sites using ligase detection reaction.[16] Direct SSOP hybridization with >9000 test samples spotted on a glass slide has been reported.[17] Therefore the development of microarrays in the field of HLA typing is still in its infancy.

THE CHOICE OF THE METHOD

Clearly, two parameters will determine the choice of the methodology: the level of resolution required (low, intermediate, and high) and the clinical setting (i.e., organ or HSC transplantation, HLA–disease associations, bone marrow donor registry screening, and population genetics studies). For solid-organ transplantation where the method has to be fast and of low resolution, PCR-SSP or reverse PCR-SSOP hybridization should be an adequate technique. For high-throughput typing, such as for bone marrow donor registry recruitment or population genetics studies, reverse PCR-SSOP hybridization is well suited, whereas for final stem cell donor matching (high resolution), PCR-SSP/SSOP or RSCA combined

with direct sequencing should provide the highest level of resolution.

NEW HLA ALLELES

Approximately 50–100 new alleles are discovered each year and most of these are classified in a given serotype based on sequence homology only. Programs for organ sharing and bone marrow donor searches are still largely based on the serological types defined by microlymphocytotoxicity assays. Through international workshops and collaborative studies, data that link individual alleles defined by molecular typing and serotypes are now available.[18] New variants are not expected to have a significant impact in clinical transplantation because of their extremely low frequency and because of the linkage disequilibrium between HLA loci. However, it is important to be able to discriminate such rare alleles, particularly in patients with hematological disorders for whom unrelated HSC transplantation is the best therapeutic option. The functional relevance of new alleles that differ in exons coding for domains of the HLA molecules that do not directly interact with TCRs is unknown. Because of new polymorphisms, past allele assignments may become outdated. Updates of previous typing results based on newly identified alleles can be performed based on stored typing patterns.[19]

CONCLUSION

Although HLA genotyping remains a challenge in molecular diagnostics, PCR-based HLA typing techniques have dramatically improved the quality of patient–donor matching and have contributed to the success of transplantation programs. For just a few diseases, HLA alleles are diagnostically useful; but for several autoimmune disorders, high-resolution HLA typing has provided important insights into pathological mechanisms. A still open question is whether to drop out serology and rely only on DNA typing. Although a few laboratories have already made that choice, a frequently mentioned argument in favor of maintaining serology is the need to monitor cell surface expression of HLA antigens and detect possible null alleles that would be mistyped as functional alleles by molecular typing because the mutation is located in a region that is not tested by the technique (intron or nonpolymorphic exon sequence motif). In kidney transplantation, where cytotoxicity crossmatch remains the gold standard, monitoring the expression of HLA antigens at the cell surface by using serology should be helpful. The diversity of the HLA system is so high that clinical laboratories must continuously cope with new polymorphisms, adapt quality assurance systems for reagents and algorithmic softwares, and ensure that appropriate interpretations are provided in case of typing ambiguities. Depending on clinical application, such ambiguities need to be resolved, sometimes at the expense of maintaining several molecular techniques running in parallel.

HLA-DQA1 Typing Using DNA Microarray

INTRODUCTION

Genes of the major histocompatibility complex (MHC) encode human leukocyte antigen (HLA) molecules and have been implicated in the genetic background of many autoimmune and infectious diseases. Among the three classes of HLA molecules, class II genes, primarily the DR and DQ loci, are thought to be functionally significant in disease susceptibility; however, associations have been demonstrated with the class I and class II regions as well.[1] The human genome project has stimulated research on the relationship between specific HLA alleles and disease susceptibility, creating a need for high-throughput HLA typing. To demonstrate the methods of developing a microarray system for high-throughput HLA typing, DQA1, being the least complex molecule of class II HLA genes, was selected as a model. Understanding experimental conditions and accuracy of data analysis to distinguish allelic single-base changes will provide a foundation for the development of a DNA microarray to detect base changes in other HLA genes of interest.

MHC AND HLA

The MHC is a genetic locus which spans 4 Mb in the p21 region of chromosome 6 and is responsible for controlling the immune response. Encoded in this region are several classes of proteins referred to as HLA, which are divided into three groups: class I, class II, and class III. The HLA class I molecules are designated HLA-A, HLA-B, or HLA-C and are encoded by genes of the MHC, which participate in antigen presentation to cytotoxic T ($CD8^+$) cells. The HLA class II molecules are designated DP, DQ, or DR and are encoded by genes of the MHC, which participate in antigen presentation to helper T ($CD4^+$) cells. The HLA class III region is located within the HLA region because its components are related to the functions of HLA antigens, or are under control mechanisms similar to the HLA genes. HLA class III contains loci responsible for complements, hormones, and intracellular peptide processing and other developmental characteristics.[2] HLA class I and class II genes play an important role in the communication between cells, determining whether transplanted tissue or bone marrow is histocompatible (accepted as self) or histoincompatible (rejected as foreign), and are thought to be functionally significant in disease susceptibility.

The expression of all MHC loci is codominant; both the set of alleles inherited from one's father and the set inherited from one's mother are expressed on each cell. In most cases, the entire linked MHC, called a haplotype, is inherited intact, without recombination.[3] Research has indicated that individuals with certain allelic genotypes may be at higher risk for developing diseases affecting the immune system. Because both alleles contribute to the phenotype equally, it is important to investigate the genotypes in disease association studies rather than alleles on their own.

There are three standard levels of HLA typing: low, medium, and high. Low-resolution typing defines broad families of alleles. Medium-resolution typing helps determine that the individual has one of the many alleles within a low-resolution group and eliminates others. High-resolution typing is an effort to definitively state which allele resides at a locus for an individual.[4] Solid organ transplant programs work well with low-resolution typing, whereas bone marrow programs require high resolution.

The HLA system has the greatest degree of polymorphism in the human genome. As of August 2003, there were over 1600 alleles recognized at the classical loci (Table 1).[5] Mutations and polymorphisms are constantly being identified, making HLA typing for donor and recipient matching in transplantation increasingly complex and creating the need for analytical tools to detect genetic patterns potentially related to disease. The completion of the human genome project has given scientists the ability to identify genomic variation in cells and tissues quantitatively, simultaneously, and automatically under a variety of conditions using high-throughput microarray analysis.[6]

MICROARRAY TECHNOLOGY

Microarray technology can be used to distinguish between DNA sequences that differ by as little as a single nucleotide polymorphism (SNP). Microarrays generally

It is not feasible to publish a comprehensive list for each loci within the HLA system, as new members of allele families are being added constantly. The most current accepted alleles at any loci can be found using the following web site link: http://www.anthonynolan.com/HIG/data.html.

work as follows: 1) DNA ''probes'' complimentary to the gene of interest are bound to a solid substrate (i.e., glass); 2) DNA ''targets'' (i.e., sample) are added and hybridize where the sequence is complimentary to the probe and anneal to form a DNA duplex; and 3) hybridized targets are detected using a reporter system [i.e., enzyme-labeled fluorescence (ELF; Molecular Probes, Eugene, OR)]. A good model system for HLA typing using DNA microarray technology is the HLA class II gene—*DQA1*.

HLA-DQA1

Class II genes are composed of both α-chains and β-chains in the HLA-D region and are responsible for 644 different alleles. The HLA-DQ molecules, consisting of two polymorphic polypeptide chains, account for 24 of the known class II alleles and are thought to be involved in the pathogenesis of several human diseases.[7] The HLA-DQA1 region of the *HLA-D* gene, located near the centromere, is responsible for assisting in the distinction of intruder cells from the body's own cells, and is one of many locations where the donor and recipient are required to have identical alleles. The DQA1 locus tends to be an ideal area of basic human identification. Because of the small number of known alleles associated with DQA1, substantially less than other areas, it makes a good model for that of other areas. This type of array serves as a model for typing other important gene regions in the HLA complex and can also be used to generate arrays for the detection of single-base changes in other genes of interest.

HLA-DQA1 TYPING (LOW RESOLUTION) USING DNA MICROARRAY

Oligonucleotide Probe Design and Synthesis

Design oligonucleotide probes by looking for an area of the sequence that matches the order for the selected allele but for no other group.[8] A combination of sense and antisense sequences can be used to formulate the microarray for low-resolution HLA-DQA1 typing (Fig. 1). When developing and choosing optimal probes, take into consideration: 1) desired probe length: the optimal probe length is 12 bases, which provides a high level of discrimination between alleles and allows hybridization to take place at room temperature; 2) placement of the mismatched base(s): optimal placement of the mismatched bases is near the center of the sequence; 3) suitable G/C content: G/C content should range from 42% to 58%; and 4) free energy values: values of free energy should be greater than $-3.1\ \Delta G$ so that the duplex formations are kept to a minimum. Manual design is not very successful. The best results are obtained by using

Fig. 1 *(Continued next page)* (b) Low-resolution probes for the typing of HLA-DQA1*01 alleles: a region of the *HLA-DQA1* gene showing variations in the sequence for each allele. Probe sequences are shown by either a light bar (sense probe) or a dark bar (antisense). (c) Low-resolution probes for the typing of HLA-DQA1*05, HLA-DQA1*04/HLA-DQA1*06 alleles: a region of the *HLA-DQA1* gene showing variations in the sequence for each allele. Probe sequences are shown by either a light bar (sense probe) or a dark bar (antisense). (*View this art in color at www.dekker.com.*)

software that implements (1)–(4) above and searches out the ideal placement of the probe along the sequence of the gene. Produce amine-modified probes by means of a standard phosphoramidite and segmented synthesis strategy for the simultaneous synthesis of a large number of oligonucleotides.

DNA Microarray Preparation

An aliquot of synthesized amine-modified oligonucleotide probes should be diluted to the desired concentration (10 μM) and attached to a glass slide. The slides should be dried at room temperature and washed with distilled deionized water before use.

Preparation of Target

Prepare DNA targets by polymerase chain reaction (PCR) amplification of the 189-bp region of the *HLA-D* gene (DNA isolates) using the 5′ biotinylated primer sequences (forward primer: 5′CACCCATGAATTTGATGGAG; reverse primer: 5′TCATTGGTAGCAGCGGTAGAGTTG). PCR is performed in a total volume of 50 μL consisting of 10 mM Tris–HCl, pH 8.0, 50 mM KCl, 0.01% gelatin,

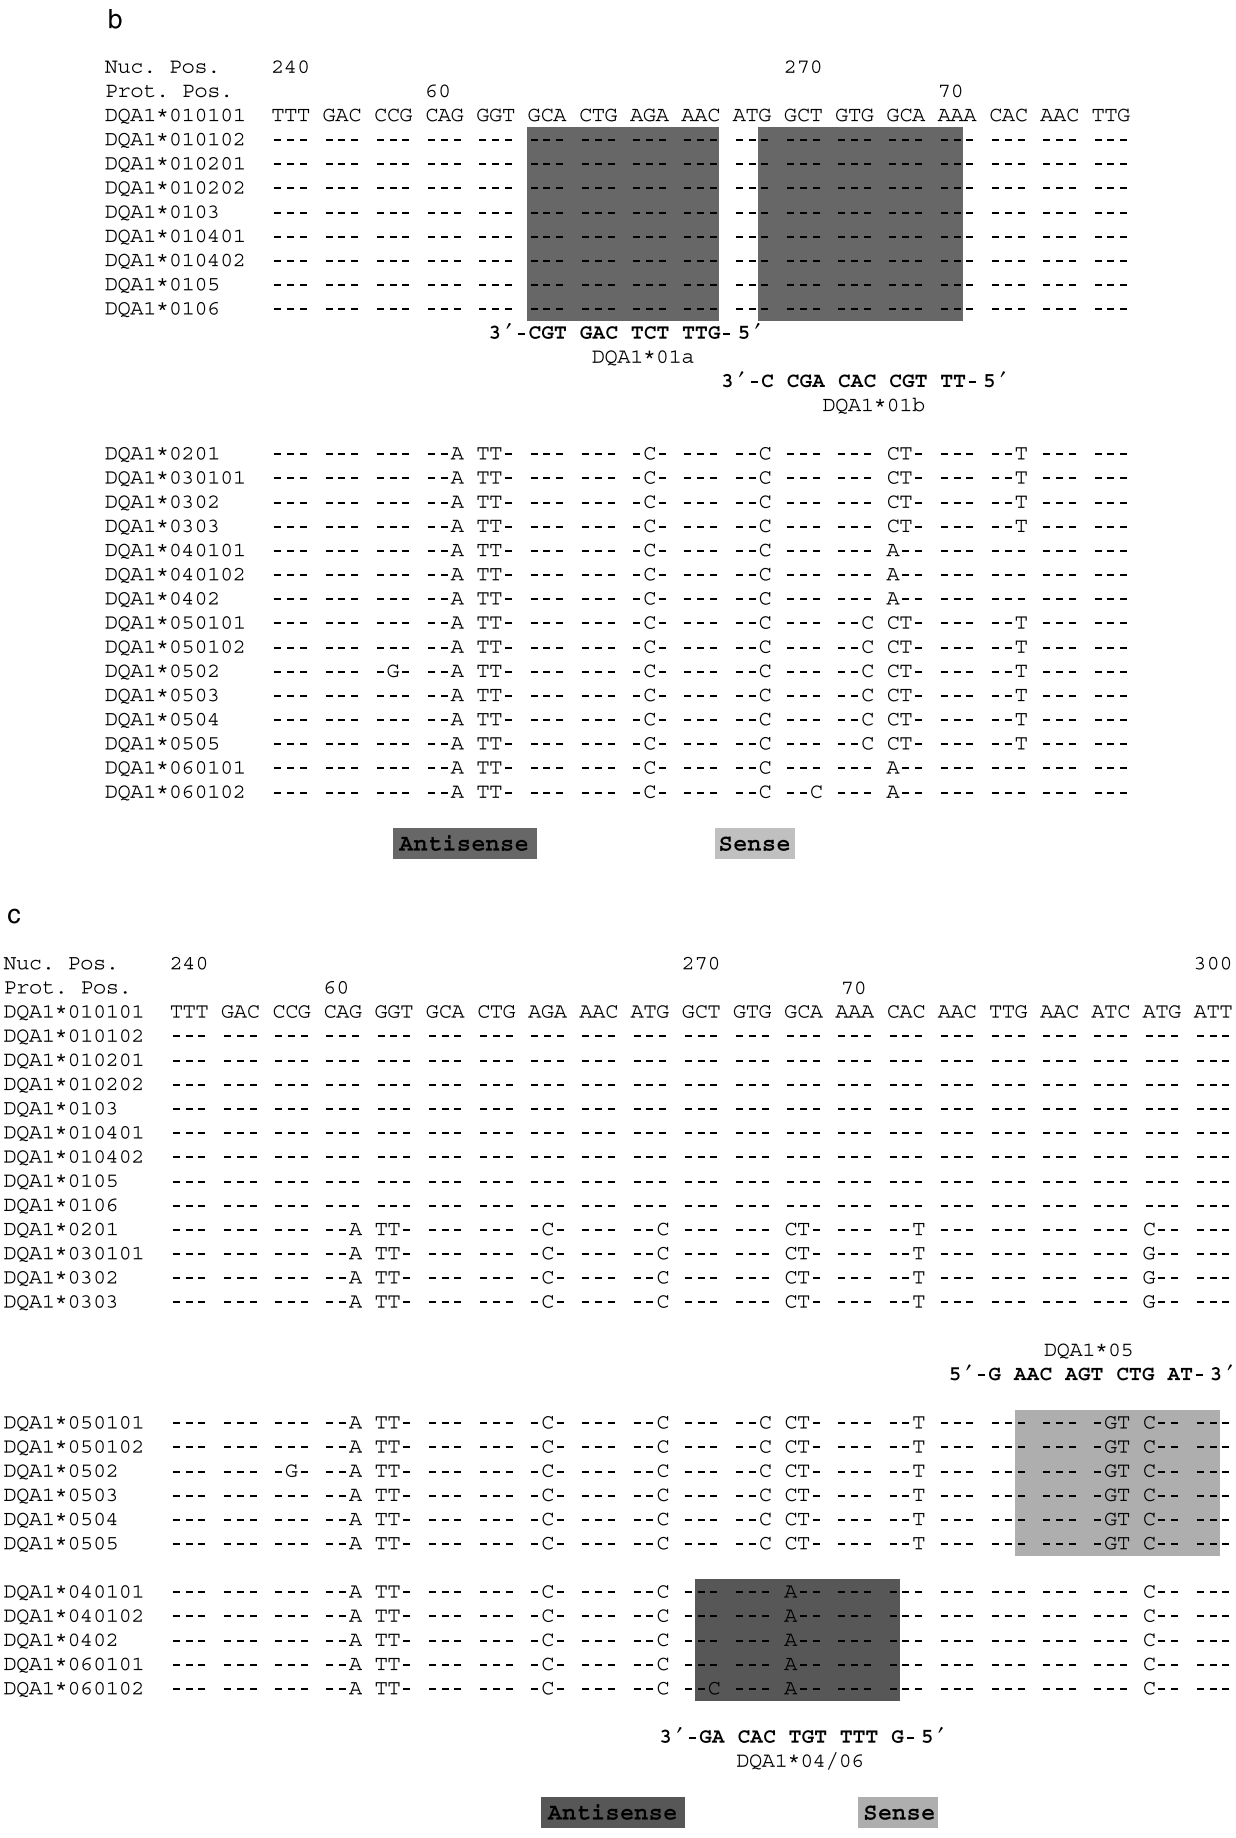

Fig. 1 (*Continued*).

[a]Antisense probe.
[b]Sense probe.

100 μM dNTP, 1.5 mM $MgCl_2$, 20 pmol of each primer, and 2.5 U of AmpliTaq Gold DNA Polymerase (Roche Molecular Systems, Branchburg, NJ). The amplification involves a 10-min activation time at 94°C, followed by 30 cycles at appropriate denaturation, annealing, and extension temperatures (i.e., 94°C for 30 sec, 54°C for 1 min, and 72°C for 30 sec) with a 5-min extension after the last cycle.

Hybridization

Resuspend cDNA targets in 5× SSC/0.1% sodium dodecyl sulfate (SDS) and denature at 99°C for 2 min. Add 50 μL of solution to a prewetted glass slide (2× SSC, 0.1% SDS), cover with a glass cover slip, and place in a moist chamber and incubate at 65°C for 12–18 hr. Then wash in 2× SSC/0.1% SDS for 2 min, 1× SSC, 0.2× SSC, and 0.05× SSC sequentially for 1 min each before scanning.

Perform hybridizations in 6× SSC, 0.3% SDS, and 5 μL of the amplified DNA. Heat-denature then wash slides for 15 min at room temperature in 3.3 M tetramethyl ammonium chloride (TMAC).

Detection of Fluorescence

Incubate slides with 50 μL of streptavidin–alkaline phosphatase conjugate (1:1500 dilution in phosphate-buffered saline/0.2% bovine serum albumin/0.1% Tween-20) for 2 hr at room temperature. After two 10-min washes

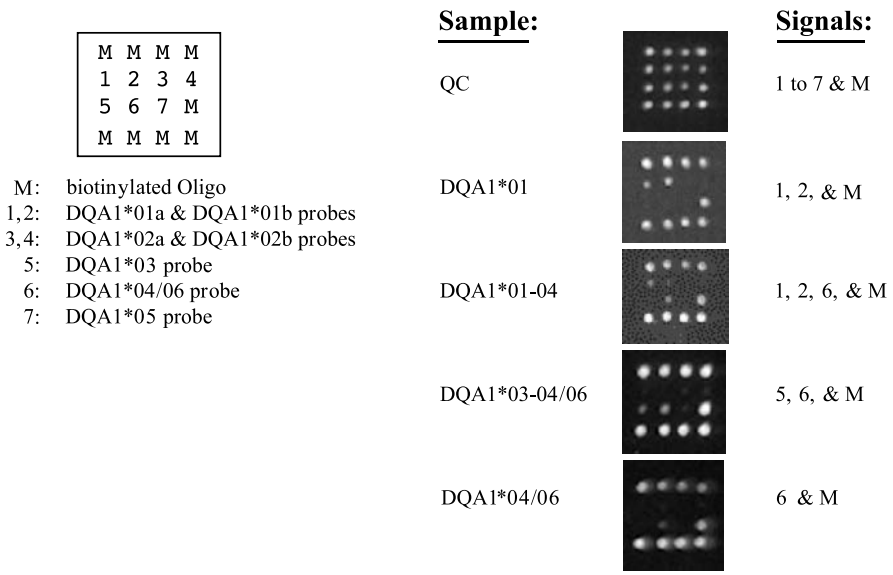

Fig. 2 Low-Resolution Typing HLA-DQA1: (Left) DNA microarray illustrating positions of probes for alleles 01, 02, 03, 04/06, and 05 in the HLA-DQA1 gene. On the bottom left is probe nomenclature for the corresponding probe numbers on the DNA microarray. (Right) Samples were tested on the array in a blinded fashion. The spot diameter is 120–130 μm, with 500 μm spacing. Alleles found by DNA chip analysis are displayed by positive probe signals. All photographs were taken with the use of a CCD camera under a UV light source.

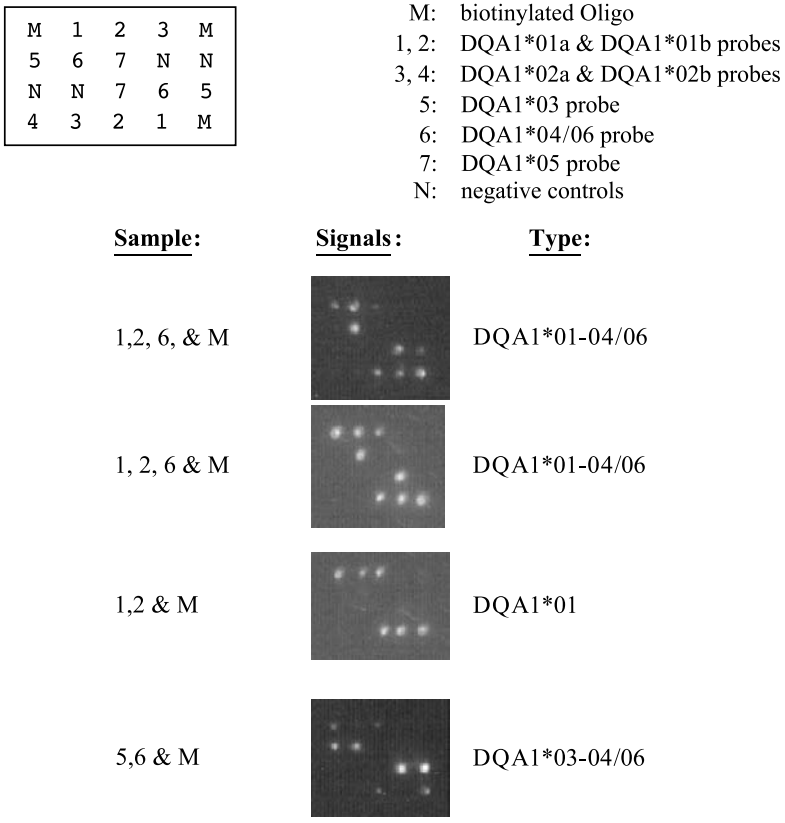

Fig. 3 HLA-DQA1 typing of cervical carcinoma and control samples using DNA microarray: (Top) DNA microarray illustrating positions of probes for alleles 01, 02, 03, 04/06, and 05 in the HLA-DQA1 gene. On the right is probe nomenclature for the corresponding probe numbers on the DNA microarray. (Bottom) The same samples used for ''gold standard''were tested on the array. The spot diameter is 120–130 μm, with 500 μm spacing. Alleles found by DNA chip analysis are displayed by positive probe signals. All photographs were taken with the use of a CCD camera under a UV light source.

in 2× SSC/0.1% SDS, add 50 μL of ELF substrate (Molecular Probes) to the slide and cover with a coverslip. Place in humidity chamber protected from light and incubate overnight. Results are obtained by viewing the slides with an ultraviolet (UV) transilluminator or with the use of a charged-couple device (CCD) camera over a UV light source.

HLA-DQA1 Typing Study

A rapid and accurate test that distinguishes one allele from another was the focus of this investigation. To distinguish one allele from another, short oligonucleotide probes 12 bases in length attached to a glass slide were utilized (Table 2). Each probe represents a different low-resolution allele in the DQA1 region. Details of the application of these inkjet microfabricated arrays for HLA-DQA1 low-resolution typing of DNA samples from HLA class II reference panel (UCLA Tissue Typing Laboratory, CA) can be found in Haddock et al.[8] HLA-DQA1 microarrays were fabricated at the Houston Advanced Research Center, The Woodlands, Texas, using microspotting quill pins. Biotinylated polymerase chain reaction (PCR) products were allowed to hybridize to the prefabricated glass slides and hybridization signals detected using enzyme-labeled fluorescence (ELF) with the aid of a charged-couple device (CCD) camera.

Low-resolution alleles were successfully typed using a 189-base pair region of the HLA-DQA1 gene by observing easily recognizable positive hybridization patterns. In Fig. 2, detection of homozygous as well as heterozygous samples was accomplished by viewing probes fluorescing under UV light. All samples were obtained from UCLA's Standardized DNA Reference Panel for HLA class II. Each DNA sample was labeled with a letter or letters, which corresponded to the key provided in the Standard Reference Material. The results were compared to the key to verify that the HLA typing of the sample was the same. This type of array is important because it encompasses the use of short oligonucleotide probes that provide a high level of discrimination between alleles. Furthermore, this type of

array serves as a model for typing other important gene regions in the HLA complex. It can also be used to generate arrays for the detection of single-base changes in other genes of interest. In order to test the above samples for HLA-DQA1 using microarray technology, a 4×5 DQA1 array was generated as illustrated in Fig. 3. DNA isolated from cervical cancer patients and normal controls were used for HLA DQA1 typing. The results indicated low-resolution typing of DQA1 of both homozygous and heterozygous individuals can be done using DNA microarray.

Quality Control

To verify the working capabilities of each probe in the array, a mixture of 20–22mer prefabricated target DNA containing species complementary to each wild type and mutation probe should be developed and used to validate DNA microarrays for each batch of chips prior to use for typing.

CONCLUSION

It has been shown that microarray technology for identification of HLA alleles can be used for HLA typing;[7,9] however, specificity of signal detection, accuracy of data analysis, optimization of experiment conditions, and ever-increasing identification of new HLA alleles being identified remain as obstacles. The future of using DNA microarrays in HLA typing lies in companies' active development of technology that can compensate for these obstacles. To date, no solid platform for HLA typing using microarrays is available commercially. However, promising development is underway. TeleChem International, Inc., NGS-ArrayIt, Inc. Division (Sunnyvale, CA) has developed Next Generation Screening™ (NGS™) technology, an exciting new technology that uses ''patient-on-the-chip'' microarray technology as a very cost-effective means of HLA analysis. BioCore Co., Ltd. (5th Floor, Heasan Building, 108-1, Yangjea-dong, Seocho-gu, Seoul, South Korea) is in the process of commercializing an HLA chip that can identify the HLA-DR genetic locus type. In the mean time, one way researchers can get around the inherent obstacles is by knowing the alleles and frequencies that are present in the populations they are studying. Web sites listing the frequencies of HLA alleles (www.allelefrequency.net) and their linkage to a particular disease in worldwide populations (Anthony Nolan Trust: http://www.anthonynolan.com/HIG/data.html) have been established.[10] Networking of accumulated HLA data could be the key in helping investigators successfully make use of DNA arrays in HLA typing and propelling the understanding of the association of disease susceptibility, clinical manifestation of disease screening, and diagnostic development.

INTRODUCTION

Several current developments in the field of human papillomavirus (HPV) research show the increasing need for HPV typing. First, the number of known HPV types is still increasing. Although novel HPV types are often isolated from malignancies, their transforming potential can only be determined from a combination of in vitro and epidemiological studies, the latter including typing. Second, many HPV infections consist of multiple HPV types and in those cases, typing is necessary to determine the contribution of the individual HPV types. Third, there is an increasing interest in HPV vaccination, which entails studies of geographical distribution of HPV types and their associated diseases as a basis for vaccination programs. Moreover, HPV typing is of utmost importance to monitor the efficacy of HPV-based vaccines, the latter being type-specific.

A large range of HPV typing methods is available, all with respective advantages and limitations. In this article, we will describe briefly the most important current HPV typing techniques and give recommendations for their respective applications.

HUMAN PAPILLOMAVIRUS TYPES

Human papillomaviruses (HPVs) are associated with various benign and malignant epithelial proliferative diseases. Over 100 genotypes of HPV are recognized.

An HPV isolate is described as a novel type if the nucleotide sequence of its E6, E7, and L1 genes differs more than 10% from that of any other HPV type. Based on tropism, a distinction can be made between *cutaneous* HPV types that infect the epidermis and *mucosal* HPV types that infect the epithelia of the anogenital or the aerodigestive tract.

In vitro studies showed that a group of phylogenetically related *mucosal* HPV types has oncogenic potential: their E6 and E7 proteins interfere with cell cycle regulation by mediating degradation of p53 and pRb proteins, respectively. These oncogenic HPVs, designated *high-risk* (HR) HPVs, are an important causal factor in carcinogenesis of the uterine cervix.[1] Epidemiological studies have shown that HR-HPVs include types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, and 82 and probably also types 26, 53, and 66.[2] Nononcogenic or *low-risk* (LR) genital HPVs are phylogenetically distant from the HR-HPVs. They include HPV 6, 11, 40, 42, 43, 44, 54, 61, 70, 72, 81, and CP6108. Their E6 and E7 proteins are less competent in interfering with p53 and pRb functions, and they can cause benign proliferations such as condylomata acuminata (genital warts). For a number of mucosal HPV types, the risk has not been determined yet.[2]

Cutaneous HPVs belong to other phylogenetic subgroups than mucosal HPVs. Some of them play a role in benign epidermal proliferation, e.g., HPV 1 which is causally related to verruca vulgaris (warts). In addition, associations between cutaneous HPVs and malignant skin diseases were discovered (reviewed in Ref. [3]). For example, squamous cell carcinomas (SCCs) from patients with the rare hereditary disorder epidermodysplasia verruciformis (EV) are associated with a particular group of 22 phylogenetically related cutaneous HPVs which are therefore designed EV-HPVs. They include HPV 5, 8, 9, 12, 14, 15, 17, and 19–25. These types were also detected in other cutaneous malignancies such as SCC in individuals without EV and basal cell carcinomas (BCC). The prevalence of HPV in skin tumors is especially high in immunosuppressed individuals.

Human papillomavirus typing methods can be divided in target-amplification methods, i.e., methods involving polymerase chain reaction (PCR), and non-PCR techniques. In the following section, technical aspects of the different currently available HPV typing methods are

described. Table 1 gives an overview of the different techniques, sorted to typing resolution and throughput if applicable. In addition, the suitability for various clinical specimen types is indicated.

DESCRIPTIONS OF METHODS

Nonamplification Methods

The best known technique in this category is the commercially available, FDA-approved Hybrid Capture 2 (HC2) method.[4] It detects 13 genital hr-HPV types by a mixture of full-length RNA probes; hence it is suitable only for group-specific detection and not for high-resolution typing. Hybridization of one or more of the probes to HPV DNA present in heat-alkaline-denatured clinical samples is detected by peroxidase-labeled antibodies that recognize the RNA/DNA hybrid and visualized by chemiluminescence. The nonamplification nature of HC2 greatly decreases the risk of false positives by reaction product carryover. It is self-evident that the analytical sensitivity of this method is lower than that of PCR-based methods (Table 1). Some cross-reaction of the HC2 probes with HPV types not represented in the probe mix, including some nononcogenic HPVs, have been described.[5]

Polymerase Chain Reaction-Based Methods

Consensus primer polymerase chain reaction

Most of the PCR-based HPV typing methods rely on the use of consensus primers that amplify a broad spectrum of HPV types, followed by detection with type-specific probes. The consensus primers may contain mismatches that are accepted under low-stringency PCR conditions as in the GP5+/6+ system.[6] Alternatively, the consensus primers may be degenerate as in the MY09/11[7] and CPI/II[8] systems or both degenerate and containing inosine residues at ambiguous base positions such as the IU/IWDO[9] and SPF[10] primers.

Typing of consensus polymerase chain reaction products—endpoint measurement

Typing of PCR products was traditionally performed by means of dot blotting or Southern blotting and hybridization with type-specific oligonucleotides. More recently, reverse hybridization techniques were introduced. These methods rely on the hybridization of labeled consensus PCR products to HPV type-specific oligos immobilized on filters. Examples are reverse line blot (RLB) analysis following MY09/11[7] or GP5+/6+[6] consensus PCR or a line probe assay (LiPa) following SPF PCR.[10] Detection of the hybridized PCR product is performed by a colorimetric reaction[7,10] or by chemoluminescence,[6] the latter allowing repeated usage of the same filter.[6] Instead of filters, glass microarrays of HPV type-specific probes can also be used.[11] A schematic representation of the principle of reverse hybridization is given in Fig. 1. These methods are far less laborious than normal hybridization methods when it comes to detection

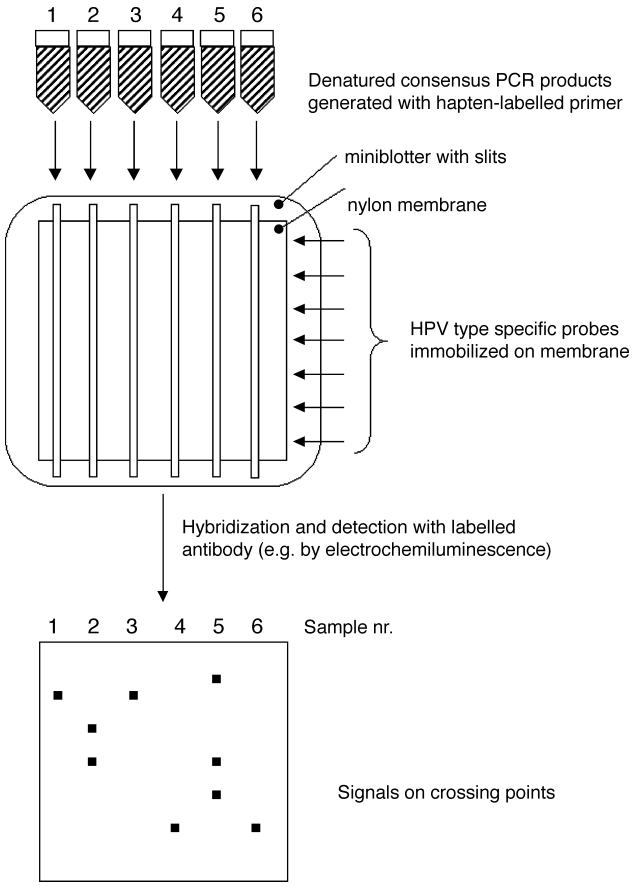

Fig. 1 Reverse hybridization methods: RLB.[6] Schematic representation of the principle. HPV type-specific probes are attached to a membrane using a miniblotter with slits. Subsequently, the membrane is rotated 90° in the miniblotter. Consensus PCR products are generated using hapten-labeled primers. After denaturation, the single-stranded PCR products are pipetted into the slits of the miniblotter. If a particular HPV type is present in a sample, hybridization will occur on the crossing point of the sample slit with the respective HPV probe line. Subsequently, hybridization is detected using a labeled antibody directed against the hapten and visualized using chemoluminescence.

of multiple HPV infections. For group-specific detection of HPVs without high-resolution typing, an enzyme immunoassay (EIA) can be applied conveniently using cocktails of, for example, HR- or LR-HPV probes.[12]

Two nonhybridization typing methods following consensus PCR are sequence analysis of the PCR product[13,14] and restriction fragment length polymorphism (RFLP) analysis.[15] RFLP implies the digestion of consensus PCR products with restriction endonucleases and comparison of the digestion pattern with those of known HPV types. These techniques are useful if unknown types of HPV are present in the specimens, but they have several drawbacks as compared with hybridization methods. For example, RFLP and sequence analysis are not suitable for the detection of infections with multiple HPV types: these will usually give an uninterpretable mix-up of digestion/sequence patterns. In addition, these two methods are less suitable for high-throughput analyses because they are relatively laborious. Finally, RFLP and sequence analysis are less sensitive than hybridization methods because more PCR product is needed to generate a positive signal.

Typing of consensus polymerase chain reaction products—real-time measurement

As opposed to typing after consensus PCR, it is also possible to type during the reaction, in real time. Various real-time PCR techniques are available, the best known being molecular beacons, the fluorescent 5′ exonuclease assay (e.g., TaqMan), and fluorescence energy resonance transfer assays (e.g., LightCycler).

At present, the only real-time assay that allows consensus HPV-PCR with simultaneous typing is a molecular beacons assay.[16] However, the multiplicity of this technique is limited because the current generation of real-time thermocyclers does not allow for more than six differentially labeled probes. Hence for typing of multiple HPV infections, reverse hybridization methods are preferred over real-time assays.

Type-specific polymerase chain reaction

If one is looking for a particular HPV type, type-specific PCR can be applied (described in Ref. [6,17] among others). Care should be taken when designing primers because they may still react with other types if chosen in well-conserved regions. Confirmation of the specificity of type-specific PCRs, as with consensus primer PCRs, is mostly performed by (regular or reverse) filter hybridization or by EIA, but can also be performed in real-time. A great advantage of real-time assays is the possibility to quantify the HPV in the specimen. However, to obtain reliable quantification data, DNA extraction is usually necessary, thus increasing the workload.

Analytical sensitivities and specificities of the assays

In general, the sensitivities of HPV typing assays are dependent on the reaction that precedes the typing step. The sensitivity of the only nonamplification technique described in this article, the HC2 method, is 5000 copies of the HPV genome per reaction well according to the manufacturer. All other methods described here consist of a PCR step followed by a typing step. These methods have a much higher analytical sensitivity than HC2, with a slight variation between the methods (reviewed in Ref. [18]). In general, less than 100 HPV genome equivalents in a reaction tube are sufficient to generate a positive PCR signal and to enable typing.

It is self-evident that specificities of the HPV typing assays rely on the specificities of the respective probes for their corresponding HPV types under the respective hybridization conditions. In addition, PCR-based methods depend on the specificity of the amplification primers.

WHAT TO CONSIDER WHEN SELECTING AN HPV TYPING METHOD

Study Design and Desired Typing Resolution

For mucosal HPVs, a simple detection of HR-HPV without typing may be sufficient in many study designs. These include population-based screening studies for cervical cancer, in particular, the identification of women with abnormal cervical cytology who are at risk of progressive cervical intraepithelial neoplasia (CIN) disease[19] and the follow-up after treatment of CIN.[20] The method of choice in such studies would be hybridization with a HR probe cocktail, either after consensus PCR or using HC2.

Other studies may call for high-resolution HPV typing. These include studies of possible relations between HPV type and clinicopathological aspects such as histology (e.g., mucosal HPVs in adenocarcinomas, SCCs, and small-cell carcinomas of the uterine cervix; cutaneous HPVs in different cutaneous diseases) and patient survival. Furthermore, HPV typing can be helpful to determine whether two HPV-associated lesions within the same patient are pathogenetically related (e.g., a cervical carcinoma and an earlier detected CIN lesion).

Especially in the light of the current interest for HPV vaccination (reviewed in Ref. [21]), it is important to study geographical distribution of HPV types and their associated diseases as a basis for vaccination programs. Once vaccination has started, HPV typing remains necessary to monitor the changes in prevalence of the type(s) represented in the vaccines.

Considerations Regarding Clinical Specimens

Finally, the type of clinical specimens available will determine the choice of the typing method. The majority of the techniques mentioned can be performed with any type of clinical material (Table 1). An exception is the HC2 test (Digene), the manufacturer of which recommends the use of a dedicated specimen collection medium for cervical and vaginal swabs. These samples can also be used for PCR, but only after DNA isolation because organic solvents in the Digene- and other cell-preserving media will inhibit PCR. In archival material (smears on slides or formalin-fixed, paraffin-embedded material), the DNA is usually degraded to fragments <200 base pairs. This renders them unsuitable for PCR-based methods that generate products of >200 base pairs.

CONCLUSION

As seen in the previous paragraphs, the aim of the study and the clinical material available will determine the choice of the HPV typing method. In general, consensus PCR followed by reverse hybridization is very sensitive and gives the most extensive typing information for many kinds of clinical specimens, including those containing multiple infections.

HTLV-1

Shimeru Kamihira
Nagasaki University, Nagasaki City, Japan

INTRODUCTION

Human T-lymphotropic virus type 1 (HTLV-1) was discovered by Poiesz et al. as the first causative retrovirus of human cancer. Since then serological and clinicopathological studies have clarified the causative relationship between the virus and other diseases such as HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP), uveitis, arthropathy, and polymyositis. However, notably, most individuals infected with the virus show no clinical features of the infection (healthy carriers). Accordingly, HTLV-1 quantitative detection by real-time polymerase chain reaction (PCR) would be significant in understanding not only the infectious status but also the pathological roles of the causative virus.

TYPE OF PATHOGEN

HTLV-1 belongs to the family Retroviridae. HTLV-1 is morphologically a type C retrovirus and mainly infects CD4 T-cells, and the proviral genome is known to be randomly integrated into the human genome with a different genomic integration site in each infected cell. The provirus consists of *gag*, *pol*, *env*, and *pX* genes. HTLV-1 is causatively implicated in the pathogenesis of human neoplastic, degenerative, and inflammatory diseases such as adult T-cell leukemia (ATL), HAM/TSP, uveitis, arthropathy, and polymyositis.[1-3] But, notably, most individuals infected with HTLV-1 are persistently asymptomatic throughout life.

CLINICAL DESCRIPTION OF INFECTION SPECTRUM

Although HTLV-1 has been demonstrated to infect several kinds of cells other than T-cells in vitro, the virus is thought to usually infect CD4 T-cells in vivo. Each T-cell infected with the virus is believed to harbor one copy of the provirus. Accordingly, the quantitative detection of the HTLV-1 proviral load by real-time PCR would not only mean the existence of HTLV-1 infection but would also provide a surrogate marker for HTLV-1-infected cell count.[4] In particular, in ATL, this indicates that the proviral load corresponds to tumor burden of ATL cells including minimal residual disease (MRD) in remission state because ATL cells usually harbor one proviral genome monoclonally integrated within the same genomic integration site of clonal ATL cells. Thus, detection of the proviral load by real-time PCR is relevant and sufficient to clinically screen HTLV-1-associated disorders and to evaluate the HTLV-1 pathological status by monitoring the infected cell count in peripheral blood, body fluids such as cerebrospinal fluid, and lymph node suspension cells.

PREVALENCE

The prevalence of HTLV-1 infection varies in different parts of the world, whether endemic to those areas or not.[5] There are two main endemic areas worldwide, Southwestern Japan and the Caribbean basin, ranging from 5% to nearly 30% seropositivities. Other parts of the world, such as Central and West Africa, Melanesia, the Middle East, and India, have also been reported to be endemic. Even in the endemic area of Nagasaki district located in Southwestern Japan, the infection rate differs, being only 1–3% in the urban area of Nagasaki and being 15–30% in rural areas in the Goto Islands located in the East China Sea about 100 km from Nagasaki. Most ATL or HAM/TSP have broken out in the endemic areas.

The three principle routes of HTLV-1 transmission include mother-to-child transfer by breast milk, sexual intercourse, and blood product transmission. However, nobody knows why the endemic areas are restricted to certain areas of the world. ATL develops 30–60 years after infection with HTLV-1 during childhood. The lifetime risk in a carrier of HTLV-1 is estimated to be about 5% in ATL and less in HAM/TSP.

MOLECULAR CHARACTERIZATION OF THE PATHOGEN

The reason HTLV-1 causes the completely different neoplastic and nervous degenerative disorders, namely ATL and HAM/TSP, remains to be elucidated. The proviral

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120021492

genome consists of *gag*, *pol*, and *env* genes, which are commonly characteristic of all retroviruses. Interestingly, the HTLV-1 genome contains a specific sequence in the 3′ site of the genome designated as the *pX* gene, encoding alternatively a 40-kDa protein (p40 tax). In ATL, p40 tax proteins are thought to play a pivotal role in the early event of tumorigenesis. Because the proteins can transactivate some cellular oncogenes/suppressor genes, growth factor genes, and cell surface receptor genes, such as c-*fos*, c-*myc*, *egr-1*, *p53*, *Bax*, c-*Jun*, *IL-2R*, *IL-1*, *IL-6*, *GM-CSF*, *TGF-β1*, *PTHrP*, and *TNF-β*.[3] Tax, then, has the potential to immortalize lymphocytes infected by HTLV-1 in vitro. These tax-immortalized cells are usually still IL-2-dependent, so that other cellular events such as *p53* and *p16* mutations are required to transform these cells. In fact, most ATL demonstrate either *p53* or *p16* mutation in clinical samples.

However, in degenerative and inflammatory disorders such as HAM/TSP and uveitis, slow viral infection, cell-mediated immunity, and an aberrant cytokine network are possible pathogenic mechanisms.[6] Recently, circulating $CD8^+$ cytotoxic T-cells specific for HTLV-1 *pX* have been notably found in patients with HAM/TSP. Furthermore, susceptibility to HAM/TSP is considered to be determined by host immunogenetic factors such as HLA haplotypes linked to HTLV-1 responsiveness.

MOLECULAR TESTING

PCR technology can quantify extremely low levels of rare (usually 1% or less) infected T-cells. The infectious status in HTLV-1 indicates that the provirus DNA sequence is integrated within the host genome from infected T-cells, so the proviral load by real-time PCR can disclose viral pathologies related to the disorders, including cell burden of the infected cells.[4,7] The technology to detect PCR products in real time has been available for more than about 7 years. Now, there are two main real-time PCR routine methods for quantitative detection of HTLV-1 proviral load: the TaqMan and Perkin-Elmer/Applied Biosystems Sequence Detection System (Applied Biosystems, Foster, CA, USA) and the LightCycler Technology (Roche Diagnostics GmbH, Mannheim, Germany). Here, we review the performance of quantitative HTLV-1 provirus detection by real-time PCR, including our experiences using the LightCycler Technology with specific probes.

Target for Detection

The detection target is mainly a part of the *pX* gene of the HTLV-1 provirus integrated within the host genome, which is highly conserved even in defective viruses. However, despite a high degree of homology among the HTLV-1 strains, deletions or mutations in the *pX* region have been described especially in patients with HAM/TSP. As specimens for quantifying the proviral load, fresh or frozen peripheral blood mononuclear cells (PBMCs) are used most often. After being collected by Ficoll–Conray gradient centrifugation, the genomic DNA is processed by the phenol–chloroform method. The genomic DNA is stored at 4°C until use. Genomic DNA doses applied to PCR assay should be precisely quantified using the dsDNA PicoGreen Quantification Kit (Molecular Probes, Eugene, OR, USA) to make precise results.

Primers and Probes

The primers and probes for the HTLV-1 provirus target should be theoretically optimized and sequences should be modified for each system. In almost all assay systems the primer pairs and probes have mainly been selected within the *pX* region of the provirus, which is the most stable to prevent false-negative results.[7–10] These designs have also been supported by our experiences with HTLV-1 Southern blot hybridization (SBH) analysis in 300 ATL cases, nearly 30% of which had defective viruses, but always conserved the *pX* region including the primer sequences and probe sequences. However, there are several reports that some assay systems especially for healthy HTLV-1 carriers use the primers designed to detect the *gag*, *pol*, or *env* regions of the provirus.[11] In particular, the *pol* gene among them has been described to be more adequate for attempts to qualify a broad spectrum of HTLV-1 strains.

Now, the primers and probes in our assay system by real-time PCR are described as follows.

Primers

Sense: 5′-CCCCCTTCCGAAATGGAT; antisense 5′-CCGGGGTGGCAAAAAATC.

Probes

Reporter probe with fluorescein isothiocyanate (FITC): 5′-GAGGGTGTACAGGTTTTGGGGC-3′-FITC; quencher probe with LC Red 640: LC Red-5′-GGAGT-CCGGGGTCTGGAAAAGA-3′ (phosphorylated at the 3′ end).

Conditions for Real-Time PCR

PCR conditions for HTLV-1

PCR conditions for quantitative HTLV-1 detection should be optimized according to the differences of primer

designs and PCR technology applied. In our laboratory, the PCR reaction has been carried out using the LightCycler Technology assay instrument. For each test sample, 30 ng of genomic DNA is used as a template for amplification using LightCycler-FastStart DNA Master Hybridization Probes Kit (Roche Diagnostics GmbH) in the LightCycler PCR instrument, and then the amplified products are automatically measured according to the manufacturer's instructions. The reaction conditions are 95°C for 10 min for activation of the Taq polymerase and then 50 cycles of 10 sec at 95°C (denaturation) followed by 5 sec at 64°C (annealing) and by 10 sec at 72°C (extension).

Standard curve and proviral load interpolation

For routine quantification of DNA or RNA, two general methods of data analysis exist: absolute quantification and relative quantification. Absolute quantification determines the exact template copy number, usually by relating the PCR signal to a standard curve. So it is important to know what kind of a template for a standard curve is used. In general, two kinds of control template—a plasmid vector inserting the region of HTLV-1 genome, and an HTLV-1-infected cell line monoclonally integrating one copy of the provirus for generation of a standard curve—are used. Then, unknown copy numbers are calculated by interpolation from such plasmid control regression curve and reported as copy equivalents per 10^{4-6} PBMCs or percent. In our case, an HTLV-1 standard curve is generated using serial dilutions as the template for the real-time PCR from 10^7 to 10^1 copies of the proviral DNA derived from a clone in pBR322 vector as follows. A 9-kb proviral DNA fragment is cloned into the pBR322 and propagated. After digestion with *Eco*RI, the insertion is purified and quantified with the PicoGreen dsDNA Quantification kit. Molecular concentrations are calculated and the purified insert is used for the generation of the standard curve (Fig. 1).

The copy numbers in the samples are estimated by interpolation from the plasmid control regression curve and an internal control of β-globin to correct for sample DNA quality differences. Copy numbers were reported as copy equivalents per 10^4 PBMCs, mainly lymphocytes.

Assessment of Detection by Real-Time PCR Assay

Accuracy and reproducibility

The HTLV-1 proviral copy load is thought to range widely from 100% to 0.1%, or less of the PBMC fraction in clinical practice. Accordingly, the assay is needed to have a broad dynamic measurable range of at least 5 $\log_{10}$, especially with the low proviral load of 0.1–0.01% or less. Indeed, the performance of real-time HTLV-1 assay

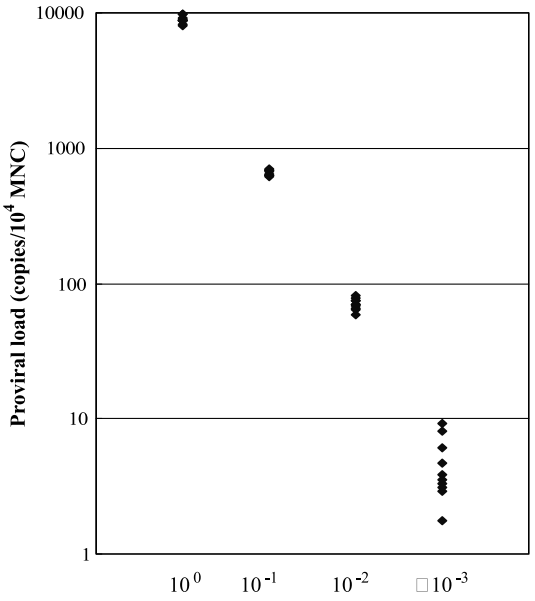

Fig. 2 Accuracy and reproductivity within run depend on different levels of proviral load. (*View this art in color at www.dekker.com.*)

systems developed is reported to be acceptable in terms of specificity, low detection limit (one copy per reaction), broad linear dynamic range, and reproducibility to be used both for qualitative detection and quantitative follow-up. Our real-time PCR system has also shown to be accurate and reproductive at different cell concentrations of 10^0–10^{-3} equivalent to about 100–0.1% infected cells/10^4 PBMCs in which 10^4 ATL cells harboring one proviral copy were diluted with normal lymphocytes, as shown in Fig. 2. The mean copies/10^4 PBMCs and coefficient values (CV) at each concentration were 8913±570, 655±32, 70±7, and 5±2, and 6.4%, 4.8%, 9.6%, and 51.8%, respectively. The between-day precision using the PBMCs from a seropositive healthy individual is reproducible with a CV of 15.9% and a mean of 189 copies. Now, Table 1 represents the practical data of the proviral load by real-time PCR in asymptomatic healthy carriers and patients with HAM/TSP, giving probably the approximate values.

Trials in clinical samples

A quantitative real-time PCR assay has been practically used to measure the HTLV-1 proviral load in PBMCs, subsequently making a diagnosis of persistent HTLV-1 infection and HTLV-1-associated disorders, and monitoring cell burden, namely, the numbers of lymphocytes or ATL cells harboring the HTLV-1 genome within their genomic DNA. These assays have been described to be excellent for diagnostic sensitivity and specificity in many articles cited using a Medline search. Our PCR assay also has given us a reasonable outcome [i.e., all of the seronegative samples were undetectable, whereas the seropositive samples were all positive in 108 cases without ATL (healthy carriers) and in 59 cases with overt ATL]. The HTLV-1 proviral load was 301±339 copies (mean±SD) per 10^4 PBMCs in healthy carriers, and ranged from 1.72×10^2 to 1.53×10^4 copies in ATL in parallel with ATL cell counts. Of the 108 healthy carriers who had no clinical manifestations without a clonal band by the HTLV-1 SBH test, the proviral load, in combination with the percentage (%) of ATL-like flower cells defined by PB smear morphology, enabled the carriers to be subgrouped into three categories [7] as shown in Fig. 3. However, in 7 of 59 ATL cases characterized by the SBH test for HTLV-1 integration status, the proviral load and ATL cell counts by morphology were discrepant. Interestingly, all of these cases showing discrepancies had two or three bands by the HTLV-1 SBH analysis using the *Eco*RI restrictive enzyme which has no cleavage site within the proviral DNA sequence. The ratio of the proviral load to ATL cell number was closely equivalent to the band number obtained by the SBH analysis, indicating that ATL cells from these cases harbored multicopies within a single ATL cell.

These cross-sectional data from each real-time PCR assay system for HTLV-1 quantification have been generally reported to be concordantly stable and significant, but the true usefulness of the ''quantification'' of

Table 1 Summary of the practical data of the proviral load by real-time PCR in asymptomatic carriers and patients with HAM/TSP in different studies

	Nagai et al.[8]	Gabet et al.[9]	Manns et al.[10]	Dehee et al.[11]
Asymptomatic carriers	120 copies/10^4 PBMCs (1.2%)	4068 copies/ 1.5×10^5 (2.7%)	1076 copies/10^5 lymphocytes (1.1%)	4532 copies/10^6 PBMCs (0.45%)
HAM/TSP	798 copies/10^4 PBMCs (8.0%)	ND	4861/10^5 lymphocytes (4.8%)	105,160/10^6 PBMCs (10.5%)

Values in parentheses represent percentage of cells infected with HTLV-1.

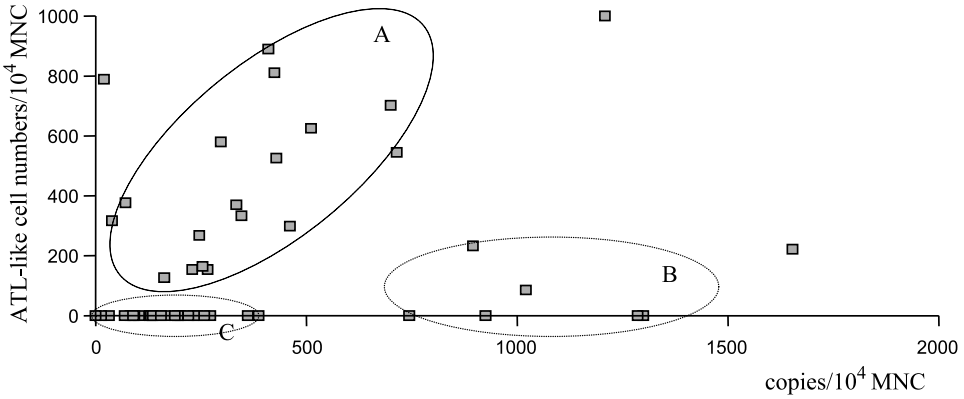

Fig. 3 Twin plot graph showing the correlation between the copy number by the proviral load and ATL-like cell counts in healthy carriers. The points corresponding to individual cases tend to fall into three subgroups A, B, and C. (*View this art in color at www.dekker.com.*)

the HTLV-1 proviral load has to be confirmed on a large series with a long-term follow-up of the carriers and the patients.

CONCLUSION

A real-time PCR assay for HTLV-1 using suitable primers and probes is relevant for quantitatively detecting the provirus of HTLV-1 in healthy carriers and patients with HTLV-1-associated disorders to understand the pathological roles of the virus.

Human Herpesvirus (HSV) 1 and 2—Resistance Testing

Florence Morfin
Emilie Frobert
Danielle Thouvenot
Claude Bernard University-Hospices Civils de Lyon, Lyon, France

INTRODUCTION

Herpes simplex virus (HSV) type 1 and type 2 are very common. After primary infection, these viruses have the ability to establish latent infection and may be responsible for frequent recurrent infections. They are most often associated with mild mucocutaneous infections and rarely with serious diseases affecting the central nervous system, the eye, and the newborn. These viruses may also be responsible for serious complications among immunocompromised patients.

HERPES SIMPLEX RESISTANCE HISTORY

Acyclovir (ACV) is the gold standard for the treatment of HSV infections. This drug is a nucleoside analogue of guanosine that has to be phosphorylated three times. The first phosphorylation is achieved by the thymidine kinase (TK) encoded by the virus; this step is important as it allows ACV to become active only in infected cells. The second and third phosphorylations are carried out by cellular thymidylate kinases. Acyclovir triphosphate is a competitive inhibitor of viral DNA polymerase and is a DNA chain terminator.[1]

Herpes simplex virus strains resistant to ACV have been reported since 1982.[2] They were most often recovered from immunocompromised patients previously treated with ACV.[3] Herpes simplex virus resistance to ACV may be associated with a mutation in one of the two viral enzymes involved in ACV mechanism of action: TK and/or DNA polymerase. Mutations occurring in the viral gene encoding TK are the most frequent and 95% of ACV-resistant isolates present a TK-deficient phenotype.[4] These mutations leading to resistance occur spontaneously during viral replication and resistant viruses are then selected by antiviral treatment. Few cases of resistance have been associated with a mutation in the viral DNA polymerase gene.[5] This mechanism is rarely involved as a functional DNA polymerase is essential for viral replication unlike viral TK.

CLINICAL DESCRIPTION AND EPIDEMIOLOGY

Among immunocompetent patients, resistance to ACV is rare, with a prevalence below 1%[6] and most often detected in the course of recurrent genital herpes. In this situation, the observed prevalence ranged from 3.5%[7] to 8.6%,[8] and in most cases, clinical course was unchanged.

Prevalence of ACV resistance among immunocompromised patients is about 5% according to several published reports recently reviewed by Bacon et al.[6] But this global incidence has to be specified according to the type of immunosuppression as resistance may be detected in up to 25% of allogeneic bone marrow transplant patients presenting with an HSV infection.[9]

Among immunocompromised patients, resistance is associated with clinical failure after 7 to 14 days of treatment. Lesions may present as large, ulcerated, and extensive. These infections are often serious and may become chronic.[10] After healing, recurrent infections are most often associated with an ACV-sensitive strain, but some cases of recurrences due to an ACV-resistant virus have been reported.[11–14]

MANAGEMENT OF RESISTANT INFECTIONS

The first way to manage ACV-resistant HSV infection is, when possible, to decrease immunosuppressive treatments.[15] An increase of antiviral dose should also be considered.[16]

Several alternative antiviral drugs are also available. Penciclovir is a nucleoside analogue of guanosine and is very similar to ACV. Indeed, most ACV-resistant HSV isolates are also resistant to penciclovir. Foscarnet, a pyrophosphate analogue, and cidofovir, a nucleotide analogue of cytidine, act directly on viral DNA polymerase without previous activation by viral TK and both these molecules are active on viruses resistant to ACV because of a mutation in the TK gene.[17,18] Acyclovir-resistant management strategies usually recommend the use of

DOI: 10.1081/E-EDGP 120024825

foscarnet as a first line treatment and cidofovir in case of failure of foscarnet.[16] However, in clinical practice, both of these drugs may be associated with a significant level of toxicity.

Cross-resistance between ACV and foscarnet has been documented in immunocompromised patients.[19–21] Nevertheless, foscarnet-resistant strains sensitive to ACV have also been reported.[21] Acyclovir-resistant strains, cross resistant or not to foscarnet, have always been shown to be sensitive to cidofovir.[9,22] In addition, resistance to cidofovir, never reported so far in clinical strains, has only been described in strains selected in vitro.[23]

PHENOTYPIC DETECTION

In vitro evaluation of HSV susceptibility to antiviral drugs is based on the multiplication of a virus in the presence of increasing concentrations of antiviral drug. These techniques allow the calculation of the antiviral drug concentration leading to a 50% inhibition of viral replication (inhibitory concentration 50%, IC50). In order to discriminate between susceptible and resistant strains, IC50 thresholds have to be defined for each virus and antiviral drug pair. These values are usually determined according to the mean value obtained for susceptible viruses: three to five times the mean value of ACV-susceptible HSV for example. But these thresholds are arbitrary and the best way is to check the evolution of IC50 values of sequential isolates from a patient.

GENETIC CHARACTERIZATION

Herpes simplex virus TK is involved in 95% of HSV resistance to ACV. It is a 376-amino acid protein, encoded by a gene of 1128 bp (UL 23). It exhibits an ATP binding site (amino acid 51 to 63) and a nucleoside binding site (amino acid 168 to 176) and six regions conserved among herpesviridae TK (amino acid 50 to 66, 79 to 91, 162 to 178, 212 to 226 and 281 to 292). Figure 1 presents the localization of mutations reported in ACV-sensitive and ACV-resistant HSV clinical isolates, in relation to the localization of active and conserved sites of the enzyme. These data were obtained by genetic characterization of about 70 ACV-resistant HSV isolates and 30 ACV-sensitive HSV isolates.[24,25] These studies revealed a large degree of polymorphism in the HSV TK gene. The mutations unrelated to resistance are located throughout the gene but

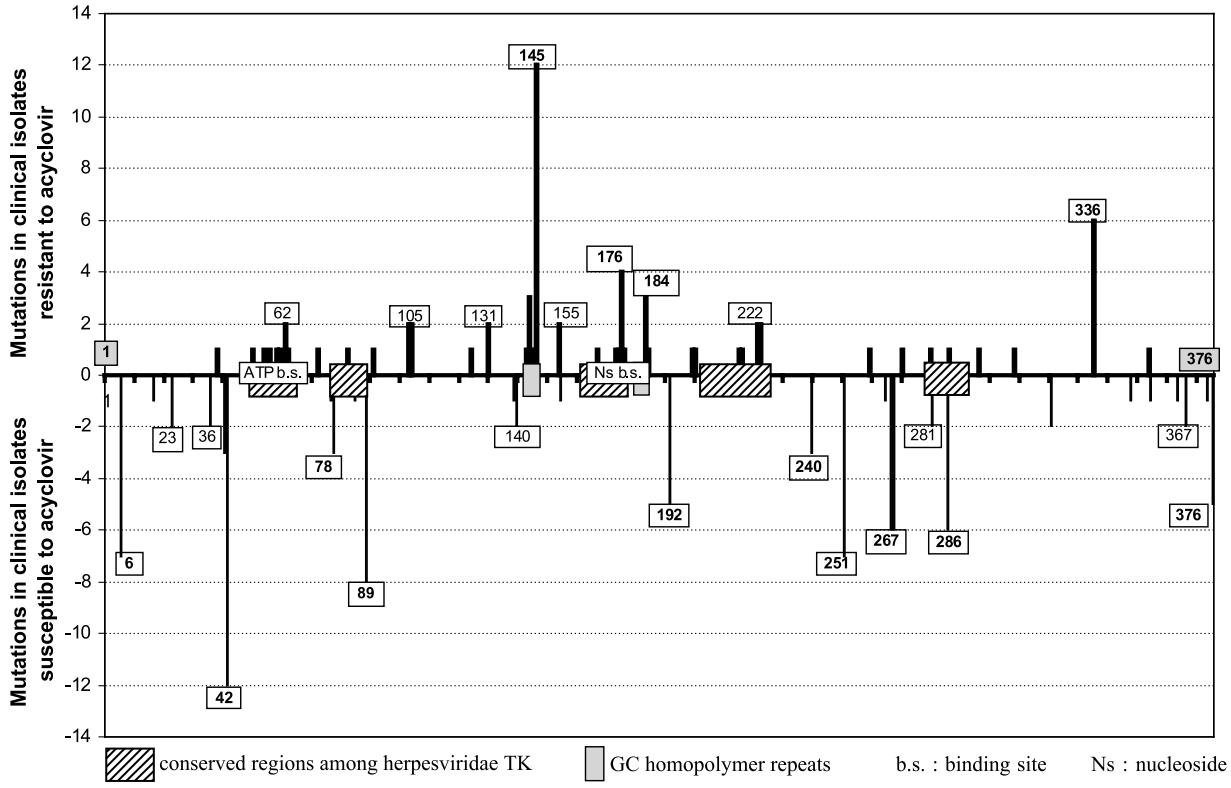

Fig. 1 Thymidine kinase mutations reported in ACV-sensitive and ACV-resistant HSV clinical isolates.

they are almost all located outside TK active and conserved sites. Gene polymorphism is four times higher for HSV 1 than for HSV 2.[26] Among mutations that could be associated with resistance, half were nucleotide insertion or deletion, and half were nucleotide substitution.[27–29] Nucleotide insertions or deletions are responsible for a frameshift and the synthesis of a truncated, nonfunctional TK. They are often located in homopolymer repeats of guanines or cytosines that are mutational hot spots. Mutations were found several times in repeats located at codon 92 (five guanines) and at codon 146 (seven guanines). The frameshift mutation in the 7Gs homopolymer of codon 146 is the most frequent mutation reported in ACV-resistant HSV isolates.[21,27,28,30] Numerous nucleotide substitutions, most often recovered in conserved regions of the TK gene, have been described in ACV-resistant clinical HSV strains, but some are reported more frequently as the substitution of arginine 176 of HSV 1 and 177 of HSV 2, and the mutation of amino acid 336.[24]

Herpes simplex virus DNA polymerase is a 1235-amino acid protein encoded by a 3705-bp gene (UL 30). It includes eight conserved regions in comparison with cellular or viral DNA polymerases; these regions are labeled I to VII according to their degree of conservation (region I being the most conserved), plus one region called A. DNA polymerase mutations associated with resistance are related to genetic characterization of about 15 resistant strains either isolated from patients[21,31] or selected in vitro.[23,32,33] As for TK, these mutations are mainly located in the conserved regions, especially in regions II and III which include more than 40% of the mutations reported so far in the DNA polymerase gene.

MOLECULAR GENETIC TESTING

Phenotypic methods require previous isolation of viral strains on cell cultures, which is time consuming and delays the change of antiviral treatment according to in vitro susceptibility. Genotypic tests are now being developed to detect resistant virus within a shorter time. The viral genes encoding the two targets of antiviral drugs (TK and DNA polymerase) are amplified by PCR and PCR products are then sequenced. The difficulty lies in the fact that numerous nucleotide substitutions may be found and these must then be identified as mutations responsible for resistance or not. This interpretation will be made easier as more and more results on mutations detected in resistant isolates are collected. In addition, site-directed mutagenesis studies are in progress to formally assess the role of the mutations in the development of antiviral drug resistance. Results already obtained by genetic characterization of clinical isolates resistant to ACV indicate that sequencing of limited areas in the TK and DNA polymerase genes is sufficient to detect most of the mutations associated with resistance. For TK, which is only 1128 nucleotides long, it is preferable to sequence all the gene, but sequencing of nucleotides 150 to 600, combined with a specific detection of mutations at codon 336, should allow the detection of 80% of the mutations associated with resistance. For DNA polymerase, we focused on the region between nucleotides 1500 and 3000, which includes 90% of the mutations reported in resistant strains.

At the present time, genetic detection of ACV-resistant HSV is based on PCR amplification and sequencing of

Table 1 Primers for TK and DNA polymerase genetic characterization

Target gene	Primers for PCR	PCR product length and localization	Primers for sequencing
Thymidine kinase (1128 bp)	**TK1**: GGGGATCCTCCCG-CACCTCTTTGGC (forward)	635 bp	• Coding strand with TK1
	TK3: CGCAAGCACCGGG-AGTACCTAGGGG (reverse)	38 nt before ATG to nt 581	• Noncoding strand with TK3
	TK2: GGGGATCCGATA-CCTTATGGGCAGC (forward)	638 bp	• Coding strand with TK2
	TK4: TGTGCCTTCCTCT-GTTACCTAGGGG (reverse)	Nt 526 to 19 after stop codon	• Noncoding strand with TK4
DNA polymerase (3705 bp)	**LP6**: GAGCACGTCCTCC-TGTTTTC (forward)	1313 bp	• Coding strand with LP6 and LP7
	RP6: CCGAGTTACACACGACCTTG (reverse)	Nt 1219 to 2449	• Noncoding strand with RP6 and RP8: ATGCAGTACTCGCCGATCAC (reverse)
	LP7: GTATTAACATCACCCGCACC (forward)	1135 bp	• Coding strand with LP7 and LP8: TGTAACTCGGTGTACGGGTTC (forward)
	RP7: CGGAGACGGTATCGTCGTAA (reverse)	Nt 1817 to 2953	• Noncoding strand with RP6 and RP7

target sequences within the TK gene and/or the viral gene encoding DNA polymerase. Primers that may be used are summarized in Table 1. These techniques have been applied to the genetic characterization of resistant isolates detected with phenotypic tests.[28] The first step of the development of genotypic tests could be the optimization of PCR amplification to increase its sensitivity so that it could be performed directly on clinical samples. A specific PCR amplification of HSV TK gene, involved in 95% of resistance cases, followed, if positive, by PCR product sequencing could allow the detection of mutations associated with resistance to ACV. A complete database of the HSV mutations associated with ACV resistance or TK polymorphism is needed to interpret sequencing results. In this way, results could be available in 24 to 48 hr, allowing early change of antiviral treatment according to virus susceptibility.

As more and more data are available on TK mutations associated with resistance, the GeneChip technology, developed by Affimetrix (Santa Clara, CA) may be considered as a promising method for the detection of resistance. This method of genetic diversity analysis relies upon the hybridization of the nucleic acid target to a large set of oligonucleotides. This technology has already been applied to detect mutations into HIV and *Mycobacterium* species genome,[34,35] giving results in a few hours. Herpes simplex virus arrays could thus represent a rapid and automatable method to detect mutations into TK and DNA polymerase genes associated with resistance to antiviral drugs.

CONCLUSION

The risk of emergence of HSV strains resistant to ACV remains a major concern because of the increase in the number of immunocompromised patients and in the use of antiviral drugs, both for prophylactic and therapeutic treatments of herpesvirus infections. So far, even if phenotypic tests are relevant to detect resistant strains, they are time consuming and delay the change of antiviral treatment according to in vitro susceptibility. Therefore it is important to develop new tests based on molecular biology techniques to allow the detection of resistant viruses more rapidly. Because of the numerous mutations reported in resistant strains, both in TK and DNA polymerase genes, and because of the high degree of polymorphism, specially in the TK gene, a complete database of the mutations associated or not with resistance to antiviral drugs has to be established for the interpretation of TK and DNA polymerase sequencing results in new isolates. Genotypic tests based on PCR associated with sequencing would be performed directly on clinical samples preventing the delay of virus isolation by culture. The development of microarrays applied to HSV could constitute a further improvement in the detection of HSV resistance. These new assays may help clinicians in the management of antiviral treatment of HSV infections.

Human Herpesvirus 6 and 7

David H. Dockrell
University of Sheffield Medical School, Sheffield, U.K.

INTRODUCTION

Human herpesvirus-6 (HHV-6) was discovered by Salahuddin et al. and HHV-7 by Frenkel et al. Both viruses cause the childhood exanthem roseola and may reactivate in immunocompromised hosts. Advances in genomics and proteomics are providing novel insights concerning these novel immunomodulating lymphotropic herpesviruses.

TYPE OF PATHOGEN

HHV-6, HHV-7, and human cytomegalovirus (HCMV) are the three known human members of the Betaherpesviridae subgroup of herpesviruses and HHV-6 and HHV-7 form the *Roseolavirus* genus.[1,2] Genetic, immunologic, and biological differences support the existence of distinct strains of HHV-6: HHV-6A and HHV-6B. The viruses contain an envelope, icosahedral capsid, and linear double-stranded DNA.

HHV-6A, HHV-6B, and HHV-7 have a similar genomic structure (Fig. 1). The central portion contains the unique (U) segment flanked at either end by duplicated sequences (DR). The number of kilobase pairs (kbp) encoded within the left end of each DR segments termed the *het* or heterogeneous region is variable and accounts for much of the variability in size between strains. The DR termini contain an analog of human telomeric repeats, a repetitive GGGTTA sequence. At either end of DR are homologs of the herpesvirus cleavage and packing signals, *pac-1* and *pac-2*. HHV-6A strain U1102 is 159 kbp, HHV-6B strain Z29 or HST is 162 kbp, and HHV-7 strains JI and RK are 145 and 153 kbp, respectively.[3–7] The majority of genes are common to all Betaherpesviridae. HHV-6B contains 115–119 potential open reading frames (ORF) (97 unique genes), HHV-6A contains 113 ORF (85 unique genes), and HHV-7 contains 101 ORF (84 unique genes). All HHV-7 genes except one have direct HHV-6A counterparts and all genes except two in HHV-6A have HHV-7 counterparts. Of the 97 unique genes in HHV-6B, it is estimated that 88 have HHV-6A counterparts and 82 have HHV-7 counterparts. Genomic differences are encoded mainly in DR and U86-100. Overall nucleotide sequence identity between HHV-6A and HHV-6B is 90%. HHV-6A strains show greatest variability and HHV-7 strains show least with differences mainly involving the telomeric reiterations.

Clinical Description of Infection

HHV-6B is the principle cause of the exanthem roseola infantum (exanthem subitum), an illness characterized by high fever and development of a rash after fever resolves.[8] HHV-7 can also cause roseola. However, the majority of children with HHV-6B or HHV-7 infection develop an undifferentiated fever, but this may be complicated in some by febrile convulsions, encephalopathy, and hepatitis. Primary infection is rare in adults but can occur including an infectious mononucleosis-type illness.

These viruses are ubiquitous and frequently reactivate. Proof that viral replication is causal in specific disease associations is usually lacking. The greatest attention has focused on links between HHV-6A and multiple sclerosis and HHV-7 and the skin rash pityriasis rosea. Links between HHV-6/HHV-7 and chronic fatigue syndrome have not been substantiated by molecular techniques.

Interactions between HIV-1 and HHV-6A, HHV-6B, or HHV-7 replication occur. Each of the herpesviruses can up-regulate or down-regulate HIV-1 replication under specific conditions, but the significance is uncertain. HHV-6 infection in the first year of life has been associated with more rapid HIV-1 disease progression in vertically infected infants. HHV-6A may contribute to the switch between CCR5 (M-tropic) and CXCR4 (T-tropic) virus late in HIV-1 infection. Reactivation of HHV-6A, HHV-6B, or HHV-7 in immunosuppressed transplant recipients can induce clinical syndromes including undifferentiated febrile illness, cytopenias, hepatitis, encephalopathy, rash, or pneumonitis. Indirect effects of reactivation of these viruses, posttransplantation may be more frequent and include increased HCMV replication, increased severity of HCMV disease, enhanced immunosuppression leading to fungal superinfection, and in association with HCMV graft dysfunction or rejection.

Prevalence

Infection with HHV-6 is most frequent at 6–12 months of age and HHV-7 is a little later at 6–24 months. More than

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020863

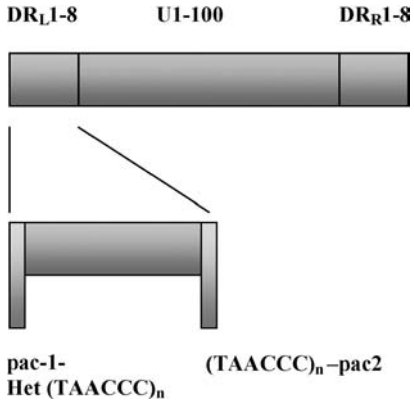

Fig. 1 Organization of viral genome. The viral genomes consist of linear double-stranded DNA with a central unique segment (U) and directly repeated sequences (DR) at each end. The DR encodes homologs of the herpesvirus cleavage and packing sequences *pac-1* and *pac-2*. The terminal and junctional segments of the DRs contain human telomere repeats $(TAACCC)_n$ and variation in length maps to the left side of each DR regions (heterogeneous or Het region). (*View this art in color at www.dekker.com.*)

90% of adults are seropositive for HHV-6 and up to 90% for HHV-7 worldwide. The majority of pediatric infections in western populations are due to HHV-6B, but HHV-6A causes pediatric infections in nonwestern populations. Neurological diseases or infections in immunocompromised individuals are more often HHV-6A-related. Saliva is likely to be an important route of transmission especially for HHV-6B and HHV-7 with mother to child transmission.

Management

Most HHV-6 or HHV-7 infections in childhood require no specific antiviral therapy, but therapy is indicated for complicated infections especially in immunocompromised patients. HHV-6 and HHV-7 lack thymidine kinase and are resistant to acyclovir. The guanine analog Ganciclovir (GCV) is, however, active: 50% effective inhibitory concentration (EC_{50}) for HHV-6A (GCV EC_{50} is 0.65 μg/mL), for HHV-6B (GCV EC_{50} is 1.33 μg/mL), and for HHV-7 (GCV EC_{50} >7 μg/mL).[9] The HHV-7 GCV EC_{50} is greater than plasma concentrations of GCV routinely achieved with administration of GCV 5 mg/kg intravenously. The U69 gene product of HHV-6 and HHV-7 is a phosphotransferase analog of HCMV UL97, a GCV kinase. It is required to phosphorylate GCV so that it inhibits the viral DNA polymerase (the U38 gene product) (Fig. 2). The HHV-7 phosphotransferase is least efficient at phosphorylating GCV. Point mutations in the U69 and U38 are associated with GCV resistance. HHV-6 and HHV-7 can respond to GCV treatment, but a report exists of prophylactic GCV, administered to transplant recipients, failing to prevent HHV-7 replication despite adequate suppression of HCMV.

The pyrophosphate analog, phosphonoformic acid (Foscarnet, FSC), inhibits the DNA polymerase of all three viruses. It may be of particular use, as in HCMV, in the treatment of infections failing to respond to or resistant to GCV. The acyclic nucleoside phosphonate, cidofovir (CDF), also inhibits DNA polymerase; CDF EC_{50} is 0.3 μg/mL for HHV-6A, CDF EC_{50} is 1.2 μg/mL for HHV-6B, and CDF EC_{50} is 3 μg/mL for HHV-7. U38 mutations may also decrease susceptibility to this agent. Because of

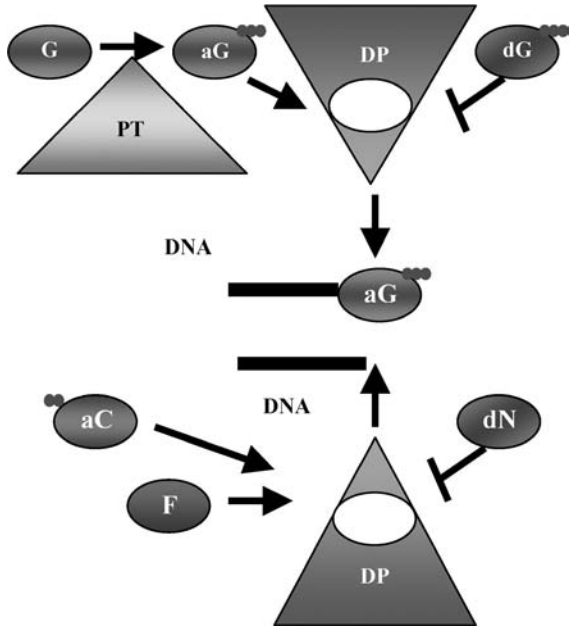

Fig. 2 Mechanism of action of antiviral compounds against HHV-6 and HHV-7. Ganciclovir (G) is phosphorylated by a phosphotransferase (PT) to become the active triphosphorylated compound (aG). aG binds to the viral DNA polymerase (DP) and competitively inhibits the binding of deoxyguanosine triphosphate (dG) to the polymerase. aG is incorporated into DNA resulting in retardation and cessation of chain elongation. Foscarnet (F) inhibits the binding of a range of deoxynucleotide triphosphates (dN) to the pyrophosphate-binding site of DP and blocks pyrophosphate cleavage. Foscarnet does not require intracellular phosphorylation. Cidofovir requires virus-independent intracellular diphosphorylation (aC). aC competitively inhibits the binding of deoxycytosine triphosphate to DP. aC is incorporated into DNA slowing elongation and, if two successive aC bind, terminating chain elongation. (*View this art in color at www.dekker.com.*)

nephrotoxicity, there is less experience with this agent in transplant recipients.

MOLECULAR CHARACTERIZATION OF PATHOGEN

Proteomic Analysis

Analysis of the sequenced genomes and by specialized protein expression systems has provided insights into protein functions. As is typical of herpesviruses, proteins are transcribed as immediate-early (IE, synthesized within minutes of infection and independently of de novo protein synthesis), early, or late proteins. Table 1 summarizes some of the principle genes and the proteins encoded.

Table 1 Human herpesvirus-6 and herpesvirus-7 genes and gene products

Gene	Product
Gene regulation	
U86–89	IE-A gene block. U89 encodes IE1
U95	IE protein (IE2)
U16–19	IE-B gene block
DNA synthesis and viral replication	
U27	Polymerase processivity factor
U38	DNA polymerase
U41	Major DNA-binding protein
U43/74/77	Helicase/primase complex
U73	Origin-binding protein
U94	RepH6
Nucleic acid metabolism	
U28	R1 subunit of ribonucleotide reductase
U45	dUTPase
U69	Phosphotransferase
U81	Uracil–DNA glycosylase
Structural proteins	
U11	Tegument protein
U14	Tegument protein
U39	gB
U48	gH
U72	gM
U82	gL
U100	Heparin-binding glycoprotein
Miscellaneous	
U53	Protease
U83	Viral chemokine, vCCL4
U12	Chemokine receptor
U51	Chemokine receptor
U69	Protein kinase
DR7	p53-binding protein

The genes encoding IE genes show variability between HHV-6 and HHV-7. The transcriptional regulation is incompletely characterized, but NF-κB and AP-1 binding sites have been identified. IE1 is a nuclear phosphoprotein that transactivates heterologous promoters and plays a role in latency-associated gene transcription. IE2 is more highly conserved between HHV-6 strains and HHV-7. The U16 gene product of HHV-6 and the p53 binding protein encoded by DR7 transactivate the HIV-1 long terminal repeat. The DR7 gene product has transforming activity.

Proteins involved in replication are highly conserved. The DNA polymerase binds a 40–41 kDa protein (DNA polymerase processivity factor) that localizes to the nucleus. Viral replication in vitro is enhanced by the presence of multiple copies of the origin of lytic replication that bind the origin of replication binding protein (OBP). U94 encodes a homolog of the human adeno-associated virus 2 (AAV-2) rep gene and is absent in HHV-7. It binds the human TATA-binding protein, a transcription factor and aids maintenance of latency by down-regulating gene transcription. It also inhibits cell transformation and transactivation of HIV-1 LTR.

Structural proteins include two heparin-binding glycoproteins, gB and the U100 product, that contain subtype-specific epitopes. U100 products include gp105 of HHV-6 (gp82–105) and gp65 of HHV-7 and are unique to HHV-6 and HHV-7. U100 can be differentially spliced and shows marked variation between HHV-6A and HHV-6B with possible biological implications. A U100-transcribed protein in HHV-6 has been identified as gQ, an 80 kDa protein, that complexes with gH and gL. gL plays a role in the transport and processing of gH. gH and gL form heterologous complexes both with each other and gH/gL of other β-herpesvirus that might facilitate viral interactions. gB, gH, and U100 products are targets for neutralizing antibodies. gM is a highly conserved glycoprotein. The glycoprotein encoded by U22 is not present in HHV-7. pp85 of HHV-7 is an immunodominant tegument phosphoprotein that forms a protein complex that is enriched in dense bodies. Other immunodominant tegument proteins include the p100 phosphoprotein of HHV-6 and p89 of HHV-7 that contain type-specific epitopes. A viral encoded protease contributes to viral maturation. HHV-6 and HHV-7 encode two G-protein-coupled receptors that are β-chemokine receptors. Signaling via the U51-encoded receptor can result in down-regulation of the chemokine RANTES. HHV-6A and HHV-6B (but not HHV-7) encode a functional chemokine

that contributes to viral immunomodulation. U83 is subject to differential splicing.

Host Pathogenesis

The roseola viruses induce acute lytic infection, latency, and some features of cell transformation. The cell receptor for HHV-6 is CD46, a ubiquitous type-1 glycoprotein that regulates complement activation. CD46 binds to gH via a gH–gL–gQ complex.[10] As CD46 is widely expressed, this explains the broad cell tropism noted. CD4+ T-lymphocytes are preferentially infected, but CD8+ T-lymphocytes, γδ T-lymphocytes, natural killer (NK) cells, macrophages, dendritic cells, bone marrow progenitors, fibroblasts, epithelial cells, and fetal astrocytes can also support viral replication. Some differences in infection of transformed lymphocytes have been noted between HHV-6A and HHV-6B, while HHV-6A has greater neurotropism. Other coreceptors for infection may exist. HHV-7 requires cell surface CD4 association with gB which is necessary but not sufficient for viral internalization. Cell surface heparin-like glycoproteins are also required for viral entry. HHV-7 tropism is mainly for CD4+ T-lymphocytes. However, HHV-7 can be identified in diverse tissue samples suggesting that HHV-7 cell tropism may be broader. In particular, HHV-7 antigens have been identified in salivary epithelial cells. HHV-7 replication has also been identified in macrophages and CD34+ hematopoietic progenitor cells.

Viral replication involves production of DNA-containing capsids in the nucleus, acquisition of tegument in the cytoplasm, and addition of a secondary envelope containing glycoproteins acquired from the annulate lamellae. Virions transit through the Golgi where glycosylation further modifies the envelope glycoproteins before release of mature virions. Infected host cells can die by apoptosis or necrotic lysis. Polypoid giant cells have been described with in vitro HHV-7 infection and result from cell cycle dysregulation. After primary infection, the virus is maintained in a latent state with low levels of gene transcription. Intermittent bouts of lytic replication allow persistence. Interestingly, specific T-lymphocyte activation stimuli can induce HHV-7 but not HHV-6B reactivation in vitro. HHV-7 replication produces HHV-6B transactivation suggesting that in vivo, there may be a sequence to viral reactivation.

The host response to infection involves production of neutralizing antibody and cell-mediated immunity. T-lymphocyte IFN-γ responses are detected against type-specific antigens. NK cells also contribute to host immunity via IL-15 production. HHV-6A and HHV-6B induce immunomodulation by depletion of CD4 T-lymphocytes via destruction of thymic progenitors and, as with HHV-7, via peripheral induction of apoptosis. The majority of apoptotic cells are uninfected and apoptosis can involve Fas ligand, TNF-α, or p53. CD4+ T-lymphocytes directly infected with HHV-7 up-regulate the antiapoptotic molecule bcl-2 and down-regulate the tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) R1 receptor to prevent apoptosis and maintain viral replication, but up-regulate TRAIL to induce apoptosis in immune effector cells. HHV-6A also depletes CD4 T-lymphocytes by formation of syncytia. A further mechanism of immune evasion described for HHV-7 is blockade of viral antigen presentation to cytotoxic T-lymphocytes by the binding of the U21-encoded glycoprotein to major histocompatibility complex (MHC) class 1 molecules that diverts the MHC molecules to lysosomes.

T-lymphocyte proliferation is inhibited by down-regulation of IL-2 and function inhibited by down-modulation of CD3, CD4, and the chemokine receptor CXCR4. Type-1 response cytokines up-regulated in T-lymphocytes include TNF-α, IFN-γ, and IL-18. TGF-β is also up-regulated. IL-8 and adhesion molecule induction enhances inflammatory injury, as may production of reactive oxygen species and PGE_2 by monocytes. HHV-6 encodes a unique chemokine analog, vCCL4, that binds to the chemokine receptor CCR2 expressed on cells including macrophages. HHV-7 also up-regulates the lymphocyte-specific G-protein-coupled receptor EB 1 which aids recruitment of infected lymphocytes to areas in which they can propagate infection.

Molecular Testing

HHV-6 or HHV-7 can be cultured from clinical specimens using coculture with stimulated lymphoblasts. Use of cord blood lymphocytes limits the chance of measuring replication of endogenous virus from the lymphoblasts. Demonstration of cytopathic effect or of viral antigen supports the diagnosis. Viral culture is, however, time-consuming. Serologic diagnosis is of greatest use in seroprevalence studies. An immunofluorescence assay or an enzyme immunoassay is most commonly employed. Appropriate controls are essential to exclude cross-reactions between Betaherpesviridae and should include a preadsorption step with appropriate antigens. An immunoblot assay has been described for detection of HHV-7 using the p89 tegument protein. Immunohistochemistry often uses antibodies against gp82 (HHV-6A), p101 (HHV-6B), or pp85 (HHV-7). In situ hybridization using HHV-7 plasmid clone (pH7SB-268) has also been described.

The most sensitive diagnostic technique is quantitative PCR that is rapid and can be performed on samples obtained by noninvasive means. Real-time PCR using TaqMan reaction combines single-step amplification with

computer-based analysis. Detection of viral DNA in whole blood does not distinguish acute from previous infection but a high viral copy number, DNA in the absence of antibody, or DNA in plasma can suggest acute infection. Quantitative PCR is also of use in diagnosing reactivation in immunocompromised hosts, but HHV-6A DNA may not be identified in peripheral blood lymphocytes. Nested or multiplex PCR methodologies are also described. Published primers include a 240-bp amplicon of HHV-6 major antigen's structural protein, 5′-ATCTC-GATTCCGTTCAGTCT-3′ and 5′-TGAGACACCTGAA-GAAAAAG-3′, and a 186-bp amplicon corresponding to the U10 encoded structural protein of HHV-7, 5′-TATCCCAGCTGTTTTCATATAGTAAC-3′ and 5′-CAAAAAATCTAGTGCTACCGCAAGGC-3′.[11] For discrimination of HHV-6A and HHV-6B, primers that amplify an IE target have been described; a 278-bp amplicon of HHV-6A is generated with primers H6fA 5′-CATGAAGATGATGACAA-TAAAATG-3′, H6bA 5′-TGGAACCATCTTGTTCTGTCC-3′, and exonuclease probe H6tmA 5′-FAM-CCGCCCAGA[TAMRA]TCTGT-CACTGAGGCTG-3′p and a 145-bp amplicon of HHV-6B with primers H6fB 5′-GAGACCGGGTCTGGACAACA-3′, H6bB 5′-GAGTTGCTGAGTTGGTAAAGG-3′, and exonuclease probe H6tmB 5′-FAM-CTCCAAGTG-TACCGAAACGC[TAMRA]TTCCTGG-3′p.[12]

CONCLUSION

HHV-6A, HHV-6B, and HHV-7 are of interest as novel lymphotropic viruses. Because of the ubiquitous nature of these viruses and the subtle ways they interact with the immune system, further studies investigating the role they play in human diseases will be of great interest.

Molecular Diagnosis of HIV-1 and HIV-2

M

John R. Clarke
Imperial College of Science, Technology and Medicine, Paddington, London, U.K.

INTRODUCTION

More than 40 million people worldwide have been infected with the human immunodeficiency virus (HIV). There are 14,000 new infections every day and approximately 10,000 people die of AIDS every day. HIV-1 and HIV-2 are retroviruses and HIV-1 is responsible for the vast majority of HIV infections worldwide but HIV-2 predominates in parts of West Africa and has been detected in Europe, Asia, and North America.

The molecular diagnosis of HIV involves two major strategies. Firstly, the monitoring of plasma HIV RNA viral load in conjunction with CD4 T-lymphocyte cell numbers as surrogate markers for disease progression and, secondly, the detection of specific point mutations in the HIV-1 *pol* gene that confer resistance to specific antiretroviral drugs. More recently, mutations in *gag* which alter the p6/p1 splice site, in *env* which confer resistance to the fusion inhibitors, and in *integrase* which confer resistance to integrase inhibitors have also become important. HIV-1 RNA viral load assays have revolutionized patient management. Quantitative measures of HIV-1 RNA have been used in the study of HIV-1 viral dynamics and as a marker for clinical endpoints in studies of new treatment regimens.[1] The dynamics of HIV-1 replication using HIV-1 show that the virus is very active during the long clinically asymptomatic stage of the disease.[2] There is a significant relationship between HIV RNA viral load in plasma and progression to AIDS. Patients with low viral load progress to AIDS at a slower rate than those with a high viral load.[3] It has become standard practice to monitor HIV-1 RNA viral load in order to assess the effectiveness of treatment and the likelihood of clinical progression.

HIV VIRAL LOAD ASSAYS

There are four commercially available HIV RNA viral load assays in common use:

Nucleic acid sequence-based amplification (NASBA), branched chain DNA amplification (bDNA), reverse transcription PCR (RT-PCR), and the ligase chain reaction (LCx). The NASBA assay (Organon Technica) utilizes the Boom method for the extraction of total RNA from a plasma sample and this method produces sufficient high-quality RNA that can be used for other investigations such as HIV genotyping. The major difficulty with NASBA is the cumbersome nature of the RNA extraction procedure and the low throughput of the method. Automation of the extraction procedure has in part addressed these difficulties but not eliminated the problem altogether. The NASBA assay utilizes three enzymes which operate at low annealing temperatures and this could result in nonspecific interactions of the primers. The absence of temperature-dependent cycling steps in NASBA reduces the extent to which the amplification process can be externally controlled and may lead to variation in amplification efficiency.

RT-PCR (Roche Amplicor) remains the most sensitive HIV viral load detection system. The new Ampliprep system provides the first fully automated system for the determination of HIV-1 viral load and this will eliminate potential variation in assay results introduced by human error. The Ampliprep system is also barcoded and is optimized for high throughput of samples. Polymerase chain reaction-based approaches increase the possibility of introduction of contaminating RNA which may then be amplified resulting in false positive results. The reliance on one set of primers derived from the *gag* gene of HIV-1 may mean that quasi-species of HIV with multiple mutations in the 3′ primer attachment sequences are inefficiently amplified leading to under-detection or not amplified at all leading to false negative results.

The bDNA method (Versant Diagnostics) amplifies signal and therefore it does not alter the number of target molecules present which reduces the effect that introduction of contamination into a sample may have .The assay is well suited to high throughput of plasma specimens with as many as 168 samples being processed per assay run in the semiautomated 340 machine. The assay has no internal control within the sample and therefore there is no way of discerning if amplification was successful or whether the test was inhibited.

More recently, Abbott Diagnostics has launched the HIV-1 LCx ligase chain reaction assay which uses similar technology to the Roche Amplicor system.

DOI: 10.1081/E-EDGP 120020859

Abbott has developed a fully automated robotic system for their assay which will reduce technical ''hands-on'' time and operator error.

COMPARISON OF VIRAL LOAD ASSAYS

A number of studies have compared the performance of these assays in clinical situations. Schuurman et al.[4] showed that interlaboratory reproducibility of the Roche, Organon, and Versant assays was very good. Others have shown that each of the assays has relatively low intra- and interassay variability.[5] The biological variation of HIV-1 RNA in plasma in clinically stable individuals is approximately threefold (0.5 log) and this variation was not associated with diurnal fluctuations.[6] The anticoagulant used is important for optimal results and the preferred anticoagulant for bDNA is EDTA while citrate or EDTA may be used for NASBA and RT-PCR. Heparin interferes with reagents used in the assays and should be avoided and there is also some question over its effectiveness as a preservative for RNA.

Some samples give discrepant results between assay systems and therefore the assays should not be used interchangeably.[7] Of concern is that all commercially available kit-based assays have been optimized against HIV-1 clade B viruses which predominate in North America and Europe but represent only 3% of infections worldwide.[8,9] The challenge for commercial nucleic acid-based tests is to detect and quantify accurately very divergent strains of HIV-1 and HIV-2. Under detection or complete lack of detection of some strains of HIV remains a major concern.[8,10] Recombination between distantly related strains may further contribute to the emergence of HIV-1 viral variants that escape detection or are underdetected by current molecular tests and there are several circulating recombinant forms or CRFs which may contain sequences from more than one strain of HIV-1. Comparison of the performance of bDNA and RT-PCR assays for the quantification of viral load from patients infected with non-clade B strains of HIV-1 has shown greater than 1.0 log variation in the detection of some strains.[10] The choice of method for quantification is dictated by throughput of samples and the genetic makeup of the patient cohort. There is an urgent requirement for international standards which should include non-clade B strains to enable quality control of viral load measurements.

VIRAL LOAD ASSAYS UNDER DEVELOPMENT

Real-time PCR methods for the determination of HIV-1 viral load uses light cycler instrumentation, and the procedure has increased speed in detection over conventional PCR methods because of the removal of manipulations required for the detection of the PCR amplicon and the incorporation of rapid amplification coupled to fluorescence detection. However, the length of time taken to extract HIV-1 RNA from biological fluids is a hindrance. A recent method which uses lysates may have resolved this difficulty.[11] A further adaptation of real-time diagnosis are tests that are able to detect low copies of HIV-1 nucleic acid[12] as low-level replication of HIV-1 below the detection of current viral load assays may have some clinical importance. The HIV-1 Taqman 5′ nuclease PCR is also under development and may have application to the large throughput applications such as the screening of plasma from blood donors.[13] Use of an internal control in each reaction is essential to monitor sensitivity. The optimization of new quantitative assays should take into consideration the diversity of HIV-1 and where possible be able to detect outlier strains and HIV-2.

Other screening assays currently in use in the molecular diagnosis of HIV-1 include the Roche Amplicor HIV-1 test which is a qualitative assay that utilizes PCR and nucleic acid hybridization for the detection of HIV DNA from whole blood. The assay was optimized for clade B viruses but there are additional primers which facilitate the detection of non-clade B viruses and has application for the detection of HIV in recently infected individuals prior to the production of antibodies. The

method may also be adapted to detect HIV DNA in patients where antibody tests may be ineffective, such as infants born to HIV seropositive mothers.

MONITORING THE DEVELOPMENT OF ANTIRETROVIRAL RESISTANCE

There are currently 18 drugs licensed for use against HIV-1 and they are shown in Table 1. The compounds are active against the viral protease (protease inhibitors) and reverse transcriptase (nucleoside, nucleotide, and nonnucleoside analogues) enzymes. Other drugs in development include compounds directed against other viral targets such as integrase inhibitors and fusion inhibitors. Point mutations that confer resistance to nucleoside analogues and protease inhibitors appear to be similar for both HIV-1 and HIV-2.[14] However, HIV-2 isolates appear to be resistant to nonnucleoside reverse transcriptase inhibitors (NNRTIs) because of preexisting polymorphisms.[15] Mutations that

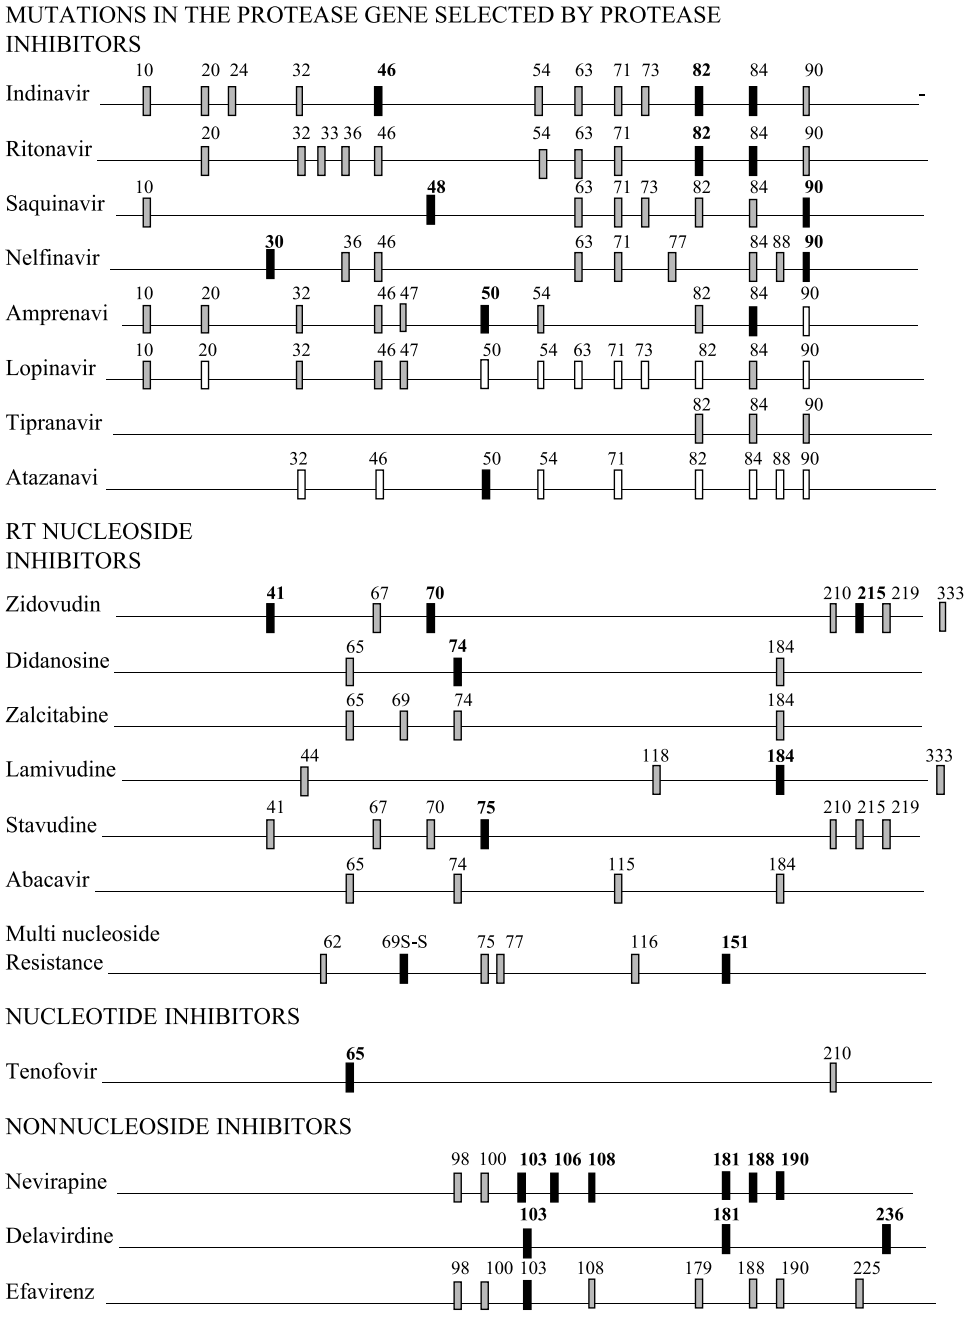

Fig. 1 Mutations in the HIV-1 *pol* gene known to reduce sensitivity of antiretroviral drugs. (*View this art in color at www.dekker.com.*)

confer resistance to antiretroviral drugs are well characterized (Fig. 1) and there are a number of PCR-based assays for the specific detection of known point mutations.

Initially, allele-specific PCR assays were developed by incorporating the specific point mutation conferring resistance into the final codon of the PCR oligonucleotide primer, and using stringent annealing temperatures to inhibit PCR amplification unless a perfect match was obtained.[16] The disadvantages of this approach were that low levels of nonspecific amplification could not be ruled out and that each mutation required a specific primer pair. An alternative approach for characterizing mutations was to use point mutation assays (PMA) which captured PCR products containing either wild-type or mutant codons using oligonucleotides containing the codon of interest.[17] The Inno-LiPA HIV-1 resistance assay is based on reverse hybridization technology.[18] The Inno-LiPA strips allow the detection of limited mutations in RT and protease. The limitation of LiPA and other hybridization assays is that HIV-1 is extremely heterogeneous and as many as 40% of samples may fail to yield results which reduces the clinical benefit of the assay in the routine detection of resistance.

The gold standard approach to the detection of mutations that confer resistance to antiretroviral drugs is DNA sequencing. Sequencing has two limitations, firstly, it is time consuming and requires well-trained personnel, and, secondly, it is relatively insensitive, the mutant strain must constitute at least 25% of the sample. Not only are known mutations detected this way, but new mutations arising with novel combinations of therapy will also be detected. Of particular concern is the emergence of new mutations that may confer cross resistance to all compounds in a class, e.g., the Q151 M mutation affecting the reverse transcriptase gene confers cross resistance to all six nucleoside analogues in clinical use.[19] Current sequencing protocols require at least 1000 copies of HIV RNA per milliliter of plasma. However, nested PCR methods increase the sensitivity of the assay and sequences may be obtained from samples containing a plasma viral load of <50 copies/mL,[20] which enables earlier detection of treatment failure. Reproducibility between kits is good with Visible Genetics and Applied Biosystems (ABI) detecting the same mutations in 91% of samples tested although some reduction in the detection of mixtures of wild type/mutant was observed in the ABI system because of the limitations of the software.[21] Viroseq (ABI) was able to sequence 97% of samples from non-clade B HIV-1 strains from Uganda.[22]

Interpretation of sequencing should take into consideration the clinical history of the patient which may be complex in the case of transmission of resistant virus either from a partner who has been extensively treated with antiretroviral drugs or as the result of the casual transmission of resistant virus from an unnamed source. A useful tool in interpreting mutations in HIV sequences and for subtyping HIV clade is the University of Stanford database which may be accessed through http://www.hivdb.stanford.edu. HIV subtype may also be determined via the National Centre for Biotechnology Information web site at http://www.ncbi.nlm.nih.gov/retroviruses/subtype/subtype.html. Usefulness of individual interpretation systems depends upon the accuracy of the algorithms used to set up the system which differ from system to system and this affects the interpretation of the influence some mutations have on the sensitivity of individual drugs.

CONCLUSION

In the next 5 years major efforts will be made to lessen the impact of HIV-1 in the developing world. The reduced costs of antiretroviral to these countries should be extended to cut-price viral load assays and sequencing machinery and kits. This would facilitate the monitoring of HIV-1 and HIV-2 infections in the growing number of infected individuals. New antiretrovirals will become available from new classes of drugs such as fusion inhibitors and integrase inhibitors which will increase the complexity of detection of resistant mutants. Improvements in the current viral load assays will allow more uniform detection of all clades of HIV-1. International standards will reduce the discrepancies observed between the current commercial viral load assays. Real-time PCR technology will further reduce the cost of carrying out viral load detection and improve the speed and sensitivity of current detection systems. The goal of molecular tests should be to detect one copy of HIV-1 RNA/mL of plasma to sequence low copies of HIV-1 RNA for residual resistance and for treatment to reduce levels of virus in plasma to absolute zero.

HyBeacon™ Probes

David John French
LGC (Teddington) Ltd., Teddington, U.K.

INTRODUCTION

Real-time PCR methods are of great importance to a multitude of diagnostic sectors, such as health care, forensics, food analysis, and defense, which require rapid genetic analysis. Traditional methods of sequence analysis are time consuming and need to be performed in specialized facilities, requiring multiple steps and techniques to achieve target amplification and detection. A range of fluorescent probe technologies, such as TaqMan, Scorpions, molecular beacons, and hybridization probes, has been developed to combine the target amplification, detection, and analysis processes required to type samples. The combination of amplification and detection in homogeneous real-time PCR reduces the duration of tests, often to less than 30 min, and decreases the possibility of cross-contamination. Such rapid analyses may be performed at the point-of-care (e.g., at hospitals and doctors surgeries) and in-the-field (e.g., on farms and battlefields) by individuals provided with minimal training.

HyBeacon™ probes provide a homogeneous method of ultrarapid sequence analysis that allows samples to be genotyped in less than 20 min. These fluorescent probes are capable of reliably detecting specific DNA targets and discriminating closely related sequences, including those containing single nucleotide polymorphisms (SNPs). As such, HyBeacon probes may be employed in a large number of applications including genetic diagnostics, disease predisposition, pharmacogenetics, and pathogen detection. HyBeacons exhibit a simplistic mode of action, possess few design constraints, yield easily interpreted melt peak data, and can simultaneously analyze multiple target sequences with a single probe. HyBeacon assays have been demonstrated to function efficiently directly from samples, such as saliva, without prior purification of nucleic acids, making the probe technology suitable for point-of-care diagnostics.

BODY OF TEXT

HyBeacons™

HyBeacon probes are target-specific linear oligonucleotides with fluorescent dyes attached to internal nucleotides.[1–3] Probes emit significantly greater amounts of fluorescence when hybridized to complementary target sequences than were single-stranded. HyBeacon probes do not possess quencher moieties attached to the oligonucleotide and the mechanism of target detection does not rely on probe secondary structures or enzymatic digestion.[1] The inherent fluorescence-quenching properties of DNA are responsible for the lower levels of probe emission in the single-stranded state, and hybridization to complementary targets directly relieves a large proportion of that quenching. This phenomenon enables specific target detection and reliable discrimination of DNA sequences. HyBeacon functionality does not appear to be dependent on nucleotide sequence or the location of guanosine residues within probe and target as reported for other single-labeled technologies such as Simple probes, LUX primers, and Smart probes.[4–6]

Melt Peak Analysis

Because the amount of fluorescence emitted from HyBeacons is determined by the hybridization state of the probe, the nature of target sequences may be determined by melting curve analysis (Fig. 1). At low temperatures, probes are hybridized to target sequences and emit elevated levels of fluorescence. As temperature increases, the level of fluorescence emission reduces as probes dissociate (melt) from their target sequences. The melting temperature (Tm) of the probe occurs when 50% is hybridized to target sequence and 50% is single-stranded. Probes hybridized to fully complementary target sequences are considerably more stable than those bound to targets containing regions of mismatch (Fig. 1). Therefore, closely related target sequences, differing by as little as a single nucleotide may be reliably differentiated on the basis of Tm. Melt peaks are highly specific and reproducible such that probe Tms may be employed directly to determine the nature of target sequences.

Single Probe Multiplex Analysis

Real-time PCR probe technologies, such as TaqMan and Scorpions,[7–10] achieve target detection through

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120025626

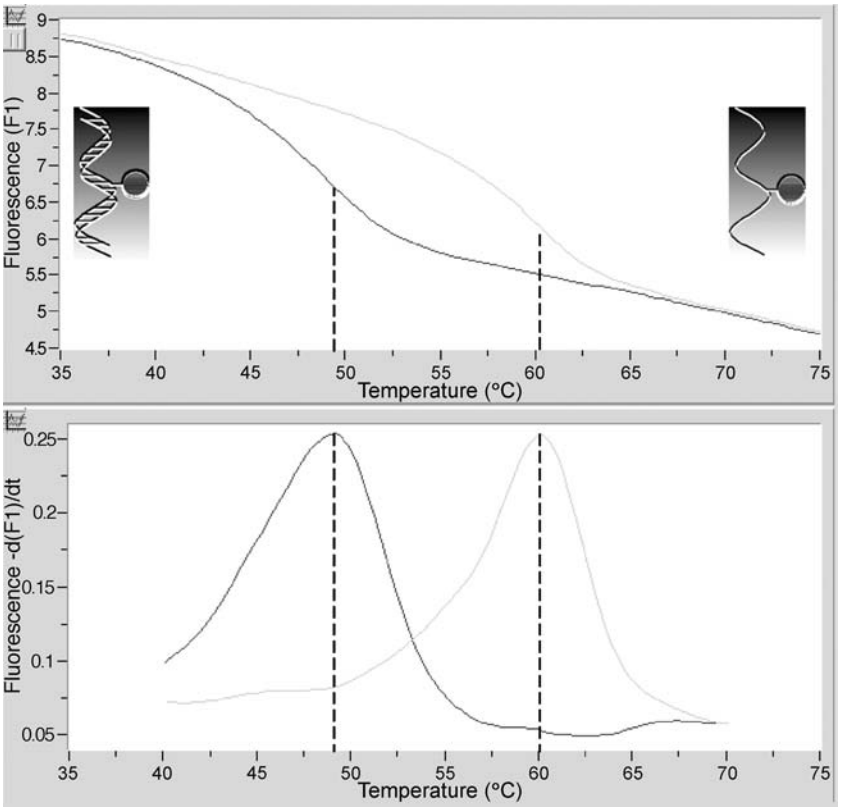

Fig. 1 Sequence analysis by Tm determination. HyBeacon fluorescence emission decreases as the temperature increases and probe/target duplexes melt to become single stranded. The upper graph displays melting curves from a probe hybridized to a fully complementary target and a sequence containing a single nucleotide mismatch. Fully complementary probe/target duplexes are more stable than duplexes containing positions of mismatch and exhibit considerably higher Tms. The lower graph displays the melt data in peaks to clearly measure probe Tm and determine the nature of the target sequence. (*View this art in color at www.dekker.com.*)

monitoring fluorescence emission during amplification. Increased levels of fluorescence are indicative of target amplification and may be employed to assess the presence or absence of particular sequences in test samples. However, numerous probes, labeled with spectrally distinct fluorophores, are typically required to simultaneously detect and differentiate multiple target sequences in a single reaction vessel. For example, different fluorescent probes are required for each allele of polymorphic genes to ensure correct identification of homozygous and heterozygous samples.

HyBeacon fluorescence typically only acquired post-amplification during melting curve analysis. Determination of melt peak Tms allows multiple target sequences to be simultaneously detected and identified using a single probe and fluorophore (Fig. 2).[1,2,4] Target sequences differing by as little as a single nucleotide may be simultaneously detected and reliably differentiated through the generation of multiple melt peaks such that samples homozygous and heterozygous for specific SNPs may be reliably genotyped with a single probe. This single-fluorophore method of multiplex sequence analysis may also be employed for applications, such as pathogen detection, that require an endogenous amplification control. Furthermore, unrelated target sequences may be simultaneously detected using multiple probes labeled with the same fluorophore. The number of target sequences that may be simultaneously analyzed depends on the Tms of each probe/target duplex, where a difference of at least 5°C is required to separate melt peaks and ensure correct identification of sequences.[1] The example presented below demonstrates simultaneous analysis of two adjacent polymorphisms in the human β globin gene, where combinations of three different melt peaks allow samples to be reliably genotyped.

Ultrarapid Diagnostics

HyBeacon sequence analysis may be performed in less than 20 min using rapid thermocyclers such as the

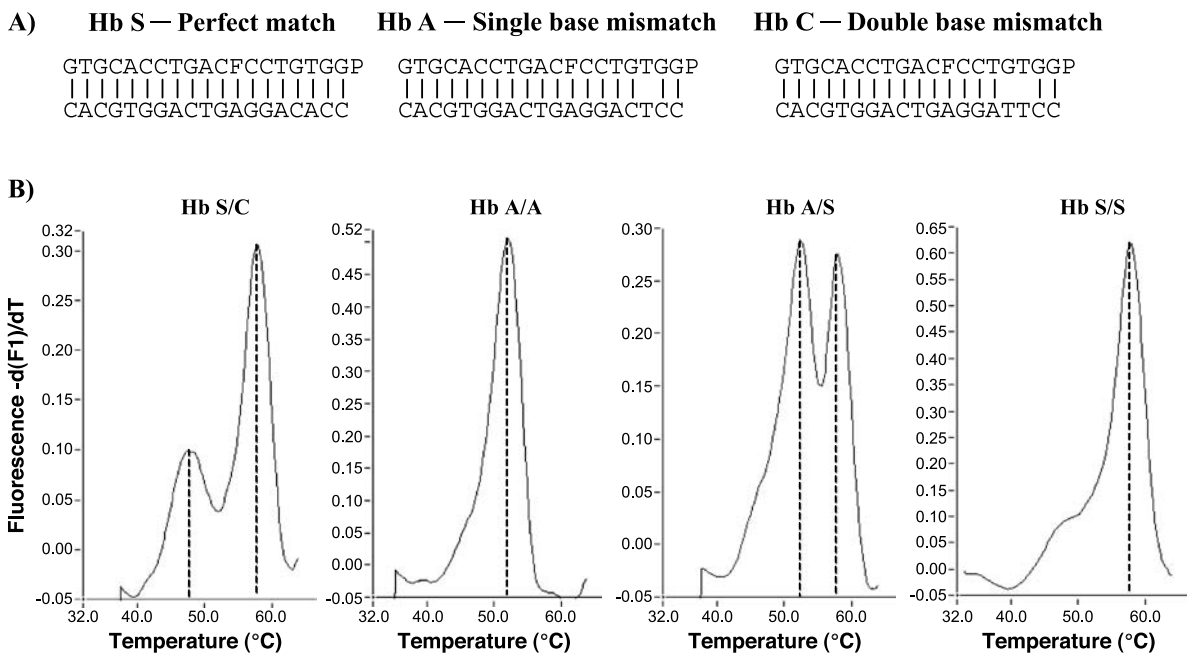

Fig. 2 Rapid analysis of sickle cell anemia polymorphisms. (A) The HyBeacon probe employed to genotype samples with respect to sickle cell disease was fully complementary to the sickle cell (HbS) allele, exhibiting single and double nucleotide mismatches when hybridized to normal β globin gene (HbA) and hemoglobin C (HbC), respectively. (B) HyBeacon probe hybridized to the fully complementary HbS allele possesses a Tm of approximately 58°C. Hybridization to the mismatched HbA and HbC alleles drops the probe Tm to 52°C and 48°C, respectively. Combinations of probe melt peaks allow determination of HbA/A, HbS/S, HbA/S, and HbA/C genotypes.

LightCycler. HyBeacon probes are capable of detecting both DNA and RNA targets, being compatible with single-tube RT-PCR, and PCR assays may comprise both three- and two-stage cycling protocols. Probes and assays may be designed such that HyBeacons are not hybridized to target sequences during PCR, thereby avoiding obstruction of DNA polymerase (cf. TaqMan) and enabling the use of extremely rapid thermal cycling conditions. Forty-five cycles of amplification have been achieved in less than 10 min using two-stage LightCycler thermal protocols and short incubation times. Following amplification, melt analysis may be completed in as little as 2 min. The length and composition of target sequences will affect amplification efficiency and determine PCR cycling conditions and assay duration. Although target sequences of 80–150 bp are typically employed in HyBeacon assays, it is sometimes necessary to analyze larger amplicons to ensure specificity in the presence of closely related sequences such as pseudogenes. The type and purity of samples to be analyzed will also affect the optimal PCR conditions and test duration.

Saliva samples may be employed directly in HyBeacon assays without the requirement for DNA purification.[2] Direct saliva analysis not only reduces the overall duration of assays, but also makes the tests noninvasive, thereby avoiding the safety issues associated with diagnostics using blood samples. Furthermore, providing saliva samples is easier, more acceptable, and less stressful for patients. Ultrarapid analyses will permit HyBeacons to be employed in point-of-care diagnostic scenarios and in-the-field applications where results are required quickly.

Model System

Sickle cell anemia is a disorder that affects red blood cells through altering the structure and function of the hemoglobin (Hb) protein that is required to carry oxygen around the body. Individuals with sickle cell anemia possess hemoglobin (HbS) which is different from the normal protein (HbA). Whereas normal red blood cells can bend and squeeze through small blood vessels easily, HbS can result in cells becoming sickle-shaped and rigid causing small blood vessels to get blocked. Such blockages can prevent sufficient passage of oxygen and may result in severe pain and damage to organs.

Sickle cell anemia was one of the first diseases found to be caused by a molecular defect, arising from a single nucleotide substitution (Fig. 2) that causes a glutamic acid

(GAG) in HbA to be changed to a valine (GTG) in the HbS protein.[11] This base difference has a major effect on the folding and functionality of the hemoglobin protein. Other types of hemoglobin, such as HbC and β thalassemia, can exacerbate the sickle cell condition when an individual possesses a copy of the HbS gene. The HbC allele arises from a base substitution adjacent to HbS that converts the glutamic acid to a lysine (AAG). A single HyBeacon probe enables multiplex analysis of the β globin variants to simultaneously genotype individuals with respect to both HbS and HbC alleles.

Rapid Analysis of Sickle Cell Samples

A HyBeacon probe was designed to simultaneously detect and differentiate HbA, HbS, and HbC target sequences. The probe was designed to be fully complementary to the HbS sickle cell allele, possessing single and double nucleotide mismatches when hybridized to HbA and HbC sequences, respectively (Fig. 2). The sickle cell HyBeacon was synthesized using methods described previously.[1,12] The probe sequence was 5′(GTGCACCTGACFCCTGTGGP)3′, where F and P were the FAM (6-carboxyfluorescein) labeled uracil and 3′ phosphate, respectively. The FAM fluorophore was included at an internal position of the oligonucleotide, and the 3′ phosphate was attached to prevent extension from probes during real-time PCR assays.

The HyBeacon probe was employed to detect a 139-bp amplicon containing the HbS and HbC loci. The sequences of the primers employed to amplify the probe target were 5′(AGGGCAGAGCCATCTATTGCT)3′ and 5′(CATCCACGTTCACCTTGCC)3′. Target sequences were amplified from genomic DNAs extracted from 12 clinical samples supplied by the National Haemoglobinopathy Reference Service (John Radcliffe Hospital, Oxford, U.K.). Samples were analyzed with a LightCycler™ instrument using materials and methods described previously.[1,2]

Melting peak analysis was performed following PCR to determine the nature of amplified targets by means of probe Tm. HyBeacon probe hybridized to the fully complementary HbS allele generated melt peaks possessing Tms of approximately 58°C (Fig. 2). Hybridization to the HbA allele resulted in a T/T nucleotide mismatch between probe and target sequence, reducing the melting temperature to 52°C. Probe hybridization to the HbC allele resulted in T/T and G/T mismatches causing the Tm to drop to 48°C. Combinations of melt peaks enabled samples to be genotyped rapidly and reliably. Melt traces possessing only 58°C or 52°C peaks were identified as being homozygous HbS/S and HbA/A, respectively. Samples that generated both 58°C and 52°C peaks were similarly typed as heterozygous for HbS and HbC alleles, whereas those producing both 58°C and 48°C peaks were typed as compound heterozygotes possessing both HbS and HbC (Fig. 2). The 12 clinical samples, analyzed blind, were found to comprise triplicates of HbS/C, HbA/A, HbA/S, and HbS/S genotypes (Table 1). Genotypes were confirmed by the National Haemoglobinopathy Reference Service.

Applications

The ultrarapid detection mechanism of HyBeacon probes will enable their use outside of specialized research facilities to analyze samples within 20 min. Utilized in hospitals and doctors' surgeries, HyBeacon assays may be employed to detect and identify nucleic acid target sequences for applications such as genetic diagnosis, disease predisposition, pathogen detection, pharmacogenetics,

Table 1 Analysis of sickle cell samples

Sample number	Hb C (46–50°C)	Hb A (50–54°C)	Hb S (56–60°C)	Genotype
1	48.04		57.78	Hb S/C
2		52.39		Hb A/A
3		52.32	58.2	Hb A/S
4			57.75	Hb S/S
5	47.29		57.68	Hb S/C
6		52.15		Hb A/A
7		52.41	58.25	Hb A/S
8			57.69	Hb S/S
9	47.3		57.86	Hb S/C
10		51.92		Hb A/A
11		52.2	58.15	Hb A/S
12			57.58	Hb S/S

Twelve genomic DNA samples were analyzed using a sickle cell-specific HyBeacon probe. Tm ranges were established to reliably detect and identify hemoglobin alleles, where combinations of peaks may be employed to determine sample genotype.

and lifestyle management. HyBeacon assays may also be utilized for in-the-field applications such as screening cattle for infectious diseases, testing water for pathogens at source, and detecting the presence of biological warfare agents for buildings, protection or on the battlefield. Because the melt peak Tms generated during analysis are characteristic of specific probe targets, samples could be typed automatically using specialized software. This would permit individuals with minimal training to interpret test data and enable HyBeacon assays to be employed in applications requiring high throughput.

CONCLUSION

HyBeacon probes are fluorescent oligonucleotides that may be employed in real-time PCR assays to rapidly detect and discriminate nucleic acid sequences for a multitude of diagnostic applications. Probes emit higher levels of fluorescence when hybridized to target sequences than when single-stranded and permit target identification through melt peak analysis and Tm determination. The lack of probe secondary structure, quencher attachment, and sequence dependence renders HyBeacons simple and relatively inexpensive to design and synthesize. Multiple target sequences may be simultaneously analyzed using HyBeacon probes and assays typically take less than 20 min to complete. Saliva samples have been utilized directly in HyBeacon assays to further decrease analytical time and increase utility for point-of-care applications. HyBeacon assays are currently in development to detect pathogens in samples of urine and blood without sample purification.

INTRODUCTION

Transplanting a failing organ or specific cell type is a logical means of restoring function for secretory diseases. While inherently appealing, the lack of suitable donor organs or tissues makes the widespread use of cell transplantation impractical. To overcome this limitation, xenogeneic cells can be encased within a selectively permeable polymeric membrane, known as immunoisolation. Immunoisolation owes much of its foundation to investigators focused on diabetes and Parkinson's disease, showing that islets and dopamine-secreting cells are protected from host rejection by encapsulating them within a semipermeable membrane. Single cells or clusters of cells can be enclosed within a selective, semipermeable membrane barrier that admits oxygen and required nutrients and releases bioactive cell secretions, but restricts passage of larger cytotoxic agents from the host immune defense system. Immunoisolation eliminates the need for chronic immunosuppression and allows the implanted cells to be obtained from human or nonhuman sources, thus avoiding the constraints associated with cell sourcing, which limit the clinical application of unencapsulated cell transplantation.

IMMUNOISOLATORY MEMBRANES

True immunoisolation requires restricting the membrane transport of all relevant molecules belonging to the host and the encapsulated cells. Whereas a molecular weight cutoff of 50–100 kDa likely prevents infiltration of IgG, greater size restrictions must be employed to achieve a complete barrier. Growth factors, cytokines, complement, and smaller metabolites several logs lower in molecular weight exist within immunoisolated systems that are immunogenic and can lead to graft rejection. Limiting passage of these smaller molecules would retain the cell-secreted molecule of interest, and thus such a system would not be practical. However, this level of protection is not always necessary, particularly in allogeneic or syngeneic transplantation, and immunosuppressants can be administered to overcome this effect.

The polymer membrane of an immunoisolatory device is a thin barrier that restricts transport between adjacent phases.[1–4] Most membranes are produced from thermoplastics such as polysulfone or acrylic copolymers that are cast into hollow fiber membranes less than 1 mm in diameter with a wall thickness of 10–15% of the total fiber diameter.[5–7] The majority of thermoplastic ultrafiltration and microfiltration membranes used to encapsulate cells are manufactured from homogenous polymer solutions by phase inversion. Ultrafiltration membranes have pore sizes ranging from 5 nm to 0.1 μm, while microfiltration (or microporous) membranes have pores ranging from 0.1 to 3 μm. Phase inversion forms membranes with a wide variety of nominal molecular weight cutoffs, permeabilities, and morphologies. The polymer is first dissolved in an appropriate solvent and then cast as a flat sheet or extruded as a hollow fiber. As part of the casting or extrusion procedure, the polymer solution is precipitated by a phase transition brought about by temperature change or solution composition. This process involves the transfer of a single-phase liquid polymer solution into a two-phase system consisting of a polymer-rich phase that forms the membrane structure and a second liquid polymer-poor phase that forms the membrane pores. Any polymer that forms a homogenous solution that will separate into two phases can be used. Thermodynamic and kinetic parameters, such as the chemical potential of the components and the free energy of mixing of the components, determine the manner of the phase separation.

CELL IMMUNOISOLATION

There are generally two categories of encapsulation, microencapsulation and macroencapsulation, each with some benefits and limitations. Several detailed reviews are available.[3–9]

Microencapsulation

Microencapsulation involves surrounding cells with a thin, spherical, semipermeable polymer film.[8] The small size, thin wall, and spherical shape of microcapsules are

DOI: 10.1081/E-EDGP 120029844

structurally optimal for diffusion, cell viability, and release kinetics. The material components of microcapsules vary from polysaccharides to thermoplastics. There are potential benefits associated with each choice; however, during the manufacture of certain thermoplastic cell-encapsulated systems, exposure to organic solvents is not easily avoided and is a potential viability risk. Thus, work has primarily focused on the polyelectrolytes, which are nontoxic during processing but are generally mechanically fragile and chemically unstable, as well as difficult to retrieve. For the polyelectrolytes, microcapsule membranes are formed by ionic or hydrogen bonds between two weak polyelectrolytes with opposite charges. Microcapsules can be prepared by gelling droplets of a polyanion/cellular suspension (e.g., alginate) in a mixing divalent cationic bath, which immobilizes the cells in a negatively charged matrix, and then coating the immobilized cells with a thin film of a polycation, such as poly (L-lysine). The poly(L-lysine)-alginate bond creates a permselective membrane whose molecular mass cutoff is on the order of 30,000–70,000 Da. Because poly(L-lysine) is not biocompatible, a second layer of alginate is generally added to the capsule surface. Alternatively, polyanions such as polyornithine have greater reactivity during capsule formation and are biocompatible. Polyelectrolyte-based techniques avoid organic solvents, and, with proper permeability control, microcapsules represent a very effective configuration for cell viability and neurochemical diffusion.

Macroencapsulation

Macroencapsulation involves filling a hollow, usually cylindrical, selectively permeable membrane with cells, generally suspended in a matrix, and then sealing the ends to form a capsule.[4] Polymers used for macroencapsulation are biodurable, with a thicker wall than that found in microencapsulation. While thicker wall and larger implant diameters can enhance long-term implant stability, these features may also impair diffusion, compromise the viability of the tissue, and slow the release kinetics of desired factors. In theory, macrocapsules can be retrieved from the recipient and replaced if necessary.

Macroencapsulation is generally achieved by filling preformed thermoplastic hollow fibers with a cell suspension. The hollow fiber is formed by pumping a solution of polymer in a water-miscible solvent through a nozzle concurrently with an aqueous solution. The polymer solution is pumped through an outer annular region of the nozzle, while the aqueous solution is pumped through a central bore. Upon contact with the water, the polymer precipitates and forms a cylindrical hollow fiber with a permselective inner membrane. Further precipitation of the polymer occurs as the water moves through the polymer wall, forcing the organic solvent out and forming a trabecular wall structure. The hollow fiber is typically collected in a water bath, allowing complete precipitation of the polymer and dissolution of the organic solvent. The ends of the hollow fiber are sealed using a biocompatible fast-curing adhesive manually applied to the ends of the device. A second method of macroencapsulation, called coextrusion, avoids the sealing problem by entrapping cells within the lumen of a hollow fiber during the fabrication process. Pinching the fiber before complete precipitation of the polymer causes fusion of the walls, providing closure of the extremities while the cells are inside.

CELLS AND EXTRACELLULAR MATRICES USED IN ENCAPSULATION

Successful cell encapsulation involves the choice of the cells to be encapsulated, the type of intracapsular matrix used, and the ability to control membrane geometry, morphology, and transport.[3–9] Cells placed within encapsulation devices generally fall into one of three categories (Table 1) including primary postmitotic cells, immortalized (or dividing) cells, and cell lines that are genetically engineered to produce specific factors. Dividing tissue has advantages over postmitotic tissue; it can be expanded, banked, and thus more easily tested for sterility and contaminants. However, dividing tissue is also constrained by the potential for overgrowth within the capsule environment, resulting in an accumulation of necrotic tissue that could diminish the membrane's

Table 1 Essential components of an immunoisolatory device

Cells	
Primary	Islets (diabetes), hepatocytes (liver failure), chromaffin cells (pain and Parkinson's disease)
Dividing	PC12 cells (Parkinson's disease)
Genetically engineered	Fibroblasts producing neurotrophic factors
Extracellular matrix	
Hydrogels	Alginate and collagen
Scaffolds	Foamy materials including urethane
Membranes	
Dialysis membranes	PAN–PVC, polysulfone, polyethersulfone
Polyelectrolytes	Alginate, polylysine, polyornithine
Combinations	Conformal coating on surface Combined with reinforcing structures

permeability characteristics, further reducing cell viability and neurochemical output.

In vivo, extracellular matrices (ECMs) control cell function through the regulation of morphology, proliferation, differentiation, migration, and metastasis. Within a capsule, ECMs are used to prevent aggregation of cells (immobilization) and resultant central necrosis, but are also beneficial to the viability and function of cells that require immobilization. For example, adrenal chromaffin cells have been immobilized in alginate to prevent aggregation and the formation of central necrotic cores. The chromaffin cells thrive in alginate whereas mitotically active fibroblasts do not. In this case, the use of alginate is essential to the optimal functioning of this device because some anchorage-dependent cells such as fibroblasts or endothelial cells are present with the adrenal chromaffin cells. In the absence of alginate or similar immobilizing matrices, the fibroblasts expand and overgrow the encapsulated milieu, resulting in a device deficient of bioactive factors produced from the chromaffin cells. In contrast, BHK cells, a fibroblastic cell line, prefer collagen, whereas PC12 cells exhibit a preference for distribution within precipitated chitosan, which provides a scaffolding structure on which the cells anchor.

Polymeric matrices can also be used as cell scaffold material. Poly(ethylene oxide) (PEO)–star copolymers have been fabricated as a potential synthetic extracellular matrix. The star copolymers provide many hydroxyl groups where various synthetic oligopeptides can be attached to desired specifications. Other more resilient polymers such as poly(ethylene terephthalate) (PET) polymers can be extruded into unique geometries which facilitate a three-dimensional arrangement of cells within the device, such as cylinders, braids, or other geometries. Polyesters such as this can be modified to have a surface microtexture for improved cell anchoring or attachment of peptides or other components desirable for cell attachment.

ONGOING CLINICAL TRIALS

As shown in Table 2, there are extensive ongoing efforts to develop cell encapsulation across a wide range of preclinical and clinical applications. Here we highlight the ongoing clinical efforts using encapsulated cells for treating CNS diseases.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a progressive degeneration of spinal motor neurons. Systemic delivery of ciliary neurotrophic factor (CNTF) has therapeutic potential but is limited clinically because of systemic side effects, short half-life, and the inability to cross the BBB.[10] Continuous intrathecal delivery of CNTF proximal to the nerve roots in the spinal cord could result in less side effects and better efficacy of CNTF in ALS patients.[11] After safety, toxicology, and preclinical evaluation, a clinical trial was performed to establish the safety of encapsulated CNTF-producing cells in ALS patients. Six ALS patients with early-stage disease received BHK cells that were encapsulated into 5 cm long $\times$ 0.6-mm diameter hollow membranes and implanted into the lumbar intrathecal space. CNTF from the cells was found in all six patients at 3–4 months post-implantation. All six explanted devices had viable cells and detectable CNTF secretion. More recently, a phase I/II clinical trial was initiated in 12 ALS patients using the same approach. CNTF was detectable for several weeks in the CSF of 9 out of 12 patients, and only a very weak antigenic immune response was detected with bovine fetuin as the main antigenic component.[12]

Huntington's Disease

Huntington's disease (HD) is an inherited neurological disorder characterized by an intractable course of mental deterioration and progressive motor abnormalities with death usually occurring within 15–17 years. There are no treatments for HD. Recent studies have suggested that CNTF might slow the neural degeneration in HD.[13–15] Clinical trials are underway to determine the safety and tolerability of CNTF-producing cells implanted into the lateral ventricle of HD patients.[16] Although the results of this trial are not yet available, the trial is designed using a device containing as many as 10^6 CNTF-producing BHK cells producing 0.15–0.50 μg CNTF/day implanted into the right lateral ventricle of six patients. In this phase I study, the principal goal is to evaluate the safety and tolerability of the procedure. HD symptoms will also be analyzed using neuropsychological, motor, neurological, and neurophysiological tests and the striatal pathology monitored using MRI and PET-scan imaging.

Retinitis Pigmentosa

Retinitis pigmentosa (RP) is an inherited disorder of the retina and is the sixth leading cause of blindness. Whereas current clinical strategies are primarily palliative in nature, research in animal models demonstrates that neurotrophic factors inhibit retinal degeneration caused by RP. Studies in the *rd* model of retinal degeneration demonstrated that CNTF gene transfer maintains retinal morphology,[17] and later studies in the *rcd1* dog model[18] using intravitreal implants of encapsulated CNTF-secreting cells demonstrated a dose-dependent preservation of rods. In the dog studies, untreated eyes showed, on

Table 2 Diseases for which cell encapsulation is being applied

Disease/model	Encapsulated cell/experimental paradigm	Results
Hormonal and whole-organ diseases		
Diabetes	Islets in rodents and dogs	Normoglycemia for 2 years
Hypoparathyroidism	Parathyroid tissue in rats	Normocalcemia for 30 weeks
Kidney failure	Orally delivered *Escherichia coli* bacteria to rats	Normalized urea metabolism
Growth hormone deficiency	Growth hormone-producing cells in dogs	Hormone secretion for 1 year
Single-gene diseases		
Hemophilia	Factor 9 cells in rats	Cell survival and secretion
Lysosomal storage disease	Beta-glucuronidase cells in mice	Behavioral normalization
Age-related/Neurodegenerative-diseases		
Age-related motor decline	Catecholamine and GDNF cells in rats	Improvement in motor function
Amyotrophic lateral sclerosis	CNTF-producing cells in mice	Protection of motor neurons
Alzheimer's disease	NGF cells in rat and primates	Protection of cholinergic neurons, improved memory
Huntington's disease	NGF and CNTF cells in rats and primates	Protection of neurons, improved behavior
Parkinson's disease	Catecholamine and GDNF cells in rat and primate brain	Improved behavior, protection of dopaminergic neurons
Retinitis pigmentosa	Human cells secreting hCNTF into the vitreous	Rod preservation
Spinal cord damage	BDNF cells in rats	Outgrowth of neurites
Oncology		
Colon cancer	iNOS cells (tet-regulated system) in mice	Enhanced survival
Glioblastoma	Endostatin cells in mice and rats	Reduced tumor growth, enhanced survival
HER-2/neu positive tumors	IL-2 fused with anti-HER-2/neu antibody in mice	Modest survival benefit
Leukemia	Hybridoma producing antibodies to p15E in mice	Enhanced survival
Ovarian cancer	iNOS cells (tet-regulated system) in mice	Enhanced survival, cures
Other		
Acute and chronic pain	Chromaffin cells in rats	Reduced pain
Clinical trials		
Amyotrophic lateral sclerosis	CNTF cells intrathecally	Sustained delivery, no toxicity
Chronic pain	Chromaffin cells in subarachnoid space	Prolonged cell survival, no pain reduction in phase II trials
Diabetes	Human islets intraperitoneally	Insulin independence for 9 months
Huntington's disease	CNTF cells into ventricles	Delivery for 6 months
Hypoparathyroidism	Parathyroid tissue	Successful in two patients
Pancreatic cancer	CYP2B1 cells in tumor vessel	Local tumor growth controlled, well tolerated
Retinitis pigmentosa	CNTF cells in eye	Ongoing

average, three layers of the outer nuclear layer, while treated eyes showed between three and six layers. The distribution of retinal preservation was homogenous throughout the retina. These experiments paved the way for the recently initiated clinical trials by Neurotech USA. Patients diagnosed with RP have received intravitreal implants of an immunoisolatory membrane containing a human epithelial cell line engineered to secrete CNTF. Results from this phase I safety study are anticipated in 2004–2005.

CONCLUSION

There is an abundance of work in the field of immunoisolation to highlight the importance of creating a synergistic system that is capable of maintaining the production and delivery of secreted factors while promoting device viability and rejecting cells and molecules of the immune system. An effective device relies on the ability of the cells to withstand transplant conditions, and likewise, the encapsulated cells must be in a favorable

immunoisolatory environment to optimally perform their function. Immunoisolation can be achieved using a variety of materials and techniques described, but the secreted component must be able to diffuse outward while inward transit of immune components is halted. Ongoing research and the products being investigated in clinical trials will provide the field of cell transplantation with a tangible picture of the true importance of immunoisolation.

Introduction of Molecular Genetics and Genomics Into Clinical Practice

Ronald J. A. Trent
Bing Yu
Melody Caramins
Royal Prince Alfred Hospital, Camperdown, Australia

INTRODUCTION

The Human Genome Project (HGP), a multibillion, multinational endeavor to sequence the entire human genome, as well as the genomes of model organisms, was started in 1990, and the completion was announced in 2000. In February 2001, the first draft of the human genome sequence was published. In 2003, the 50th anniversary of the discovery of the DNA double helix, a high-quality version of the human genome sequence became available. The HGP-driven research is leading to a rethinking of genetics and the impact of genes on human health. This will have a profound influence on clinical practice.

Molecular genetics is a relatively new entry into pathology. It was only in 1978 that the first prenatal diagnosis was made with this approach. Today, the DNA-based test has become an integral component of clinical genetics. As knowledge gained from the HGP expands our understanding of human genetic disorders and genetic components of common complex diseases, the scope for DNA testing increases. Current interest in DNA diagnostics predominantly focuses on single-gene disorders. The challenging developments ahead are in the fields of DNA diagnostics involving somatic cell (acquired) disorders for which there is a genetic predisposition, and multifactorial disorders that involve genetic susceptibility interacting with the environment.

The HGP has brought about another change, with the traditional concept of genetics expanding into genomics. With the term ''genetics,'' the focus was on a single disorder. In this situation, a mutation in the DNA allowed a diagnosis to be made, and perhaps some understanding of pathogenesis was gained. In contrast, genomics has wider ramifications, and it has been used to refer to all genes in the genome rather than individual ones, including their function, sequence, and interactions with the environment.

DNA TECHNOLOGY

As will be illustrated in this encyclopedia, technological developments in molecular genetics and genomics are impressive. Particularly relevant will be microarrays (discussed further in ''Classes of DNA Tests'') and nanotechnology. The latter will allow miniaturization of all steps in DNA testing. Small, compact analytical platforms will ensure mobility, thereby allowing DNA testing to move to the bedside or the consultant's office. This will have direct relevance to the emerging field of pharmacogenetics and pharmacogenomics because it will allow health professionals to test individuals to determine their susceptibility to drugs, and, from this, to personalize various treatment regimens.[1,2] This will be discussed further under ''Classes of DNA tests.''

When the controversy about the patenting of human genetic sequences is settled, there is likelihood that commercial companies will have significant control over the range of DNA tests provided. This will be accomplished through licensing. Control will also be exerted through the development of kits. For these kits to be commercially viable, they will need to be user-friendly—and this, coupled with nanotechnology, will greatly expand the availability of DNA testing to health professionals.

CLASSES OF DNA TESTS

The unique feature of DNA in molecular genetics/genomics is its ability to use this approach to investigate many clinical scenarios (Table 1). The range is extensive, starting with the straightforward DNA diagnostic test confirming that an individual with a clinical problem has a genetic disease. The next level of complexity involves population screening, or DNA predictive testing for late-onset genetic disorders. Many of these DNA tests require

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120025589

Table 1 Classes of DNA genetic tests

DNA test and description	Examples
Diagnostic—A DNA test used to confirm a clinical suspicion that the patient has an established disorder. The DNA test in this circumstance is comparable to a blood count or measurement of a biochemical analyte, although a positive result has implications for family members.	A suspected case of hemochromatosis can be confirmed by a liver biopsy, a procedure that has associated morbidity and mortality. An alternative is a DNA test, used to look for the common hemochromatosis mutation (C282Y) to confirm the clinical suspicion.
Prenatal—DNA test to detect a genetic disorder in the fetus or embryo.	1) *Fetal prenatal diagnosis*. Straightforward DNA test in an at-risk fetus. Sources of fetal DNA include desquamated cells in the amniotic fluid (obtained during amniocentesis) or chorionic villi (chorion villus sampling, or CVS). 2) *Preimplantation genetic diagnosis* (PGD). A few cells obtained from the developing preembryo allow genetic diagnosis in vitro (i.e., in vitro fertilization, or IVF). This allows early detection of an abnormality and avoids termination of pregnancy. PGD is still not robust enough to be routinely available.
Screening—A DNA test used to look at asymptomatic individuals (or populations) to determine who are carriers or who have a genetic predisposition.[3,4] Various types of screening options are available.	1) *Reproduction screening*. DNA tests are undertaken to identify couples who are at risk for a genetic defect in the fetus. Presently, most reproduction screenings are undertaken because there is a family history, or because the couple demonstrates a risk factor (e.g., advanced maternal age). 2) *Newborn screening*. Newborns are screened for a number of genetic disorders that are treatable or preventable, provided they are diagnosed early. 3) *Community screening*. This involves the DNA testing of populations who have *no prior risk*. The populations can be whole communities (comparable to mammography screening for breast cancer) or selected communities. An example of whole community testing would be DNA-testing all pregnant women for cystic fibrosis. A selected community screening program is exemplified by testing for Tay Sachs disease in Ashkenazi Jews.
Predictive or presymptomatic—A DNA test used to predict the development of a genetic disorder in advance of any signs or symptoms (for convenience, a distinction is not made between predictive and presymptomatic).[5]	1) *Neurological adult-onset disorders*. Huntington disease (HD) develops around the fourth decade of life. The DNA predictive test is used to identify whether an at-risk individual has inherited the mutant or normal gene from an affected parent. Although no treatment is available, the HD predictive test is useful because penetrance is very high in HD. 2) *Cancers*. Individuals with a high risk of familial breast cancer can have DNA testing of *BRCA1* and *BRCA2* genes to look for a mutation that might guide them in future treatment decisions, as well as identify risks in other family members. However, unlike genetic forms of colon cancer, such as familial adenomatous polyposis, the penetrance with *BRCA1* and *BRCA2* is quite variable (36–85% lifetime risk) and so understanding the significance of breast cancer gene mutations is not easy.

(*Continued*)

Table 1 Classes of DNA genetic tests (*Continued*)

DNA test and description	Examples
Individualizing—A form of DNA screening test involving drug metabolism pathways to predict a patient's response to treatment.[6] Unlike screening mentioned above, this type of test is directed to the individual.	1) *Malignant hyperthermia*. Individuals exposed to anesthetic agents can develop life-threatening complications if they have a genetic abnormality involving the ryanodine receptor genes (*RYR1*).[4] 2) *Oral anticoagulation with warfarin*. Side effects of anticoagulation treatment include life-threatening bleeding episodes. Two genetic variants of the important warfarin-metabolizing enzyme (hepatic microsomal enzyme CYP2C9) are associated with decreased enzymatic activity.[2]

a more sophisticated approach to interpretation and greater resources to ensure that they are undertaken optimally. A final class that is not yet a component of routine practice is the potential to individualize treatment options to avoid drug-induced morbidity and mortality.[7]

DNA screening is worth considering in more detail because it will continue to remain topical for some time. Newborn screening is well accepted as an approach to detecting genetic or metabolic disorders for which intervention is possible, thereby preventing the disease or its consequences from developing. A good example is phenylketonuria. By identifying this early in the newborn, the development of mental retardation can be prevented by a phenylalanine-restricted diet. More controversial is DNA newborn screening for cystic fibrosis. Because there are no specific preventative measures, the value of this test has been questioned. However, it has been justified on the basis that the earlier detection of cystic fibrosis avoids anxiety and uncertainty in the parents if their child is ill and a diagnosis is not made. There is also some evidence that the long-term outlook is improved.[8]

Another type of DNA screening, which involves the testing of *asymptomatic* individuals in the community for recessive conditions, has provoked a lot of discussion. The article by Grody[4] notes that cystic fibrosis has the ''honor of being the first disease subject to nationwide, pan-ethnic molecular genetic screening.'' However, the National Institutes of Health (NIH) reference quoted specifically advises against cystic fibrosis genetic testing in the general population or newborns. Apart from DNA testing in those with a positive family history, the NIH consensus statement recommends cystic fibrosis DNA testing in couples planning a pregnancy or seeking prenatal care.[9] Despite this, the routine DNA testing of couples in relation to reproduction has not been adopted universally. Problems that need to be addressed include the logistics of pretest and posttest counseling. In multicultural societies, there is the additional consideration of risk variability and the optimal mutation profile is required. The latter is relevant for cystic fibrosis DNA testing, which has low sensitivity because of the large number of mutations present.

The potential utility for genomics on clinical decision making is illustrated by a microarray example, which allowed 295 patients with primary breast cancer to be studied by measuring the expression of 70 genes likely to influence the natural history.[10] These 70 genes involving cell cycle regulation, invasion, metastasis, and angiogenesis were initially selected from a 25,000-gene array. Based on gene expression patterns, patients were stratified into high-risk and low-risk groups. It was claimed that this was a more powerful predictor of clinical outcomes in breast cancer than conventional clinical or histopathological criteria. Decisions about benefits patients would derive from adjuvant treatment (hormonal or chemotherapy) could then be based on more objective data.[10]

UNDERSTANDING DISEASE PATHOGENESIS

Cystic fibrosis illustrates how our understanding of this disorder has changed through molecular genetics. What was previously a ''disease'' is now a syndrome because DNA-based knowledge has shown that a number of sporadic conditions are part of the cystic fibrosis spectrum. These include meconium ileus in the fetus, male infertility related to congenital bilateral absence of vas deferens (CBAVD), some forms of disseminated bronchiectasis,

and chronic idiopathic pancreatitis. Evidence that the aforementioned are mild forms of cystic fibrosis has come from population studies in which it was shown that mutations in the cystic fibrosis gene known as *CFTR* (cystic fibrosis transmembrane conductance regulator) were more commonly found in the patient group compared with controls. For example, 13% of 134 patients with chronic pancreatitis had one *CFTR* mutation compared with the population frequency of 5%. In addition, 10% of the patients (twice the expected frequency) had 5T splicing abnormality, which is associated with impaired function of *CFTR*.[11] A similar story is seen in disseminated bronchiectasis, with increased finding of 5T defect and a greater number of *CFTR* mutations compared with what would be expected in the normal population. In CBAVD, the 5T allele and a *CFTR* mutation (R117H) are often detected. In up to 50% of patients with CBAVD, it is possible to detect two *CFTR* mutations.[12]

RESOURCES FOR EDUCATION

The rapid changes occurring in molecular genetics mean that Internet-based resources play an important role in educating health professionals. Patients and families can be well informed about genetic disorders, and this places additional pressure on health professionals to have access to the most recent developments. OMIM (Online Mendelian Inheritance in Man™: http://www.ncbi.nlm.nih.gov/Omim/)[13] is a reputable catalogue of human genetic disorders. Two other sites providing teaching and learning resources include http://www.nchpeg.org[14] and http://genes-r-us.uthscsa.edu/resources/genetics/primary_care.htm.[15] Computer-based decision making is another option to consider in the rapidly progressing field of molecular genetics and genomics. An example of this is shown in a pilot study utilizing 36 UK general practitioners. Patients with a positive family history of breast cancer were assessed using the traditional pen-and-paper approach vs. a computerized pedigree drawing package or a computerized decision support package. Perhaps not surprisingly, decision making was superior with the latter option.[16]

ETHICAL, SOCIAL, AND LEGAL ISSUES

There are a number of potential ethical and social issues emerging in molecular genetics/genomics.[17] The main areas of concern include access, equity, and an enlarging gap between what is being tested for and what can be done in terms of therapy and prevention. There are also issues related to privacy, discrimination, and stigmatization. The first three require societally determined standards to ensure that DNA tests are used appropriately, particularly when resources are limited. To complicate this further, there are likely to be tensions between industry and the publicly funded health and research organizations. This union is of mutual benefit and is needed to provide expensive resources for many of the large gene discovery and genomics enterprises (an example of this is the microarray study described earlier). However, as industry has greater involvement in clinical genetics, there is the potential for more extensive (but not necessarily relevant) DNA testing. In this environment, health professionals can also be bypassed by direct company-to-consumer advertising and DNA testing.[18]

Issues with more implicit legal implications arise when there are threats to privacy/confidentiality raised by the specter of DNA tests identifying information on individuals for which consent has not been given. Related to this is the potential for DNA information to lead to discrimination or stigmatization because an individual has a particular DNA change, which either has the propensity for developing into disease at some time in the future, or, even more complex, is associated with a behavioral trait. Because of the community's fear that these may occur, there is often pressure for new laws to be passed. In some circumstances, a law may be necessary, but rapid changes occurring in genetics/genomics make legal options less than ideal because laws can be inflexible. Hence, alternative approaches such as education should be tried, as many of the problems that arise do so because of ignorance.

From the clinical perspective, the ethical, social, and legal issues add another layer of complexity when dealing with molecular genetics/genomics. The concepts of informed consent and duty of care are well established and provide health professionals with broad guidelines for clinical consultation. However, molecular genetics (and particularly genomics) adds new dimensions: 1) knowledge is often changing; and 2) effects can be far-reaching (i.e., results for a patient will have implications for other family members). In this environment, continuity of care and long-term follow-up become particularly important.

CONCLUSION

Molecular genetics—and now the genomics era—has brought clinical genetics to the cutting edge of medical practice. Not only is clinical genetics impacting on internal medicine and family practice, but it is relevant to many other disciplines. Specialized clinical genetics

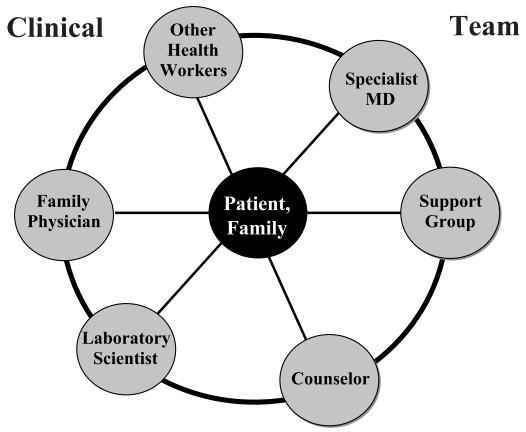

Fig. 1 Central to genetic issues are the patient and the family. Various interactions involving a range of health professionals and support groups provide the optimal approach in dealing with molecular genetics (genomics) issues. What particular combination is needed will depend on the underlying problem and the ability of the patient and the family to deal with associated issues.

units have formed in many medical centers, and the work undertaken extends from traditional fetal medicine and pediatrics problems to adult genetics. The distinction is made because training in genetics has often come through pediatrics, but this is now changing because molecular genetics has relevance to any age group. For example, the geriatrician of the future will need to understand molecular genetics as knowledge is gained about the molecular basis for aging, including common disorders at this time of life such as dementia, heart disease, and osteoporosis, to name a few.

Genetics clinics, comprising the specialist physician and the genetic counselor, ensure that DNA testing is appropriate. The clinics provide relevant counseling and support, particularly in circumstances of predictive DNA testing where an adverse result has implications for the patient and the family members. Because of the nature of molecular genetics, these clinics are often broadly based and deal with issues ranging from dysmorphology to pediatric genetic problems, to reproductive genetics, and to an increasing range of adult-based genetic issues and community ''public health'' screening genetics. This arrangement has allowed molecular genetics to develop rapidly. However, it is now time to rethink and consider the future model for clinical genetics, particularly in the light of the vast amount of data that will emerge in the next few years.

The clinical practice of the future will need to contend with an expanding database of knowledge gained from genomics that will overlap many clinical disciplines. The physician of first contact, the family physician, is asked by patients about genetic tests that have been featured in the media. Patients and families are becoming increasingly aware and knowledgeable about genetic disorders and DNA testing because of the media and access to the Internet. The complexities and sheer volume of knowledge about the genome require novel and computer-based learning activities. Greater specialization is inevitable, and general genetics clinics will increasingly need to move into multidisciplinary clinics involving a number of health professionals including family support groups. This *molecular medicine team* will ensure that the level of knowledge is contemporary, and that the patients and their families can have access to advice from a range of experts, as well as access to support from other parents or families with experience in genetics problems (Fig. 1). Without this division of work and close interactions between various disciplines, resources and expertise will be severely limited when our understanding of multifactorial genetic disorders (common conditions such as dementia, heart disease, stroke, and sporadic cancers) adds a DNA dimension to their prevention and treatment.

Invader® Assay

Stephen Day
Andrea Mast
Third Wave Technologies, Madison, Wisconsin, U.S.A.

INTRODUCTION

The Invader® platform (Third Wave Technologies Inc., Madison, WI) is a homogeneous, isothermal, DNA probe-based system for highly sensitive, quantitative detection of specific nucleic acid sequences. It is an accurate and specific detection method for single-base changes, insertions, deletions, gene copy number, infectious agents, and gene expression. Invader reactions can be performed directly on genomic DNA- or on RNA-, PCR-, or RT-PCR-amplified products. A target-specific signal is amplified but not the target itself.

BACKGROUND

The Invader technology is based on the ability of a Cleavase® enzyme to recognize and cleave a specific nucleic acid structure generated by an overlap of two oligonucleotides (oligos)—the Invader oligo and the primary probe—on the nucleic acid target. Cleavase enzymes are a family of naturally occurring as well as engineered thermophilic structure-specific 5′ endonucleases.[1] Cleavase enzymes for use in DNA assays are derived from members of the flap endonuclease (FEN-1) family, typically found in thermophilic archaebacteria.[1] Invader RNA assays use Cleavase enzymes that are engineered from the 5′-exonuclease domain of DNA polymerase I of thermophilic eubacteria.[2] The optimal substrate for these nucleases is composed of distinct upstream, downstream, and template strands, which mimic the replication fork formed during displacement synthesis. The enzymes cleave at the 5′ end of the downstream strand between the first 2 base pairs and remove the single-stranded 5′ arm or flap.[1]

STRUCTURE FORMATION

The primary probe consists of two functionally different regions: a 5′-flap sequence and a 3′ target-specific region (TSR). The sequence of the 5′-flap varies in length (typically 1–15 nucleotides) and, because it is independent of the target, can consist of any sequence. The 3′ base of the Invader oligo overlaps with the TSR of the primary probe at a base referred to as ''position 1,'' creating a substrate for the Cleavase enzyme. The specificity of the Cleavase enzymes requires that position 1 of the primary probe be complementary to the target for cleavage to occur, providing the ability to discriminate single-base changes. The generation of the proper enzyme substrate is dependent on association between the primary probe, Invader oligo, and target. A noncomplementary base in the target at position 1 results in the formation of a nicked structure, rather than an invasive structure, because position 1 of the primary probe effectively becomes part of the flap. The nicked structure is not a substrate for the Cleavase enzyme, and thus the noncomplementary primary probe does not get cleaved. Discrimination relies on enzymatic recognition of the properly assembled structure in addition to the sequence specificity of oligonucleotides to the target sequence.

DNA DETECTION

The target-specific region of the primary probe is designed to have a melting temperature close to the reaction temperature, typically 63°C. Its inherent instability allows for the exchange of cleaved and uncleaved probes onto the target. When the specific sequence is present, the Invader oligo and TSR of the primary probe form an invasive structure on the target. The Cleavase enzyme removes the 5′-flap plus position 1 of the target-specific region. Following cleavage, the primary probe dissociates from the target and is replaced with another uncleaved primary probe, which is present in excess. Thus numerous 5′-flaps are released for each target molecule present, resulting in a linear amplification of signal, but not target.

The cleaved 5′-flap then acts as an Invader oligo to generate another invasive structure with a synthetic molecule, the fluorescence resonance energy transfer (FRET) oligo, which contains a donor fluorophore on the overlapping base (position 1) and a quencher fluorophore on the other side of the cleavage site.

DOI: 10.1081/E-EDGP 120023541

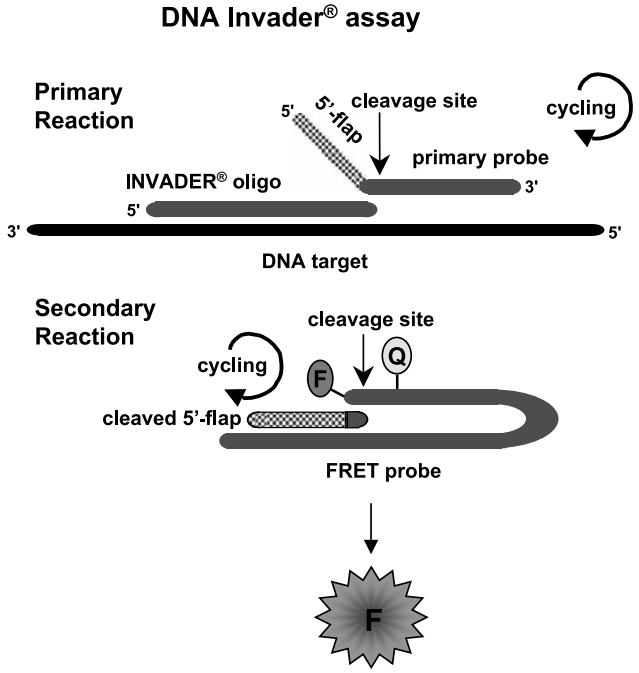

Fig. 1 Schematic of the Invader® DNA assay. (*View this art in color at www.dekker.com.*)

Cleavage of the FRET oligo separates the donor fluorophore (F) from the quencher fluorophore (Q) to generate a fluorescent signal. Using two different 5′-flap sequences and their complementary FRET oligos, each labeled with different fluorophores, two different target sequences may be detected in a single well. In addition to producing signal, the FRET oligo provides a second level of signal amplification. In the DNA assay, the 5′-flap forms an unstable, invasive duplex with a FRET oligo. After the fluorophore has been released, the 5′-flap dissociates and is able to form an invasive structure with a new, uncleaved FRET oligo. Signal amplification results from the combined effect of having multiple flaps cleaved for each target molecule and from each of those released flaps driving the cleavage of multiple FRET oligos. Both reactions—cleavage of the primary probes and of the FRET probes—occur simultaneously at a single temperature near the melting temperature of the primary probe (Fig. 1).[3–5]

RNA DETECTION

The FEN-type Cleavase enzymes that are used in Invader DNA assays are not able to recognize RNA targets; instead, pol-type Cleavase enzymes that recognize both DNA and RNA targets are used. The altered substrate specificity of the pol-type Cleavase enzymes requires an adaptation to the reaction used to cleave the FRET oligo. RNA assays occur in two sequential steps: the primary reaction and the secondary reaction. During the primary reaction, the Invader oligo and primary probe form an invasive structure on the RNA target. An additional oligo, the stacker oligo, is designed to coaxially stack with the 3′ end of the primary probe. The stacker oligo allows the primary probe to cycle on and off the target at a higher temperature and increases the sensitivity of the assay. In the secondary reaction, the cleavage product of the primary reaction (the cleaved 5′-flap plus one base of the TSR) forms a one-base overlap structure with a secondary reaction template (SRT) and a FRET oligo. The enzymatic cleavage of the FRET oligo separates a fluorophore from a quencher molecule, as described for DNA assays, generating fluorescent signal. In contrast to the DNA format, the released 5′-flap remains bound to the SRT while the FRET oligos cycle on and off the SRT. Consequently, multiple FRET oligos are cleaved per 5′-flap, resulting in a linear accumulation of fluorescence signal. An arrestor oligo, which hybridizes to the TSR plus a portion of the 5′-flap of uncleaved primary probes, is also included in the secondary reaction. The arrestor oligo allows for greater signal generation by sequestering uncleaved primary probes and preventing competitive inhibition of 5′-flap hybridization with the SRT during the secondary reaction (Fig. 2).[3,4,6]

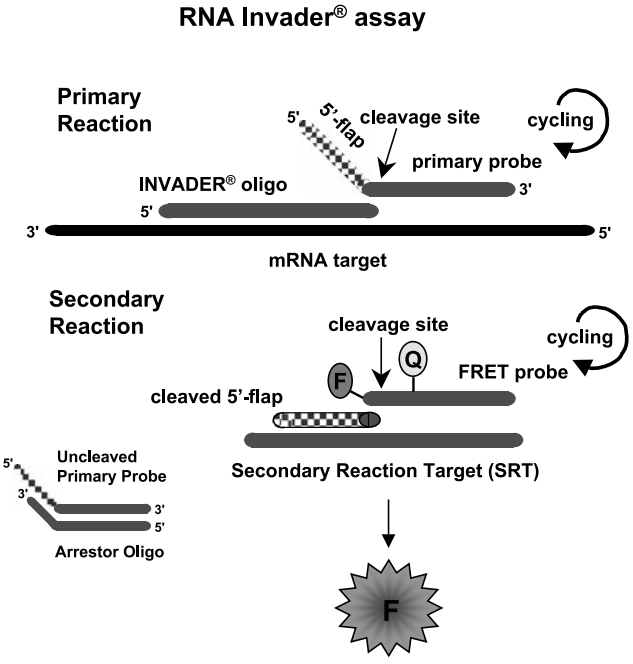

Fig. 2 Schematic of the Invader® RNA assay. (*View this art in color at www.dekker.com.*)

DETECTION FORMATS

Because its composition is independent of the target being detected, the 5′-flap can be detected in a variety of ways, e.g., by size, sequence, charge, or fluorescence. Based on these properties, the Invader technology can be applied to numerous alternate detection formats including mass spectrometry, capillary electrophoresis, microfluidics, universal array chips, capture, eSensor™, fluorescence polarization, and time-release fluorescence.

ACLARA Biosciences (Mountain View, CA) produces small, electrophoretically distinct, fluorescent molecules called eTag reporter molecules that can be incorporated into primary probes as 5′-flaps. The released eTag flaps are resolved and quantitated using universal separation conditions on standard capillary DNA-sequencing instrumentation. High-level multiplex capabilities are possible with the development of hundreds of eTag reporters. ACLARA has demonstrated the ability to detect 26 Invader RNA assays from a single tube.

SPECIFICITY

Superior specificity has been achieved with the Invader technology by combining sequence identification with enzyme structure recognition. The key to the assay's specificity is the strict requirement for an invasive structure. If the sequence at the cleavage site is not complementary to the intended target, an invasive structure does not form, and the 5′-flap is not released for detection in the secondary reaction. For mutation detection applications, such as cystic fibrosis transmembrane conductance regulator (CFTR) gene screening, this discrimination capability provides high accuracy, as demonstrated by its ability to classify the three possible CFTR ΔF508 genotypes and discriminate between the ΔI507 and ΔF508 mutations (Fig. 3). In a multisite study to determine the accuracy of genotyping five polymorphisms associated with venous thrombosis, the Invader assays correctly genotyped 99.9% of samples compared with 98.5% correct genotypes called by PCR-based methods.[7] Such ability to discriminate single-base changes also makes the Invader platform ideally suited for genotyping highly homologous strains of infectious agents.

The Invader platform is capable of specifically genotyping highly polymorphic regions such as the cytochrome P450 gene family, which contain multiple pseudogenes, gene deletions, and gene duplications. To prevent false positive results or inflated wild-type signals caused by association of Invader oligos to the pseudogenes, the region of interest can be amplified using PCR primers specific to the region of interest. The resulting amplicons can be used as templates for Invader assay-based detection. Using this approach, results from 11 Invader CYP2D6 assays provided a clear genotype for 100% of the 171 anonymous donor samples that had a visible PCR product on an agarose gel.[5]

The quantitative aspect of the Invader platform allows for the determination of chromosome and gene copy number directly from genomic DNA. This analysis may be accomplished by comparing the specific signal generated from the gene or chromosome of interest with that of a reference gene such as α-actin, which is not known to be polymorphic for either duplication or deletion.[5] Careful design of the Invader oligos to regions with minimal homology to other regions within the genome enables accurate quantitation of the desired target sequence.

Invader RNA assays have the same ability as the DNA assays to discriminate single-base changes. By positioning the cleavage site of the primary probe at a nonconserved site within the mRNA target, Invader assays are able to differentiate highly homologous RNA sequences. Cross-reactivity is undetectable in the presence of 10,000-fold excess of highly related mRNA.[4] In addition, assays with cleavage sites located at particular exons or splice junctions can distinguish alternatively spliced mRNA variants.[6]

SENSITIVITY

Because of its high level of precision, Invader assays can determine changes in gene expression as low as 1.2-fold.[6] Intraassay coefficients of variation (CVs) are typically less than 10% and range, on average, from 2% to 3%.[4,6] Reading the assays in real time or at multiple time points can extend the dynamic range of detection, which covers three orders of magnitude with a single endpoint read.[4]

Signal amplification eliminates the need for target amplification prior to analysis, which, in turn, simplifies sample processing. Genomic DNA obtained from small blood volumes can be used directly in genotyping assays. Invader DNA assays are able to statistically detect as little as 10 ng of genomic DNA (approximately 1500 heterozygous genomic copies);[3] however, a minimum of 100 ng is generally recommended. For RNA assays, sample preparation can be simplified by using unpurified cell lysates directly in the assay. The Invader RNA assays can routinely detect as little as 0.005–0.01 amol RNA target (approximately 3000–6000 copies of RNA transcript or messenger RNA).[6]

Invader assays have the unique ability to tolerate the presence of secondary polymorphisms. Whereas the formation of the proper enzyme substrate is dependent on base pairing at critical positions within the primary probe, other regions may be mismatched. This provides the ability to detect or disregard polymorphisms, which

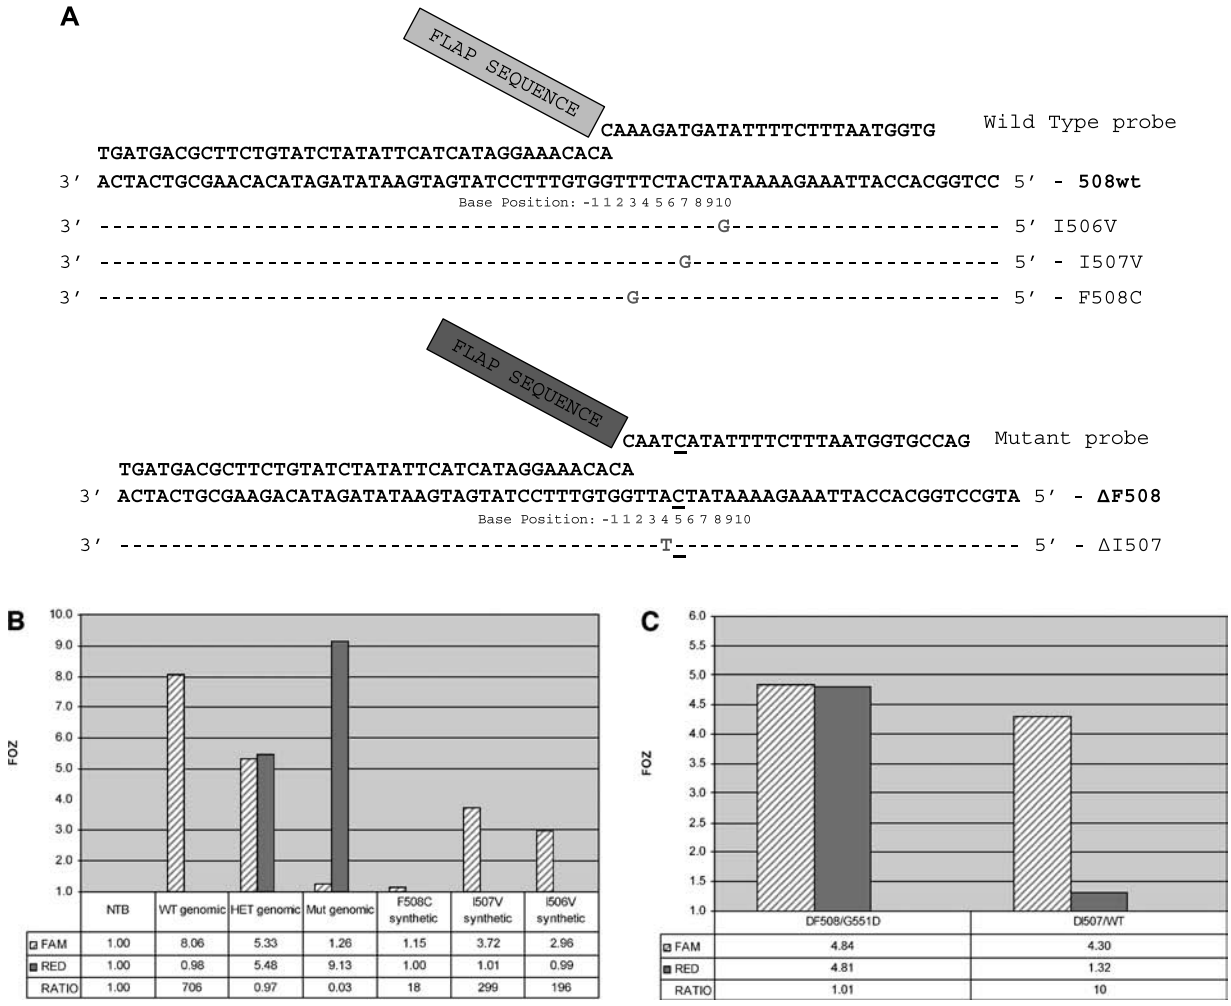

Fig. 3 Discrimination and detection of ΔF508 DNA. (A) ΔF508 assay design and alignment of WT, I506V, I507V, F508C, ΔF508, and ΔI507 DNA sequences. The wild-type (WT) probe is completely homologous to the WT target but mismatches at position 3, 7, and 10 on the respective targets F508C, I507V, and I506V. The Mutant (Mut) probe has a single mismatch at position 5 (underlined) on the ΔF508 target and two mismatches (positions 4 and 5) on the ΔI507 target. The position 5 mismatch was designed to reduce cross-reactive signal on the ΔI507 target, which differs from ΔF508 only at position 4. (B) The specific signal generated on WT, HET (WT/ΔF508), and Mut (ΔF508/ΔF508) genomic samples. The WT probe generates sufficient signal with the I507V and I506V targets (mismatches at positions 7 and 10, respectively), but not with the F508C target (mismatch at position 3). An additional test is required to determine F508C genotype. (C) The specificity of the Mut probe: the mismatch at position 5 does not hinder the signal generated from a ΔF508 HET genomic sample and creates additional discrimination of the ΔI507 genomic sample. (*View this art in color at www.dekker.com.*)

increases the assays' detection sensitivity in highly polymorphic genes or strains of infectious agents.

ROBUSTNESS

Ease of use, flexibility, and scalability are some of the advantages that make the Invader platform ideally suited for automation. Assays are readily adaptable from manual to semiautomated to fully automated ultra-high-throughput settings using a variety of standard plate formats. Most automated liquid handling systems can handle the assay setup, which requires only a few pipetting steps. Regardless of format, e.g., 96 or 384 wells, or setup, e.g., manual or automated, the robustness of the platform remains constant.[3]

The Invader platform—a highly accurate, cost-effective, and specific method for the detection of specific nucleic acid sequences—has been applied to the detection of thousands of SNPs in genome-wide association studies.[8,9] Simple, fast, reliable, and inexpensive diagnostic tools are essential not only for research purposes, but

for clinical settings as well. Several analyte-specific reagents (ASRs) have been developed for use in clinical diagnostics, including Factor V Leiden (FVL), apolipoprotein E (ApoE), and cystic fibrosis (CFTR) mutation detection. The current clinical applications of the Invader platform include detection of coagulopathies and inherited diseases.

CONCLUSION

The Invader platform is a homogeneous, isothermal DNA probe-based system for the quantitative detection of specific nucleic acid sequences. Invader assays can be performed directly on DNA-, RNA-, PCR-, or RT-PCR-amplified products. Based on the ability of the Cleavase enzymes to recognize and cleave-specific nucleic acid structures, the Invader platform is a highly specific method for detecting single nucleotide polymorphisms, insertions, deletions, and gene copy number. Its ability to amplify signal and tolerate secondary polymorphisms makes the Invader platform extremely sensitive as well. Because of the flexibility, ease of use, and robustness of the technology, it can be used in both small and high-throughput laboratories.

Inverse PCR

I

Philip Lewis White
Sam Hibbitts
University of Wales College of Medicine, Cardiff, U.K.

INTRODUCTION

Polymerase chain reaction (PCR) is widely accepted as one of the most powerful tools in molecular biology capable of amplifying over 10^6 identical copies of small (few kb), specific DNA regions. It utilizes the thermostability of the enzyme *Taq* DNA polymerase I, and allows quick and efficient exponential amplification of a target region between known DNA sequences. This removes the need for time-consuming cloning, although it does have two key limitations. It is only efficient in amplifying relatively small DNA fragments and secondly, but more importantly, PCR can only be used to amplify regions of known DNA sequence. As such, PCR alone cannot be used to amplify DNA sequences adjacent to an unknown sequence, thus making chromosomal walking unfeasible.

In the late 1980s and early 1990s, research was performed to overcome this restriction, and inverse PCR (IPCR) was one of the developments.[1–9] Inverse PCR is a novel molecular method utilizing the basic principles of PCR, but in a reverse manner so regions of unknown sequence can be amplified. This procedure is one of numerous tools utilized for furthering our understanding of the complexities of DNA, and facilitates cloning and sequencing of otherwise unknown elements of a genome.

TECHNICAL OVERVIEW

The basic theory behind inverse PCR requires a core DNA region of known sequence to be adjacent to an unknown target. This region is digested to produce a fragment of suitable size for PCR that is ligated together to produce a circular construct. The core region provides the sequence information required for synthesis of primers, designed to hybridize to the ends of this core region, which, because of the nature of the circular construct, flank the unknown sequence. Extension occurs divergently toward the unknown sequence with PCR amplification of the uncharacterized region.

BASIC PROTOCOL FOR PCR OF AN UNKNOWN DNA TARGET

IPCR within a Circular Construct

A quality target genomic DNA extract should be obtained, and 500 ng digested with an appropriate restriction enzyme in a 30 μL volume and adequate digestion should be confirmed by agarose gel electrophoresis. The resulting fragment should contain a region of known sequence flanked by the unknown target. The enzyme is then inactivated, DNA-precipitated, and diluted (approximately 1:5) prior to ligation in a media of ligase buffer, water, and ligase to optimize conditions for intramolecular ligation. Following incubation according to the manufacturer's instructions (approx. 1–12 hr at room temperature), complete ligation with production of a circular construct can be verified by Southern blotting using the known sequence as a probe.

A titration series (5–10 μL) of the circular construct should be used for the PCR reaction in a final volume of 50 μl to optimize the chances of target DNA amplification. Primers should be designed based on the known sequence and PCR conditions to include a high annealing temperature to prevent any nonspecific priming, a long extension time (2 min), and up to 40 cycles to maximize the chances of amplification of rare templates.

A nested PCR maybe performed to increase the specificity of the reaction (Fig. 1). In this case, following the first-round PCR and analysis of the product by agarose gel electrophoresis, another titration series of the first-round product (up to 15 μL) should be added to a second-round PCR reaction containing primers located inside the region previously amplified. Annealing temperatures should be increased with an extension time of 1 min (approx.). Final products should be analyzed by electrophoresis.

In general, the objective of inverse PCR is to elucidate the sequence of the unknown region, and so the inclusion of a proofreading enzyme (e.g., *PfU*) in the PCR reactions will reduce errors that may be introduced during amplification. Products obtained after PCR are then cloned into a vector for subsequent DNA sequencing.

DOI: 10.1081/E-EDGP 120020687

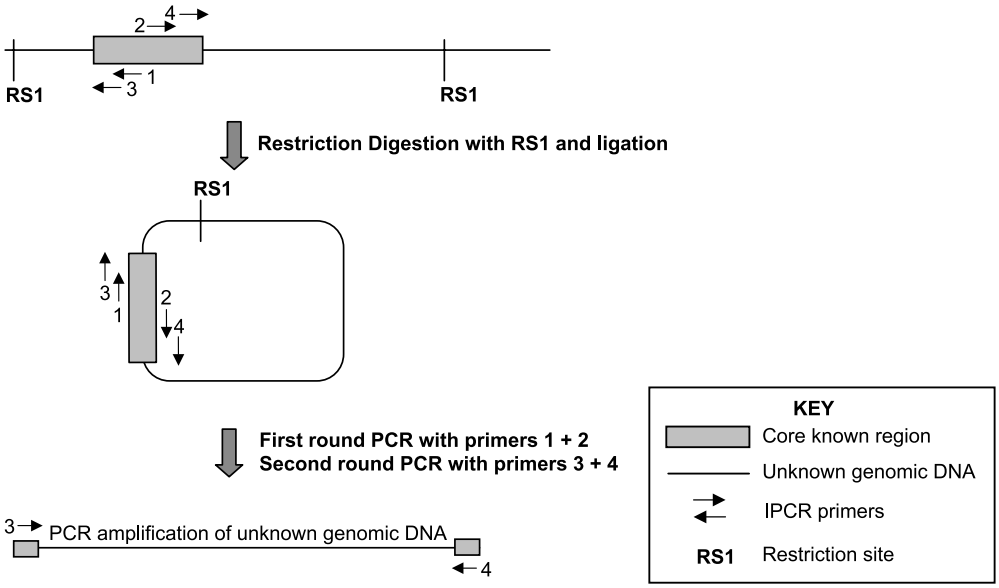

Fig. 1 Inverse PCR using a circular construct. Schematic for the PCR amplification of an unknown region from a circular construct.

IPCR of a Linearized Construct

An alternative procedure for PCR amplification of an unknown target requires that the circular construct produced as described in ''IPCR within a Circular Construct'' should be linearized by using a restriction enzyme located in the known sequence between the 5′ regions of the PCR primers. This additional step has been shown to increase the efficiency of the PCR amplification reaction up to 100-fold.[4] In theory, covalently closed circular double-stranded DNA is a poor substrate for PCR with reannealing of the DNA strands during the extension step of PCR. However, linearization or nicking of such a construct will reduce this and make it a more ideal template for amplification (Fig. 2).

INVERSE PCR MUTAGENESIS

This procedure utilizes the basic principle of IPCR to introduce a genetic change within a plasmid. As in traditional IPCR, the primers are oriented ''back-to-back'' but anneal in opposite directions around the plasmid, and one of the primers contain the required mutation. PCR of the plasmid with a proofreading enzyme will introduce the genetic change present in one primer and yield a blunt-ended product. Self-ligation of the final product will reproduce the original plasmid plus the introduced mutation (Fig. 3). This procedure can be utilized for point mutations or insertions. If a region of the plasmid is to be deleted, primers can be designed on either side of this area, and the subsequent PCR product when religated will be complete except for the region that the primers flanked (Fig. 4).

Transformation of ligated mutated plasmids into *Escherichia coli* gives a high efficiency of mutant plasmid isolation (approximately 80%).

POINTS TO CONSIDER/LIMITATIONS

Irrespective of the application of inverse PCR, the basic principle remains the same with an optimized protocol designed according to: 1) DNA origin; 2) restriction enzymes utilized; and 3) PCR conditions.

The origin of the DNA will determine the extraction procedure used to obtain a quality DNA sample. Various commercial kits exist for DNA extraction, and optimal procedures vary depending on the starting material. For example, commercial kits are available for both manual and automated genomic DNA extraction from whole blood and include Qiamp DNA Blood Kits (Qiagen, Crawley, UK), Genelute Blood Genomic DNA Kit (Sigma, Poole, UK), Generation Capture Column Kit (Gentra, Minneapolis, USA), and Magna Pure LC DNA isolation Kit I (Roche, Lewes, UK). Meanwhile, genomic DNA extraction from human/animal/plant tissue tend to utilize alternative extraction kits or procedures [DNeasy Plant and Tissue System (Qiagen); Magna Pure LC DNA Isolation Kit II (Roche); Genelute plant or mammalian genomic DNA kit (Sigma) and NuCleon® phytopure genomic DNA extraction kit (Amersham Pharmacia

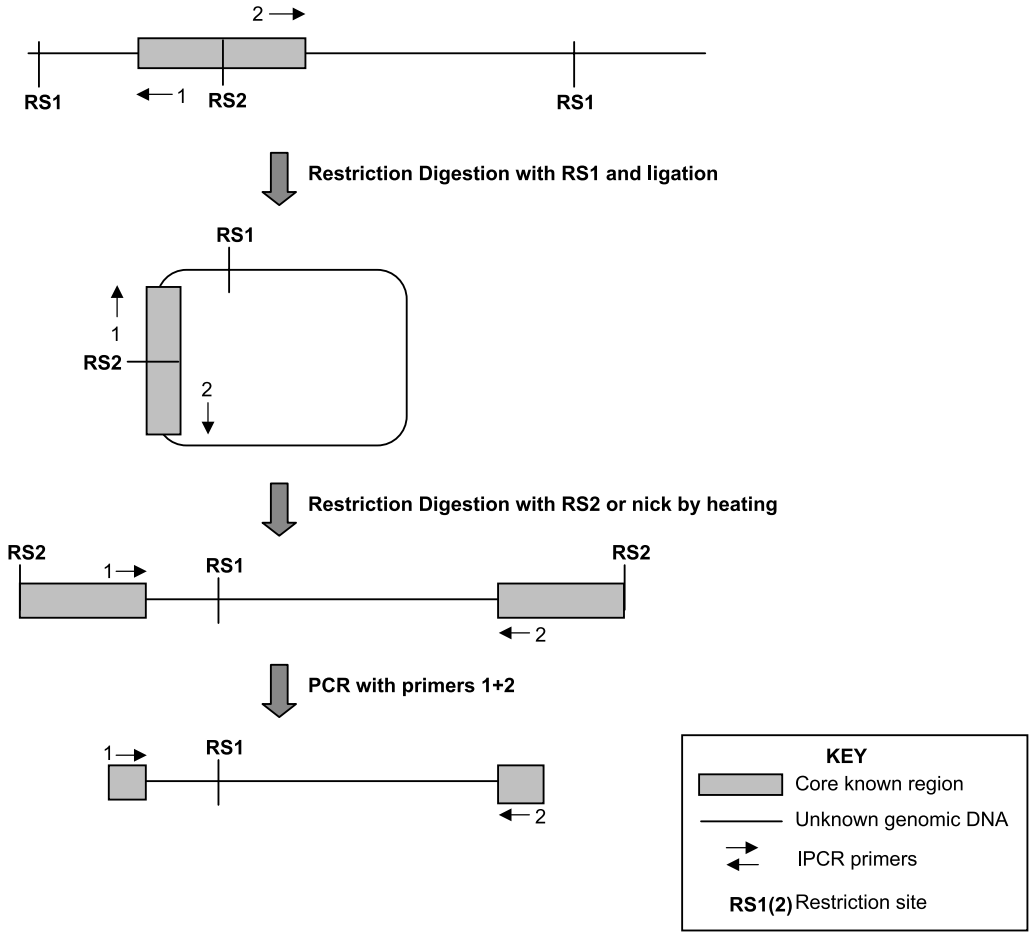

Fig. 2 Inverse PCR of a linear construct. Schematic for the PCR amplification of an unknown region from a linear construct.

Biotech, Little Chalfont, UK)]. Because a quality DNA starting material is important for efficient IPCR, this should be the first issue that needs to be addressed.

The restriction enzyme required to cleave the target DNA region is crucial in that it must produce a fragment of appropriate length for the subsequent ligation and PCR. Small fragments (<200 bp) prove difficult to circularize, whereas larger fragments (>3 kb) may be problematic for PCR amplification. However, Benkel and Fong[10] have published a hybrid method allowing amplification of larger fragments by combining long-range (distance) PCR with IPCR, and accordingly labeled it long-range inverse PCR (LR-IPCR). In addition to the fragment size, the positions of the restriction sites are important when deciding what is required from the amplification. If amplification of both flanking regions is sought, then it is essential that the restriction enzyme of choice does not cleave within the known core region. Alternatively, if only amplification of one side of the core region is necessary, the enzyme must cleave inside the core region, but leave enough core sequence to allow the design of a primer pair for PCR.[3,11]

The element of IPCR becomes more difficult when there is no restriction map available of the unknown region. It has been suggested that by using a restriction enzyme with a four-base recognition sequence, enough IPCR suitable fragments would be generated.[11] However, this method could be very random and the use of Southern blots to identify restriction sites is a more controlled option. In all cases, numerous restriction digests should be evaluated to elucidate the most appropriate and efficient for PCR of the unknown region.

If IPCR on a linear construct is to be undertaken, care should be taken regarding the choice of restriction enzyme used to linearize the circular construct. The restriction site has to be within the known region between the 5′ ends of the primers, not downstream of this or in the unknown sequence, or the template for subsequent PCR will be destroyed. An alternative to restriction digestion of the circular construct, yet still enhancing it as a PCR template,

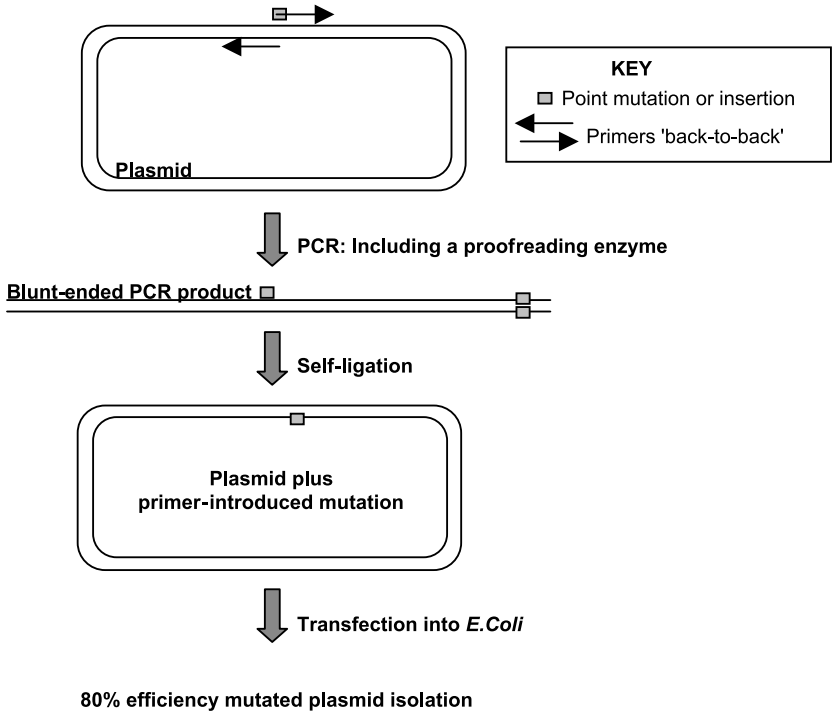

Fig. 3 Inverse PCR mutagenesis 1. Schematic for the introduction of a point mutation or insertion into a plasmid.

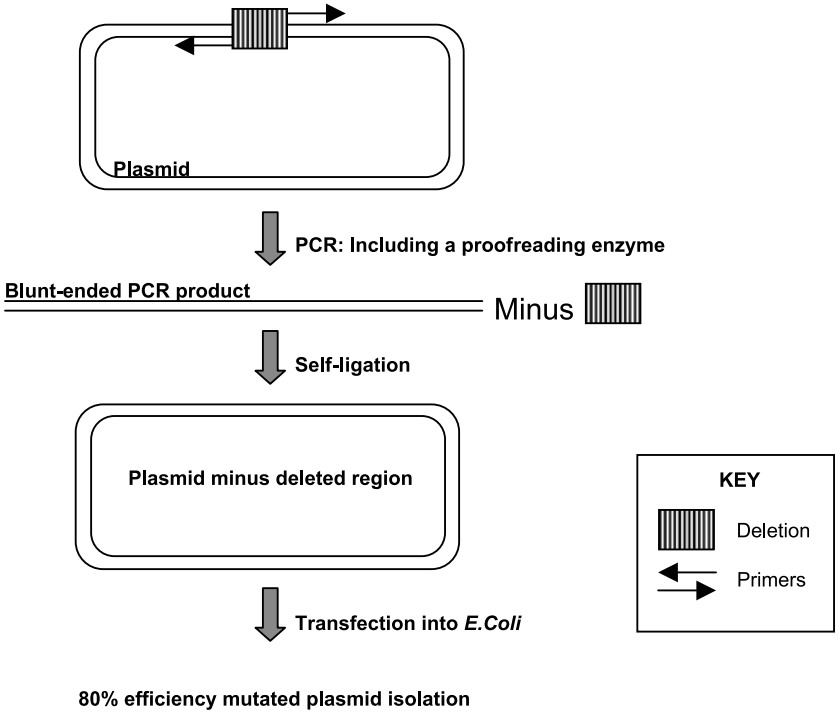

Fig. 4 Inverse PCR mutagenesis 2. Schematic for the deletion of a region within a plasmid.

would involve introducing random nicks that can be caused by heating[1] or limited DNase treatment. However, a major drawback to this approach is the difficulty in controlling the degree of nicking to the construct.

The PCR component of the IPCR reaction needs to be optimized both in relation to the quantity of template, primers, and *Taq* polymerase, and in terms of the cycling conditions. As discussed, titration of the starting material in the PCR reactions will help to overcome some of these problems, and it is essential that appropriate controls are included in the PCR reaction. Analysis of products by electrophoresis will also elucidate any technical difficulties. A common problem is the formation of primer dimers or multimers, as is smearing recognized after the first-round PCR, which can be attributed to nonspecific amplification that maybe caused by an excess of template or inefficient digestion and/or ligation. Increased annealing temperatures as well as decreased primer and *Taq* polymerase concentrations may alleviate nonspecific primer binding and also minimize the formation of primer dimers, although it is recommended that when designing primers, the appropriate software packages (e.g., Netprimer: www.premierbiosoft.com/netprimer) are used to reduce the opportunity of primer dimer/polymer formation.

CLINICAL AND GENETIC APPLICATIONS

The genetic applications of inverse PCR have been widespread and diverse. They include:

1. characterization of long stretches of unknown DNA sequence adjacent to specific genes, e.g., chromosome mapping/walking[5] and identification of upstream and downstream regulatory elements;
2. establishing the insertion sites of mobile genetic elements,[12] including the integration of viral genomes into the host;[13–15]
3. aiding in the understanding of mutational mechanism involved in deletions and translocations;[16]
4. the construction of knockout vectors to disrupt genes;[17]
5. fingerprinting of microorganisms;[18,19]
6. evolution of organisms;[20]
7. generation of end-specific probes.[3]
8. defining new pathways of disease;[21]
9. determining the differential expression of genes.[22]

CONCLUSION

Despite the numerous benefits of PCR, it was limited by its inability to amplify unknown genomic regions. The development of IPCR overcame this limitation and has helped to further our understanding of unidentified genes without the need for more complex chromosomal walking techniques.

Note that a new edition of PCR Technology: Principles and Applications for DNA amplification was published by Oxford University Press in 2002.

Keratin Disorders

Eli Sprecher
Rambam Medical Center, Haifa, Israel

INTRODUCTION

Keratins are part of a large group of proteins known as intermediate filaments, which, together with actin filaments and microtubules, form the cell cytoskeleton. Keratins are widely expressed in the cytoplasm of epithelial cells, to which they confer mechanical resilience. Keratins are expressed in a tissue-specific manner and, accordingly, often demarcate pathways of embryonic development and cell differentiation. For example, keratins 8 and 18 are the only keratins detectable in preimplantation blastocyst; in the epidermis, keratins 5 and 14 are expressed in proliferating basal cells, whereas keratins 1 and 10 are the major keratins produced in more differentiated suprabasal cells.

OVERVIEW

Keratin intermediate filament (KIF) assembly initiates with the formation of a heterodimer composed of a basic keratin molecule and an acidic keratin molecule intertwining in a coiled coil parallel fashion. Keratin heterodimers then interact in a staggered antiparallel manner to form stable tetramers, which associate longitudinally and laterally to generate 2-nm protofilaments. Protofilaments are then assembled into protofibrils, which eventually interact to yield 10-nm KIF.

Types I and II keratin-encoding genes are clustered on 17q and 12q, respectively. Approximately 50 distinct keratin or keratin-like genes, and more than 150 keratin pseudogenes have been identified in silico in the human genome. Some of those pseudogenes are readily expressed as mRNA, thus significantly complicating the molecular diagnostics of inherited keratin disorders.[1] A number of techniques are now available to avoid keratin pseudogene amplification.[2]

The following article presents a succinct description of keratinopathies and relevant diagnostic strategies. More detailed information can be found at http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM using the OMIM numbers given in Table 1. References including specific molecular diagnostic strategies, primer lists, and polymerase chain reaction (PCR) conditions for amplification and sequencing of various keratin genes are given in Table 1. An exhaustive list of keratin mutations can be obtained at http://www.interfil.org.

Keratins can be classified according to their isoelectric point and amino acid sequence (e.g., basic or type I, and acidic or type II), their major site of expression (e.g., epithelial keratins and hair keratins), or, their cysteine content (e.g., hard and soft keratins).

As for all other intermediate filaments, keratins are organized into two nonhelical end domains of varying sequence, flanking a central α-helical rod segment (Fig. 1). The sequences found at both ends of the rod segment are remarkably conserved across species and keratin types. They are known as the helix initiation motif (HIM) and the helix termination motif (HTM).[1]

EPIDERMAL DISORDERS

Epidermolysis Bullosa Simplex

Inheritance: Autosomal dominant (rarely autosomal recessive).

Clinical description: Epidermolysis bullosa simplex (EBS) is part of a heterogeneous group of inherited blistering diseases collectively known as epidermolysis bullosa (EB). All EB subtypes are characterized by the appearance of cutaneous blisters upon exposure of the skin to mechanical trauma (Fig. 2a). The major EB subtypes are defined by the location of blister formation within the skin.[19] In EBS, blisters form within the epidermal basal cells. The age of onset of EBS is variable. Progressive improvement with age is common. Three clinical forms of EBS have been delineated. Blisters occurring exclusively over the feet and hands distinguish the Weber–Cockayne type of EBS. In EBS Koebner type, blistering is generalized. The most severe, fortunately rare, and often life-threatening form of EBS is known as Dowling–Meara EBS and is characterized by skin and mucosal hemorrhagic blisters arranged in small clusters. EBS Dowling–Meara type is occasionally associated with milia formation, nail dystrophy, and severe palmoplantar keratoderma (PPK).

DOI: 10.1081/E-EDGP 120025805

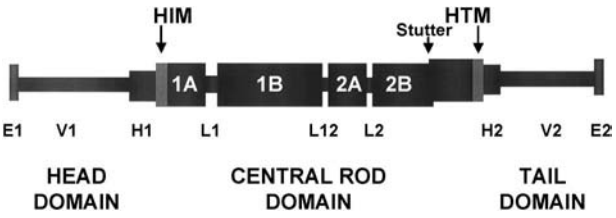

Fig. 1 Schematic structure of a prototypic keratin molecule. The central rod domain is divided into four regions, which are separated by three nonhelical short linker sequences and the stutter sequence, where helix polarity is reversed. The rod domain is flanked by the highly conserved HIM and HTM. The head and tail domains consist of extreme end domains (E1, E2), variable domains (V1, V2), and homology domains (H1, H2). In contrast with the central rod domain, head and tail domains greatly vary in structure between different keratin types.

Skin pathology: Blister formation and typical vacuolar changes are seen within the epidermal basal cell layer. Keratin filament clumping is typical of Dowling–Meara cases.

Molecular genetics: Mutations in two keratins specifically expressed in epidermal basal cells, K5 and K14, underlie most cases of EBS.[2,20] The majority of EBS-causing mutations are missense mutations, affecting amino acids located within the rod segment or at its boundaries. The same regions have been shown in many other keratin disorders to carry deleterious mutations,[2] leading to the implementation of a diagnostic strategy based on initial pathological examination of skin tissues, followed by mutation analysis of rod boundaries-encoding regions, and ending with examination of the rest of the keratin gene (Fig. 3). Mutations affecting the end domains of the rod segment have been shown to exert a dominant negative effect, resulting in the synthesis of aberrant keratin proteins with altered three-dimensional structure, which interferes with normal protein functions during KIF assembly. Abnormal KIF affects cell resilience so that on exposure of the skin to friction, the cytoskeleton collapses, leading to cell cytolysis and intraepidermal blistering. Recessive K14 nonsense mutations are considered to be rare except in populations characterized by a high inbreeding coefficient.[21] As a rule, recessive mutations as well as dominant mutations located within the conserved helix end motifs are associated with severe phenotypes; missense mutations located outside these regions generally cause milder forms of EBS. The nature of an amino acid substitution, and not only its location, is also a major determinant of phenotype severity.[20]

Mutations in K5 end domains have also been reported. A recurrent mutation, P25L, located in the V1 head domain of K5 has been found to cause a rare subtype of EBS associated with mottled pigmentation. P25L has been suggested to impair melanin granule aggregation and keratin filament function by interfering with posttranslational processing.[20] Mutations in K5 tail domain have been shown to cause dominant EBS, possibly because of abnormal protein folding.[22,23]

Those major advances in our understanding of the molecular basis of EBS and other keratin disorders have led to the development of DNA-based prenatal testing, usually carried out during the first trimester (Fig. 4). Prenatal diagnosis is provided based on previous knowledge of mutation(s) in the family, sequencing of fetal and parental DNA, and confirmation of mutation using ancillary tests such as polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP) or allele-specific PCR. A particular problem arises when prenatal diagnosis is requested with no prior knowledge of the mutation. Microscopical examination of fetal skin biopsy, which entails significant risks and is carried out late in pregnancy, has rarely been performed in such cases.

Differential diagnosis: The differential diagnosis of EBS encompasses a large spectrum of inherited blistering conditions, including other EB types[19]; epidermolytic hyperkeratosis (EHK); Kindler syndrome (MIM173650), caused by mutations in kindlin, typically accompanied by pigmentary and atrophic changes affecting sun-exposed skin; ectodermal dysplasia with skin fragility (MIM604536), typified by suprabasal separation and due to plakophilin 1 deficiency; EB with muscular dystrophy (MIM226670), due to mutations in plectin gene; and incontinentia pigmenti (MIM318310), characterized by congenital blisters distributed along the lines of Blashko. In addition, EBS can result from mutations in genes coding for integrinβ4, plectin, and collagen XVII, known to be usually involved in the pathogenesis of non-EBS phenotypes.[24–26] EBS should also be distinguished from congenital blistering resulting from infectious, autoimmune, and neoplastic causes.

Management: Patient care involves wound care, including sterile dressings and lancing of blisters to prevent spread; infection control; and nutritional support. Novel therapeutic approaches include the use of biological dressings or skin equivalents, and burgeoning attempts to cure EB through gene therapy.

EHK and Other Epidermal Disorders

Inheritance: Autosomal dominant.

Clinical description: EHK, also known as bullous congenital ichthyosiform erythroderma, manifests at birth with skin erythema and blistering.[2] Over time, blisters become less prominent and patients develop generalized

Table 1 Spectrum of keratin disorders

Keratin	Disease	OMIM number	References for primer lists and PCR conditions

hHb1	Monilethrix	158000	[31]
K6hf	Loose anagen syndrome	600628	[18]

ichthyosis of variable severity, often accompanied by PPK (Fig. 1B).

Skin pathology: In contrast with most ichthyoses, histopathological features of EHK are distinctive and include orthohyperkeratosis, hypergranulosis, and vacuolar degeneration confined to the upper epidermal layers. Electron microscopical examination demonstrates an increased number of clumped tonofilaments located at the periphery of suprabasal cells and poorly attached to plasma membrane desmosomes.

Molecular genetics: EHK results from mutations in K1 or K10, which are expressed in the suprabasal layers of the epidermis. As for other keratin disorders, most EHK-causing mutations affect conserved amino acid residues located at both ends of the central K1/K10 rod segment and result in aberrant KIF formation, leading to perinatal skin blistering.[2,20] Mutations in *K1* or *K10* genes also interfere with normal epidermal outer barrier formation, causing subsequent hyperkeratosis. Epidermolytic PPK results from mutations in K9, a type I keratin that is specifically expressed in palmoplantar skin.[2] K9 may compensate for K10 abnormal function, explaining the fact that PPK in EHK is strongly associated with K1, but not with K10 mutations.[27] In addition, marked interfamilial and intrafamilial variations in phenotypic expression of K1/K10 mutations are typical.[27] Somatic mutations in K10 have been identified in individuals with epidermolytic epidermal nevi, manifesting with a mosaic distribution of hyperkeratotic lesions. Affected individuals are at risk for children affected with EHK; therefore, they qualify for prenatal diagnosis.[2] Finally, mutations affecting the nonhelical end domains of K1 have been shown to underlie a number of phenotypically distinct clinical entities. The pathophysiology of this group of disorders is likely to involve aberrant interactions between KIF and desmosomes.[20,22]

Differential diagnosis: Congenital ichthyosiform erythroderma (MIM242100) is characterized by erythroderma

Fig. 2 Clinical spectrum of keratin disorders. (a) Skin blister in a 1-month-old girl with EBS Dowling–Meara type. (b) Palmar hyperkeratosis in a 26-year-old individual with EHK. (c) Multiple steatocystomas and (d) nail dystrophy in a 25-year-old patient with PC-2.

and scaling at birth; however, blistering is absent and inheritance is recessive. In contrast, EBS manifests with blistering, but hyperkeratosis is usually absent. Ichthyosis bullosa of Siemens (IBS) is caused by mutations in K2e.[2] Affected individuals display mild scaling in the flexural areas, over the shins and elbows, as well as a superficial form of skin peeling, known as mauserung phenomenon. Intraepidermal separation and tonofilament clumping occur in a layer higher than that in EHK—within the granular layer.

Management: Conservative treatment measures such as lubrication, wound dressing, management of skin infections, and nutritional support are essential, especially during the first years. Satisfactory response to retinoids has been reported more often in carriers of K10 mutations than in carriers of K1 mutations.[28]

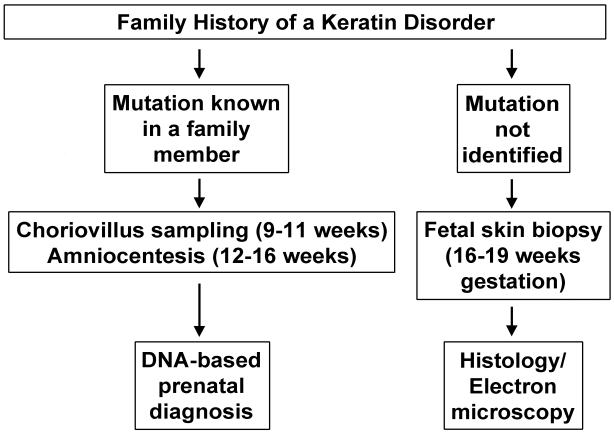

Fig. 4 Methods in use for prenatal testing of pregnancies at risk for keratin disorders.

NAIL, HAIR, AND MUCOSAL DISORDERS

Pachyonychia Congenita

Inheritance: Autosomal dominant.

Clinical description: Pachyonychia congenita (PC) type I or Jadassohn–Levandowsky syndrome (PC-1) is characterized by subungual hyperkeratosis, resulting in nail thickening and yellowish discoloration, accompanied by focal PPK, follicular hyperkeratosis, and oral leukeratosis. In contrast, PC-2, also known as Jackson–Lawler syndrome, is accompanied by less severe nail dystrophy and milder keratoderma, and is distinguished by the presence of multiple steatocystomas, a history of neonatal teeth, and the occasional occurrence of pili torti and/or alopecia (Fig. 2c–d). Additional variants with corneal leukokeratosis (PC-3) and laryngeal lesions with mental retardation (PC-4) have been described.[2]

Molecular genetics: PC-1 is caused by mutations in *K6a* or *K16* keratin genes, whereas PC-2 results from mutations in *K6b* or *K17* keratin genes.[2] The pattern of expression of these two pairs of keratin underlies the specific clinical manifestations of the two PC subtypes: K6a/K16 are expressed in the nail bed and nail fold as well as in palmoplantar skin and oral mucosa; K6b/K17 are found in the nail bed, hair follicle, and selected areas of palmoplantar skin. Although most PC-causing mutations are located at both ends of the keratin central rod segment, a somatic mutation in the head domain of K16 was recently shown to cause a mosaic form of PPK.[29]

Phenotypic heterogeneity is typical of PC. Mutations in K16 have been shown to underlie keratoderma in the absence of nail changes, and mutations in K17 have been shown to cause steatocystoma multiplex with no other PC-2 manifestations.[2] To complicate the picture even further, combined features of PC-1 and PC-2 have recently been shown to result from a deleterious mutation in K6a.[30]

Differential diagnosis: PC differential diagnosis includes toenail dermatophytic infection; psoriasis; lichen planus; dyskeratosis congenita (MIM305000), characterized by hypoplasia of the nails, oral leukokeratosis, hyperpigmentation, and hematological abnormalities; and hidrotic ectodermal dysplasia (MIM129500), manifesting with congenital nail dysplasia and focal PPK.

Management: Treatment is mainly symptomatic and involves the use of emollients or keratolytics to treat the PPK. Retinoids have been found useful in some patients. When hand or foot function is compromised by nail disease, nail matrix ablation can be considered.

Monilethrix

Inheritance: Autosomal dominant.

Clinical description: Monilethrix is characterized by the beaded appearance of hair shafts due to alternating elliptical wide (nodes) and narrow (internodes) hair segments. Hairs tend to break at the constricted sites, resulting in varying degrees of alopecia. Abnormal hair may be visible at birth or, more often, appears during the first months of life. Marked improvement is usual after puberty. Interfamilial and intrafamilial variations in disease severity have been observed.[31] In addition, patients may display additional cutaneous anomalies including follicular hyperkeratosis, and nail and tooth abnormalities.[2]

Molecular genetics: Pathogenic mutations have been identified in hair cortex keratin genes, *hHb6* and *hHb1*.[2] As for most other keratin disorders, mutations are clustered at the ends of the central α-helical rod.

Differential diagnosis: Monilethrix hair has been observed in Menkes syndrome (MIM309400), an X-linked disorder characterized by neurological and hair manifestations due to deleterious mutations in the *ATPA7A* gene, encoding a copper-binding protein.[32] Abnormal posttranslational processing of keratin molecules due to intracellular copper deficiency may explain the occurrence of beaded hair in Menkes syndrome. Pseudo-monilethrix (MIM177750) is characterized, in contrast with monilethrix, by irregularly spaced nodes with narrow internodes representing normal hair shafts.

Management: Spontaneous improvement is frequent.

White Sponge Nevus

Inheritance: Autosomal dominant.

Clinical description: Buccal involvement is most common, although the disease also manifests in other noncornified stratified squamous epithelia, including the

esophagus, nose, vagina, and rectum. Clinically, white, spongy plaques cover involved areas as a result of massive mucosal overgrowth.

Molecular genetics: The disorder is caused by mutations in two keratin genes, *K4* and *K13*, specifically expressed in mucosal tissues.[2]

Differential diagnosis: White sponge nevus may be confused with PC-1, Darier disease (MIM124200), dyskeratosis congenita, oral lichen planus, lupus erythematosus, candidiasis, and precancerous leukoplakia and oral florid papillomatosis.

Management: Antibiotics, including topical tetracyclines, have been shown to provide significant improvement. In most cases, no treatment is necessary.

OTHER KERATIN DISORDERS

The spectrum of keratin disorders also encompasses a number of extracutaneous diseases. Meesmann corneal dystrophy (MSD) is inherited in an autosomal-dominant fashion with incomplete penetrance. Slit lamp identification of typical fine, round cysts in the corneal epithelium aids in differentiating this disorder from other inherited corneal dystrophies.[33] Although vision is only rarely impaired to a serious degree in MSD, cyst rupture can cause corneal erosions and intermittent decrease in visual acuity during adulthood.[33] The disorder results from dominant mutations in *K3* and *K12* genes that are specifically expressed in the corneal epithelium.[2]

Recent studies have revealed that mutations in keratins expressed in simple epithelia may be involved in the pathogenesis of a number of gastrointestinal diseases.[20] Cryptogenic cirrhosis is a diagnosis of exclusion applicable to an individual with cirrhosis who does not carry a hepatitis B or C virus; who does not test positive for serological markers associated with autoimmune hepatitis or primary biliary cirrhosis; who has normal iron, ceruloplasmin, and α_1-antitrypsin levels; and who has no history of alcohol or toxin ingestion. Recurrent mutations in human *K8*/*K18* genes have been shown to predispose individuals to cryptogenic cirrhosis, chronic pancreatitis, and inflammatory bowel disease.[20,34,35] How K8/K18 mutations cause liver disease is still a matter of debate. Animals deficient in K8/K18 are highly susceptible to proapoptotic signals, suggesting that keratins may play a cytoprotective role in the gastrointestinal tract.[20]

CONCLUSION

The past recent years have witnessed tremendous progress in our understanding of keratinopathies, which in turn has led to dramatic advances in the management of this group of disorders. Prenatal diagnosis of EBS or EHK has become widely available, and novel gene therapy approaches for dominant—and not only recessive—keratin disorders are surfacing.[36] Beyond these immediate benefits, keratin disease research is radically transforming our traditional classification schemes of inherited skin disorders, establishing keratin disorders as a separate and legitimate clinical entity.[2] With the completion of the Human Genome Project and the ensuing identification of numerous novel keratin and keratin-associated genes,[20] one can logically anticipate seeing the spectrum of keratin disorders to further enfold and rechallenge our current conceptions.

Lamivudine Resistance-Associated Gene Mutations

Harald H. Kessler

INTRODUCTION

Hepatitis B virus (HBV) infection remains a major health problem in many regions of the world. Antiviral treatment of chronic hepatitis B aims to reduce viral replication and/or to affect the immune response to the virus and virus-infected cells. Development of reverse transcriptase inhibitors such as lamivudine, which has been shown to be a safe and potent inhibitor of HBV replication, has facilitated major advances in the antiviral treatment of chronic hepatitis B.[1,2] Today, lamivudine is a first-line therapy for prophylaxis of HBV recurrence in decompensated cirrhotic patients and liver transplant recipients. In most patients, treatment with lamivudine results in a substantial reduction of the serum HBV DNA level and normalization of serum alanine aminotransferase.[2,3] Moreover, therapy with lamivudine has been shown to improve liver function and histology, to produce hepatitis B e antigen/antibody seroconversion in a substantial proportion of patients, and slow disease progression in patients with cirrhotic liver disease.[2,3] In combination with hepatitis B immunoglobulin, lamivudine has been demonstrated to be effective in preventing recurrence of infection after liver transplantation.[4] Lamivudine is also effective in patients infected with precore mutants of HBV.[5] Relapse following the cessation of lamivudine therapy, however, is common and seroreversion from hepatitis B e antibodies to hepatitis B e antigen may occur.[6]

LAMIVUDINE-ASSOCIATED MUTATIONS IN THE HBV POLYMERASE GENE

A major problem with lamivudine therapy is the emergence of drug resistance, which increases with extended duration of therapy. The selection of drug-resistant HBV mutants is associated with viral breakthrough.[2,3,7] In 57% of patients treated with lamivudine continuously for 3 years, lamivudine-resistant HBV mutants developed.[8] Resistant variants have been localized in the reverse transcriptase (rt) region of the HBV polymerase (P) gene. Lamivudine-resistant amino acids have been described at position rt204 (rtM204V, rtM204I, or rtM204S) in the YMDD motif that encodes the catalytic center of the enzyme.[9,10] Another lamivudine-related mutation has been localized at position rt180 (rtL180M) and linked to the rtM204V or rtM204I changes.[11,12] More recently, mutations at positions rt173 (rtV173L) and rt207 (rtV207I), which had earlier been described as associated with famciclovir treatment, have been found in patients with lamivudine monotherapy and significant increase of serum HBV DNA load.[13]

Steric blockade between mutant amino acid side chains and lamivudine is the basis for the lamivudine-resistance phenotype as shown by molecular modeling studies using an HBV polymerase homology model.[14] At position rt204, a steric conflict between the methyl group of isoleucine or valine and the sulfur atom in the oxathiolane ring of lamivudine accounts for the resistance observed on rtM204V/I mutations.[14]

Lamivudine-resistant mutants have impaired replication capacity compared with the wild type.[15] Nevertheless, the selection of lamivudine-resistant mutants is associated with reappearance or significant increase of serum HBV DNA and often leads to deterioration of liver function, which occasionally may be severe or even fatal.[3]

LAMIVUDINE-ASSOCIATED MUTATIONS IN THE HBV S GENE

Four open reading frames, the S, C, X, and P genes, have been identified within the HBV genome. Because of the overlap of the P and S genes, lamivudine-associated mutations produce changes in the S gene, too. Consequently, lamivudine-resistant HBV isolates show alterations in the ''a'' determinant of the HBsAg protein.[16] Lamivudine-selected HBsAg protein changes may have important virological and clinical implications: They may escape neutralization by vaccine-induced anti-HBs antibodies and thus may have the potential to become

DOI: 10.1081/E-EDGP 120020869

vaccine escape mutants. Widespread use of lamivudine may lead to infection of vaccinated individuals and potentially reduce the efficacy of current HBV vaccines.

LABORATORY DIAGNOSIS OF LAMIVUDINE-ASSOCIATED GENE MUTATIONS

Methods for the identification of mutations in the HBV P gene include DNA sequencing, restriction fragment length polymorphism analysis, and reverse hybridization. Conventional direct DNA sequencing has been the gold standard method. Both conventional direct DNA sequencing and restriction fragment length polymorphism analysis, however, are labor-intensive and time-consuming methods and thus not useful for the routine diagnostic laboratory. Presently, two assays based on the reverse hybridization principle on DNA sequencing are commercially available.

The INNO-LiPA HBV DR assay (Innogenetics, Ghent, Belgium) is based on the reverse hybridization principle. After extraction, HBV DNA is amplified with a two-round PCR. Both PCR products are visualized on an agarose gel. The second-round PCR product is used for hybridization to the LiPA strip. The probes on the INNO-LiPA HBV DR strip cover codon 180 (wild-type L and mutant M), codon 204 (wild-type M and mutants V and I), and codon 207 (wild-types V, L, and M and mutant I). This assay cannot detect any mutations other than those on the strip but it is highly sensitive and easily applicable.[17]

The Trugene™ HBV Genotyping Kit (Bayer HealthCare, Toronto, Ontario, Canada) is a standardized and largely automated sequencing assay. After HBV DNA extraction, a 1.2-kb sequence of the HBV P gene, representing the central portion of the rt domain, is amplified by PCR, and sequencing reactions are then performed on this amplification product with the CLIP™ sequencing (Bayer HealthCare) technology. CLIP sequencing allows both directions of the amplification products to be sequenced simultaneously in the same tube with use of two different dye-labeled primers for each of the four sequencing reactions. Electrophoresis and subsequent data analysis are performed automatically with the automated OpenGene™ and GeneObjects™ DNA sequence analysis system (Bayer HealthCare). Data are acquired with the GeneLibrarian module of GeneObjects software by combination of the forward and reverse sequences. The query sequence is compared with the consensus sequences of HBV genotypes A to G in the Trugene HBV Module of the OpenGene software to determine the HBV genotype of the sample. Mutations in the rt region of the HBV P gene as well as in the overlapping S gene are also automatically detected and reported. The detection limit of this assay is $\sim 2.0 \times 10^3$ HBV DNA copies/mL, and all viral variants present at concentrations $\geq 20\%$ of the total can be detected. This assay is able to provide HBV genotype and resistance information from the same data and is useful for the molecular diagnostic laboratory.[13]

THERAPY FOR LAMIVUDINE-RESISTANT HEPATITIS B

The benefit of long-term lamivudine therapy must be balanced against concern about any possible risk produced by lamivudine-associated mutations. Alternative treatment includes adefovir dipivoxil and tenofovir.

Adefovir dipivoxil has been shown to significantly reduce serum HBV DNA levels in patients with lamivudine-associated mutations and to produce improvement in liver histology and decrease of serum alanine aminotransferase (ALT) levels.[18] Molecular modeling studies have shown that adefovir dipivoxil can be accommodated more effectively in the more constrained and ''crowded'' deoxynucleoside triphosphate-binding pocket that carries the rtM204V/I mutations, which may explain the low level of resistance that has so far been observed.[19] Recently, adefovir dipivoxil resistance has been associated with a mutation at position 236 (rtN236T).[20,21] Development of adefovir dipivoxil resistance, however, seems to be uncommon within the first 12 months of treatment.

Tenofovir has shown excellent short-term results in management of chronic hepatitis B in HIV-positive patients.[22] No tenofovir-associated mutation in the HBV P gene has been observed so far.

CONCLUSION

For adequate clinical management of HBV infection, detailed molecular information on the type or virus is clearly important. The most accurate way to provide detailed molecular information is by rapid accumulation of full genomic sequence information. Recent developments in automated sequencing technologies permit reproducible and sensitive sequence analysis to be used in the routine diagnostic laboratory. For patients with lamivudine-resistant hepatitis B, alternative drugs have recently been introduced.

INTRODUCTION

The molecular analysis of diagnostic tissue specimens has given significant insight into the pathogenesis of human disease and led to the identification of a broad range of diagnostic and prognostic markers, especially for neoplastic disorders. High-throughput approaches for the examination of DNA, mRNA, and proteins will have a profound impact on tissue-based diagnostics and will complement conventional histological examination. However, the reliability of many tests based on tissue or cell extracts critically depends on the abundance of the cell population in question. Primary tissues contain a variety of cellular elements including specialized, organotypic parenchyma and a large range of stromal and inflammatory cells. The relative percentages of these different cell types vary widely, especially in pathologically altered tissues. This inherent complexity of primary tissues can lead to false negative results in diagnostic molecular tests. Whereas the PCR detection threshold for some genetic alterations such as tumor-specific chromosomal translocations are in the range of 1 in 10^4 cells or less carrying the marker, other tests such as the detection of clonal immunoglobulin or T-cell receptor gene rearrangements with consensus primers or loss of heterozygosity at tumor suppressor gene loci require higher percentages of target cells. In addition, the examination of early or precursor lesions such as carcinoma in situ and epithelial dysplasias, which can shed light on the first seminal steps of carcinogenesis, is virtually impossible from bulk tissue extracts.

These problems are magnified at the mRNA and protein level, as, frequently, the relative abundance of the target, rather than its presence or absence, is of diagnostic relevance. In situ studies such as immunohistochemistry and in situ hybridization provide valuable alternatives, but are limited in their application range. For these reasons, microdissection strategies, ranging from relatively crude, manual microdissection to micromanipulation of single cells, have been used increasingly for the isolation of pure cell populations from primary tissues.

PRINCIPLES OF LASER CAPTURE MICRODISSECTION

Recently, a variety of laser-assisted microdissection devices have been developed and are available on the market. Two different technical principles can be discerned. One of them, initially termed laser microbeam microdissection (LMM), uses a pulsed UV laser with a small beam focus to cut out areas or cells of interest by photoablation of adjacent tissue.[1] The second technique is laser capture microdissection (LCM), which is described in more detail below.[2–4]

Laser capture microdissection is based on the selective adherence of visually targeted cells and tissue fragments to a thermoplastic membrane activated by a low-energy infrared laser pulse (Fig. 1). The basic system (marketed by Arcturus, Mountain View, CA) consists of an inverted microscope, a solid-state near-infrared laser diode, a joystick-controlled microscope stage, and hardware and software for laser control and image archiving. A new system for automated microdissection with expanded technical capabilities has recently been introduced by the same company. The thermoplastic membrane used for the transfer of selected cells is mounted on an optically clear cap which fits on standard 0.5-mL microcentrifuge tubes for further processing.

After visual selection of the targeted cells, laser activation leads to focal melting of the ethylene vinyl acetate (EVA) membrane, which has its absorption maximum near the wavelength of the laser. The melted polymer expands into the section, resolidifies within milliseconds, and forms a composite with the tissue. This allows selective removal of the cells attached to the activated membrane. Laser ''shots'' can be repeated multiple times across the whole cap surface to collect large numbers of cells.[2] Depending on the chosen laser spot size, the architectural features of the tissue, and the desired precision of the microdissection, even thousands of cells can be collected within a few minutes. After dissection, the cap is transferred to a tube containing the buffer solutions required for isolation of the molecules of interest. As most of the energy is absorbed by the

membrane, the maximum temperature reached by the tissue upon laser activation is in the range of 90°C for several milliseconds, thus leaving intact biological macromolecules of interest. The precision of LCM mainly depends on the ability to visually identify the desired cell population on the noncoverslipped slide, and to a lesser degree on the size and configuration of target cells. The current smallest spot size achievable is approximately 7.5 μm. Special caps hovering slightly above the section surface rather than being in direct physical contact with it have been designed for single-cell applications.

APPLICATIONS OF LCM

Laser capture microdissection can be applied to a wide range of different cell and tissue preparations, including

frozen sections, sections from fixed, paraffin-embedded archival material, and certain cytological preparations.[3,4] The most important parameters to consider for LCM are the type and fixation of the tissue to be examined, the morphologic features suitable for target identification, the desired target biomolecule—DNA, mRNA, or protein—and the type of downstream analysis.

DNA is relatively resistant to fixation and staining procedures and provides an ideal target for PCR-based analysis. Detection of point mutations or loss of heterozygosity (LOH), or identification of lymphocyte clonality in lymphomas can be greatly facilitated by collecting highly enriched tumor cell populations with LCM, thus increasing the diagnostic yield and obviating the need for more labor-intensive analytical strategies. Microdissection is crucial for the molecular analysis of discrete functional anatomic units such as glomeruli, or small lesions such as preneoplastic changes or areas of tumor heterogeneity which are not amenable to conventional examination of bulk tissue extracts. The investigation of precursor lesions allows the correlation genetic alterations with the morphological stages of tumor development, thus testing models of the stepwise acquisition of progressive genetic changes in vivo. In combination with techniques for the random amplification of the whole genome, comparative genomic hybridization (CGH), whole genome allelotyping, or other applications can be performed on a small number or even single cells.[4] However, the smaller the amount of template available, the higher is the risk for artefacts such as allelic dropout, biased amplification of certain sequences, or introduction of Taq polymerase errors. Critical evaluation of results and introduction of multiple controls, such as repeat analyses and continuous parallel investigation of adjacent normal tissue, are mandatory.

For most purposes, detachment of captured cells from the membrane by proteinase digestion without further purification steps renders DNA template of sufficient quality. Although frozen tissues usually show superior DNA quality, paraffin-embedded archival tissues can be used for most DNA-based analyses.[3]

Gene Expression Analysis

The analysis of tissue- or cell-specific gene expression is of paramount importance for many fields of biological and biomedical research. However, tissue heterogeneity can make it very difficult to assign gene expression profiles or specific messages to defined cell populations if gross tissue extracts serve as a source for mRNA, and significant efforts have been put into developing microdissection strategies which allow cell- or tissue-specific gene expression analysis. In contrast to DNA, mRNA is more sensitive to fixation, is quickly degraded by ubiquitous RNases, and requires stringent RNase-free conditions during specimen handling. Keeping these requirements in mind, mRNA of good quality can be recovered from microdissected frozen tissue samples down to the single-cell level, suitable for RT-PCR or quantitative real-time RT-PCR.[5] Rapid, optimized immunohistochemical or immunofluorescence staining protocols allow the combination of phenotypical identification of target cells with mRNA analysis.[6,7] The superior speed of LCM and the fact that capturing is performed from dried slides allow sampling of large numbers of cells without significant RNA degradation during the procurement procedure. If very small numbers of cells serve as template or if large-scale expression profiling using cDNA or oligonucleotide arrays is used, random mRNA amplification protocols can be employed.[8] In most studies, T7 RNA polymerase-based strategies have been the preferred technique in order to achieve an unbiased mRNA amplification from small amounts of tissue. Array-based expression screening of LCM-captured tissues has been used successfully for delineating expression differences of microdissected small and large neurons from dorsal root ganglia[9] or expression changes during breast cancer progression,[10] to name only a few examples.

Another application of LCM is the generation of expression libraries from purified cell populations, which has been performed at a large scale for the cancer genome anatomy project (CGAP; http://www.ncbi.nlm.nih.gov/ncicgap) sponsored by the National Cancer Institute.[11] This approach is intended to give a more faithful representation of gene expression patterns in epithelial neoplasms at all stages of development, in contrast to established cell lines which are usually derived from terminal-stage cancer patients, and in addition may show the artefacts of prolonged culture and the lack of an accompanying tissue microenvironment.

Although frozen tissue is the preferred source for mRNA analysis, the vast amounts of available archival specimens make paraffin-embedded tissues a valuable resource, and several groups have demonstrated that RNA derived from formalin-fixed paraffin blocks is suitable for certain types of analysis, such as conventional and real-time RT-PCR. A few hundred cells from paraffin sections render enough RNA for several RT-PCR assays without the need for preamplification steps, provided that the amplified fragment is below 100–120 bp.[12] Using the TaqMan technology with fluorescence-labeled probes, highly reproducible expression values can be obtained from microdissected archival material over a broad range of starting material and template concentrations.[13] The precision achievable by combining target cell purification by LCM with quantitative

RT-PCR and the ease with which these two techniques can be applied to paraffin sections make this approach a valuable tool for advanced molecular diagnostics.

Protein Analysis

Proteins are the effector molecules of the cell and can be modified through a variety of posttranscriptional mechanisms. Therefore a cell-specific analysis of protein patterns may ultimately prove to be more informative than expression profiling in primary tissues. For these reasons, a variety of proteomic techniques have recently been applied to microdissected tissues, although the inherent limitation of starting material can present a major obstacle for protein analyses.[14–17] Nevertheless, standard techniques such as the two-dimensional polyacrylamide electrophoresis for the detection of differential protein expression have been tested successfully on microdissected samples, and protocols for optimal fixation and protein recovery have been published.[18,19] Microdissection may also prove valuable to reduce sample complexity for mass spectrometric techniques such as surface-enhanced laser desorption/ionization time-of-flight (SELDI-ToF),[14] which need significantly less starting material than most gel-based techniques. Novel approaches such as the reverse-phase protein microarray[20] may prove useful to study multiple proteins, such as whole signal transduction pathways, in microdissected samples.

CONCLUSION

Laser capture microdissection and related laser-assisted microdissection techniques have developed into a key technology for the in-depth molecular analysis of primary tissues for both diagnostic and research purposes. The ease of use and versatility of LCM help to integrate microdissection into the workflow of any molecular pathology laboratory without much additional effort. Combined with downstream high-throughput techniques, microdissection is a big step toward ''molecular morphology.''

Legionella spp.

Nele Wellinghausen
University of Ulm, Ulm, Germany

Michael Steinert
Universität Würzburg, Würzburg, Germany

INTRODUCTION

Legionella species are aquatic microbes and pathogens of protozoa. Only a few of the more than 40 species cause infections in humans. The disease spectrum ranges from mild flulike symptoms to a highly lethal, severe form of pneumonia, called Legionnaires' disease. The pathogenic potential of *Legionella* was first recognized during an outbreak at the 56th annual American Legion convention in Philadelphia, PA, USA, in 1976, which led to the description of the pathogen. Today, legionellae are considered as one of the most important causative agents of community- and nosocomial-acquired pneumonia. Intensive research in the areas of molecular biology and genomics has greatly improved our understanding of the environmental fitness and pathogenicity of *Legionella* spp. Recent advances in molecular diagnostics offer a fast and specific diagnosis of the disease caused by *Legionella* species.

TAXONOMY AND DESCRIPTION OF THE PATHOGEN

Legionellae belong to the Gammaproteobacteria and are non-spore-forming gram-negative rods. To date, 42 species and 65 serogroups of *Legionella* have been described. *Legionella pneumophila* with its 15 serogroups is the main pathogen and accounts for more than 90% of infections, with serogroup 1 being the most common one. Several other legionellae, such as *Legionella micdadei*, *Legionella bozemanii*, and *Legionella dumoffii*, also cause disease.[1]

Legionellae are intracellularly replicating bacteria. They live primarily in environmental aquatic habitats and replicate within protozoa, such as amoeba and flagellates. Upon inhalation by humans of aerosolized water from contaminated tap waters, air-conditioning systems, or cooling towers, *Legionella* replicates in monocytes, alveolar macrophages, and epithelial cells.[1] In vitro, legionellae show fastidious growth characteristics.

Highest concentrations of legionellae are found in man-made hot-water systems because legionellae grow best at temperatures between 37°C and 50°C and can even tolerate temperatures above 60°C.[2]

INTRACELLULAR LIFE CYCLE

The broad protozoal host spectrum of *Legionella* and the exploitation of basic cellular mechanisms of eukaryotes enables *Legionella* to replicate within human cells. Striking similarities in both host systems include the uptake by phagocytosis, the formation of a *Legionella*-specific vacuole that does not follow the endosomal pathway, the association of this vacuole with ribosome-studded membranes that originate from the endoplasmic reticulum, and finally, host cell lysis. In this life cycle, *Legionella* switches from a nonreplicating, flagellated, stress-resistant, cytotoxic phase (transmission form) to a replicating, nonflagellated phase (growth form). The conversion is triggered by a stringent response-like mechanism.[2]

In recent years, much progress has been made toward the characterization of how *Legionella* infects host cells. Because the reprogramming of the endocytic pathway occurs between the initial attachment and the replicative phase of the bacteria, it is highly likely that cell surface components and secreted factors are involved in this process. Various surface structures including the major outer membrane protein (MOMP), which mediates the uptake of *Legionella* via the CR1 and CR3 receptors of macrophages, the type IV pilus biogenesis, and the macrophage infectivity potentiator (Mip) protein have been characterized. Moreover, the Dot/Icm secretion system plays a pivotal role during infection. Yet, unidentified factors that are injected into host cells by this type IV secretion system obviously prevent the *Legionella*-containing vacuole from endosomal maturation. Recently, macrophage-specific virulence genes such as *mil* (macrophage-specific infectivity loci) and protozoa specific virulence genes such as legionella infectivity gene (*ligA*), type II secretion system (*lsp*), alternative sigma factors (*rpoS*) have been identified. This suggests that besides many similarities, notable differences in the mechanisms of entering and exiting the host cell exist.[3]

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020872

Comparison of the nucleotide sequence of different *Legionella* species revealed 23% nucleotide sequence variation within the 16S rRNA gene and 56% variation for the *mip* gene. However, knowledge of genetic diversity between different isolates of the same or of different *Legionella* species is still very limited. The current *Legionella* genome project (http://genome3.cpmc.columbia.edu/~legion/) may soon reveal the relation between the presence of specific genes and the prevalence of certain species in epidemiological investigations.[4]

In order to study the host side of infection, guinea pigs, primary cell culture systems, and cell lines derived from human leukemias such as U937, HL60, HeLa, Vero, and McCoy cells have been used. In addition, the infection of axenically grown protozoa such as *Acanthamoeba*, *Hartmannella*, and *Naegleria* have increased our knowledge about the ecology of *Legionella*.[5] Especially, the haploid soil amoeba *Dictyostelium discoideum* has proven to be a suitable model system for studying cellular mechanisms of pathogenesis. This surrogate host system is amenable to genetic manipulation and evolutionarily expresses highly conserved cellular markers. In the future, the combination of full-scale genomic sequencing and high-throughput expression analysis with *Legionella* and *Dictyostelium* should reveal important aspects of the pathogen–host cross-talk.[6,7]

CLINICAL SIGNIFICANCE OF *LEGIONELLA* SPP.

Legionella causes two different manifestations of pulmonary disease: a mild, flulike illness, called Pontiac fever, and pneumonia. Pontiac fever has an incubation period of 1–2 days and is characterized by malaise, myalgias, fever, headache, and, sometimes, nonproductive cough. Only symptomatic therapy is required, and complete recovery within 1 week can be expected. Pneumonia, on the other hand, is the predominant manifestation of the more severe form of legionellosis, Legionnaires' disease. This pneumonia can be associated with multiorgan failure. The incubation period of legionnaires' disease ranges from 2 to 10 days, and antimicrobial chemotherapy is necessary for complete recovery of the patients. Nevertheless, in elderly or pulmonary-compromised patients, Legionnaires' disease has a mortality rate of up to 50%.[5,8]

Infection of humans mainly occurs through close contact with contaminated water sources, such as droplets and aerosols in spas, hot showers, and air-conditioning systems. Legionellae are responsible for 2–15% of community-acquired pneumonias, but the estimated number of infections is much higher. In addition, legionellae are a significant cause of nosocomial pneumonias, especially in immunocompromised and ICU patients.[5,8] Nosocomial infections caused by legionellae are more often caused by *L. pneumophila* nonserogroup 1 and by legionellae other than *L. pneumophila*,[9] corresponding to the epidemiology of the different *Legionella* species in water sources.

DETECTION OF *LEGIONELLA* SPP. IN CLINICAL AND ENVIRONMENTAL SAMPLES

Culture is still regarded as the gold standard for diagnosis of *Legionella* infection, but it is hampered by the slow replication rate and the fastidious growth requirements of legionellae. *Legionella* urinary antigen detection assays have greatly improved the diagnosis of acute *Legionella* infection. However, they only detect *L. pneumophila* serogroup 1 with high sensitivity and specificity.[10]

More recently, nucleic acid amplification techniques, such as the polymerase chain reaction (PCR), have shown promise for the rapid diagnosis of *Legionella* infection.[11] Nucleic acid amplification techniques enable specific amplification of minute amounts of *Legionella* DNA, provide results within a short time frame, and have the potential to detect infections caused by any *Legionella* species and serogroup. New real-time PCR methods, such as the LightCycler® PCR technique, can even speed up the process of detection to a few hours.

Molecular Detection of *Legionella* in Water Samples

Detection of legionellae in environmental and building water samples by PCR has been centered on hospital and cooling tower water samples. Target genes included the 16S and 5S rRNA gene of *Legionella* spp. and the *mip* gene of *L. pneumophila*.[12–15] Compared to conventional culture, the published PCR protocols showed a sensitivity of 71.8% to 98.1% and 54.5% to 82.1% for the detection of legionellae and *L. pneumophila*, respectively. However, the main limitation of all PCR assays is the high prevalence of PCR inhibitors in water samples. The presence of waterborne PCR inhibitors that will be enriched during concentration of the water samples also limits the sample size and thus the sensitivity of the PCR assays. Nevertheless, legionellae were detected in 60% to 100% of culture-negative water samples in several studies.[12,14,15] Because of the labor- and time-intensive nature of *Legionella* culture and the presence of viable and infectious but nonculturable Legionellae and *Legionella*-like organisms in water samples, PCR methods are a valuable tool for the detection of legionellae in water samples. However, further studies are necessary to clarify the significance of PCR-positive but culture-negative

Table 1 Nucleic acid amplification tests for detection of legionellae in respiratory samples [bronchoalveolar lavage (BAL), sputum, bronchial washing]

The table exclusively shows studies that investigate a minimum of 10 patients.

samples and to establish limits for PCR results to be used in infection control and surveillance practice.

Molecular Detection of *Legionella* in Clinical Samples

Target sequences of the hitherto developed *Legionella*-specific PCR assays were the 16S rRNA gene and the 5S rRNA gene of *Legionella* spp. and the *mip* gene of *L. pneumophila*. Due to the nature of infection, materials from the deep respiratory tract, such as bronchial alveolar lavage fluid and sputum, are the samples of choice for investigation and have been studied extensively during the last decade (Table 1). In the studies, the PCR assays consistently detected all culture-positive samples. Real-time PCR assays even allowed a diagnosis of *Legionella* infection within a few hours. Notably, in most studies PCR-positive samples that were negative by culture were also observed, ranging from 3% to 12% of the samples investigated.[16–23] Because most of these samples were obtained from patients with a serologically confirmed *Legionella* infection or from patients with otherwise undefined pneumonia, a higher sensitivity of the PCR assays compared to culture can be assumed. Although all studies suffer from a small sample size, PCR may be considered the method of choice for detection of acute legionellosis, especially in patients with a higher risk of infections caused by legionellae other than *L. pneumophila* serogroup 1 in nosocomial settings or in certain geographical regions.

However, less than half of the patients with legionellosis can produce sputum, and, thus, PCR testing of other materials has been evaluated in several studies. In accordance with antigen detection assays, legionellae can be detected in urine of affected patients; however, the sensitivity was much lower than in respiratory samples and adds little to that of antigen detection assays.[11] In addition to urine, serum was evaluated in a few studies. Whereas Lindsay et al.[25] recorded positive results by PCR and probing in five out of five patients with legionellosis, others found sensitivities for serum PCR assays of only 30% to 43% in studies comprising up to 28 patients.[11] Clearly, further evaluation of nonrespiratory samples and sample types is necessary to determine their role in the diagnosis of legionellosis.

DISINFECTION AND TREATMENT

Person-to-person transmission of legionellosis has not been published. Therefore, prevention of *Legionella* infections refers to the elimination of the pathogen from water supplies. Several methods for controlling the growth of legionellae in drinking water (superheating, ultraviolet light irradiation, ozonation, metal ionization, chlorination) have been described.[24]

With respect to human infection, prompt diagnosis and treatment appear to be critical, because delay in starting an appropriate therapy has been associated with increased mortality. Legionellae are intracellular pathogens, and thus antibiotics that achieve high intracellular concentration are more efficacious than those with poor intracellular penetration. Historically, erythromycin has been the drug of choice. Macrolides, quinolones, rifampicin, trimethorpim–sulfamethoxazole, and tetracyclines are effective agents in vitro. According to in vitro studies, the newer macrolides, especially clarithromycin and azithromycin, and quinolones are the drugs of choice for *Legionella* infections.[5,8]

CONCLUSION

Because the coevolution of the legionellae–protozoa interaction can be viewed as a ''living fossil'' of the adaptation of bacteria to professional phagocytes this pathogen has become a prominent model system in this respect. Main characteristics of the intracellular lifestyle and the regulation and function of replication- and pathogenicity-associated genes have already been elucidated. In addition, detection of legionellae by molecular methods has taken a significant role in clinical as well as in environmental diagnostics. The characterization of the genetic diversity of different *Legionella* species will provide information about the core genome of *Legionella* and genes present only in certain isolates. This may allow the identification of marker genes that can be used as tools for detection and risk assessment. In a long perspective, the molecular approach may also help to understand the infection cycle and the life cycle in the environment, which is the prerequisite for successful elimination of *Legionella* from high-risk areas.

Ligase Chain Reaction (LCR) and Ligase Detection Reaction (LDR)

Jürgen Fuchs
Maurizio Podda
J.W. Goethe University, Frankfurt, Germany

INTRODUCTION

The polymerase chain reaction (PCR) has revolutionized molecular biology and has become an indispensable tool in molecular diagnostics. The ligase chain reaction (LCR) and the ligase detection reaction (LDR) were developed as alternative nucleic acid amplification methods for analyzing known point mutations associated with genetic diseases. In contrast to target amplification techniques such as PCR, SDA, 3 SR, and NASBA, LCR and LDR are not based on primer extension, but on amplification of ligated probes.[1,2] Excellent reviews on LCR and its diagnostic applications have been published.[3–7]

HISTORIC DEVELOPMENTS

DNA ligase was discovered in the late 1960s and the enzyme is an essential component of DNA replication, recombination, and repair systems, which catalyzes the formation of covalent phosphodiester bonds at single-stranded breaks on dsDNA. In 1972, ligation of flanking oligonucleotides while hybridized to a template was investigated,[8] and soon it became apparent that DNA ligase could be used as an analytical tool for detecting the presence of two adjacent pieces of oligonucleotides hybridized to a complementary target DNA strand.[3,9] After synthetic oligonucleotides became readily available, the practical use of this concept was further exploited and Landegren et al. developed the oligonucleotide ligation assay (OLA).[5] Wu and Wallace described a technique called ligase amplification reaction (LAR), which uses two sets of complementary oligonucleotide probes and repeated cycles of heat denaturation, hybridization, and ligation using a mesophilic DNA ligase, leading to exponential amplification.[10] Barany reported a technique called ligase detection reaction (LDR) and ligase chain reaction (LCR) that uses a thermostable ligase which dramatically improved the sensitivity of the reaction and exquisitely discriminated between single-base mismatches at the junction of the two oligonucleotide probes.[3]

LIGASE CHAIN REACTION AND LIGASE DETECTION REACTION

Ligase chain reaction utilizes two complementary oligonucleotide probe pairs, which are specific for a DNA target sequence. In the presence of the target sequence, each probe of a pair hybridizes to adjacent positions on the template such that the 5′-phosphate of one oligonucleotide abuts the 3′-hydroxyl of the other. The resulting nick is subsequently sealed by a DNA ligase. By temperature cycling, bound ligated units dissociate from the target and the released ligated unit becomes the target for the next round of ligation which is initiated by aligning the opposite sense adjacent probes. After repeated cycles of denaturation, annealing, and ligation the target sequence is amplified exponentially (Fig. 1). Ligase detection reaction employs only one set of oligonucleotide probes in a thermal cycling reaction similar to the one described above, resulting in linear product increase. Attaching biotin on the first probe and a suitable reporter group on the second probe allows for product capture and detection in a manner amenable to automation.[3,4] Ligase chain reaction and ligase detection reaction are very sensitive assays for discriminating DNA sequences that differ by only one single base pair. A mismatch in the ligation junction inhibits the ligation reaction thus conferring an excellent resolution power to hybridization, decreasing the need for high stringency conditions and thus providing excellent conditions for multiplexing reactions.[3,5] A great potential of LCR is its compatibility with other nucleic acid amplification techniques such as PCR, 3 SR, and the Qβ replicase assay. Real-time applications,[11,12] multiplexing assays,[13,14] competitive LCR and multiplex-competitive LCR,[15] quantitative LCR,[16] and nested LCR[4] have been described. The sensitivity of LCR is dependent on the fidelity of the ligase. Four thermostable ligases are commercially available: 1) Taq ligase (New England Biolabs, Beverly, MA); 2) Tth (Abbott Diagnostics, Abbott Park, IL); 3) Pfu (Stratagene, La Jolla, CA); and 4) Ampligase (Epicenter Technologies, Madison, WI). Pfu was advertised to have higher ligation specificity and lower background than Tth.[7] Although

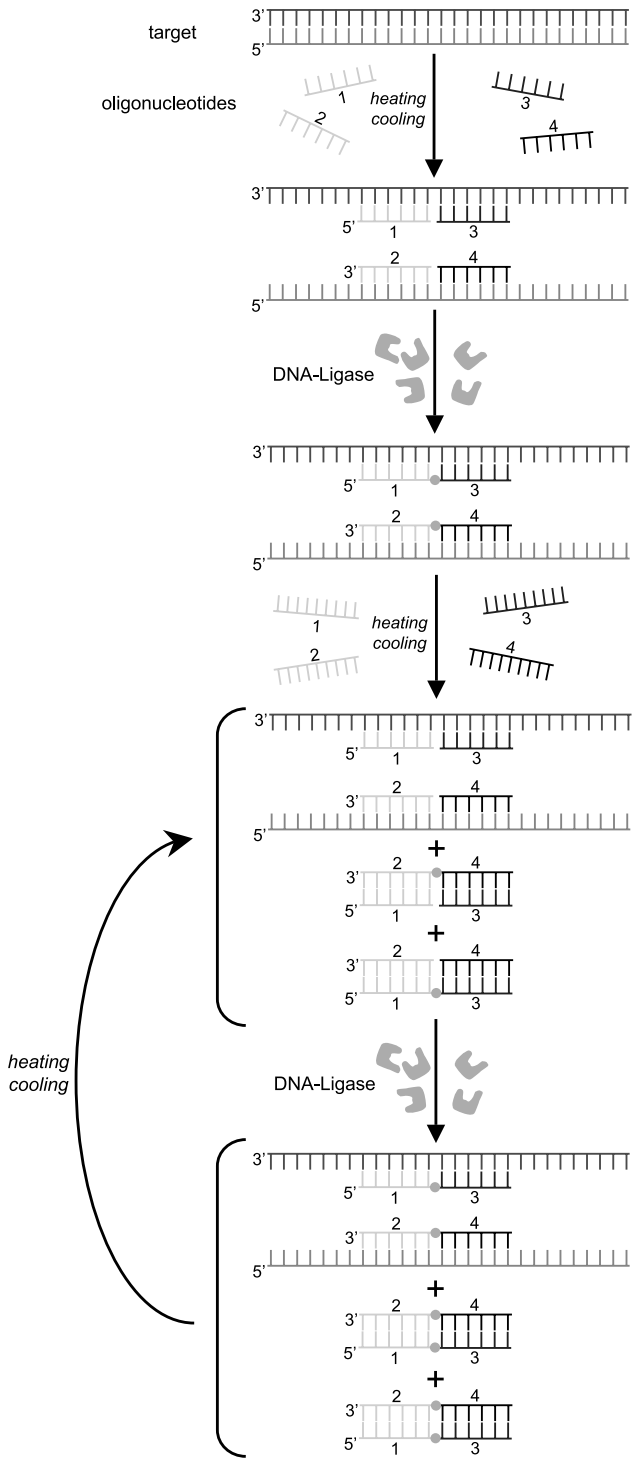

Fig. 1 Ligase chain reaction. The probes are annealed to template molecules in a head-to-tail fashion with the 3′ end of one probe abutting the 5′ end of the second probe. DNA ligase then joins the adjacent 3′ and 5′ ends to form a copy of one strand of the target. The copy is subsequently separated from the target by heat denaturation. Released ssDNA forms new templates for further probe binding. A second set of probes, complementary to the first, uses the duplicated strand, as well as the original target, as a template for ligation. (*View this art in color at www.dekker.com.*)

LCR was reported to be less affected by inhibitors in some specimens than PCR, LCR is subject to contamination that is at least as much of a problem as for PCR.[7] In particular, the inhibitory effect of phosphate on LCR can pose a problem,[17] and duplicate dilution analysis of negative specimens was recommended.[18]

PCR/LDR AND Gap-LCR

A major problem of the LCR reaction is joining of blunt end duplexes to each other and to themselves, all of which can serve as templates for further amplification, although no real target DNA is present in the original sample[7] and this poses significant limitations on the sensitivity of LCR.[6] To overcome this problem, several modifications have been developed, including a combined PCR/LDR method and Gap-LCR (G-LCR). In PCR/LDR, the amplification step for LDR is PCR utilizing outside primers and employing only one pair of adjacent probes to detect the proper sequence in the PCR produced. This procedure does not produce double-stranded oligonucleotides to blunt end ligate.[4] A recent study showed that PCR/LDR was more accurate than FISH in the quantification of HER2/neu gene copy numbers.[19] Gap-LCR is a version of LCR where the probes are not adjacent but are separated by one to three bases on both the sense and antisense strand. A nonstrand displacing thermostable DNA polymerase, supplied with the necessary dNTPs, adds the missing bases to the 3′ internal end of one of the two probes, thus initiating a template-dependent extension. Once the gap between the two probes is filled, the probes are once again adjacent and can be ligated. The same process occurs on the opposite strand (Fig. 2). By this modification, G-LCR prevents target-independent ligation very efficiently[20,21] and has the advantage of having the additive effect of polymerase and ligase on specificity.[22] Excellent discrimination of mutations was achieved using multiplex G-LCR,[13,14] and a real-time G-LCR for rapid detection of p53 mutations in clinical specimens was recently described.[23] Gap-LCR assays have been developed for the detection of *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and *Mycobacterium tuberculosis* (Abbott, IL, USA). Several studies have evaluated the usefulness of commercially available nucleic acid amplification assays, comparing G-LCR with PCR and SDA for detection of *C. trachomatis* and *N. gonorrhoeae*. In these comparative studies G-LCR proved to be a robust, specific, and sensitive technique.[24–29]

AMPLIFICATION OF RNA TARGETS

The natural target of DNA ligase is dsDNA. DNA ligase has been shown to join DNA oligonucleotides hybridized

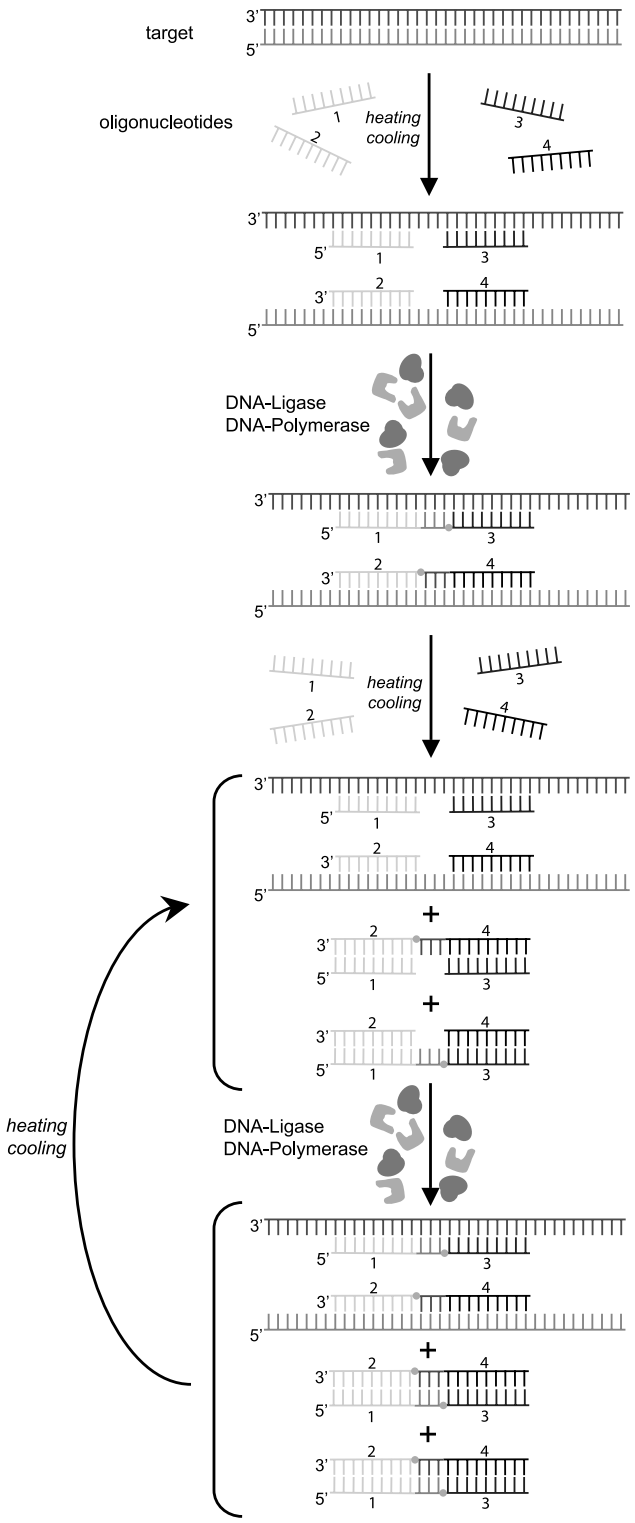

Fig. 2 Gap-ligase chain reaction. Gap-LCR differs from LCR in that a short gap is formed after annealing of the four oligonucleotide probes to the template. The gap is filled in by a non-strand-displacing thermostable DNA polymerase and the resulting nick is ligated. (*View this art in color at www.dekker.com.*)

to RNA templates, although with a significantly lower efficiency than DNA-templated reactions.[30] Consequently, LCR and G-LCR cannot amplify RNA efficiently. To overcome this problem, an asymmetric G-LCR was developed that allows for the detection of RNA via a cDNA step.[21] Another approach allows direct analysis of RNA sequences without a preceding cDNA synthesis by defining specific reaction conditions to increase the efficiency of the enzyme on a DNA/RNA hybrid.[31,32]

CONCLUSION

In the mid-1990s commercial G-LCR kits were developed for the detection of *C. trachomatis*, *N. gonorrhoeae*, and *M. tuberculosis* (Abbott), and these assays played a significant role in clinical STD (sexually transmitted disease) diagnostics. Due to modernized regulations in quality assurance, modifications performed in the manufacturing process and component changes made these assays not as robust as they used to be, resulting in high failure rates in internal testing since 2001 (personal communication, Judy H. Yu, Abbott, IL). In 2003, Abbott discontinued the distribution of its LCR-based diagnostic products and is now using PCR-based technology for its commercial diagnostic kits (LCx HCV and LCx HIV). Currently, there are no commercial LCR-based nucleic acid amplification tests on the market, and in molecular STD diagnostics LCR has lost ground against PCR. Nonetheless, DNA ligation assays continue to play an important role in molecular diagnostics, as is exemplified by the development of ligase-detection PCR (LD-PCR)[31] and the use of LDR in combination with DNA array technology.[33] DNA ligase was used in combination with PCR in a probe amplification assay named LD-PCR to increase the accuracy and sensitivity of target nucleic acid determination.[31] This method utilizes a capture probe for target isolation, two hemiprobes for target detection, and a PCR step to amplify the ligated full probe. Ligase-detection PCR was more sensitive than conventional RT-PCR for the detection of HCV DNA in formalin-fixed paraffin-embedded liver specimens.[34] Ligation assays are useful methods for mutation analysis on microarray platforms and are gaining wide attention due to their excellent discriminatory power of allele variants.[35] Ligase detection reaction was successfully used on microarrays for discriminating between different bacterial groups,[36] for rapid and sensitive identification of drug-resistant *M. tuberculosis* strains,[37] and, in combination with PCR, for detecting and genotyping human papillomavirus[38] or for characterizing p53 mutations in a multiplex PCR/LDR assay.[39–41]

LightUp® Probes

Mikael Leijon
LightUp Technologies AB, Huddinge, Sweden

INTRODUCTION

Real-time monitoring of the polymerase chain reaction (PCR) product by fluorescent probes has recently enabled the homogeneous detection of pathogen deoxyribonucleic acid (DNA) or ribonucleic acid (RNA0) in a closed-tube format. The reduced risk of carry-over contamination and the superior sensitivity of PCR-based assays have made real-time PCR the method of choice in many clinical settings. The LightUp® Probe is a novel of fluorescent probe where the fluorescent reporter dye is coupled to an oligomer of the uncharged DNA analog peptide nucleic acid (PNA). Peptide nucleic acid provides strong, but still specific, binding and serves as the sequence-recognizing element of the probe. The fluorophore is an asymmetric cyanine dye that fluoresces when the probe binds its target DNA, but is virtually nonfluorescent when the probe is free in solution.

RESULTS

The extraordinary sensitivity of PCR-based assays is an important factor behind the recent tour de force of real-time PCR in molecular biology in general and viral diagnostics in particular.[1,2] Besides the inherent sensitivity of the PCR technique, the real-time fluorescence detection used in modern PCR instrumentation has the added advantage of providing accurate quantification of the initial amount of the amplified nucleic acid. This is achieved by comparing C_t values, i.e., the PCR cycle where the fluorescence signal reaches a certain level, for unknown clinical samples with the C_t values of a dilution series of a reference material with known concentration. This is generally carried out via a standard curve:

$$C_t = \frac{\log(c)}{\log(1+E)^{-1}} + C_t(1)$$

where the parameter E is the PCR efficiency, ideally equal to unity, and $C_t(1)$ is the threshold cycle value where one copy of the standard would appear. Assuming that the standard curve parameters also apply to the clinical samples, the concentration of the clinical samples can be determined from the measured C_t values.

DNA-based sequence recognizing fluorescent probes commonly utilize a fluorophor/quencher pair that is, in some manner, separated in the course of the amplification reaction. TaqMan® probes, for example, are degraded by the 5′-nuclease activity of the DNA polymerase, which releases the fluorophore from its sequence-recognizing element, and thereby separates it from the quencher, so that a light signal is emitted upon excitation.[3] Molecular beacons achieve the same goal by a rearrangement of the secondary structure upon hybridization, which causes a separation of the quencher and the fluorophore.[4] Fluorescence resonance energy transfer (FRET) probes work slightly differently. Instead of the acceptor dye functioning as a quencher, it emits the detectable fluorescence when the two probes bind adjacent to each other on the target DNA molecule.[5]

The LightUp® Probe[6] (Fig. 1) represents a significant departure from this paradigm, because the DNA has been entirely replaced by the homomorphous but uncharged and achiral DNA analog PNA (Fig. 2). Peptide nucleic acid is composed of *N*-(2-aminoethyl)glycine subunits[7] and forms very stable hybrid complexes with both DNA and RNA with a sequence specificity that is higher than that DNA has for itself.[8] An asymmetric cyanine dye, such as a thiazole orange derivative or 4-[(3-methyl-6-(benzothiazol-2-yl)-2,3-dihydro-(benzo-1,3-thiazole)-2-methylidene)]-1-methyl-pyridinium iodide (BEBO),[9] is generally used as the fluorescent marker (Fig. 1). This type of dye releases excitation energy by internal motion when it is free in solution and is, under these conditions, virtually nonfluorescent. When bound to DNA, however, the dye becomes brightly fluorescent.[10–13] Because the dye is positively charged, a significantly higher background signal would result from internal binding of the dye if DNA is used instead of PNA.

The LightUp Probes have several advantages compared to probes with sequence recognizing elements consisting of DNA. Because it binds during the annealing phase, an optimal three-step PCR cycle can be used. The primer design is also very flexible because the amplicon does not need to be kept short, apart from what is compatible with maximum sensitivity of the PCR system. A typical amplicon length is generally in the range of 100–500 bp. Because PNA is not degraded by proteases or nucleases, kits utilizing LightUp Probe detection are very stable with

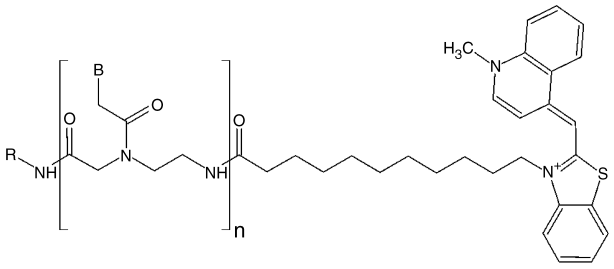

Fig. 1 A schematic view of the LightUp Probe. The dye may be different.

typical storage conditions at 4–6°C for at least 1 year. Possibly, the different chemistry by which the dye is attached to the PNA as compared to DNA contributes to this favorable stability. Recently, it has become increasingly apparent that the long (typically 20–40 bases) DNA probes are not suitable in some applications where high specificity is desirable, for instance, in SNP detections. Obviously, a one base mismatch out of 40 bases makes a smaller difference than one base out of ten. For this reason, minor groove binding (MGB) probes were designed, where minor groove binding ligands have been covalently attached to the DNA probes to increase stability upon hybridization and enable a shortening of the probe.[14] The uncharged LightUp Probe is intrinsically much more stable than a DNA probe because of the absence of electrostatic backbone–backbone repulsion. Furthermore, the positively charged dye (Fig. 1) plays a similar role as the minor groove-binding moiety of the MGB probes. Hence, the LightUp Probes are typically 8–12 bases long, about one-third of the length of a typical DNA probe and one-sixth of the length of a FRET pair. Many viral pathogens have rapidly mutating genomes, making it very challenging to find conserved target regions for DNA-based probes/quencher system. The LightUp technology provides a significant advantage in these applications.[13] Finally, the spectral region occupied by a LightUp Probe is just one-half that of a fluorophor/quencher pair or a FRET pair, because the LightUp Probe contains only a single dye. This should be advantageous in multiplex applications, but because

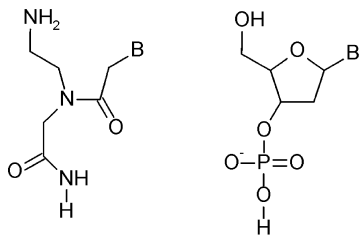

Fig. 2 The homomorphous DNA and PNA subunits.

several instrument platforms use a single wavelength excitation source (e.g., the ABI real-time PCR instruments and the Roche LightCycler), it is necessary to design asymmetric cyanine dyes with greatly varying Stokes' shift, which may prove difficult, to enable multiplex detection with LightUp Probes. However, the trend is that new real-time PCR instrumentation provides several excitation wavelengths (e.g., the Rotor-Gene™ from Corbett Research, the SmartCycler® from Cepheid Research and the iCycler from Bio-Rad).

Figure 3A shows the real-time amplification curves, in duplicates, for a successive dilution of an Epstein–Barr virus (EBV) DNA solution, obtained by using the LightUp ReSSQ EBV Assay. The initial EBV template concentration ranges from 20 to 200,000 genome copies, as indicated. Prominent Hook effects are observed at all concentrations and the end signal is independent of the initial template amount. This shows that the probe is stable throughout the PCR run. With DNA probes, the end signal commonly decreases for low template concentrations, which is likely to be an effect of probe degradation. By fitting a standard curve to the threshold cycle numbers in Fig. 3A and the logarithm of the known concentrations (Fig. 3B), it is found that the PCR efficiency is 96% and that the $C_t(1)$ value is 36.4 cycles.

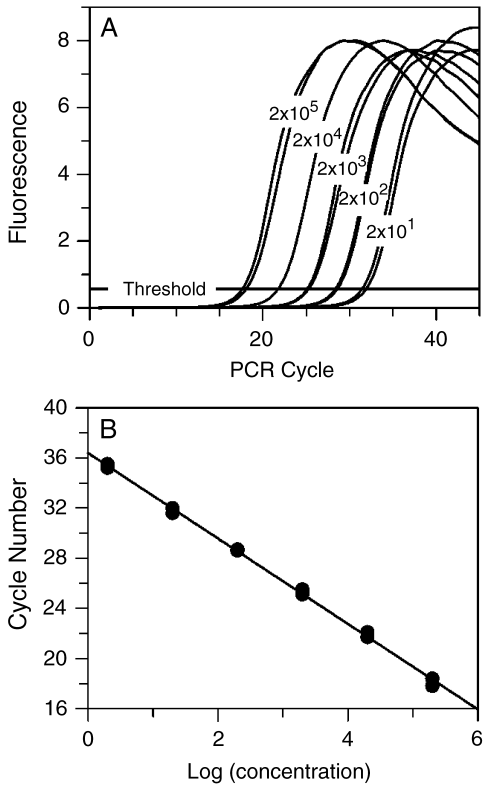

Fig. 3 The LightUp ReSSQ™ Epstein–Barr virus assay.

The viral load of an unknown clinical sample could easily be determined from its C_t value and this standard curve. As an example, a clinical evaluation study shows that quantification with the LightUp Cytomegalovirus (CMV) ReSSQ Assay is very similar to that of the Roche COBAS Amplicor CMV Monitor, but with higher sensitivity (to be published).

Applications of LightUp Probes also include bacterial DNA diagnostics. One example is Salmonella typing. It has been shown that the *Salmonella bongori* serotype could readily be distinguished from the *Salmonella entertidis* and *Salmonella anatum* serotypes from a single mismatch in the probe target region.[13] In another study, *Yersinia enterocolitica* was quantified over four log units.[15] LightUp probes have also found application in cancer diagnostics. The relative expression of the immunoglobulin κ and λ genes is a sensitive marker for non-Hodgkin B-cell lymphomas. In a healthy individual, 60% of the B-cells produce κ chains, while the rest produce λ chains. A significant perturbation of this ratio is indicative of B-cell lymphoma. In a recently published study, 28 of 32 clinical samples were correctly diagnosed B-cell lymphoma by cDNA quantification using LightUp Probes.[16]

CONCLUSION

LightUp Probes provide a useful combination of strong affinity and high specificity. The resistance against degradation is an important advantage when storing and manufacturing diagnostic kits. Freeze–thaw cycles are often deleterious to long DNA, such as viral genomes and plasmids. This can be avoided by using LightUp Probe technology, because the probe does not need to be stored frozen. Furthermore, the probes can be made short: 8–12 residues is typical. This is a very useful property in viral diagnostics, where the mutation frequency often is high and long conserved target regions may be rare. This is particularly true for RNA viruses such as HIV, influenza, and severe acute respiratory syndrome (SARS). In fact, several probes could, in principle, be targeting the same amplicon-generating independent signals, thereby making the assay even more robust and less prone to false negatives. The greatest challenge for the future success of the LightUp Probe technology will be to develop and implement fluorescent dyes suitable for multiplex applications.

Liposomal Nonviral Delivery Vehicles

Nancy Smyth Templeton
Baylor College of Medicine, Houston, Texas, U.S.A.

INTRODUCTION

Optimization of cationic liposomal complexes for in vivo applications is complex, involving many diverse components including nucleic acid purification, plasmid design, delivery vehicle formulation, administration route and schedule, dosing, detection of gene expression, and others. Optimizing all components of the delivery system is pivotal and will allow broad use of liposomal complexes to treat human diseases or disorders. This article will highlight the features of liposomes that contribute to successful delivery, gene expression, and efficacy.

Delivery of nucleic acids using liposomes is promising as a safe and nonimmunogenic approach to gene therapy and would overcome the numerous disadvantages of viral vectors. Furthermore, gene therapeutics composed of artificial reagents can be standardized and regulated as drugs rather than as biologics. Cationic lipids have been used for efficient delivery of nucleic acids to cells in tissue culture for several years.[1] Much effort has also been directed toward developing cationic liposomes for efficient delivery of nucleic acids in animals and in humans. Most frequently, the formulations that are best to use for transfection of a broad range of cell types in culture are not optimal for achieving efficacy in animals or people. Functional properties defined in vitro do not assess the stability of the complexes in plasma, pharmacokinetics, biodistribution, and colloidal properties that are essential for optimal activity in vivo. Nucleic acid–liposome complexes must also traverse tight barriers in vivo and penetrate throughout the target tissue to produce efficacy for the treatment of many diseases. These are not issues for achieving efficient transfection of cells in culture with the exception of polarized tissue culture cells. Therefore, optimized in vivo liposomes may differ from those used for efficient tissue culture transfection.

Different types of nucleic acids of unlimited size can be delivered using liposomes. Recent advances have dramatically improved transfection efficiencies and efficacy of liposomal vectors.[2–6] We demonstrated broad efficacy of a robust liposomal delivery system in small and large animal models for lung,[3] breast,[5] head and neck (Hung and Templeton, unpublished data), and pancreatic cancers,[4] and for hepatitis B and C (Clawson and Templeton, unpublished data). This liposomal delivery system is currently used in a clinical trial to treat non-small-cell lung cancer and will be used in upcoming clinical trials to treat other cancers and cardiovascular diseases. Reviews of other in vivo delivery systems and improvements using cationic liposomes have been published recently.[7,8]

OPTIMIZATION OF LIPOSOMAL DELIVERY

Efficient in vivo nucleic acid–liposome complexes have unique features, including their morphology, mechanisms for cell and nuclear entry, targeted delivery, and ability to penetrate across tight barriers and throughout target tissues. Liposomes have different morphologies based on their composition and the formulation method that contribute to their ability to deliver nucleic acids in vivo. Formulations frequently used for the delivery of nucleic acids are lamellar structures, including small unilamellar vesicles (SUVs), multilamellar vesicles (MLVs), or bilamellar invaginated vesicles (BIVs) recently developed in our laboratory (Fig. 1). Hexagonal structures have demonstrated efficiency primarily for the transfection of some cell types in culture and not for in vivo delivery. SUVs condense nucleic acids on the surface and form ''spaghetti and meatballs'' structures.[9] SUV complexes produce little or no gene expression upon systemic delivery, although these complexes transfect numerous cell types efficiently in vitro.[1] Furthermore, SUV liposome–DNA complexes cannot be targeted efficiently.

SUV complexes also have a short half-life in circulation, about 5 to 10 min. Polyethylene glycol (PEG) has been added to liposome formulations to extend their half-life;[10–12] however, PEGylation created other unresolved problems. PEG also hinders delivery of cationic complexes into cells because of its sterically hindering ionic interactions and interferes with optimal condensation of nucleic acids into complexes. Furthermore, extremely long half-life in the circulation, e.g., several days, caused problems for patients because the bulk of the PEGylated liposomal formulation, doxil, which encapsulates the cytotoxic agent, doxorubicin, accumulates in the skin, hands, and feet. Patients contract mucositis and hand and foot syndrome[13,14] that cause

DOI: 10.1081/E-EDGP 120029834

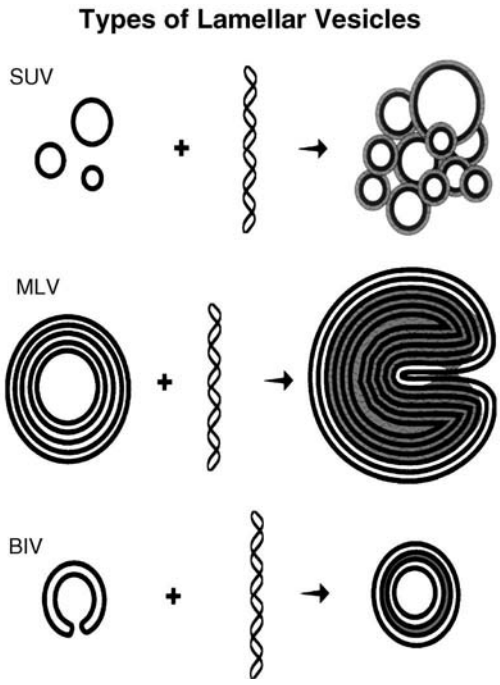

Fig. 1 Diagrams drawn from cryoelectron micrographs of lamellar liposomes and complexes. SUVs, ''spaghetti and meatballs'' structures, condense nucleic acids on the surface. MLV complexes appear as ''Swiss rolls.'' BIVs efficiently encapsulate nucleic acids between two bilamellar invaginated structures. (From Ref. [2].)

extreme discomfort to the patient. Adding ligands to doxil for delivery to specific cell surface receptors did not result in much cell-specific delivery, and most of the injected targeted formulation still accumulated in the skin, hands, and feet. Addition of PEG in BIVs also caused steric hindrance that prevented efficient encapsulation of nucleic acids, and gene expression was substantially diminished. MLV complexes appear as ''Swiss rolls'' when viewing cross sections by cryoelectron microscopy.[15] These complexes can become too large for systemic administration or deliver nucleic acids inefficiently into cells because of inability to ''unravel'' at the cell surface. Addition of ligands onto MLV liposome–DNA complexes further aggravates these problems.

BIVs efficiently encapsulate large amounts of nucleic acids of any size between two bilamellar invaginated vesicles.[2] We created these unique structures using 1,2-*bis*(oleoyloxy)-3-(trimethylammino)propane (DOTAP) and synthetic cholesterol (Chol) and a novel formulation procedure. Addition of other DNA condensing agents including polymers is not necessary, and encapsulation of nucleic acids by BIVs alone is spontaneous and immediate. The BIV complexes are also large enough so that they are not cleared rapidly by Kupffer cells in the liver, and yet extravasate and penetrate across tight barriers. BIVs penetrated barriers including the endothelial cell barrier in normal mice and the posterior blood retinal barrier in adult mouse eyes, and diffused throughout large tumors[3] and several layers of smooth muscle cells in pig arteries. We demonstrated efficacy for treatment of non-small-cell lung cancer[3] using BIV DOTAP:Chol-p53 DNA–liposome complexes and not by using SUV DOTAP:Chol-p53 DNA–liposome complexes. Therefore, morphology of the complexes is essential.

A common belief is that artificial vehicles must be 100 nm or smaller to be effective for systemic delivery. However, this belief is most likely true only for large, inflexible delivery vehicles. Blood cells are several micrometers (up to 7000 nm) in size, and yet have no difficulty circulating in the blood including through the smallest capillaries. However, sickle cell blood cells, which are rigid, do have problems in the circulation. Therefore, we believe that flexibility is a more important issue than size. In fact, BIV DNA–liposome complexes in the size range of 200 to 450 nm produced the highest levels of gene expression in all tissues after intravenous injection.[2] Kupffer cells in the liver quickly clear delivery vehicles (including nonviral vectors and viruses) that are not PEGylated and are smaller than 200 nm. Therefore, increased size of liposomal complexes could extend their circulation time particularly when combined with injection of high colloidal suspensions. BIVs encapsulate nucleic acids and viruses apparently because of the presence of cholesterol in the bilayer, whereas formulations including L-alpha dioleoyl phosphatidylethandamine (DOPE) instead of cholesterol could not assemble nucleic acids by a ''wrapping type'' of mechanism, and produced little gene expression in the lungs and no expression in other tissues after intravenous injections. The DOTAP:Chol BIV complexes are flexible and not rigid, are stable in high concentrations of serum, have extended half-life, and circulate efficiently in the bloodstream.

Colloidal properties of nucleic acid–liposome complexes also determine the levels of gene expression produced after in vivo delivery.[2,16] These properties include the DNA:lipid ratio, the overall charge density of the complexes, complex size and shape, lipid composition, formulation, and encapsulation efficiency and the colloidal suspension monitored by turbidity measurements at OD400. Our data showed that transfection efficiency in all tissues corresponded to the OD400 of complexes measured prior to intravenous injection. Colloidal properties affect serum stability, protection from nuclease degradation, blood circulation time, and biodistribution of the complexes.

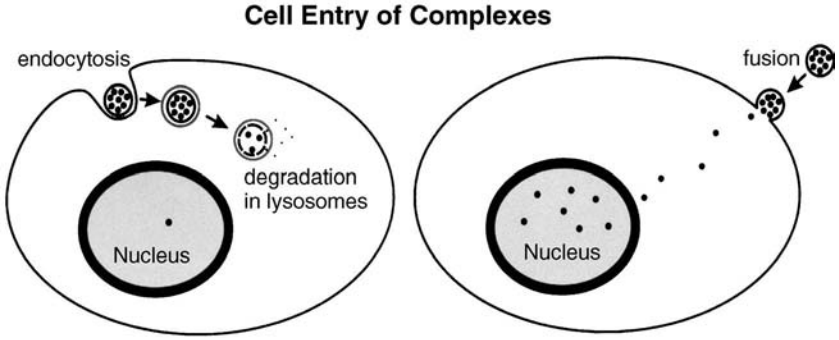

Fig. 2 Mechanisms for cell entry of complexes by endocytosis or by direct fusion with the cell membrane. Cell fusion allows delivery of more nucleic acids to the nucleus because the bulk of the nucleic acids do not enter endosomes.

The BIV complexes efficiently deliver DNA into cells by fusion with the cell membrane and avoid the endocytic pathway (Fig. 2). Cells are negatively charged on the surface, and cationic complexes have nonspecific ionic charge interactions with cell surfaces that, in part, contribute to efficient transfection. Therefore, we create targeted delivery of our complexes in vivo without the use of PEG to retain predominant entry into cells by direct fusion. These ligand-coated complexes reexpose the overall positive charge by shedding the ''mask'' as they approach the target cells, using a reversible masking technology to bypass nontarget organs and tissues. Through ionic interactions or covalent attachments, we have added monoclonal antibodies, Fab fragments, proteins, partial proteins, peptides, peptide mimetics, small molecules, and drugs to the surface of BIV complexes after mixing. Using novel methods for addition of these ligands to the complexes results in further increased gene expression in the target cells after transfection. Figure 3 shows our optimized strategy to achieve targeted delivery, deshielding, cell fusion, cell and nuclear entry of nucleic acids, and production of gene expression.

Stability of BIV complexes was studied at 37°C out to 24 hr at concentrations of serum ranging from 0% to 100%. The results showed serum stability at the highest

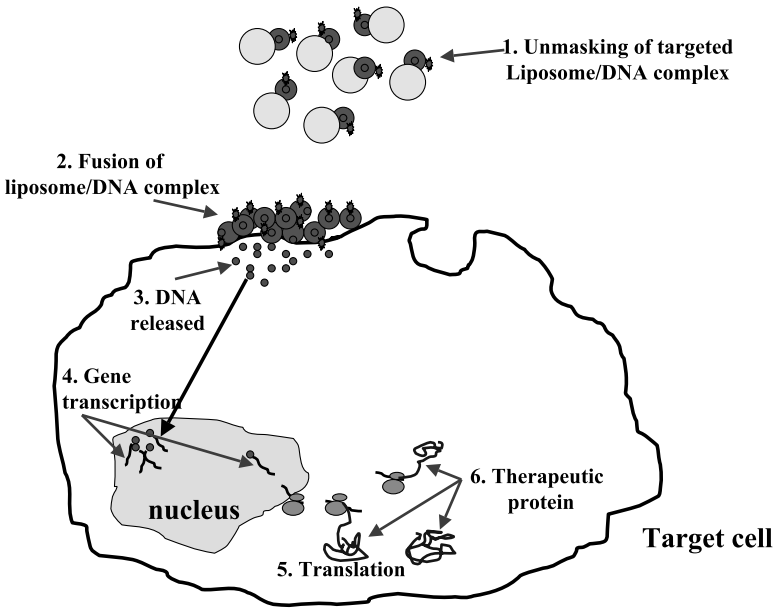

Fig. 3 Optimized strategy for delivery and gene expression in the target cell including targeted delivery, deshielding, fusion with the cell membrane, entry of nucleic acids into the cell and to the nucleus, and production of gene expression of a cDNA cloned in a plasmid. (*View this art in color at www.dekker.com.*)

concentrations of serum, about 70% to 100%, which are physiological concentrations of serum found in the bloodstream, and at no or low concentrations of serum. The complexes were unstable at 10% to 50% serum, perhaps because of salt bridging. Therefore, in vitro optimization of serum stability for formulations of cationic complexes must be performed over a broad range of serum concentration to be useful for applications in vivo.

Delivery of DNA to the nucleus and subsequent gene expression may be poorly correlated.[6,17] The following issues should be considered independent of the delivery formulation, including suboptimal promoter-enhancers in the plasmid, poor preparation of plasmid DNA, and insensitive detection of gene expression. Plasmid expression cassettes typically have not been optimized for animal studies. For example, many plasmids lack a full-length CMV promoter–enhancer, and some variations produce greatly reduced or no gene expression in certain cell types.[6] Ideally, investigators design custom promoter–enhancer chimeras that produce the highest levels of gene expression in their target cells. For example, we designed a systematic approach for customizing plasmids used for breast cancer gene therapy by using expression profiling.[6] To increase long-term expression, use of replication-competent plasmids increase gene expression over time posttransfection. Plasmids can also be engineered to provide for specific or long-term gene expression, replication, or integration.

The transfection quality of plasmid DNA is dependent on the preparation protocol and training of the person preparing the DNA. We have also identified large amounts of contaminants in laboratory- and clinical-grade preparations of plasmid DNA and developed three proprietary methods for their detection. These contaminants copurify with DNA by anion exchange chromatography and by cesium chloride density gradient centrifugation. Endotoxin removal does not remove these contaminants, and HPLC cannot detect them. To provide the greatest efficacy, safety, and gene expression, these contaminants must be assessed and removed from plasmid DNA preparations. These contaminants belong to a class of molecules known to inhibit both DNA and RNA polymerase activities. Our group and other investigators have shown that intravenous injections of high doses of improved liposomes alone cause no adverse effects. Plasmids with most of CpG sequences removed apparently reduced toxicity after intravenous injections of cationic complexes.[18] However, only low doses containing up to 16.5 μg of DNA per injection into each mouse reduced toxicity, and no significant dose response to CpG motifs in plasmid DNA was demonstrated. Therefore, we believe that removal of the other contaminants in current DNA preparations is the major block to safe intravenous injection of high doses of DNA–liposome complexes.

Choosing the most sensitive detection method for gene expression is also essential. For example, detection of β-galactosidase (β-gal) expression is far more sensitive than that for the green fluorescent protein (GFP). Specifically, 500 molecules of β-gal per cell are required for detection using X-gal staining, whereas about 1 million molecules of GFP per cell are required for direct detection, and its detection may be impossible if the fluorescence background of the target cell or tissue is too high. Detection of chloramphenicol acetyltransferase (CAT) is extremely sensitive with little or no background detected in untransfected cells. Few molecules of luciferase in a cell can be detected by luminescence assays of cell or tissue extracts posttransfection, and the sensitivity is highly dependent on the type of instrument used to measure luminescence. Luciferase data may not predict the therapeutic potential of a nonviral delivery system if several hundred or thousand molecules per cell of a therapeutic protein are required to produce efficacy for a certain disease. Furthermore, noninvasive detection of luciferase expression in vivo is not as sensitive as luminescence assays of cell or tissue extracts posttransfection. My colleagues detected luciferase expression in mice by cooled charge-coupled device (CCD) imaging after intravenous injections of BIV DOTAP:Chol-luciferase DNA–liposome complexes and detection of HSV-TK gene expression using microPET imaging.[19]

To establish the maximal efficacy for the treatment of certain diseases or for vaccine production, administration of the nonviral gene therapeutic, etc. via different routes may be required. The optimal dose and administration schedule should be determined because administering the highest tolerable dose most frequently may not necessarily produce maximal efficacy. Loss of the therapeutic gene product will vary with the half-life of the protein produced. Therefore, if a therapeutic protein has a longer half-life, then the gene therapy could perhaps be administered less frequently.

CONCLUSION

Some hurdles remain in the broad application of nonviral delivery; however, we are confident that we will successfully overcome these challenges. We predict that eventually the majority of gene therapies will utilize artificial reagents that can be standardized and regulated as drugs rather than biologics. We will also continue to incorporate the molecular mechanisms of viral delivery that produce efficient delivery to cells into artificial systems. Therefore, the artificial systems, including liposomal delivery vehicles, will be further engineered to mimic the most beneficial parts of the viral delivery systems while circumventing their limitations. We will

also maintain the numerous benefits of the liposomal delivery systems discussed in this article.

ACKNOWLEDGMENT

I thank Dr. David D. Roberts at the National Cancer Institute, NIH, Bethesda, MD, for preparation of the figures.

Listeria spp.: DNA Probes and Conventional PCR Assays

Philippe Gilot
Institut National de la Recherche Agronomique, Nouzilly, France

INTRODUCTION

Listeria spp. are facultatively anaerobic, nonspore-forming rod-shaped bacteria which belong to the gram-positive bacteria with a low G+C DNA content. The genus *Listeria* comprises six species: *Listeria monocytogenes*, *Listeria ivanovii*, *Listeria seeligeri*, *Listeria innocua*, *Listeria welshimeri*, and *Listeria grayi*. All of these species are widespread in the environment, but only *L. monocytogenes* is considered as a significant human and animal pathogen. Besides *L. monocytogenes*, however, occasional human infections because of *L. ivanovii* and *L. seeligeri* have also been reported. *L. ivanovii* is nevertheless mainly responsible for abortion in sheep. The identification of *Listeria* species has long been hampered by small number of tests allowing the differentiation between these closely related species. Hemolysis, a major characteristic for *Listeria* species identification, may, in some cases (and especially for environmental and food isolates), be difficult to read on blood agar and tests monitoring the acid production from carbohydrates are time-consuming. In last years, the necessity to rapidly identify *Listeria* spp. has nevertheless led to the development of some new methods, including commercial methods. All rapid commercial methods need a selective enrichment step before the application of the assay. Some of them use an immunocapture step with antibodies specific to *Listeria* genus or *L. monocytogenes* bound to solid matrices; others are based on the unique characteristics of the DNA molecules. Herein and in the next entry, we will focus on molecular techniques based on the DNA molecule, which, unlike identification techniques based on phenotypic characters, are uninfluenced by environmental growth conditions and protein expression mechanisms.

HUMAN LISTERIOSIS

Human disease because of *L. monocytogenes* usually occurs in pregnant women, the elderly, and immunocompromised patients. Clinical manifestations range from mild flulike symptoms and gastroenteritis to septicemia, central nervous infections, and feto-maternal infections with abortion, premature labor, or birth of an infected child. Despite the low incidence of listeriosis (2–15 people per 100,000 people per year), the disease is associated with high mortality rates (20–30%).[1–3] At first sight, this is difficult to understand because *Listeria* strains are, in general, susceptible to a wide range of antibiotics. Unfortunately, most antibiotics are not bactericidal for *Listeria*. Furthermore, the efficacy of therapy is limited by the fact of intracellular habitat of pathogenic *Listeria*. The clinical experience shows that the combination of amoxicillin and gentamicin is the best therapeutic option for listeriosis (for a review, see Ref. [4]).

VIRULENCE-ASSOCIATED GENES

The pathogenesis and molecular mechanisms underlying *Listeria* virulence have been particularly well studied. Many of the genes encoding proteins involved in *Listeria* pathogenesis are clustered in a 9-kb chromosomal fragment that is involved in functions essential to intracellular survival. This locus comprises genes coding for the hemolysin (*hly*A), the phospholipases C (*plc*A and *plc*B), the actin-polymerizing protein (*act*A), the metaloprotease (*mpl*), and the virulence factor regulator (*prf*A). Some other genetic determinants also implicated in the virulence of the bacteria, such as, for example, the internalin locus (*inlAB*), the invasion-associated protein gene (*iap*), or the *clp* stress response mediator locus, were also identified outside of the virulence cluster (for a review, see Ref. [5]). Heterogeneity in the virulence of *L. monocytogenes* strains has been observed. Whereas in most cases this heterogeneity is unexplained, attenuated or nonvirulent strains could be associated with truncated forms of the virulence factors InlA and ActA.[6–9]

ECOLOGY

All *Listeria* species have been isolated from soil, decaying vegetable matter, silage, sewage, water, animal feed, fresh and processed meats, raw milk, cheese, slaughterhouse waste, and asymptomatic human and animal carriers. Because of their widespread occurrence, *Listeria* species have many opportunities to enter food production and processing environments. Because of their psychrotrophic

DOI: 10.1081/E-EDGP 120020876

nature, they are then able to grow in food, even at temperatures such as those of refrigerators.[1,2] Consequently, outbreaks and sporadic cases of listeriosis have been traced to different foodstuffs such as pasteurized milk, cheese, coleslaw, and meat products.[2,3,10] The coexistence of several *Listeria* species on the same food is not unusual, and often, the incidence of *Listeria* species other than *L. monocytogenes* is higher than the incidence of *L. monocytogenes* itself. Because all *Listeria* species are potential food contaminants, the presence on foodstuffs of any of these species can be considered as an indicator of their contamination and of the potential presence of *L. monocytogenes*.[11] However, as the threat to public health posed by contamination of foods by each *Listeria* species is not similar, it is very important that all of them could be rapidly and reliably detected and identified.

DNA-BASED IDENTIFICATION

DNA Probes

Several probes targeting genes such as those encoding the hemolysin (LLO), the invasion-associated protein, the DTH-18 gene, the PrfA regulator, the 16S rRNA gene, or the 16S/23S rRNA spacer have been described to differentiate *Listeria* genus and mainly the species *L. monocytogenes*.[12–18] Commercial DNA probe-based assays are now available for the rapid confirmation of *L. monocytogenes* from colonies (AccuProbe®, Gene-Probe, San Diego, CA; GENE-TRAK® *L. monocytogenes* Assay, Gene-trak system, Framingham, MA). Both assays are nonradioactive hybridization methods (chemiluminescently labeled probe or fluorescein-labeled probe for AccuProbe and Gene-trak, respectively) based on the detection of unique sequence in the 16S rRNA region. The sensitivity of both methods is achieved by the high copy number of 16S rRNA in the bacterium cell. The Gene-trak system is also usable for the rapid detection of *Listeria* spp. or *L. monocytogenes* from samples previously grown in selective enrichment broths.[19] The usefulness of these probes is restricted to the species containing nucleotide sequence that hybridize with the specific probe. In contrast, the analysis of the rRNA gene restriction patterns, after restriction hydrolysis of whole chromosomal DNA and hybridization with a 16S rRNA gene, allowed the identification of each *Listeria* species.[20] More recently, a fluorescence in situ hybridization (FISH) technique with 16S rRNA-targeted oligonucleotide has been developed for the identification of *Listeria* genus (but not *L. grayi*) by epifluorescence microscopy in a mixture with other bacteria. In addition, a technique for in situ detection of *iap* mRNA within intact cells of *L. monocytogenes* has also been devised.[21,22] These latter two methods will help in the analysis of the structure and dynamics of complex microbial communities and of the spatial distribution of probe–target populations in microbial biofilms and tissue samples.

Conventional Polymerase Chain Reaction Assays

As an alternative to DNA hybridization methods, PCR procedures were proved to be rapid and highly specific for the detection of a number of pathogens. Polymerase chain reaction assays based on the flagellin A encoding gene (*fla*A), the 16S/23S intergenic spacer region of the rRNA operon, and the *iap* gene have been developed for the identification of the *Listeria* genus.[23–25] Continuous efforts for the specific identification of *L. monocytogenes* using polymerase chain reaction assays were made. Apart from PCR identification procedures targeting the 16S rRNA gene, the 16S/23S spacer region, and the aminopeptidase C gene (*pep*C), these assays amplified DNA sequences derived from genes proved or suspected to be implicated in the virulence mechanism of this species, such as *hly*A, *plc*B, *act*A, *prf*A, *inl*A, *inl*B, *iap*, the gene coding for LmA antigen (*lma*A or Dth18 gene), or the fibronectin-binding protein (*fbp*) gene.[17,23,24,26–36] The most frequently chosen target has been the *hly*A gene from which amplification fragment of different sizes has been generated with specific primers designed by several authors.[37] As *L. monocytogenes* strains with mutations or deletions in one or more virulence determinants can be encountered, a multiplex PCR for the simultaneous detection of multiple genes in a single step has also been developed.[6–9,26] Whereas vast number of protocols for the PCR identification of *L. monocytogenes* have been published, only few studies have considered the identification of the other members of the genus *Listeria*.[37] Nevertheless, the identification of non-*L. monocytogenes* species can also be achieved by the specific amplification of part of the 16S rRNA gene of *L. ivanovii*, internal *iap* sequences of *L. grayi*, *L. seeligeri*, *L. welshimeri*, and *L. innocua*, part of the *L. welshimeri fbp* gene, and part of the *L. innocua* gene encoding the *lin046* putative transcriptional regulator.[16,27,38,39] One of the above PCR assay is a multiplex PCR that allows the simultaneous detection of all *Listeria* species and the differentiation between some (but not all) of them, in a single step.[38] The comparative analysis of genome sequences of *L. monocytogenes* and *L. innocua* revealed also the presence of 270 *L. monocytogenes* and 149 *L. innocua* strain-specific genes.[40] These genes are putative targets for the further development of PCR assays for the specific identification of both species.

The introduction of commercial PCR kits such as the Probelia *L. monocytogenes* system which targets the *hly*A gene (Bio-Rad Lab., Richmond, CA) and the Bax system for *L. monocytogenes* and also for *Listeria* genus (Qualicon-Dupont, Willington, DE) has made easier the routine use of the PCR method for the identification of *Listeria*. PCR products are detected by agarose gel electrophoresis for the Bax system or in a microplate postamplification capture hybridization assay for the Probelia system. These automatized methods, developed to screen food and environmental samples, need a pre-enrichment step of the samples before the PCR assays to increase the number of target bacteria and to avoid the detection of dead cells by diluting out any nonviable cells that may be present.

CONCLUSION

DNA probes and conventional PCR assays were developed to facilitate the identification of this bacterium from both clinical samples as well as in contaminated food. In the next entry, less conventional DNA-based identification procedures and DNA-based typing methods will be reviewed. It can be expected that the application of all of these methodologies will allow an early and efficient identification of *Listeria* spp. and will lower the risk associated with listeriosis.

Listeria spp.: Other DNA-Based Identification Procedures and DNA-Based Typing Methods

Philippe Gilot
Institut National de la Recherche Agronomique, Nouzilly, France

INTRODUCTION

In the previous *Listeria* spp. entry, the clinical spectrum and management of human listeriosis, the ecology of *Listeria* species, and the identification methods based on DNA probes and standard polymerase chain reaction (PCR) assays were described. In this entry, less conventional DNA-based identification procedures and DNA-based typing methods will be reviewed.

DNA-BASED IDENTIFICATION

Ligase Chain Reaction

A ligase chain reaction (LCR) assay with the thermostable *Thermus aquaticus* DNA ligase has been devised for the specific detection of *Listeria monocytogenes*. This assay is based on a single base-pair difference in the V9 region of the 16S sequence of the genes coding for rRNA, which distinguishes *L. monocytogenes* from other closely related *Listeria* spp. To achieve a higher sensitivity, the 16S rRNA gene was initially amplified by PCR prior to LCR. The LCR was originally performed with radioactive-labeled primers, and ligation products were detected by autoradiography after denaturing gel electrophoresis (DGGE). The method was further adapted for the detection of LCR products with a nonisotopic readout using chemiluminescent or colorimetric substrates. The latter method gave a sensitivity of 10 CFU of *L. monocytogenes* and is amenable to automation.[1,2]

Microarray-Based Assays

A rapid oligonucleotide microarray hybridization assay for the discrimination of the six species of the *Listeria* genus has been developed. The approach involves one-tube multiplex PCR of six target virulence factor genes (*iap*, *hly*A, *inl*B, *plc*A, *plc*B, and *clp*E), synthesis of fluorescently labeled single-stranded DNA with primer extension of DNA synthesized in the first round of multiplex PCR, and hybridization to the multiple individual oligonucleotide probes specific for each *Listeria* species and immobilized on a glass surface. This microarray technique was proven to correctly identify all *Listeria* species.[3]

Quantitative PCR

Recently, a number of investigators have described semiquantitative PCR methods that allow to identify and to know the number of bacteria present in the sample, and that simplify the need to perform postamplification techniques. An enzyme-linked immunosorbent assay-mediated PCR technique was described to detect and quantify *L. monocytogenes* in food products. Using this method, a fragment of the *iap* gene and of an internal standard are amplified in the presence of fluorescein dUTP. PCR products were then hybridized in streptavidin-coated microtiter plate prepared with biotinylated specific DNA probes. After the addition of an alkaline phosphatase-conjugated antibody to fluorescein, the PCR products are quantitated based on an optical density reading.[4] Bassler et al.[5] described a 5′ nuclease PCR-based assay for *L. monocytogenes* that uses the hydrolysis of a dually labeled internal fluorogenic probe (TaqMan® PCR detection, Applied Biosystems, Foster City, CA) to monitor the amplification of the target (a region of the *hly*A gene). Quantification was found to be linear over a range of 5×10 to 5×10^5 CFU. A variation of the above method was described by Koo and Jaykus[6] for the detection of *L. monocytogenes* using *hly*A or *iap* as a target, and an inexpensive asymmetric probe set in place of the TaqMan probe. The above methods are endpoint detection assays and the PCR products have to be detected by fluorescence or optical density reading immediately following termination of the PCR.

Strategies based on the detection of PCR products simultaneously as the PCR is progressing (real-time PCR) and avoiding further postprocessing were also developed for the detection and quantification of *L. monocytogenes* and *Listeria innocua*. Those methods exploit also the 5′ nuclease activity of the *Taq* DNA polymerase and a dually labeled fluorogenic TaqMan hybridization probe, but use the ABI Prism® 7700 sequence detection system of Perkin-Elmer (Foster City,

DOI: 10.1081/E-EDGP 120026896

CA) and either the *hly*A or *iap* genes as target.[7–9] A protocol enabling the simultaneous detection and quantification of *Escherichia coli* O157:H7, *L. monocytogenes*, and *Salmonella* strains was also formatted using commercial Bax PCR kits (for Bax, see *Listeria* spp. entry: DNA probes and standard PCR assays) and by monitoring the PCR in real time with the iCycler of Bio-Rad Laboratories (Hearles, CA) after the addition of the nonspecific fluorescent dye SYBR Green I. A melting curve analysis of PCR amplicons serves as a confirmatory test, with the T_m of each amplicon being dependent on the length as well as the G+C content of the sequence.[10]

Other PCR-Based Assays

The PCR single-strand conformation polymorphism (PCR-SSCP) technique was also tested for the identification of *Listeria* genus and individual *Listeria* species. This approach employs the PCR amplification of a variable region of the 16S rRNA, and the analysis of the denatured amplified product by electrophoresis in a nondenaturating polyacrylamide gel. The method was found to be able to identify almost all species of the *Listeria* genus.[11,12] A variation of this method was also used by Manzano et al.,[13] who analyzed a short amplified fragment of the 16S rRNA gene by PCR temperature gradient gel electrophoresis (PCR-TGGE) in a polyacrylamide gel. By the use of PCR-TGGE, the species *L. monocytogenes*, *Listeria seeligeri*, and *Listeria ivanovii* were distinguished, whereas the *L. innocua* and *Listeria welshimeri* PCR products migrated to the same position in the gel. More recently, an identification approach based on the PCR of a fragment of the *iap* gene and on the analysis of the PCR product obtained by DGGE (PCR-DGGE) was also developed for the direct identification of *Listeria* spp. in food samples. Species-specific DGGE migration that allows the identification of individual *Listeria* species was obtained. Nevertheless, it should be noted that the specificity of the PCR-TGGE and PCR-DGGE methods was not tested toward *Listeria grayi*.[14] Other PCR-based identification approaches, such as repetitive sequence base PCR (rep-PCR) with primer sets targeting the enterobacterial repetitive intergenic consensus sequence (ERIC), 16S-amplified rDNA-RFLP analysis (ARDA), randomly amplified polymorphic DNA (RAPD) technique, and rDNA spacer PCR analysis, have also been described.[11,15–18]

Reverse Transcription PCR

Detection of pathogens in contaminated food products by PCR can result in false positive data due to amplification of DNA from nonviable cells. Most bacterial mRNA have very short half-life due to rapid degradation by endogenous RNases. As a consequence, nonviable cells that are disrupted in cellular transcription will rapidly lose their cellular mRNA. Studies were undertaken to develop a sensitive method for the detection of viable *L. monocytogenes* based on amplification of mRNA by reverse transcription PCR (RT-PCR). In a first attempt, Klein and Junega[19] isolated total RNA from *L. monocytogenes* samples and, following DNase treatment, amplified the RNA by RT-PCR with recombinant *Thermus thermophilus* DNA polymerase and primers specific for the *iap* gene. Amplicon detection was then accomplished by Southern hybridization to a digoxigenin-labeled gene probe. Viable *L. monocytogenes* in a cooked meat sample that was originally inoculated with ca. 3 CFU/g could be detected. A modification of the fluorogenic 5′ nuclease PCR assay of Bassler et al.[5] to detect mRNA as a monitor of viable *L. monocytogenes* has also been developed.[20] This assay, after a DNase treatment of the sample, amplifies *hly*A transcript by using the *Tth* DNA polymerase. The test, with primers that included the 3′-end of the transcript, was proven to be an accurate indicator of viability as measured by colony-forming unit determination.[20] Koo and Jaykus have also adapted their quantitative PCR method with fluorogenic asymmetric probes for the amplification of *hly*A or *iap* transcripts. Because of a special design of the RT-PCR primer set, they used no DNase treatment of the RNA extract prior to RT. The method utilized the AMV reverse transcriptase and *Taq* DNA polymerase in place of the *Tth* DNA polymerase for cDNA synthesis and both cDNA amplification and 5′ hydrolysis of the fluorogenic probe, respectively.[6] Based on a different concept, an isothermal nucleic acid sequence-based amplification assay (NASBA) was devised to detect *L. monocytogenes* by targeting *hly*A mRNA. The generated amplicons, which incorporated biotin-labeled UTP, were then hybridized with an immobilized capture probe and detected by colorimetry.[21] Other investigators reported the development of a NASBA system amplifying *Listeria* 16S rRNA sequences. The latter system utilizes a hybridization method to specifically detect *L. monocytogenes* amplimers.[21] The specificity of the method was not tested toward *L. grayi*, and is not amenable to the detection of viable bacteria as, contrary to mRNA, rRNA is an extremely stable molecule.

Other DNA-Based Techniques

Genomic fingerprinting of *Listeria* DNA via pulsed-field gel electrophoresis (PFGE) was also found to discriminate between *Listeria* species.[22] Finally, the A511 phage, a

broad host range bacteriophage specific for the genus *Listeria*, has been genetically engineered by the incorporation of the *lux* operon of *Vibrio fischeri* in its chromosome. The A511*luxAB* phage transduces bacterial bioluminescence into infected cells, allowing a rapid and easy testing of contaminated food and environmental sample for the presence of viable *Listeria* cells.[23]

DNA-BASED TYPING

Serotyping and bacteriophage typing have traditionally been used for intraspecies differentiation of *L. monocytogenes* isolates and epidemiological survey of listeriosis. An improved discrimination between *L. monocytogenes* isolates has been obtained following the development of multilocus enzyme electrophoresis, which differentiates isolates according to the mobility of a great number of housekeeping enzymes.[24] Several DNA-based typing methods such as restriction enzyme analysis (REA) of chromosomal DNA, plasmid profiling, restriction fragment length polymorphism (RFLP), and PCR-based fingerprinting techniques have also been developed for this purpose.[25] Some standardized protocols have been defined to allow comparisons between laboratories and to favor the recognition of potential outbreaks as quickly as possible. For that aim, ribotyping, an RFLP technique that allows the analysis of the rRNA gene restriction patterns after hybridization with a rRNA gene, has been automatized (Riboprinter Qualicon, Willmingtonn, DE).[26] A standardized protocol of PFGE has also been developed by a national network of public health and food regulatory laboratories in the United States (PulseNet). PFGE patterns identified by PulseNet are stored in a national electronic database maintained at the Centers for Disease Control and Prevention (Atlanta, GA). Fingerprinting techniques based on PCR amplification of DNA segments flanking either undetermined sequences [RAPD and arbitrarily primed PCR (AP-PCR)] or defined and conserved sequences [rRNA genes (PCR ribotyping), the repetitive elements REP and ERIC (rep-PCR) and infrequent DNA restriction fragments (IRS-PCR and AFLP)] have also been used to study the genetic structure and epidemiology of *L. monocytogenes*.[17,27–29] Restriction endonuclease analysis of PCR-amplified virulence-associated genes (RE-PCR) has also been devised for that aim.[30,31] More recently, DNA sequence-based subtyping strategies were developed to reduce interpretation ambiguity and to make easier the exchange and comparison of subtype data among laboratories. These methods to determine allelic variations include pyrosequencing of a short sequence of the *inl*B gene, multilocus sequence typing (MLST) of several housekeeping genes, and sequencing of multiple genes with various evolving speeds (virulence genes, stress response genes, intergenic region, and housekeeping genes).[32–34] Finally, DNA microarrays were found to be promising tools for differentiating among closely related *L. monocytogenes* isolates.[35,36]

Studies of the genetic diversity and population structure of *L. monocytogenes* by using many of the above methods revealed that this species is composed of two distant phylogenetic divisions of strains, which are correlated with the flagellar antigen groups, division (division I, which is composed of strains of serotypes 1/2a and 1/2c, and division II, which is composed of strains of serotypes 1/2b and 4b). An additional division has also been proposed based on the sequence of several genes involved in virulence. This latter division, consisting of serotypes 4a and 4c strains, has recently been shown to be a branch of the first division.[37] A mismatch amplification mutation (MAMA-PCR) assay targeting the hemolysin gene has been developed to characterize *L. monocytogenes* isolates with regard to these lineage types.[38]

CONCLUSION

As the detection and identification of *L. monocytogenes* by conventional methods are not easy, new procedures were developed to facilitate the recovery and characterization of this bacterium from both clinical samples as well as in contaminated food. Among these methods, a great variety of nucleic acid-based techniques were devised by many researchers. Some of these methods are now available as commercial assays. The sequencing of the complete genome of *L. monocytogenes* and *L. innocua* has opened the way for the development of microarrays, sequence-based standardized strategies, and semiautomated platforms. By simplifying application methods and by allowing an early and efficient identification of *Listeria* spp., these procedures will put molecular-based methods within the reach of most routine laboratories and will certainly lower the risk associated with listeriosis.

Long-Distance PCR

Philip Lewis White
Sam Hibbitts
University of Wales College of Medicine, Cardiff, U.K.

INTRODUCTION

The polymerase chain reaction (PCR) is a common tool of molecular biology and is utilized in the field of medical diagnostics to identify genetic disorders and the causative agents of human infections. PCR is also used for typing microorganisms, thus playing an important role in both epidemiology and phylogenetics. The PCR method is a starting point that when used together with cloning is influential in the sequencing of novel genes and genomes.

When compared to cloning techniques, PCR is both more economical and straightforward to perform; however, it is limited by the fidelity and size (<5 kb) of the amplicon generated. Despite various publications[1–3] reporting longer PCR amplifications (>10 kb), only low yields of amplicon are produced, thus limiting further applications.[4]

Long-distance/range PCR (LD-PCR) has been developed to overcome these restrictions and allows amplification of up to 40 kb.[4–7] This methodology has extensive applications in the field of molecular biology and these will be discussed later.

TECHNICAL OVERVIEW

The principle of LD-PCR is essentially the same as for any standard PCR technique, with primers specific for two known regions flanking a target DNA sequence, enabling quick and efficient exponential amplification of the target amplicon. Standard PCR procedures tend to use only *Taq* polymerase, whereas in LD-PCR a proofreading enzyme (*Pfu* polymerase; from *Pyrococcus fuirosus*) must be used to correct possible nucleotide mismatches and prevent stalling of the extension process or introduction of a mutation into the sequence. Furthermore, it is preferential to replace the *Taq* polymerase with a more thermostable enzyme such as r*Tth* DNA polymerase (the recombinant form of the DNA polymerase from *Thermus thermophilus*). As with all PCR procedures, the reaction conditions and reagents must be optimized, but for LD-PCR it is also beneficial to obtain a high-quality (purity and length) DNA template, design primers optimally, and use a buffer composition optimal for the polymerase activity.

BASIC PROTOCOL FOR LONG-DISTANCE PCR

A quality target genomic DNA extract is essential for LD-PCR, and time should be taken to develop an extraction procedure. Standard concentrations of PCR reagents do not guarantee a successful amplification, and it is necessary to optimize all components for each LD-PCR reaction. In addition, the thermal cycling parameters and DNA template concentrations have to be evaluated, with too much DNA leading to nonspecific binding or even PCR inhibition and too little DNA leading to non-detectable amplicons, especially for low copy number targets. LD-PCR amplifications have been performed in as little as 10 μL[8] and up to 100 μL[5] reaction volume, although 50 μL is now more regularly used because of enhanced heat transfer over 100 μL. Individual reagent concentrations may or may not vary from a normal 50-μL PCR reaction; listed below are concentrations that have been used:

1. Mg^{2+} [$MgCl_2$, $Mg(OAc)_2$] concentration: Range 1.1[4] to 3.5 mM.[5] Typical concentration 2.5 mM.
2. dNTP concentration: Range 0.2[4] to 1.0 mM (non-limiting).[9] Typical concentration 0.2–0.25 mM, although 0.5 mM is regularly used.
3. Primer concentration: Range 0.12[10] to 2.0 μM.[11] Typical concentration 0.4 to 1.0 μM. Usual length 21–34 bp, with a balanced T_m of >58°C (usually 65–70°C).[7]
4. Typical PCR buffer: Tris–HCl 20–50 mM (pH 8.3–9.2) or 20–25 mM Tricine (pH 8.5–8.7), KOAc 85 mM, >10% glycerol, 2% DMSO.[4] Other reagents used in LD-PCR buffers include Tween 20 (0.1%), BSA (150–200 μg/mL), and $(NH_4)_2SO_4$ (16 mM), which is used instead of K^+ salts for certain polymerases.
5. Polymerase concentration: 2.6 U for a mix *Taq* and *Pwo* polymerases;[12] 1.5–2.5 U for *Tth* polymerase;[9,13,14] 0.9/0.02–1.75/0.02 U for a mix of r*Tth* and Vent polymerases, respectively;[4] 3.3 U of Expand Long-Template DNA polymerases.[10]
6. DNA template: Genomic template DNA Range 50[9]–625 ng (125 ng/10 μL reaction).[8] Typical

Table 1 Commercially available LD-PCR polymerases and kits

Kit name	Manufacturer	Enzyme	PCR buffer	Maximum amplification
KlenTaq LA Core Kit	Sigma	KlenTaq-1 DNA polymerase[a] and a proofreading enzyme	10X optimized buffer supplied	Up to 10 kb
Accutaq LA DNA Core Kit	Sigma	*Taq* DNA polymerase and a proofreading enzyme	10X optimized buffer and a vial of DMSO supplied	>20 kb
Expand Long-Template PCR system	Roche	*Taq* and *Pwo* polymerases	Three types of 10X optimized buffers supplied	0.5–12 kb 12–15 kb >15 kb[b]
Expand 20-kb^{plus} PCR system	Roche	*Taq* and *Pwo* polymerases	10X buffer (27.5 mM $MgCl_2$) with an extra vial of $MgCl_2$ for optimization	>20 kb
Arrow *Taq* DNA polymerase	Qbiogene	*Taq* and *Tfu* polymerases	10X buffer supplied	Up to 21 kb
KOD XL DNA polymerase	Novagen	KOD HiFi DNA polymerase[c] and a 3′–5′ exonuclease-deficient KOD HiFi mutant	10X buffer and dNTP mix supplied	Up to 30 kb
Extensor Hi-Fidelity PCR Master Mix	Abgene	Thermoprime plus DNA polymerase and a thermostable proofreading enzyme	Two types of 10X buffer (22.5 mM $MgCl_2$) are supplied with an extra vial of $MgCl_2$ for optimization. dNTPs are included	Up to 12 kb >12 kb[b]
Advantage™ 2 PCR Kit	Clontech	Advantaq™ DNA polymerase, proofreading enzyme and Taqstart antibody	*Advantage* 2 PCR buffer, dNTP mix, control DNA, and primer mixes. PCR-grade water	Up to 18.5 kb
Advantage Genomic and GC Genomic Kit	Clontech	*Tth* DNA polymerase and a proofreading enzyme	Buffer, dNTPs, and controls (as above), magnesium acetate. In GC kit GC-melt reagent to aid in amplification of GC-rich templates	Up to 10 kb (complex templates) Up to 40 kb
Hot Tub DNA polymerase	Amersham Biosciences	DNA polymerase from *Thermus* ''ubiquitous''	10X buffer supplied[d]	>10 kb
Elongase® Amplification system	Invitrogen	*Taq* DNA polymerase and *Pyrococcus* species *GB-D* polymerase	Two types of 10X buffer (either 5 or 10 mM $MgSO_4$), dNTPs, control primers, and DNA. Water and oil	Up to 30 kb
TaqPlus® *Long PCR system*	Stratagene	*Taq2000*™ and *PFU* DNA polymerases	Two types of 10X buffer (low salt and high salt)	Up to 35 kb

[a]A 5′ exo-minus, N-terminal deletion of *Taq* DNA polymerase.
[b]Range of fragments amplified is dependent on what buffer is used.
[c]KOD HiFi DNA polymerase is a recombinant form of *Thermococcus kodakaraensis* KOD1 DNA polymerase.
[d]Amersham now supplies premixed nucleotide blends (Nucleix Plus PCR) that are functionally tested in long PCR.

concentration 50–250 ng. Phage template DNA range 0.1–100 ng.[5] Typical concentration 0.1–10 ng.

There is a broad diversity in LD-PCR master-mix compositions and this highlights the necessity to optimize each component in the master mix when developing an in-house method. Foord and Rose[9] reported initial parameters to be used as a starting point for developing LD-PCR protocols. Since then, an extensive range of LD-PCR commercial kits and DNA polymerase mixes have been developed, providing the user with a choice of starting reagents complete with DNA polymerases with their respective buffers, and occasionally dNTP mixes and controls (Table 1). This removes the need to optimize polymerase/proofreader mixes and the buffer composition (apart from Mg^{2+} concentration), thus saving both time and expense.

Like every other aspect of LD-PCR the thermal cycling parameters must also have extensive optimization, but the most widely used conditions are as follows:

Initial denaturation: 92–95°C for up to 2 min.

10–30 cycles of:

Denature: 92–95°C for 10–30 sec.
Anneal: >58°C (dependent on T_m of primers) for 30–60 sec.
Extension: 68°C (with DMSO/glycerol)/72°C (without DMSO/glycerol) for 3–15 min (dependent on size of fragment being amplified).

20 cycles of:

Denature: 92–95°C for 10–30 sec.
Anneal: >58°C for 30–60 sec.
Extension: 68°C/72°C for 3–15 min (with a 15- to 30-sec extension every cycle).
Final extension/polish: 68°C/72°C for 5–6 min.

Another method, based on the above parameters, utilizes primers that bind at 68°C, and so the anneal and extension steps are combined into one. Alternatively, other methods exclude the cyclic addition of 15–30 sec to the extension time and simply have a longer extension time throughout the procedure. All appear to work and it is recommended that different thermal cycling protocols be tried to achieve maximum efficiency.

To separate LD-PCR amplicons, standard gel electrophoresis is generally the method of choice for fragments below 20 kb. However, when differentiating larger amplicons (20–50 kb), gels must be of a lower agarose percentage and be longer to acquire a good resolution. For accurate separation and sizing of very large products (>50 kb), pulsed-field gel electrophoresis is recommended. Staining with ethidium bromide in conjunction with UV illumination is commonly used to visualize high molecular weight amplicons, although a large (entire) volume of the reaction mix is usually needed to achieve the required sensitivity.[9]

To avoid the hazards associated with ethidium bromide it is worth considering the use of the fluorescent stain sybr gold. Like ethidium bromide it binds to the minor groove in double-stranded DNA, and although it can be visualized using UV light it is optimal to use a blue light transilluminator (e.g., a Dark reader, Clare Chemical Research, Denver, USA). One drawback with sybr gold staining is that it can retard movement through a gel, and so it is essential to stain gels after they have been completed. To check amplicon specificity Southern hybridization can be performed, and although radio-labeled probes have been used, it is preferential to use fluorescent-labeled probes or biotinylated probes, which avoid the hazards of working with radioactive material (e.g., ^{32}P). The use of fluorescent-labeled uracil nucleotides has also been successfully performed[9] and is another alternative to be considered.

POINTS TO CONSIDER/LIMITATIONS

As with all molecular methods, the quality of the DNA/RNA is of particular importance, and this is highlighted in LD-PCR where obtaining high-quality DNA template is paramount. If the DNA is nicked or fragmented, then the size of amplicon that can be produced will obviously be limited, and if the DNA is impure, then the PCR amplification is going to be inhibited.

Many commercial kits that extract genomic DNA from a variety of starting materials are now available (as discussed in Inverse PCR). They provide DNA of high purity and length (average length 50–100 kb Genomic-tip 100/G columns, Qiagen, Crawley, UK)[13] and remove the need for time-consuming purification procedures e.g., pulsed-field, low-melting point agarose gel electrophoresis.

As for all PCR primer pairs, the quality of their design can only be conclusively demonstrated by experimentation, although if certain strategies are adhered to optimal theoretical design can be achieved. For LD-PCR, it is essential to minimize secondary structures, especially at the 3′ ends, as the formation of dimers/polymers will create a competition for reagents and reduce the concentration of the amplicon. Thus, it is important to ensure that the primers are of the highest specificity to minimize nonspecific amplification and prevent the design of a competitive PCR. This can be achieved by design of longer primers, although there is a balance between specificity and optimal amplification, and reports vary as to the optimal length for LD-PCR. In general, optimal primer

length is similar to that for normal PCR (18–25 bp),[4,9] although longer primers (27–33 bp) have been shown to reduce the frequency of failed LD-PCR reactions.[5] The concentrations of LD-PCR primers are similar to a normal PCR (0.1–1.0 μM), although increased concentrations (4 mM) have been used, in an attempt to reduce the annealing time required.[9] However, at higher concentrations this benefit may be negated by the formation of secondary structures and the possibility of mispriming. For further information on primer design, see Foord and Rose.[9]

When LD-PCR was initially developed, the use of many individual polymerases was evaluated and r*Tth* DNA polymerase provided a consistent and reproducible amplification.[4,7,9] As the LD-PCR technique progressed, it was discovered that the use of a polymerase/exonuclease mix could benefit the LD-PCR amplification,[4,5,7,12] but had the drawback of determining optimal enzyme concentrations and buffer solutions. Since then, a variety of commercial LD-PCR kits and enzyme mixes are available (Table 1), providing optimal relative enzyme concentrations and buffers. Recently, the use of *Escherichia coli* exonuclease III was found beneficial when trying to perform LD-PCR. It permitted amplification of moderately damaged DNA templates when added to the polymerase mix, although it had no benefit where extensive damage had occurred.[15]

Typical buffer compositions have been stated above and generally are similar to normal PCR buffers except concentrations are nonlimiting. Certain protocols report the use of Tricine instead of Tris–HCl because its pK_a is less temperature dependent, and so provides DNA with a greater protection against nicking and depurination.[7] By adding certain cosolvents, i.e., glycerol (up to 8%), DMSO (1–3%) or a mix of the two (5% of each), the melting and strand-separation temperature can be lowered. This can increase the length of amplification by 10 kb by facilitating denaturation[4] and minimizing the exposure of any heat-labile components (DNA template) to extended high temperatures.[5]

CLINICAL AND GENETIC APPLICATIONS

LD-PCR has extensive uses as a supplement to cloning, as a time and cost-saving alternative, or where the DNA sequence is unclonable. They include the following:

1. Detection of DNA mutations such as:
   a) deletions within human mitochondrial DNA (mtDNA)[12] and viral genomes.[16]
   b) insertions, e.g., duplications, in human mtDNA.[17]
   c) rearrangements, e.g., inversions in disorders such as hemophilia.[8,18]
2. Chromosomal and genetic analysis of single cells for possible medical, forensic, and archaeological purposes.[11]
3. Typing of genetic markers for genome diversity studies.[14]
4. It has now been adapted to perform long-distance RT-PCR[19] and long-distance vectorette PCR.[20]
5. Fingerprinting of organisms by amplification of specific interspersed repetitive elements.[9]
6. Characterization of unknown, unclonable, long DNA sequences.[4]
7. Analysis of viral heterogeneity to aid in drug design and viral association in certain disorders.[7]

CONCLUSION

PCR is an important tool in many aspects of molecular biology, and in association with cloning is imperative in identifying and sequencing novel genes and genomes. However, it is limited by the size and fidelity of the amplicon generated and because of this, LD-PCR was developed permitting the accurate amplification of long DNA sequences (>40 kb).

INTRODUCTION

The long QT syndrome (LQTS) is an inherited arrhythmogenic disease occurring in the structurally normal heart that may cause sudden death and that usually manifests in children and teenagers. The estimated prevalence of this disorder is between 1:10,000 and 1:5000. Two major phenotypic variants have been originally described in early 1960s one autosomal dominant, the Romano–Ward syndrome[1] and one autosomal recessive, the Jervell and Lange-Nielsen syndrome. Both variants share a common cardiac phenotype but Jervell and Lange-Nielsen syndrome is also associated with neurosensorial deafness. The Romano–Ward syndrome accounts for the vast majority of LQTS cases.[2] In early 1990s, the discovery of the genetic bases of LQTS provided novel tools for the understanding of the pathophysiology of this disease. The most relevant genetic and phenotypic features will be reviewed in this article.

CLINICAL MANIFESTATIONS

The LQTS is caused by a genetically determined abnormality of cardiac excitability. As a result, the affected patients have prolonged repolarization (QT interval at the surface electrocardiogram), abnormal T-wave morphology, and life-threatening cardiac arrhythmias, often with the typical pattern of ''torsades des pointes''[2] (Fig. 1). Syncope and a high risk of sudden death are the main features. The mean age of onset of symptoms is 12 years and earlier onset of symptoms is usually associated with a more severe form of the disease. Cardiac events are often precipitated by physical or emotional stress even if in a smaller subset of individuals, cardiac events occur at rest.[2]

CLINICAL MANAGEMENT

The link between the onset of cardiac events and increased adrenergic activity suggested the use of beta-blockers as a therapy for LQTS.[2] The clinical efficacy of this approach was confirmed in an international collaborative project.[3] Left cardiac sympathetic denervation (LCSD) might be an option when beta-blockers fail or are not tolerated.[4] Cardiac arrest survivors are always to be considered a high-risk subgroup. Therefore, the implant of an implantable cardioverter defibrillator (ICD) is recommended in these patients.

GENETIC BASES OF LONG QT SYNDROME

The discovery of the genetic basis of LQTS started in the early 1990s with the mapping of four LQTS loci on chromosomes 11, 3, 7, and 4[5] (OMIM IDs: 192500, 152427, 603830, 600919) (Table 1). Subsequently, the gene on chromosome 11 (LQT1) was identified as *KCNQ1* by Wang et al.[6] using positional cloning whereas the candidate gene approach led to the identification of *KCNH2* and *SCN5A* as the genes on chromosomes 7 (LQT2) and 3 (LQT3).[7,8] More recently, mutations in two additional genes on chromosome 21, *KCNE1* (LQT5; OMIM id: 176261) and *KCNE2* (LQT6; OMIM id: 603796), were reported. All the LQT1-3 and LQT5-6 genes encode for cardiac ion channel subunits. Based on these evidences, LQTS was initially considered a disorder specifically affecting plasmalemmal ion channel controlling the cardiac excitability. However, recent data show that the gene of LQT4 is *ANK2*: an intracellular protein called ankyrin involved in ion channels anchoring to the cellular membrane (see below).[9]

MOLECULAR EPIDEMIOLOGY

KCNQ1 (LQT1) and *KCNE1* (LQT5)

KCNQ1 and *KCNE1* encode, respectively, for the alpha (KVLQT1) and the beta (MinK) subunit of the potassium channel conducting the I_{Ks} current, the slow component of the delayed rectifier current (I_K), and the major repolarizing current during phase 3 of the cardiac action potential.

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120025783

Table 1 Clinical and genetic variants of LQTS

	Symbol	OMIM ID	Gene	Protein	Function
Romano–Ward	LQT1	192500	*KCNQ1*	KvLQT1	I_{Ks} alpha subunit
	LQT2	152427	*KCNH2*	HERG	I_{Kr} alpha subunit
	LQT3	603830	*SCN5A*	NaV1.5	I_{Na} alpha subunit
	LQT4	600919	*ANK2*	Ankyrin B	Anchoring protein
	LQT5	176261	*KCNE1*	MinK	I_{Ks} beta subunit
	LQT6	603796	*KCNE2*	MiRP	I_{Kr} beta subunit
Jervell and Lange-Nielsen	JLN1	220400[a]	*KCNQ1*	KvLQT1	I_{Ks} alpha subunit
	JLN2	–	*KCNE1*	MinK	I_{Ks} beta subunit

[a]OMIM database has only one entry for JLN1 and JLN2.

LQT1 is the most prevalent genetic form of LQTS accounting for approximately 50% of genotyped patients. Several different mutations have been reported (http://pc4.fsm.it:81/cardmoc) and in vitro expression studies of mutated proteins suggested multiple biophysical consequences, all of them ultimately inducing a loss of function, with or without a dominant negative effect on the wild-type protein.[10] Homozygous or compound heterozygous mutations of *KCNQ1* also cause Jervell and Lange-Nielsen form of LQTS (JLN1).[11]

KCNE1 (LQT5) mutations are rather infrequent accounting for approximately 2–3% of genotyped LQTS patients and they may cause both Romano–Ward (LQT5) and Jervell and Lange-Nielsen (JLN2) syndromes.[12,13]

KCNH2 (LQT2) and *KCNE2* (LQT6)

KCNH2 and *KCNE2* gene encode, respectively, for the alpha (HERG) and the beta (MiRP) subunit of the potassium channel conducting the I_{Kr} current, the rapid component of the cardiac delayed rectifier (Fig. 1). LQT2 is the second most common variant of LQTS accounting for 35–40% of mutations (http://pc4.fsm.it:81/cardmoc). Functional expression studies have demonstrated that *KCNH2* mutations cause a reduction of I_{Kr} current,[14] but, similarly to LQT1 mutations, this effect is realized through different biophysical mechanisms.[10] Mutations in the *KCNE2* gene[15] cause the LQT6 variant of LQTS, which is the most uncommon subtype of the disease (<1%).

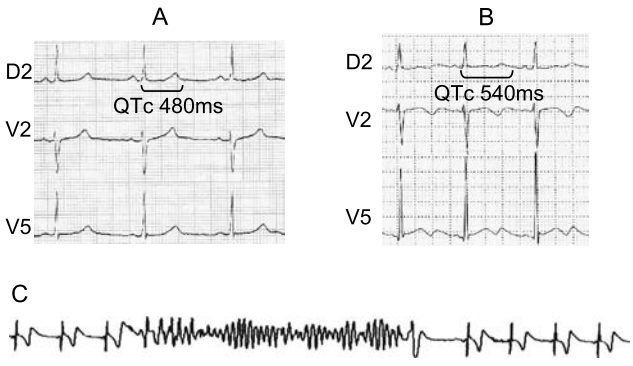

Fig. 1 Electrocardiogram (ECG) in the long QT syndrome. Examples of resting ECG in patients with a KCNQ1 mutation (A) and a KCNH2 mutation (B). Panel C shows a typical self-terminating polymorphic ventricular tachycardia in a LQTS patient. The arrhythmia was recorded by means of an insertable loop recorder (Reveal™).

SCN5A (LQT3)

SCN5A encodes for cardiac sodium channel conducting the sodium inward current (I_{Na}). The first reported *SCN5A* mutations[8] were clustered in the regions functionally associated with channel inactivation. Subsequently, several allelic variants have been reported (http://pc4.fsm.it:81/cardmoc) and functional expression studies showed that, at variance with LQT1- and LQT2-asociated mutations, LQT3 defects cause a gain of function with an increased I_{Na}.[16] Interestingly, *SCN5A* mutations are also found in other clinical syndromes allelic to LQT3: Brugada syndrome, cardiac conduction defect, and sinus node disease (for a review see Ref. [17]). The prevalence of LQT3 among LQTS patient is estimated to be 10–15%.

ANK2 (LQT4)

As of today, only one family linked to this locus (4q25–q27) has been reported.[5] Of note, the phenotype of the LQT4 patients differs from the typical LQTS. Most of the affected individuals, besides QT interval prolongation, also present with severe sinus bradycardia, paroxysmal atrial fibrillation (detected in >50% of the patients), and polyphasic T waves. Recently, a missense mutation in the *ANK2* gene was identified in this family.[9] *ANK2* encodes for an intracellular protein (ankyrin) that regulates the proper intracellular localization of plasmalemmal ion channels (calcium channel, sodium channel, sodium/calcium exchanger), sarcoplasmic reticulum channels

(ryanodine receptor, inositol triphosphate receptor), and other adhesion molecules.[18]

MOLECULAR SCREENING OF THE LQTS GENES

The primary consequence of the large heterogeneity of LQTS is that the vast majority of probands have their own ''private mutation'' with no or few hot spots so far identified. Therefore, the molecular screening of the entire ORF on the known gene is the only available option. In order to complete the analysis, 16 exons of *KCNQ1*, 15 exons of *KCNH2*, 28 exons of *SCN5A*, and 2 exons of *KCNE1* and *KCNE2* must be completely screened. *ANK2* encompasses 46 exons, but a routine analysis did not indicate that the only LQT4 family so far reported has a very peculiar phenotype (see above).

A fast and standardized screening methodology is still not available. Denaturating high-pressure liquid chromatography (DHPLC) and DNA sequencing are the most widely used techniques among laboratories offering LQTS genotyping.

Nonetheless, the number of cardiologist and geneticists requesting the screening is increasing and it is therefore important to make few relevant statements concerning implications and value of genetic screening. The major implication of finding the molecular alteration in LQTS lies in the possibility to obtain information that adds to the phenotypic assessment. This is true especially for LQT1, LQT2, and LQT3 genetic variants where a genotype-based clinical management is progressively entering the clinical practice.

When the genetic defect is identified in a proband, genetic screening could be made available to family members. In this step, genetic testing moves from being a method that confirms and refines a known diagnosis to being a diagnostic technique may be applied to healthy individuals (nonpenetrant carriers). Learning to be a ''gene carrier'' may expose asymptomatic individuals without clinical phenotype of the disease to the evidence that they carry and may transmit a potentially fatal disease. Counseling these patients is very difficult. It is recommended that before undergoing genetic testing these individuals are informed about the implication of a positive result.

GENOTYPE–PHENOTYPE CORRELATION

Electrocardiogram and Cardiac Events

In the last few years, several studies have outlined the distinguishing features of the three most common genetic variants of LQTS (LQT1, LQT2, LQT3), while the low prevalence of the other genetic variants so far prevented a precise characterization of the associated phenotypes.

Gene-specific EGC features have been initially described by Moss et al.[19] and subsequently refined by Zhang et al.[20] Schwartz et al.[21] have provided evidence that LQT1 patients present 97% of cardiac events during physical activity as opposed to LQT3 who present the majority of cardiac events at rest. Furthermore, it has been proposed that auditory stimuli and arousal are a relatively specific trigger for LQT2 patients, whereas swimming is a predisposing setting for cardiac events in LQT1 patients.[22,23]

Natural History and Risk Stratification

The increased availability of data collected among genotyped LQTS patients has allowed developing risk-stratification models based on the genetic substrate. Zareba et al. in 1998 provided the first gene-specific assessment of the natural history of the disease.[24] Such observations were further refined by Priori et al.[25] who also provided the first risk-stratification scheme based on the genotype. This study showed that the QT interval duration, the genotype, and the gender are significantly associated with the outcome. A QTc interval >500 msec determines a worse prognosis. However, LQT1 patients have a better prognosis vs. LQT2 and LQT3 with similar QT. Gender has no influence among LQT1 patients, whereas a higher risk was identified for LQT2 females and LQT3 males.[25]

Recent, still preliminary evidences suggested that risk stratification may be further refined when the position of a mutation on the predicted protein topology is taken into consideration. Among others, epidemiological findings from the International LQTS Registry[26] showed that LQT2 patients with mutation in the pore region are at greater risk of cardiac events (syncope and cardiac arrest) than patients with nonpore mutations.

LOW PENETRANCE AND VARIABLE EXPRESSIVITY IN LQTS

Likewise, as in other mendelian diseases, LQTS is characterized by a high degree of genetic heterogeneity and variable penetrance that translates into a range of possible phenotypes including subclinical forms with borderline of QT interval and no arrhythmias or syncope.[27,28] The demonstration of incomplete penetrance in LQTS leads to the speculation that carriers' subclinical mutations, although not manifesting any phenotype, may be more susceptible to develop arrhythmias when exposed to precipitating factors. The prevalence of such variants in the population is not known, but

it is appealing to speculate, and preliminary evidences exist,[29] that these defects may have a role in modulating the phenotype and may create a vulnerable substrate.[15,30]

GENETIC DIAGNOSIS AND COUNSELING

Long QT syndrome genotyping is progressively entering in the clinical practice. The availability of the genetic diagnosis may allow a more thoughtful clinical management and risk stratification. Genetic counseling should be regarded as a fundamental component of the clinical management, and the availability of effective therapeutic options is the main reason to encourage an early identification of all gene carriers in a family.

Unfortunately, gaps of knowledge and availability still exist and limit a wide spread applicability of genetic testing.

The ''knowledge'' issue is represented by the fact that the molecular screening of the entire open reading frame of the known genes allows identifying a pathogenetic mutation in 60–65% of probands. This implies that there is one or more LQTS gene(s) still to be identified, but it also leads to the practical consequence that a negative result from a molecular genetic lab has no capability of excluding the diagnosis.

On the other hand, the limited availability of laboratories offering clinical genetic testing for LQTS and the lack of fast and low-cost screening methodologies constitute additional limitations.

CONCLUSION

In the last decade, major achievements have been made in the understanding of the genetic basis of LQTS, the first inherited arrhythmogenic disease to enter the ''molecular era.'' Thanks to the contribution of several research laboratories pioneered by the seminal work of Mark Keating, it is now clear that the LQTS phenotype is the common pathway of mutations in several different genes.

Genotype–phenotype correlation analysis showed gene-specific distinguishing clinical features and risk of life-threatening cardiac. However, the power of such studies is partially limited by the variable penetrance identified in several families.

Looking to the future and trying to foresee directions of research, one would certainly anticipate that studies should be directed at the identification of factors (genetic or epigenetic) that may modify the penetrance and the clinical manifestations of the disease in patients with the same primary genetic defect. A natural extension to this approach would be the definition on the prevalence of these modifiers in the general population to define their role in arrhythmogenesis.

INTRODUCTION

To perform molecular biology studies based on the analysis of nucleic acids such as DNA and RNA, nucleic acid amplification technology is necessary because the gene content of almost all specimen is extremely low. Because these methods can be useful in the diagnosis of infections and genetic diseases, including predictive genetic and pharmacogenetic testing, diagnostic laboratories including hospital laboratories frequently use such technology as molecular diagnostic tools. In the medical field, amplification technology will play an important role in facilitating point-of-care testing to improve patient care. To widely apply such technology for practical use in the medical field, low cost and rapid performance are important. To achieve a cost-effective method, the apparatus being used must be simple. Moreover, the time from the start of a reaction until the result is obtained should be no more than 30–60 min. For example, methods amplifying genes under isothermal conditions have been developed (see other sections), but they require more than one enzyme and present difficulty in the selection of suitable reaction conditions.

To solve such problems, we have developed a new method of gene amplification. This method is named loop-mediated isothermal amplification (LAMP), and it involves gene amplification under isothermal conditions using only one enzyme with a high specificity, which is of particular importance for diagnostic techniques. Indeed, LAMP can be used for a direct detection of *Mycobacterium tuberculosis* in clinical diagnostic applications. However, compared to other methods [including polymerase chain reaction (PCR)], LAMP seems to be much less frequently used in laboratory diagnostics, because it was only developed recently or the principle and the primer design are a little complex (although the experimental procedure is simple).

In this section, we introduce the features and principles of LAMP, including the rapid method using a loop primer and single nucleotide polymorphism (SNP) typing.

FEATURES OF THE LAMP METHOD

Amplification Under Isothermal Conditions

The LAMP method, which differs from conventional methods of amplification, has several advantages.[1] Although there are other methods that can amplify genes under isothermal conditions, only the LAMP method does so with the aid of a single enzyme. Because no special reagents are required, suitable reaction conditions can be easily established and the procedure is inexpensive. For the LAMP method, the reaction, which used betaine at a temperature of around 60°C, destabilizes the double-stranded structure of nucleic acids, so this reaction can be initiated without previously denaturing double-stranded DNA.[2]

High Specificity

Conventional methods of gene amplification determine specificity on the basis of two regions, whereas the LAMP method requires six regions and four primers for gene amplification. A very high specificity of gene amplification ensures highly reproducible results, so that the presence of the target nucleic acid in the specimen is judged just by the amplification reaction.

Direct Gene Amplification From RNA

When the target is ribonucleic acid (RNA), complementary DNA (cDNA) is usually synthesized by using reverse transcriptase before amplification reaction is performed.[1] Because reverse transcriptase also substitutes the synthesized strands, LAMP is capable of amplifying a gene from RNA in exactly the same way as from DNA when reverse transcriptase is added to the reaction system.

Rapidity and High Sensitivity

Because the LAMP method has a high specificity, the target gene alone can be amplified with high efficiency. In

fact, it is possible to detect a target gene within 1hr. We have also developed a method of rapid gene amplification by adding new primers called loop primers to amplify the loop region of products with which the inner primers do not anneal.[3] The LAMP method, like PCR, has a sensitivity of a few copies (Fig. 1A). Because a strand substitution reaction is used for the synthesis, no amplicon leads to product inhibition during the amplification, so that the yield of the products reaches as high as 0.5 mg/mL.

Easy Detection

The reliability of results is of critical importance when gene amplification is performed for testing and diagnosis. With conventional methods, a separate detection reaction is required after amplification to confirm the gene that has been amplified. This adds to the complexity of genetic testing. On the other hand, the LAMP method accomplishes very specific gene amplification and the results can be judged directly. Furthermore, because it produces amplification products in far larger quantities, a simple method of detection can be selected. For example, if gene amplification is performed in the presence of a fluorescent intercalating dye such as ethidium bromide (EtBr), which binds to double-stranded nucleic acids, amplification products can be detected with the aid of an ultraviolet lamp. The efficiency of amplification is so high that pyrophosphoric acid is formed in large quantities as a product of DNA synthesis. When it combines with magnesium, turbidity is produced. Gene amplification can therefore be confirmed by visual detection of turbidity or a white precipitate.[4] Turbidity can also be measured so that gene amplification can be detected in real-time (Fig. 1B).

PRINCIPLE OF THE LAMP METHOD

Original LAMP Method

The LAMP method is performed with two inner primers, forward inner primer (FIP) and backward inner primer (BIP), and two outer primers, F3 and B3 primers. Forward inner primer has the same sequences as the F2 region and the F1C region of the target DNA, while BIP has the same sequences as the B2 region and the B1C region. The mechanism of the method and the expected reaction steps are illustrated in Fig. 2. The reaction involves three steps—''stating material producing step,'' ''cycling amplification step,'' and ''elongation step.''

First, for stating material producing step, the inner primer BIP hybridizes to B2c in the target DNA and initiates complementary strand synthesis (structure 1). The outer primer B3, which is a few bases shorter and is present at a low concentration, slowly hybridizes to B3c in the target DNA and initiates strand displacement DNA synthesis that releases a BIP-linked complementary strand (structure 2). Next, the inner primer FIP hybridizes to F2c in the released single-stranded DNA, and outer primer F3 hybridizes to F3c, releasing DNA as a dumbbell-like structure (structures 3 and 4).

The dumbbell-like DNA (structure 4) is quickly converted to stem–loop DNA (structure 5) by self-primed DNA synthesis. This stem–loop DNA then serves as the starting material for LAMP cycling, which is the second stage of the reaction (cycling amplification step; structures 4, 5, 6, and 7).

The DNA derived from structure 5 is also involved in ''elongation step'' of the reaction. Thus the 3′ region of structure 5 is released by BIP-primed DNA synthesis,

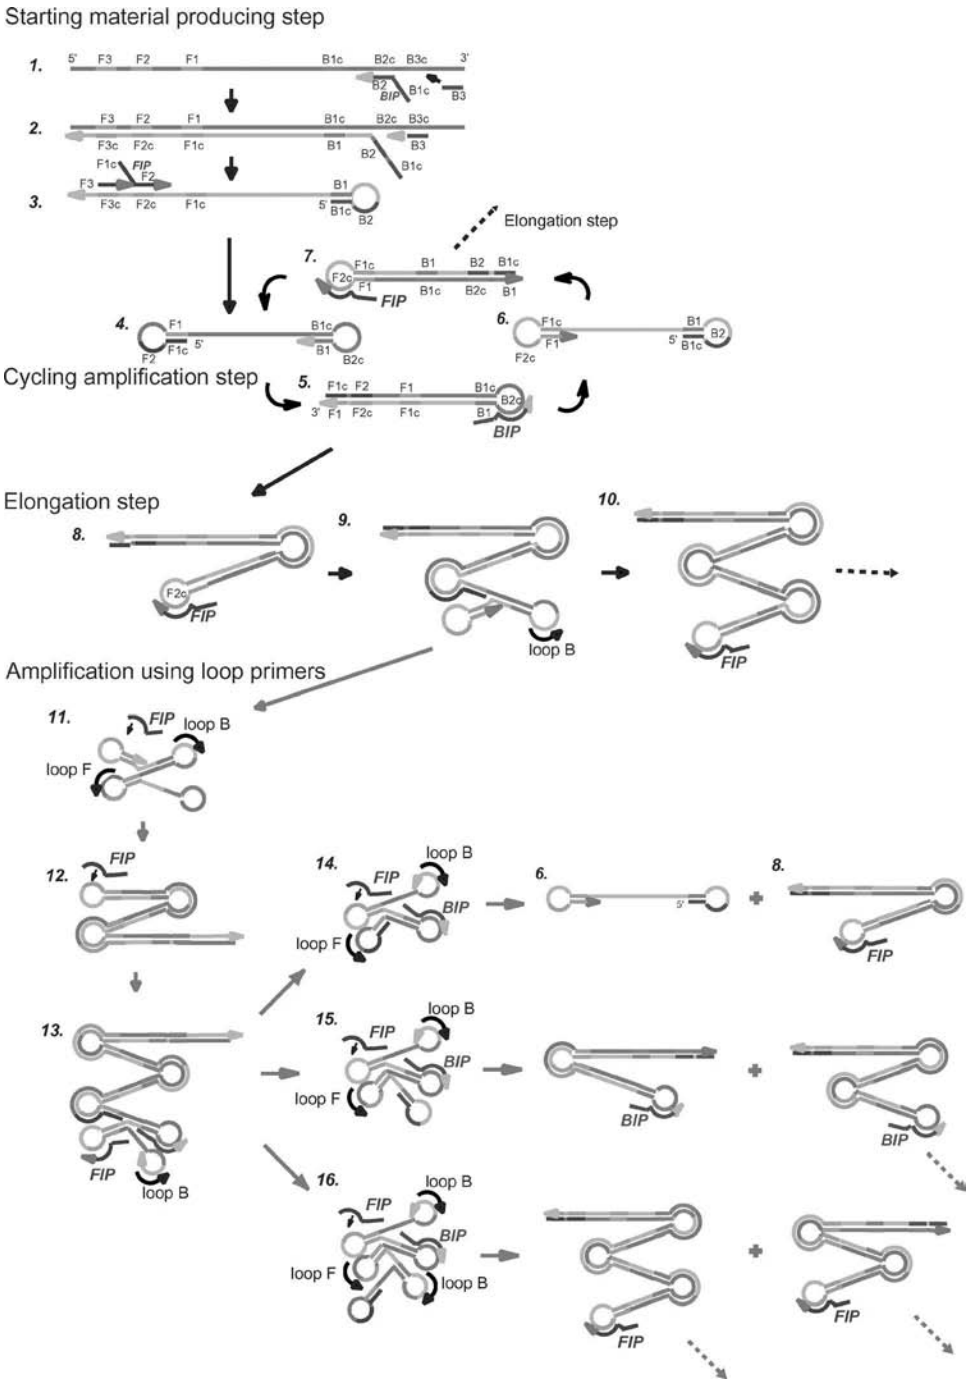

Fig. 2 Schematic representation of the LAMP mechanism. In the first step, the starting structure is generated with dumbbell-like DNA (structure 4) being formed. Then, the starting structures are cyclically produced in cycling amplification step. The elongation reaction starts from the subproducts (structures 5 and 7) of the cycling amplification step, generating products of various sizes. F2c and B2c regions on the target gene are hybridized by the inner primers. Structure 11 is generated by the reaction starting from the loop primers. The region between F1 and F2 (or B1c and B2c) is hybridized by the loop primer. Dotted arrows represent continuous reactions. (*View this art in color at www.dekker.com.*)

and then self-primed DNA synthesis generates stem–loop DNA with a stem that is elongated to twice as long (structure 8). This reaction also occurs from structure 7 (following reactions not shown). Because the stem loop—including the single-stranded region containing the target sequence of the primer—is present in each structure, this reaction continues until the decay of the substrates or primers. The final products are a mixture of

stem–loop DNAs of various stem lengths and cauliflower-like structures, with multiple loops induced by annealing between alternately inverted repeats of the target sequence on the same strand. When the products are electrophoresed on agarose gel, followed by staining with an intercalating dye such as EtBr, many bands of different sizes are detected (Fig. 1A).

Rapid LAMP Method

To accelerate the LAMP reaction, loop primers act from the elongation steps of the original LAMP reaction (Fig. 2, lower). The loop primer called loop B hybridizes to single-stranded loop region of the stem–loop DNA in structure 9 before initiating strand displacement DNA synthesis. Then, DNA synthesized from this loop primer is displaced by extension from the 3′ end of the target DNA, generating structure 11, which is not created in the original LAMP reaction. Structures 6 and 8 generated by loop primers are also obtained in the original method and are reused in the LAMP reaction. All of the stem–loop DNAs are used by either the inner or loop primers, e.g., structures 14, 15, and 16. The loop primers hybridize to the stem–loop region in structure 9, as well as in the other structures that are generated by the LAMP reaction, resulting in dramatic amplification.

Upper and lower panels show the reactions using wild-type and mutant templates, respectively. B: Real-time detection of SNP in CYP2C19. The CYP2C19*1 (636G) primer (left) and CYP2C19*3 (636A) primer (right) were used for the LAMP reaction. (*View this art in color at www.dekker.com.*)

SNP TYPING USING THE LAMP METHOD

To detect a single nucleotide difference by LAMP-based SNP typing, both FIP and BIP were designed to contain SNP nucleotides on the target sequence at each 5′ end. Figure 3A shows the basic principles of the LAMP cycling reaction with the WT primer set, using WT DNA (Fig. 3A, upper) and MUT DNA (Fig. 3A, lower) as templates.

When LAMP reaction using the WT primer set is carried out with WT DNA as the template, a dumbbell-like structure is generated with both ends being overlapped by self-annealing (Fig. 3A, upper). This dumbbell-like structure served as the starting point for cycling amplification step (Fig. 2, structure 4 or 6). DNA synthesis is initiated from the 3′ end, using the structure itself as the template (similar to the original LAMP method). As a result, DNA strands consisting of inverted repeats of the target sequence are formed. When MUT DNA is used as the template, the 3′ end of the dumbbell-like structure cannot self-anneal completely at its end (Fig. 3A, lower). Thus DNA synthesis is only primed from the 3′ end of FIP or BIP that anneals to the loop region of the structure, resulting in the formation of double-stranded DNA and the halt of the LAMP cycling process. When DNA synthesis proceeded as a result of a miscopy and the dumbbell-like structure was produced, further DNA synthesis from the turnover structure is halted through the steps mentioned above. Because two primers are designed to recognize a single nucleotide difference of the dumbbell-like structure or its turnover structure, LAMP-based SNP typing could precisely discriminate single nucleotide differences.

To demonstrate the usefulness of LAMP-based SNP typing, we assessed the typing of CYP2C19, a gene belonging to the cytochrome P450 family and showing various polymorphisms. Although homology between the CYP2C subfamilies is very high, the LAMP method was capable of specifically amplifying CYP2C19 and detecting a single nucleotide difference during single-step amplification, because the method uses four primers that recognize six regions and detects a single-base difference after each cycle of amplification. To demonstrate the value of LAMP, CYP2C19*1 (WT), 2C19*3 (G636A), 2C9, 2C18, and 2C8 genes were used as templates and the reaction was carried out in the presence of an intercalater for real-time detection (Fig. 3B). Only 2C19*1 alone was amplified when the 2C19*1 primer was used, while the 2C19*3 gene with a single nucleotide difference and genes of other 2C subfamilies were not amplified (Fig. 3B, left). Similarly, only the 2C19*3 gene was amplified and genes of the other 2C subfamilies were not amplified when the 2C19*3 primer was used (Fig. 3B, right). These results indicate that the LAMP reaction can detect a single nucleotide difference on a target gene when LAMP-based SNP typing is performed with human genomic DNA in the presence of many homologous family genes.

CONCLUSION

The LAMP method bears the following features: 1) it can be performed under isothermal conditions; 2) the reaction can be accelerated by using a loop primer; 3) it generates large amounts of the amplified products; and 4) it can also amplify RNA by addition of reverse transcriptase with a single step.

Furthermore, the LAMP method can be used for SNP typing with a distinctive primer. Considering that SNPs are associated with constitutional factors, such as disease susceptibility, drug responsiveness, and adverse drug reactions, the LAMP method holds the promise of application to tailored medical care. The LAMP method can be used for tests in various fields such as the diagnosis of hereditary disease, identification of viral infections as point-of-care testing, sex determination (humans and other animals), and testing for contamination of food or water by bacteria and other agents.[5,6]

INTRODUCTION

Proteomics is made possible by the high-throughput detection, identification, and characterization of proteins in complex mixtures. High throughput refers to both the ability to detect many proteins per sample and to analyze many samples. While no method presently allows the rapid identification and quantification of all proteins in a mixture, intense research over the past decade has considerably accelerated the pace of protein measurements. Such measurements open the door to many applications in clinical and basic research.

Proteomics measurements rely on a combination of chemical separations, such as chromatography or electrophoresis and mass spectrometry (MS). For top–down proteomics, the proteins themselves are separated and then analyzed, whereas for bottom–up proteomics the proteins are first digested with enzymes; the resulting peptides are then separated and analyzed by MS. Peptides detected are used to identify proteins by bioinformatics. The classical proteomic analysis tool is two-dimensional gel electrophoresis (2-D GE). This technique is powerful, allowing as many as 10,000 proteins to be detected in a single analysis. Spots detected on gels can be identified by extraction from the gel followed by enzyme digestion and MS analysis. 2-D GE is hindered by two disadvantages: 1) it requires relatively large samples (10^{-13} to 10^{-12} mol); 2) it is slow and laborious, often requiring days for separation and much longer to extract and perform MS analysis of the spots.

Novel, automatable techniques that are faster and utilize miniscule samples are presently being developed to replace 2-D GE. One technique under investigation is microscale separation, such as capillary liquid chromatography (cLC) or capillary electrophoresis (CE), coupled with matrix-assisted laser desorption/ionization-mass spectrometry (MALDI-MS). In this approach, protein or peptide samples are resolved by cLC or CE and the fractions stored on the surface of a plate that is inserted into the mass spectrometer. Samples are examined by MALDI-MS to determine molecular weights and ultimately identify the protein or peptide. The method has been demonstrated to be able to detect as little as 10^{-18} to 10^{-15} mol of analyte in an automated, parallel format for high-throughput analysis. This potentially important proteomic technique is not presently commercially available, but is rapidly being developed. This article will discuss the state-of-the-art in coupling CE and cLC to MALDI-MS.

IONIZATION TECHNIQUES: MALDI AND ESI

MS provides highly accurate measurements of the mass-to-charge ratio (m/z) of gaseous ions in vacuum. The m/z can be used to calculate the mass of the ion and, from this, the identification of the species can often be deduced. Peptides and proteins are not volatile enough to form gaseous ions using traditional approaches; however, the advent of electrospray ionization (ESI) and MALDI has rendered these important analytes amenable to MS analysis and, along with several other innovations, led to the ongoing revolution in proteomics. In ESI, sample flows out of a capillary tube that has voltage applied at the outlet, resulting in the formation of a spray of sample droplets. As the droplets evaporate, ionized sample molecules are formed and introduced to the mass spectrometer. In MALDI, samples are cocrystallized with a radiation-absorbing molecule (matrix) of low molecular weight, such as α-cyano-4-hydroxycinnamic acid (CHCA) or 2,5-dihydroxybenzoic acid (DHB). Ionization is performed by exposing the sample to short bursts of radiation from a laser. Either ultraviolet (UV)-absorbing matrix with a UV-emitting laser (UV-MALDI) or infrared (IR)-absorbing matrix with an IR-emitting laser (IR-MALDI) can be utilized. The rapid heating caused by radiation absorption results in explosive volatilization of the matrix and formation of charged analytes in the gas state that can be transferred to the mass spectrometer. Usually, a tiny fraction of the sample is vaporized by a single laser shot, so signal from multiple shots are averaged to obtain good-quality spectra. MALDI-MS has a high mass range (routinely up to 30 kDa), good detection limits (attomol range), and high mass accuracy (0.01% at high mass).

MALDI is tolerant of additives (such as salts or surfactants) that might be contained in a sample, and is

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020807

compatible with parallel analysis as discussed below. Because the sample is deposited on a surface in MALDI, the sample can be stored and reanalyzed. The latter feature enables data-dependent workflows, wherein results from an analysis can be used to determine the next type of experiment to perform on the sample. Experiments may include multidimensional MS (MS^n), wherein a selected ion is degraded in the gas state by irradiation with an infrared laser or collision with neutral molecules (collision-induced dissociation), resulting in dissociation of the ion into characteristic fragments, called product ions or daughter ions, which are then analyzed. The resulting spectra can be used like puzzle pieces to identify the parent ion. Alternatively, a sample may be chemically degraded or modified, such as digestion with an enzyme, and reanalyzed providing further information.

A significant weakness of MALDI is the difficulty of quantification. As the laser spot is focused on different regions of sample, the relative amounts of analyte detected will vary. In many cases, this effect can be quite extreme so that in some regions, no signal is detected and in others, the so-called ''sweet spots,'' strong signals are observed.

ESI and MALDI have proven to be complementary in many ways.[1] Perhaps, the most important reason for both MALDI and ESI to be developed is that they appear to be effective in ionizing different classes of peptides. Thus, in analysis of complex mixtures, detected peptides will vary significantly depending on the ionization method used.[1] Therefore, application of both methods may prove effective.

CAPILLARY SEPARATIONS COUPLED TO MS

While ESI and MALDI have enabled proteins and peptides to be analyzed by MS, the complex mixtures represented by clinical and other biological samples require fractionation prior to analysis. Without fractionation, competitive ionization induces only the species that most avidly take up charge to be detected in a sample, resulting in poor sensitivity for many ions; this effect is known as ion suppression. In addition, the mass spectra of unfractionated mixtures can be so complex as to defy interpretation even if extremely high resolution mass spectrometers are used. Resolution of mixtures by a separation technique prior to MS ameliorates these problems. Of the separation techniques available, cLC and CE are two that have received considerable attention for coupling to MALDI-MS.

cLC is comparable to high-performance liquid chromatography (HPLC), with the main difference being a much reduced internal bore of the column for cLC. Whereas an HPLC column may have an inner bore of 2–5 mm, a cLC column may have an inner bore of 25–300 μm. As mobile phase flow and sample volume requirements scale with the square of inner diameter (i.d.), this miniaturization results in much reduced sample consumption, increased sensitivity (for same amount injected), reduced operating costs (less mobile phase and disposal), and feasibility of parallel operation. Most of these advantages have been demonstrated in a research setting; however, commercial cLC systems are just now becoming available.

In CE, samples are separated by applying an electric field along a capillary tube, typically 25–75-μm inner diameter and 10–100 cm long, filled with buffer. The extremely narrow bore of the capillaries allows rapid heat dissipation, because of the high surface area/volume ratio. Because the limit to the electric field applied is typically set by heat buildup from current flow, the capillary arrangement allows electric fields (100–1000 V/cm) that are much higher than those observed in conventional gel electrophoresis (10–30 V/cm). As the resolving power and speed of an electrophoretic separation are directly dependent upon the field applied, CE allows for much faster and higher resolution separations than gel electrophoresis.[2,3] In addition, the extremely small inner diameter capillaries require only nanoliter volume samples, thus reducing sample consumption. In CE, samples are typically injected onto one end of the capillary and then detected near the opposite end. Electroosmotic flow (a type of flow generated in tubes with voltage applied) causes most analytes, regardless of charge, to migrate in the same direction—allowing detection at a single point. Analyte molecules are separated according to their electrophoretic mobility, which is a function of their charge and hydrodynamic radius in solution.

Coupling of liquid separation with MS is relatively straightforward when using continuous flow ionization methods such as ESI. Therefore, ESI has been the method of choice for coupling to modern separation methods, and many proteomic methods have been developed around this combination. MALDI requires samples to be crystallized with matrix, and it is conventionally a vacuum ionization technique. Therefore the coupling of liquid separation to MALDI-MS is more difficult, resulting in a longer development time. Most systems utilize off-line coupling, meaning that the sample is stored on a surface (target plate) that is later introduced to the MS. While off-line methods are seemingly cumbersome, they can present significant advantages such as: 1) independent optimization of separation and MS conditions, and 2) saving the sample after analysis and allowing reanalysis or other experiments such as protein digest to be performed later.

cLC–MALDI–MS

While several combinations of cLC–MALDI-MS have been reported, a system recently developed at the Genomics Institute of the Novartis Research Foundation is indicative of the state-of-the-art.[4] As illustrated in Fig. 1, the outlet of the cLC column is fixed over the target plate mounted on a motor–driven translation stage, allowing fractions to be collected at discrete locations on the plate. To control the deposition of a fraction, droplets formed on the column outlet are pulled down to the plate by application of a voltage pulse. Novel use of voltage to dislodge droplets allows complete and automated control of sample deposition and, because the column is not in contact with the plate surface, opportunities for cross-contamination and damage to the column or plate are minimized. The target plate consists of hydrophobic surface punctuated with an array of 400-μm-diameter wells containing a hydrophilic surface coating.[5] The use of a prestructured surface prevents a deposited fraction from spreading on the surface and confines it to the predetermined area. In addition, it allows for fairly large samples to be concentrated onto a small area because large droplets adhere to the hydrophilic spot and are confined to the spot as they evaporate. The small sample area allows the laser to irradiate the entire spot, eliminating the ''sweet spot'' effect. Matrix may either be added postcolumn via a Y-connector or precoated onto the target plate in a multistep deposition, depending on the properties of the matrix. This prototype instrument utilizes up to four cLC columns (300-μm i.d., 15 cm long) in an array. Because chromatography separations can take 10–100 min, the use of the array can substantially increase the throughput of analysis.

The performance of this instrument was demonstrated by analysis of a tryptic digest of bovine serum albumin using a Fourier-transform ion cyclotron resonance (FT-ICR) instrument as the MS. A sample of the three-dimensional data output with separation time, *m*/*z*, and signal intensity as the dimensions is illustrated in Fig. 2.

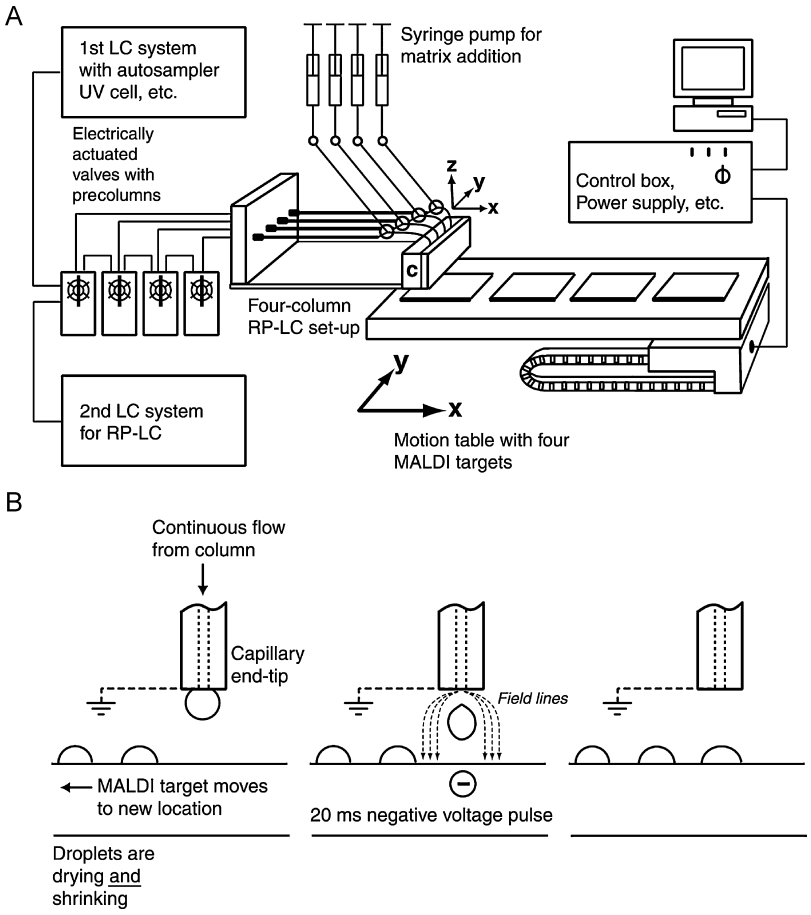

Fig. 1 Automatic deposition of effluent from cLC directly down to a MALDI target plate. A) The automated off-line system for cLC-MALDI. B) Deposition of the effluent from the LC column down to the target plate by application of a negative voltage. (From Ref. [4].)

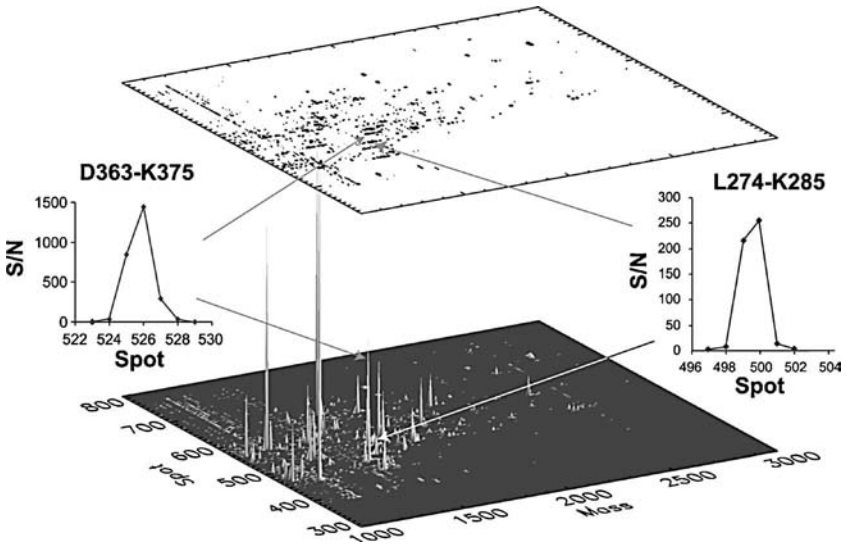

Fig. 2 3-D plot of LC/MALDI-MS analysis of 200 fmol BSA tryptic digest with elution profiles for two peptides (D363–K375 and L274–K285). 20 μL of a 10 fmol/mL digest solution was injected each onto four parallel columns. The effluent was deposited every 10 sec onto the target plate. A sequence coverage for BSA of 78% was obtained. (From Ref. [4].) (*View this art in color at www.dekker.com.*)

The detection limit for the instrument, when coupled to a time-of-flight mass spectrometer (TOF-MS), was better than 50 attomol. The instrument could collect up to 384 fractions from 4 columns, or 1536 fractions from a single column. This large number of fractions would make it possible for operators to obtain multiple fractions for all resolved analytes, because the peak capacity of an LC column, i.e., the maximum number of resolvable components, is typically $\sim$200.

Off-line coupling of cLC–MALDI-MS may be achieved in other ways as well. For example, the effluent can also be deposited as a continuous trace on the target instead of discrete spots.[6] In this case, the column effluent passes through a heated nebulizer that sprays the effluent directly onto the target plate. The continuous trace deposition method allows the full chromatographic peak capacity to be retained.

CE-MALDI

As with cLC–MALDI-MS, CE–MALDI-MS is still under development and several designs have been reported. Off-line deposition onto a continuously moving target was one of the earliest designs used.[7] In another type of off-line coupling, a piezoelectric flow-through microdispenser was connected to a CE system.[8] Pressure pulses cause the microdispenser to eject droplets with volumes of 60–100 pL collected at the target plate. This decreased the spot size to $\sim$400 μm in diameter, compared to a diameter of 1–4 mm for the dried-droplet method. The sensitivity increased as well as the detection limits (100 attomol for peptides).

More recently, on-line interfacing has been performed by depositing the capillary effluent onto a moving surface under vacuum inside the MS. Moving surfaces used include a rotating ball,[9] a wheel,[10] and a moving tape.[11] In the moving-tape design (Fig. 3), the CE capillary outlet is juxtaposed with an infusion capillary in a liquid junction. The liquid junction allows the circuit for the electrophoresis to be separated from the MS. In addition, the gap in the capillaries is used to mix matrix with capillary effluent. Flow from the separation capillary across the junction is maintained by electroosmosis (100–400 nL/min). The infusion capillary transfers sample and matrix mixture into the vacuum of the mass spectrometer and is in contact with the tape. Small volumes of deposited solvent are rapidly evaporated within the vacuum region, leaving fractionated sample crystallized with matrix deposited as a continuous trace 40 μm wide on the tape. The tape transfers the sample to the laser irradiation region for analysis by MALDI-TOF-MS. The laser spot is wider (100×100 μm) than the deposited trace; therefore, a full segment of the trace is irradiated with each shot. This arrangement yields extremely high sensitivity; detection limits of 10^{-18} mol for peptide standards demonstrated. In addition, the reproducibility of 15% was very good when compared to 20–90% for conventional MALDI experiments. The instrument is robust enough to operate for 24 hr without interruption. In principle, this

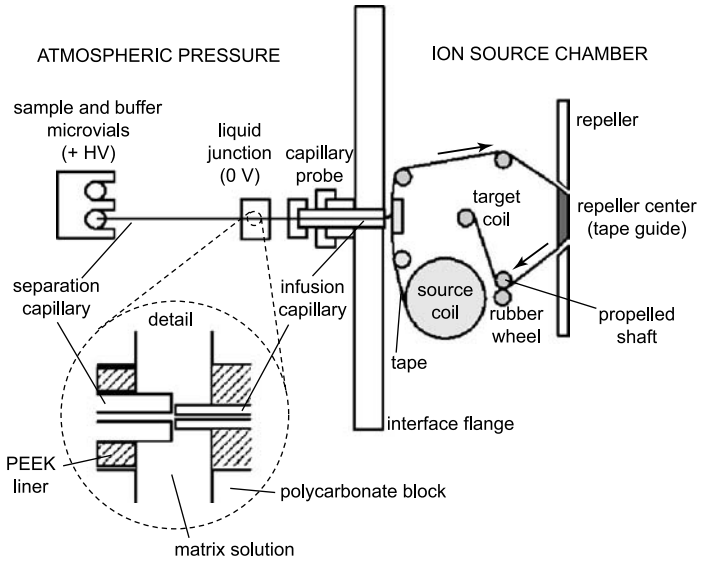

Fig. 3 Schematic of the on-line coupling of CE to MALDI. (From Ref. [11].)

system could also be operated in parallel with multiple capillaries and the laser directed toward different traces on the same tape.

CONCLUSION

It is likely that cLC and CE coupled to MALDI will continue to evolve, ultimately leading to commercial instruments and a plethora of new proteomic applications. cLC–MALDI-MS or CE–MALDI-MS is inherently compatible with other proteomics innovations, such as the isotope-coded affinity tag (ICAT) reagents for quantification and database searching for protein identification. It is anticipated that parallel operation will become the standard for high-throughput analysis. The advent of MALDI performed under atmospheric pressure[12] may facilitate simpler interfaces between the separation and the mass spectrometer. While MALDI is inherently a pulsed source lending itself to mass spectrometers acquiring rapid spectra, such as the TOF-MS, innovative ion optics have enabled the MALDI to be coupled to other spectrometers such as the FT-ICR (see above), quadrupole time-of-flight, and quadrupole ion trap. These instruments, along with the TOF–TOF, enable operators to perform MS^n, which provides much more powerful chemical identification capability than single-dimensional MS. In this regard, the off-line coupling schemes have a significant advantage over on-line methods in that time is available to acquire multiple spectra from a single fraction, whereas the on-line coupling schemes require on-the-fly spectra acquisition. A possible scenario for future development is off-line systems for detailed, complex analyses and on-line systems for high-throughput, routine proteomics applications.

The advent of such techniques would enable a variety of proteomics measurements, including top–down or bottom–up approaches, to be performed in a rapid, sensitive, and automated format. The methods described in this article are clearly more sensitive, automated, and faster than 2-D GE. The individual separation techniques such as CE and cLC have a peak capacity of $\sim$200, and cannot match the resolving power for 2-D GE. More extensive separation prior to MS analysis will likely be necessary for complete proteome analysis.

MALDI-TOF Mass Spectrometry

Christian Jurinke
SEQUENOM, Inc., San Diego, California, U.S.A.

INTRODUCTION

Mass spectrometry (MS), in general, is concerned with generating, separating, and detecting gas-phase ions. The underlying concept goes back to 1913 and was demonstrated by Thomson[1] in a series of cathode ray tube experiments. One of the inherent limitations of MS is the need to convert the analyte molecules or atoms into gas-phase ions because electromagnetic forces can easily manipulate those and they can readily be detected. This necessity has hampered the widespread use of mass spectrometric techniques in the biological sciences because it usually results in severe decomposition of biological macromolecules. Matrix-assisted laser desorption/ionization (MALDI) time-of-flight (TOF) MS, as practiced today, goes back to a concept introduced in 1989 by Karas and Hillenkamp.[2] With the introduction of this technique, limitations resulting from desorption efficiencies for large biomolecules have been overcome. Consequently, the use of MS techniques is exploding and is becoming more and more a routine.

THE MALDI PROCESS

The main principle of MALDI goes back to the observation that in a laser-irradiated mixture of substances that differ in their absorption efficiency, the less efficient absorbing substance is already desorbed into the gas phase at less laser energy than would be required for this substance alone, if the more efficiently absorbing substance is provided in excess. This enables desorption of substances (e.g., large biomolecules) that would undergo fragmentation and decomposition if desorption is attempted without matrix assistance. In a typical MALDI experiment, the matrix is present in a 10^3-fold to 10^4-fold excess.

To conduct the MALDI process, the sample is deposited on a conductive sample support and cocrystallized with matrix. Typical matrix substances are small organic molecules (mainly acids) that have an absorption maximum at the laser wavelength and are able to efficiently cocrystallize with the analyte and to induce its ionization in the gas phase. The choice of the appropriate matrix is key to a successful MALDI-TOF experiment. Some common matrix compounds, their solvents, absorption wavelength, and the compatible analytes are listed in Table 1.

Several techniques have been reported to efficiently cocrystallize the matrix and the sample. The most commonly used is the so-called dried droplet method. Here, the sample is premixed with the matrix and the mixture is allowed to evaporate slowly at ambient temperature. Other techniques include the fast evaporation and sandwich matrix technique. For the fast evaporation method, a small amount of matrix (usually in a water–acetone mixture) is deposited on the sample. The acetone (or a comparable solvent) rapidly evaporates and leaves a homogeneous crystal surface. The sandwich matrix technique starts with a thin layer of matrix that is applied first, followed by the sample solution and an additional layer of matrix. There is a vast variety of variations of these techniques and usually the user will have to determine empirically which one is suited best for a particular application.

To induce desorption, the matrix sample cocrystals are irradiated with a nanosecond laser beam [e.g., from an ultraviolet (UV) laser with a wavelength of 266 or 337 nm]. Lasers used for MALDI-TOF purposes are mainly UV lasers [e.g., frequency-quadrupled neodymium/yttrium aluminum garnet (Nd/YAG) lasers], but nitrogen and CO_2 lasers are also in use. The use of infrared (IR) lasers is suitable for several applications and has been reported to successfully analyze large DNA fragments.[3] The energies introduced by the laser irradiation are in the range of 1×10^7 to 5×10^7 W/cm^2. This energy introduction causes a structural decomposition of the crystal and generates a particle cloud (the plume). The process of desorption can be described as a conversion of laser energy to vibrational oscillation of the crystal molecules. This results in the disintegration of the crystal. The plume contains ions that follow a Boltzmann distribution of their initial velocities. Out of the plume, ions are extracted by an electric field.

TOF-BASED SEPARATION AND DETECTION

Following acceleration, the extracted ions drift through a field-free path and finally reach a detector (e.g., a

secondary electron multiplier, or SEM). Ion masses (mass-to-charge ratios, m/z) are typically calculated by measuring their TOF, which is longer for larger molecules than for smaller ones (provided their initial energies are identical). In mathematical terms, the velocity (v) of desorbed ions that are accelerated through a constant electric field is inversely proportional to the square root of their mass-to-charge ratio.

The most prominent detectors that are used to analyze the ion beam resulting from a MALDI experiment are SEMs. The basic concept relies on the emission of so-called secondary electrons from a coated surface resulting from a strike of fast-moving ions. In these detection devices, a series of dynodes is connected together via a resistor chain. A high voltage is applied across the first dynode (conversion dynode) and the last dynode (anode). The impact of ions on the conversion dynode results in the generation of secondary electrons that are accelerated toward the second dynode where more secondary ions are emitted. This process is repeated multiple times and leads to an amplification of secondary ions at each successive step. The achieved gain in signal amplification is in the range of 10^7. It has to be noted that the sensitivity of these devices decreases with increasing analyte mass because the electron yield depends on the momentum of the incoming particle, not its energy. A commonly used version of the electron multiplier is the channel electron multiplier (CEM). The CEM provides a higher amplification gain and is more compact and less expensive. Another detector device is the channel plate that essentially is a multichannel version of the CEM. It consists of a multitude of fiber optic cables that provides an increased length-to-diameter ratio. In addition, photomultipliers that convert an incoming beam of ions into photons that are amplified by a conventional photomultiplier are used.

Because the MALDI process predominantly generates single-charged, nonfragmented ions, parent ion masses can easily be determined from the resulting spectrum without the need for complex data processing. The masses are accessible as numerical data for direct processing and subsequent analysis. TOFs measured during a typical MALDI experiment are in the range of microseconds. The MALDI process and instrumentation as described in the above paragraphs are illustrated in Fig. 1.

PERFORMANCE CHARACTERISTICS OF MASS SPECTRA

The most important performance characteristics for a MALDI-TOF spectrum are resolution and signal-to-noise (S/N) ratio. The resolving power of a mass spectrometer is its ability to distinguish between ions with slightly different m/z ratios. Usually, the resolution of a particular peak in the mass spectrum is expressed as the peak width measured at half of its maximum height (full width at half maximum, or FWHM). Numerically, resolution is expressed as $R = m/\Delta m$, or the ratio of the mass of one ion to the difference of a closely neighbored second ion. The intensity is given in arbitrary units or in relative units, where the most abundant signal is assigned the 100% value. The S/N ratio is an additional factor to characterize the quality of a mass spectrum. It is expressed as the ratio of a particular signal intensity to the average noise intensity. To increase sensitivity and/or S/N ratios, spectra can be summed up, which simply means that spectra from multiple laser shots are averaged. Typically, sensitivities are in the low femtomole to attomole range.

The quantitative abilities of MALDI-TOF MS are limited. Absolute quantitation of isolated signals cannot

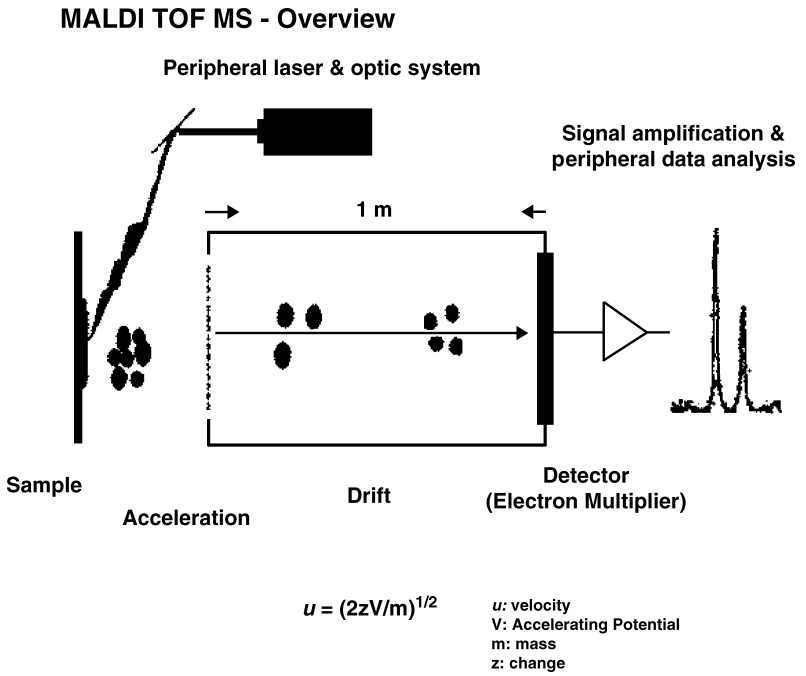

Fig. 1 Depicted is a schematic overview of the MALDI-TOF process. The text provides a detailed description.

be achieved. However, relative quantitation employing a reference standard with a known concentration is possible. Relative quantitation with MALDI-TOF is, for example, routinely used to analyze the allele frequency of single nucleotide polymorphisms (SNPs) in equimolar mixtures of genomic DNA (DNA pools). For more details, the reader is referred to the respective chapter in this encyclopedia.

ADVANCED TECHNIQUES AND INSTRUMENTATION

Important enhancements to MALDI-TOF experiments are provided by additional instrumentation. Examples for improving instrumentation are the use of delayed extraction methods and reflectron devices. The principle of delayed extraction is to have a small time window between the ionization pulse and the extraction pulse. During this time window, ions are allowed to disperse according to their initial velocities, and neutral (non-ionized) molecules that are generated during desorption are pumped away. Therefore ion–molecule collisions are minimized, which otherwise would contribute to a spread of translational energies. The application of delayed extraction[4] leads to significant increases in mass resolution (e.g., at 3000 Da from about 5000 without DE to over 10,000 with DE) and accuracy[5] (from about 100 ppm to about 10 ppm). Another important performance enhancement comes with the application of reflectron devices. A reflectron essentially is an electrostatic ion mirror. It consists of a series of electrical lenses with increasing repelling potential. The reflectron corrects for initial energy and positional dispersions of isomass ions. Faster-moving ions spend less time in the drift region but enter to a greater depth into the reflecting field. The extra time spent in the field compensates for their shorter flight time in the drift regions, with all isomass ions arriving simultaneously at the detector. The performance enhancement compared to nonreflectron instruments (called linear TOF instruments) is significant, especially for molecules with masses greater than 10 kDa. An excellent overview on the underlying principles of MALDI-TOF and the effect of reflectron devices is provided by Guilhaus.[6]

An important technique used to conduct structural studies with MALDI-TOF MS is the so-called postsource decay (PSD). The MALDI process results in different classes of desorbed particles, ions, neutral particles, and metastable particles that undergo decay during their drift toward the detector. The decay is initiated by low-energy collisions of neutral matrix molecules with analyte ions. To analyze the PSD products, precursor ions are preselected (based on mass) via an ion gating device. Products and precursors are resolved through the use of single-staged or two-staged reflectrons. Some applications for the PSD approach are described in ''Applications in Proteomics.''

APPLICATIONS IN PROTEOMICS

Peptide and protein analyses are the most widespread applications of MALDI-TOF MS in the biological sciences today. The most important applications are structural analysis of peptides and proteins (such as sequencing and investigation of bisulfide bonds), modification analysis (investigation of phosphorylation and glycosylation sites), investigation of noncovalent interactions, and protein identification in mixtures or from two-dimensional gels. Because of the number of applications, their complexity, and space constraints, this section can only provide a brief outline and the reader needs to be referred to the respective scientific publications for more details.[7]

Structural Peptide and Protein Analysis

A generic outline to the structural analysis includes the following steps:

1. Purification of the targeted protein or peptide out of the sample (tissue, cell culture, etc.) via gel electrophoretic (e.g., two-dimensional), affinity-based, or gel permeation-based techniques.
2. Mass measurement of the intact protein via MALDI-TOF. At this point of time, databases (such as SWISSPROT, PIR, EMBL, and others) can be used to investigate the identity of the targeted protein.
3. Analysis of disulfide bonds and free suflhydryl groups via chemical reduction and carboxymethylation. The protein is measured prior to and after reduction of disulfide bonds (e.g., using mercaptoethanol) and the subsequent carboxymethylation (e.g., via iodacetamide). This treatment provides information on the number of disulfide bonds and free sulfhydryl groups, respectively. In addition, this procedure facilitates the subsequent cleavage step into peptide fragments by eliminating secondary and tertiary structures, thus providing additional cleavage sites.
4. Chemical and or enzymatic cleavage into smaller peptide fragments is accomplished through amino acid-specific cleavage reagents. Common reagents to perform specific cleavage reactions are specific proteases (e.g., trypsin and certain endoproteinases), nonspecific enzymes (e.g., chymotrypsin), and chemical agents (e.g., chlorosuccinimide or cyanogen bromide). The cleavage products are usually fractionated by high-performance liquid chromatography (HPLC)-based techniques prior to MALDI-TOF MS-based analysis. The obtained masses provide a specific signature (fingerprint) that can be used in databases searches. If the information generated in this step is not sufficient to accomplish the identification of the analyte (e.g., for de novo protein and peptide analysis), an additional step has to be performed to obtain the sequence of the purified cleavage products.
5. Peptide ladder sequencing is performed through the generation of C-terminal and N-terminal peptide ladders. For this purpose, carboxypeptidases (e.g., carboxypeptidase Y) are used. Usually, several different carboxypeptidases have to be applied to cover the whole sequence because most of them exhibit preferences to release certain residues out of the chain. The N-terminal information is obtained similarly through treatment with aminopeptidases or controlled Edman degradation. Analysis of the products is performed on reflectron TOF instruments or with electrospray ionization (ESI) MS. PSD MALDI provides a very sensitive alternative analysis format.

Modification Analysis

The analysis of posttranslational modifications (PTMs) of peptides and proteins, such as phosphorylation and glycosylation, is important to elucidate the functions and interactions of peptides and proteins. The initial steps to analyze PTMs are similar to those performed for structural analysis. In fact, following the initial purification step, the material will usually be fractionated for structural and modification analyses.

A straightforward method for the analysis of peptide and protein phosphorylation is to generate short peptide fragments and to compare mass spectra recorded before and after treatment with phosphatases. Residues that are potential phosphorylation sites are: serine, threonine, and thyrosine. Antibodies, specific to the phosphorylated form of the protein, provide a convenient tool for purification.

The analysis of glycosylation can be performed through treatment with residue-specific glycosidases. Similar to phosphoproteins, glycoproteins can be specifically purified via affinity chromatography. The residues that are usually potential glycosylation sites are serine, asparagine, and threonine. To release *N*-linked carbohydrate chains from glycopeptides, endoglycosidases (mainly peptide *N*-glycosidase F, PNGase F) are used. In addition, chemical reagents such as trifluoromethanesulfonic acid can be used. *O*-linked carbohydrate chains are released via reductive β-elimination (through $NaBH_4$ treatment). Comparative analysis of tryptic digests before and after treatment is used to identify the extent of the glycosilation and to identify the glycosilation sites. The structural characterization of carbohydrate site chains is a complex undertaking. Partially, it can be achieved through mass measurement of the isolated carbohydrate

Table 2 Overview on common covalent posttranslational modifications

Modification	Amino acid residue	Function	Δm
Phosphorylation	Tyr, Ser, Thr	Reversible activity regulation	+80
Glycosylation	Asn, Ser, Thr	Cell–cell recognition, molecular targeting	*N*-linked: >800; *O*-linked: +203, >800
Acylation	Cys, N-terminal Gly	Cellular localization, membrane anchoring	Farnesyl: +204, myristoyl: +210, palmitoyl: +238
Acetylation	Lys, N-terminus	Modulation of protein–DNA interaction and protein stability	+42
Hydroxylation	Pro, Lys	Modulation of protein stability and interactions (collagen triple helix formation)	+16
Carboxylation	Glu, Asp	Ca^{2+} storage, prothrombin clotting	+44
Sulfation	Tyr	Modulation of protein–protein interactions	+80
Proteolytic cleavage	Various	Activation/deactivation	—
Ubiquitination		Degradation signal	>1000
GPI anchor	C-terminus	Membrane anchoring	>1000
C-terminal amidation	C-terminus	Activity modulation	−1

Amino acid abbreviations are standard symbols. Δm is mass difference associated with the modification (in daltons).

component and subsequent database searches (e.g., http://us.expasy.org/tools/glycomod/). In addition, sequential exoglycosidase treatments can be used to release individual residues from complex carbohydrate chains to identify the structure. A detailed discussion on all techniques used to investigate the structural composition of complex carbohydrates is beyond the scope of this contribution.

Other posttranslational modifications occurring (such as acetylation, acylation, carboxylation, methylation, etc.) cannot be discussed in sufficient detail in the scope of this contribution. Table 2 provides an overview of common PTMs and their function, as well as associated changes in mass. For a review, the reader is referred to the scientific literature.[8]

APPLICATIONS IN GENOMICS

The main application of MALDI-TOF MS for DNA analysis today is in the field of SNP analysis and the quality control of oligonucleotide synthesis. Applications for resequencing, gene expression analysis, and haplotyping have been reported and are of increasing importance. In addition, the analysis of methylation patterns (imprinting) is a growing field of interest. In general, the analysis of nucleic acids with MALDI-TOF is more cumbersome than that of proteins and consequently less widespread. For a more detailed information on SNP and sequence analysis with MALDI-TOF MS, the reader is referred to the respective chapters in this encyclopedia and the scientific literature.[9]

CONCLUSION

MALDI-TOF MS provides a superior detection format for qualitative and quantitative analyses of all main classes of biomolecules and their modifications.

Marfan Syndrome and Related Fibrillinopathies

M

Gwenaëlle Collod-Béroud
Catherine Boileau
Université Paris V, Hôpital Necker-Enfants Malades, Paris, France

INTRODUCTION

Marfan syndrome (MFS; OMIM no. 154700) is the founding member of connective tissue disorders. It is autosomal dominant and has an estimated incidence of 1 in 5000 with probably over 25% of sporadic cases. The syndrome involves many systems (skeletal, ocular, cardiovascular, pulmonary, skin and integumentary, and dural), but its more prominent manifestations are skeletal, ocular, and cardiovascular. It is characterized by extreme variability in phenotype severity between different affected members of a given family. At least two genes are implicated in MFS: in the majority of cases, mutations in *FBN1*, the gene encoding fibrillin-1 (the major component of microfibrils), are implicated. Linkage analyses have localized a second gene in 3p24.2–p25. Because no specific clinical anomaly is associated with mutations in each gene, both must be tested for molecular diagnosis.

CLINICAL DEFINITION

In 1986, an international group of experts agreed on diagnostic criteria to distinguish classical MFS from many related disorders. These criteria constitute what is currently referred to as the ''Berlin nosology.''[1] Patients are diagnosed based on the involvement of the skeletal system and two other systems with at least one major manifestation (ectopia lentis, aortic dilation/dissection, or dural ectasia). Patients with an affected first-degree relative are required to have involvement of at least two other systems, with one major manifestation preferred but not required. This nosology has been revised in 1996 and referred to as the ''Ghent nosology.''[2] This new formulation requires involvement of three systems with two major diagnostic manifestations. It provides for major skeletal manifestations and considers affected first-degree relatives or molecular data as major diagnostic criteria.

MFS AND *FBN1*

In 1986, Sakai et al.[3] identified a new extracellular matrix protein, which they named ''fibrillin'' (OMIM no. 134797). This protein is the major component of microfibrils, which are structures found in the extracellular matrix either as isolated aggregates or closely associated with elastin fibers. Ultrastructurally, microfibrils display a typical ''beads-on-a-string'' appearance consisting of a long series of globules connected by multiple filaments. In 1990, Hollister et al.,[4] using a monoclonal antibody against fibrillin, reported abnormalities of the microfibrillar system in MFS. Kainulainen et al.[5] demonstrated through linkage analysis that the gene involved in classical complete forms of the MFS was located on human chromosome 15. The gene encoding fibrillin-1 (*FBN1*) was cloned and located in 15q15–q21.1,[6,7] and the first mutations in the gene were identified in MFS patients.[8]

FBN1 GENE

The gene encoding type 1 fibrillin (*FBN1*) is very large (over 230 kb) and is highly fragmented into 65 exons, transcribed in a 10-kb mRNA that encodes a 2871-amino acid protein.[7,9] Three additional alternatively spliced exons, most likely untranslated and well conserved between humans, mice, and porcine, were found upstream of exon 1. This region is GC-rich, contains a CpG island, and lacks conventional TATA or CCAAT boxes.[10]

The deduced primary structure reveals a highly repetitive protein that contains essentially three repeated modules:

- *EGF-like module*, which is homologous to the one found in the epidermal growth factor. These modules contain six cysteine residues that form three intradomain disulfide bonds. There are 47 of these throughout the fibrillin-1 protein. Among these, 43 contain a conserved consensus sequence for calcium binding and are called cb EGF-like modules. The presence of calcium ions significantly protects full-length or recombinant fragments of fibrillin-1 from proteolysis by trypsin, elastase, endoproteinase Glu-C, plasmin, and matrix metalloproteinases.[11]
- *Transforming growth factor (TGF) β1-binding protein-like module* (TGF β1-BP-like module), which is found seven times interspaced with cb EGF-like in the

DOI: 10.1081/E-EDGP 120020607

protein and is homologous to modules found in the TGF-β1 binding protein. This domain appears to be limited to proteins that localize to matrix fibrils [fibrillins and latent TGF β-binding proteins (LTBPs)]. These modules contain eight cysteine residues. No specific function has yet been ascribed to these modules. However, some evidence suggest that these domains mediate specific protein–protein interactions.[12]

- *Hybrid module*, which combines features of the former two. This consists of approximately 65 amino acids, and is found twice in the protein. This module is also found in LTBPs, which have a single hybrid domain.

Finally, the protein contains three unique regions: a *proline-rich region* that may act as a ''hingelike'' region[13] and the *amino* and *carboxy terminal domains*. The N-terminal and C-terminal domains of fibrillin display two prominent features: the presence of an even number of cysteine residues (four in the N-terminal and two in the C-terminal domains) and the presence of the basic consensus sequence for processing by furin-type enzymes BXBB (B=basic amino acid residue, K or R) in each domain. The four-cysteine domain in the N-terminus of fibrillin is homologous to similar four-cysteine domains in the N-terminal extended forms of the LTBPs. The C-terminal domain of fibrillin is homologous to the C-terminal domain of all four members of the fibulin family; thus a new type of extracellular module of approximately 120 amino acid residues in length has been proposed.[14] This type of homology is not shared by LTBPs.

Other members of the fibrillin family were identified: *FBN2* gene in 5q23–q31 (fibrillin-2 protein) carrying mutations in congenital contractural arachnodactyly (CCA) (OMIM no. 120150); and *FBNL* gene (or *EFEMP1* gene) in 2p16 (fibrillin-like protein) carrying mutations in Doyne honeycomb retinal dystrophy (DHRD; OMIM no. 126600) or malattia Leventinese (MLVT).

FIBRILLIN PROTEINS

Fibrillins are extracellular matrix glycoproteins that show a wide distribution in both elastic and nonelastic tissues and are integral components of 10-nm-diameter microfibrils. Fibrillin-1 is synthesized as profibrillin and is proteolytically processed to fibrillin. Wild-type profibrillin is not incorporated into extracellular matrix until it is converted to fibrillin. The N-terminal region of each protein directs the formation of homodimers within a few hours after secretion, and disulphide bonds stabilize the interaction.[15] Dimer formation occurs intracellularly, suggesting that the process of fibrillin aggregation is initiated early after biosynthesis of the molecules. Fibrillin is posttranslationally modified by β-hydroxylation and N-linked and O-linked carbohydrate formation.[16] Baldock et al.[17] predicted fibrillin maturation from a parallel head-to-tail alignment. This model accounts for all microfibril structural features, suggests that intermolecular and intramolecular interactions drive conformation changes to form extensible microfibrils, and defines the number of molecules in cross section.

Fibrillin-1 and fibrillin-2 codistribute in elastic and nonelastic connective tissues of the developing embryo, with a preferential accumulation of the *FBN2* gene product in elastic fiber-rich matrices. Mouse study of the developmental expression of fibrillin genes has revealed different patterns. Except for the cardiovascular system, in which *Fbn1* gene activity is early and always higher than *Fbn2*, *Fbn2* transcripts appear earlier than *Fbn1* transcripts and accumulate for a short period of time just before overt tissue differentiation (i.e., a window of time immediately preceding elastogenesis). In contrast, the amount of *Fbn1* transcripts increases at an apparently gradual rate throughout morphogenesis and is mainly expressed during late morphogenesis and well-defined organ structures. Furthermore, *Fbn1* transcripts are predominantly represented in stress-bearing and load-bearing structures such as aortic adventitia, suspensory ligament of the lens, and skin. Thus spatio-temporal patterns of gene expression suggest distinct but related roles in microfibril physiology. Fibrillin-1 would provide mostly force-bearing structural support, whereas fibrillin-2 would predominantly regulate the early process of elastic fiber assembly.[18] Fibrillins could contribute to the structural and functional heterogeneities of microfibrils.

FIBRILLINOPATHIES

To date, over 600 mutations have been identified in the *FBN1* gene in MFS patients and related diseases[19] (http://www.umd.be). *FBN1* gene mutations have been identified in complete and incomplete forms of MFS, but also in various overlapping disorders: severe neonatal MFS, dominantly inherited ectopia lentis, isolated skeletal features of MFS, Shprintzen–Goldberg syndrome, Weil–Marchesani syndrome, and familial or isolated forms of aortic aneurysms. These results define the new molecular group of ''type 1 fibrillinopathies.''

PATHOGENIC MECHANISMS

Microfibrils are suggested to determine the form and the orientation of elastic fibers, thus directing fiber assembly as a scaffold on which elastin is deposited.[18] This model explains the typical fragmentation and disarray of elastic fibers observed in the media of Marfan patients. However,

unlike elastin, fibrillin-1 is also highly expressed in the vascular adventitia. Therefore reduction of this protein in the adventia is very likely also involved in the mechanism for dilatation and for increased risk of aneurysm because the role of the adventia is to maintain the vascular diameter. The pleiotropic manifestations of the disease can be explained by the observation that numerous microfibrillar aggregates devoid of elastin are found in the zonule, as well as cartilage and the extracellular matrix of many organs. However, the actual pathogenic mechanisms in these tissues still remain speculative.

At the molecular level, two different groups of mutations are distinguishable: mutations leading to a shortened protein and missense mutations. The first group corresponds to one third of the mutations. They can be responsible for: 1) the appearance of a premature stop codon that reduces the stability of the mutant transcript and, consequently, greatly reduces protein production from the mutated copy of the gene (in the affected subjects, the amount of fibrillin-1 protein produced is 50% that of normal and is produced only from the normal gene copy), or, 2) the production from the mutated copy of an abnormal monomer that considerably interferes with the assembly (polymerization) of fibrillin molecules (the amount of fibrillin is greatly reduced, <35%). The second group represent two thirds of mutations and corresponds to missense mutation. Among them, three quarters are located in calcium-binding modules. They are implicated either in creating or substituting cysteine residues potentially implicated in disulfide bonding and, consequently, in the correct folding of the monomer. The majority of remaining mutations of this type of module affect residues of the calcium consensus sequence that playa major role in defining interdomain linkage. An increased protease susceptibility is a mechanism also suggested for missense mutations. Other modules are carriers of one quarter of missense mutations and pathological mechanisms have yet to be clearly demonstrated.

What is still unknown are the multiple consequences triggered by the various mutations and the effects of unknown modifier (enhancing or protecting) genes on clinical expression. These mechanisms and the great number of mutations identified in the *FBN1* gene explain the great variability of the disease observed not only between families but also among affected individuals in a single family.

GENETIC HETEROGENEITY

The clinical variability of MFS is only partly explained by the great number of mutations identified in the *FBN1* gene. In effect, we have demonstrated the existence of genetic heterogeneity (i.e., the involvement) in certain cases of MFS of mutations located in another gene named *MFS2* (for MFS type 2) through the study of a very large French family in which affected individuals display an incomplete form of the syndrome: typical skeletal and cardiovascular features as well as involvement of the skin and integument. No ocular manifestations were observed until one of the children in the fourth generation developed ectopia lentis. We showed that fibrillin-1 was normal in several affected family members and excluded linkage between the *FBN1* gene and the disease in the family.[20] By exclusion mapping, we located the *MFS2* gene on the short arm of chromosome 3.[21] We are now identifying *MFS2* through positional cloning. Several families comparable to the French family in that they are not linked to, or do not carry, a mutation in the *FBN1* gene have been identified. Other teams, through protein studies, have identified between 7% and 16% of MFS patients with normal fibrillin metabolism.[22,23] The precise determination of this percentage is important for laboratories involved in the diagnosis of MFS because it will give the risk associated with investigation of only the *FBN1* gene.

DIAGNOSTICS

The discovery of the involvement of fibrillin-1 has raised high hopes for a protein or DNA test applicable to MFS patients. Immunofluorescence studies of cultured fibroblasts and skin sections of patients using monoclonal antibodies against fibrillin have revealed that the amount of fibrillin deposition or fibrillin microfibrils is greatly reduced.[4] Therefore immunofluorescence analysis could be helpful in diagnosis. However, the method has proven to be insufficiently sensitive and specific because of the existence of non-MFS type 1 fibrillinopathies and genetic heterogeneity. Therefore an abnormal test result does not diagnose MFS, and a normal test result does not rule out MFS.

The identification of the *FBN1* gene has allowed the development of two types of diagnostic tests: genetic family studies or mutation identification. Family studies can be performed with specific *FBN1* polymorphic markers to identify the mutation-bearing haplotype.[24] These studies are only reliable in families in which several affected individuals are available because the involvement of an *FBN1* mutation (and not that of another gene) must be clearly demonstrated. However, most family structures do not comply with this requirement. Furthermore, the method is inappropriate in sporadic cases. In practice, these instances represent over 40% of the cases referred for biological diagnosis. The second molecular test is mutation identification. Mutation identification is very costly and long. In effect, there is no quick and 100% reliable method to investigate a large ($\sim$230 kb) and highly fragmented (10 kb of coding sequence fragmented

in 65 exons) gene, knowing that almost each family has its own specific defects and that the mutations are essentially point mutations. Finally, this very costly analysis may fail to identify a mutation because only the coding sequence and closely surrounding regions are investigated. However, in the case of neonatal MFS, where a clustering of mutations is found in exons 24–32, molecular diagnosis can be performed. In all other instances and until better molecular tools are available, mutation identification cannot be performed on a systematic basis. However, in a few cases where family mutation had been identified, it was possible to perform prenatal diagnosis on chorionic villus samples, or to offer presymptomatic diagnosis in children of affected subjects who are at risk.

CONCLUSION

Although no specific therapy exists for MFS, it is of great importance to confirm or firmly exclude the diagnosis in family members at risk as early as possible because of the potential fatal complications of the disease. Development of preventive measures, and surgery for aortic aneurysms and dissection have led to treatments of life-threatening cardiovascular complications associated with MFS and have considerably altered life expectancy for patients. At present, diagnosis is still based on thorough clinical examination, including measurements of body proportions, echocardiography of the aorta, slit-lamp ophthalmological evaluation, and radiographs. A complete family history is also an essential part of the diagnosis. However, in some cases, the manifestations are not evident until adolescence and the clinical expression of the disease varies greatly between affected members of a single family. Therefore there is an absolute need for an accurate diagnostic test.

Mass Spectrometric Genotyping of Single Nucleotide Polymorphisms

Christian Jurinke
Dirk van den Boom
SEQUENOM, Inc., San Diego, California, U.S.A.

INTRODUCTION

Single nucleotide polymorphisms (SNPs) are biallelic single-base changes with a minor-allele frequency of at least 1%. Genotyping of SNPs has become of increasing importance to elucidate the interindividual differences in populations and to investigate the genetic foundations of major common diseases.

Matrix-assisted laser desorption/ionization (MALDI) time-of-flight (TOF) mass spectrometry (MS) has become a powerful tool for the analysis of biomolecules in the past decades. Besides its earlier focus nearly entirely on peptide and protein analysis, MALDI-TOF MS is more widely used today for the investigation of queries related to the structure and function of genes and genomes.

SNP GENOTYPING

Single nucleotide polymorphisms provide powerful markers for genetic analysis. Their high-frequent abundance within genomes, especially their presence within coding regions of genes, discriminates them from markers used earlier (e.g., microsatellites). Single nucleotide polymorphisms are not merely markers but can also be the causative agent for diseases on a genetic level. In addition, the biallelic nature of SNPs makes them easier to analyze and the corresponding analytical procedures more amenable to automation, enabling large-scale whole-genome studies. These properties contributed to the unprecedented success of SNP markers in many genetic studies. For more details on the nature of SNPs and typing methods the reader is referred to the respective chapters in this encyclopedia.

MALDI-TOF MASS SPECTROMETRY

MALDI-TOF MS basically relies on the laser-induced desorption of large molecules that are cocrystallized with an excess of matrix substance. The so-called matrix absorbs laser energy and evaporates into the vacuum of the mass spectrometer. The analyte molecules are co-desorbed with the matrix and ionized by proton transfer. Molecules are accelerated in an electric field and their flight time is measured following their impact on a secondary electron multiplier. The advantages for using MALDI-TOF for the analysis of DNA molecules are that no surrogates (e.g., labels) are detected but an intrinsic property of the analyte molecule (the molecular mass) is used for the identification. The analysis time is in the range of seconds for any given assay. The data analysis is completely automated and straightforward.

For more details on the principles and applications of MALDI-TOF MS to proteomics the reader is referred to the respective chapters in this encyclopedia.

MALDI-TOF MS FOR SNP GENOTYPING

Nucleic acids are more difficult to analyze under MALDI conditions than peptides, which had limited its application in this field. Because of their negatively charged phosphate backbone nucleic acids are susceptible to adduct formation. They form salt adducts with cations present in the surrounding medium (e.g., buffers). Adduct formation results in a broader distribution of the signal. For example, sodium ions attached to the analyte will cause an additional signal with a mass of plus 22 Da (23 for sodium minus 1 for an exchanged hydrogen). Consequently, adduct formation lowers sensitivity and analytical accuracy. In addition to strong adduct formation, nucleic acids also tend to fragment under MALDI conditions.

The main reaction contributing to DNA fragmentation under MALDI conditions is depurination. Depurination occurs through protonation of the nucleobases A or G (at position N7). The protonation induces polarization of the *N*-glycosidic bond between sugar and nucleobase. The result is nucleobase elimination. Subsequent to depurination reactions, further fragmentation occurs via backbone cleavage.

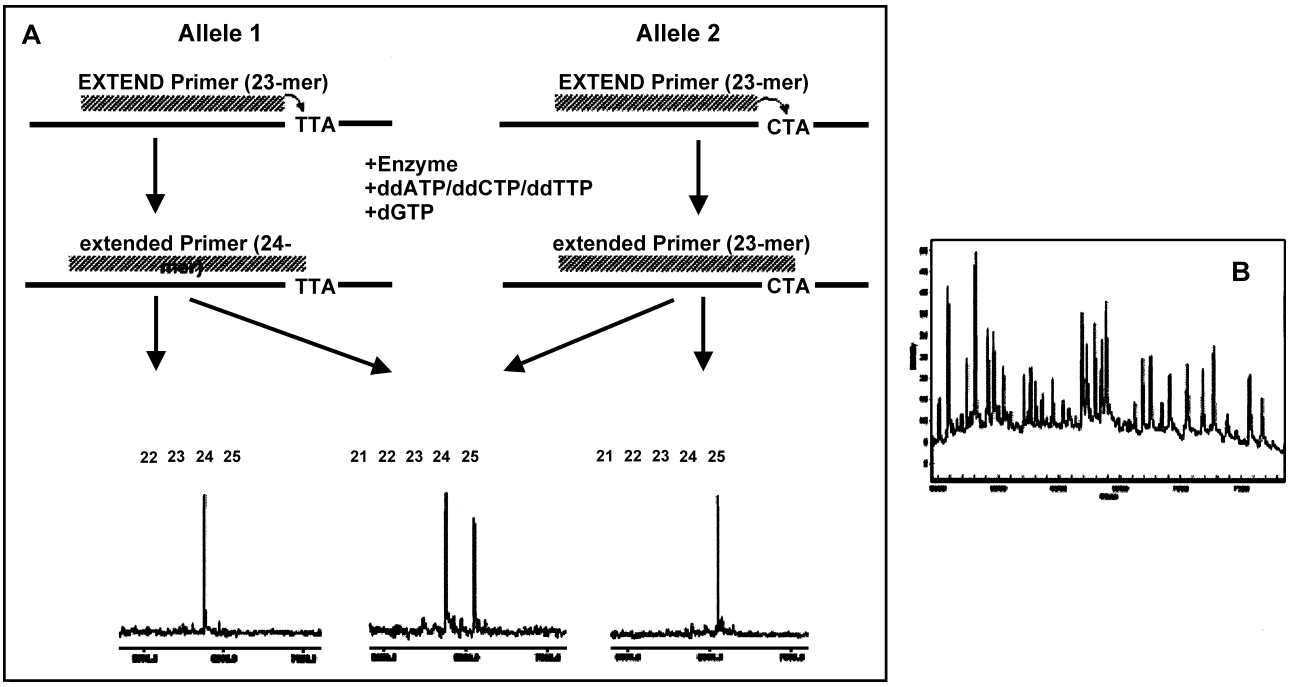

Fig. 1 Box A illustrates the MassEXTEND® primer extension concept for SNP genotyping. Spectra derived from a uniplex reaction are displayed for both homozygote cases and the heterozygote condition. Box B provides raw data for a highly multiplexed reaction for SNP genotyping following the same schema as outlined in A but employing multiple PCR and MassEXTEND® primer in one reaction vessel.

The availability of favorable matrices for DNA analysis is an important factor for the success of MALDI-TOF MS in the field of DNA analysis. Especially, the introduction of 3-hydroxypicolinic acid (3-HPA) as matrix[1] is a cornerstone in this respect.

The most predominant method used for MALDI-TOF MS-based SNP genotyping relies on primer extension concepts—the so-called MassEXTEND® assay.[2] MassEXTEND® assays combine primer extension with MALDI-TOF MS. The assay consists of a post-PCR primer extension reaction that is carried out in the presence of one or more dideoxynucleotides (ddNTPs) generating allele-specific terminated extension products. Primers are designed to anneal adjacent to the SNPs of interest. Depending on the SNP identity, extension products of different lengths and masses are generated. In the case of heterozygosity, two products with distinguishable mass are generated. Following PCR amplification, shrimp alkaline phosphatase (SAP) is added to dephosphorylate remaining dNTPs from the PCR cocktail. The samples are diluted with water and cation exchange beads (NH_4^+ form) are added and the supernatant is used for MALDI-TOF MS analysis. A schematic representation of this reaction is presented in Fig. 1. Other approaches for MALDI-TOF-based genotyping include the so-called invader[3] and GOOD[4] assays.

Multiplexing

Performing multiple PCR and extension reactions in a single well (i.e., multiplexing) is a way to increase the throughput and to reduce the effective cost per genotype. In other words, assays for different SNPs can be combined in a single reaction to save time, reagents, and to preserve DNA samples. MALDI-TOF MS provides the high resolution, high accuracy, and wide mass range needed to perform highly multiplexed genotyping assays.

To design SNP assays for multiplexing, several considerations must be taken. Among those:

1. Primers for the PCR amplification reactions must be designed in a way to avoid cross-loci amplification. In addition, PCR primer designs should have the following properties: 1) optimal primer length (20 mer); 2) optimal T_m (60°C); 3) optimal G-C content (50%); and 4) optimal amplicon length ($\sim$100 bp). Potential primers should be blasted against public databases to avoid individual assay failures due to competing kinetics or cross-hybridization.

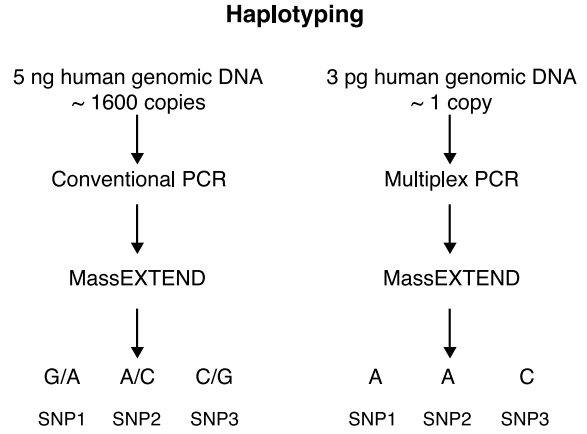

Fig. 2 The differences between molecular haplotyping and genotyping methods are exemplified and illustrated in this graph. The main difference is the use of dilutions of genomic DNA down to a level where statistically only one molecule is present in the sample.

2. Primers for the MassEXTEND® reaction must be designed so the combination of expected peak masses are resolvable for unambiguous genotyping. For the MassEXTEND® primer design there are two choices available as either site adjacent to the SNP can be used. The following should be considered: 1) optimal length (17–24 mer); 2) primers may not contain uncertain bases in the target sequence; 3) primers with low T_m should be disregarded because of hairpin formation, false priming, and primer–dimer potential; 4) problematic sequence repeats such as GGGG should be avoided; and 5) potential mass conflicts with by-products (e.g., depurination products and possible extend-pausing products) need to be avoided. For example, a MassEXTEND® primer prematurely terminated with dA would have exactly the same mass as if normally terminated with ddG.

A 12- to 15-fold multiplex assay can be routinely carried out and 20–30-fold plexing levels may be achievable with assay optimization. The 15-fold multiplexing with ~1 hr acquisition/real-time analysis of 384 elements translates into an analytical speed of ~100 genotypes per minute (or 5760 genotypes/hr). This throughput coupled with a cost/genotype of currently below 10¢ renders whole-genome scans studies feasible and affordable.

Haplotyping

Haplotypes are combinations of phase-determined genetic markers. Their unambiguous identification provides additional statistical power for detecting genes involved in common diseases. One approach that can be directly translated to the above-described MALDI-TOF platforms employs multiple short PCR reactions spanning several kilobases which are amplified from a genomic DNA template that is diluted down to the single molecule level. A subsequent multiplex primer extension reaction delivers the genotypes for the targeted SNPs. This approach has successfully been used to haplotype markers that are separated over 24 kb.[5] The process is outlined in Fig. 2.

QUANTITATIVE ANALYSIS OF SNPs IN DNA POOLS

Genotyping thousands of SNPs over hundreds to thousands of individuals still remains cost intensive. Pooling DNA samples from case and control populations has therefore been proposed as an alternative to individually genotyping populations for association studies.[6] The analysis of allele frequency distributions in pools of individual DNA samples is a tool to study the abundance of particular alleles in populations and to compare these between different populations. This information can be used to identify causative genetic loci associated with complex diseases via linkage disequilibrium between two or more loci.

Relative quantitation of allele frequencies with MALDI-TOF MS is achieved by calculating the areas of peaks associated with specific primer extension products. Peak characteristics (such as intensity, etc.) are generally stored when spectra are acquired on the MALDI-TOF MS. The area calculations can be conducted by a mathematical

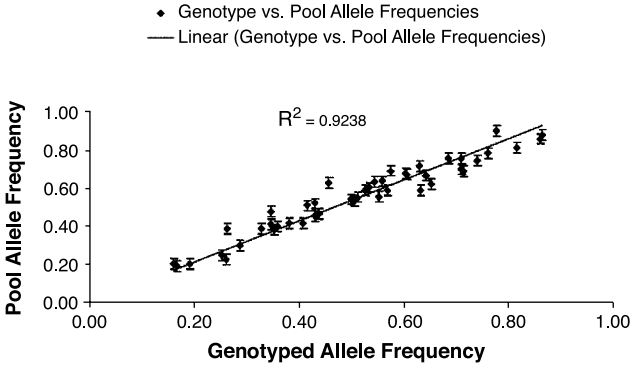

Fig. 3 The scatter plot represents quantitative results derived from a comparison of data for multiple SNPs resulting from genotyping of individual DNA samples and ''allelotyping'' of a pool of the respective individual DNAs.

method of choice. Today, software is available to automatically perform the peak area calculations in real time, during the measurement. The allele frequency of a particular SNP is calculated as the ratio of the area of each allele to the total summed area of both alleles. The sum of the two alleles is always 1. Allele frequencies down to 5% can be accurately discerned using MALDI-TOF MS in DNA pools. Frequencies below 5% are routinely detected but their accuracy must be approached with caution because of the small peak area associated with a minor allele at a 50:1 ratio relative to the major allele.

MALDI-TOF MS measurement of primer extension reactions has been found to be at least as sensitive and reproducible as other available technologies based on several studies. Figure 3 is a scatter plot with allele frequencies determined for 48 assays in a DNA pool of 96 individuals vs. the observed frequency based on the genotype for all 96 individual samples for each of the 48 assays. As can be seen from the coefficient of determination (R^2) there is not a perfect 1:1 correlation between the allele frequencies calculated from a pool of individuals and the actual frequency determined by genotyping. Several factors contribute to this difference independent of the technology used. However, a ''correction'' factor can be applied for each individual assay based on the peak areas observed for individual heterozygous samples from the population under investigation. Individual heterozygotes have two alleles at a 1:1 ratio for any given biallelic SNP. Based on this, the peak areas observed for each allele on the MALDI-TOF MS should be equal. If they are not, then a ''skewing'' of one allele over the other has occurred at some point in the process (whether it be at the level of PCR, EXTEND, or analyte ionization during MALDI-TOF or at some other point). This bias can be quantified on the MALDI-TOF MS and corrected for. This correction factor has already been applied to generate the plot in Fig. 3. The precision of this method is sufficient for many semiquantitative applications such as the comparison of SNP allele frequency in nucleic acid pools or the differential protein–DNA binding associated with allelic variants of a gene.

CONCLUSION

MALDI-TOF MS as a detection format provides accuracy, throughput, and semiquantitative capabilities for the analysis of SNPs in individual and pooled DNA samples. Furthermore, it provides the means for generating haplotype information. The application of MALDI-TOF MS to the analysis of genes and genomes will be an important tool for future research projects.

INTRODUCTION

Mast cells (MCs) are tissue-fixed hematopoietic cells that store numerous vasoactive and immunoregulatory mediators.[1] A complex network of cytokines is involved in the regulation of growth and differentiation of MCs.[1] A most important growth factor for MCs appears to be stem cell factor (SCF). Notably, SCF induces the development of MCs from uncommitted $CD34^+$ progenitors.[2] The effects of SCF on MCs and MC progenitors are mediated through c-kit, a tyrosine kinase receptor for SCF encoded by the c-*kit* proto-oncogene.

Systemic mastocytosis (SM) is a clonal disease leading to pathological accumulation of MCs in the bone marrow (BM) and other internal organs.[3] In a high proportion of cases, point mutations in the c-*kit* gene are detectable.[3–5] The most frequent mutation leads to substitution of valine by aspartate at codon 816 (D816V). This mutation is associated with constitutive activation of c-kit and is considered to play a critical role in the pathogenesis of SM.[5,6] However, the clinical picture in SM is variable, ranging from asymptomatic to highly aggressive courses.[3] Therefore, apart from this mutation, several other factors may influence the clinical course in these patients. The current article provides a short overview on c-kit mutation D816V in SM, with special reference to the application of this molecular defect in the diagnostic workup and staging of SM patients.

CLINICAL ASPECTS OF MASTOCYTOSIS

Based on clinical findings, four major types of SM have been defined by the World Health Organization (WHO): indolent systemic mastocytosis (ISM), SM with an associated clonal hematological non-MC lineage disease (SM-AHNMD), aggressive systemic mastocytosis (ASM), and mast cell leukemia (MCL).[3] In patients with ASM and MCL, significant organopathy caused by MC infiltration is found.[3] The organ systems most frequently affected are the BM, skeletal system, liver, and gastrointestinal tract. In some cases, eosinophilia and lymphadenopathy are prominent clinical features.[7] Mast cell leukemia is a rare form of SM characterized by progressive organopathy, circulating MCs, and short survival.[3,8]

So far, no curative therapy for ASM or MCL has become available. Some patients may benefit from interferon-α (IFN-α), glucocorticoids, or cladribine.[8] However, in most cases, treatment responses are only short-lived. Therefore, a number of attempts are currently made to identify molecular targets and novel effective

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120023680

drugs that interfere with neoplastic cell growth in ASM and MCL.

PATHOLOGY OF SM AND PHENOTYPE OF NEOPLASTIC MCs

The pathological hallmark in SM is the multifocal dense infiltrate of MCs in the BM (or/and other visceral organs).[9] Other typical features of SM include BM fibrosis,[9] increased BM angiogenesis,[10] and tissue and blood eosinophilia.[7,11] Recent data suggest that neoplastic MCs express several angiogenic and fibrogenic mediators such as vascular endothelial growth factor (VEGF), tryptase, or bFGF.[10] Other data suggest that several surface molecules such as CD2 or CD25 are overexpressed in MCs in patients with SM compared to normal MCs.[12,13] However, little is known about the regulation of expression of these molecules in neoplastic MCs. An attractive hypothesis is that the c-kit mutation D816V is involved in the regulation of expression of such genes.

SIGNAL TRANSDUCTION PATHWAYS ACTIVATED BY THE c-Kit RECEPTOR

The c-kit receptor is a glycoprotein of 145 kDa and belongs to the type III class of the receptor tyrosine kinase family.[14] c-Kit contains five immunoglobulin-like domains in its extracellular portion and an inter-kinase sequence that splits the intracytoplasmic domain into the ATP-binding domain and the phosphotransferase domain (Fig. 1).[15] Binding of SCF to c-kit leads to receptor dimerization and autophosphorylation of tyrosine residues in the cytoplasmic domain. As a consequence, c-kit activates a number of signal transduction pathways.[16] Especially the activation of PI3 kinase has been shown to contribute to important c-kit-dependent cellular functions such as proliferation, survival, or adhesion.[17,18] Apart from PI3 kinase, c-kit also leads to activation of Ras and MAP kinases.[16,19] Other signaling pathways reportedly activated by c-kit include JAK2, STAT family members,[20] as well as members of the Src family.[16]

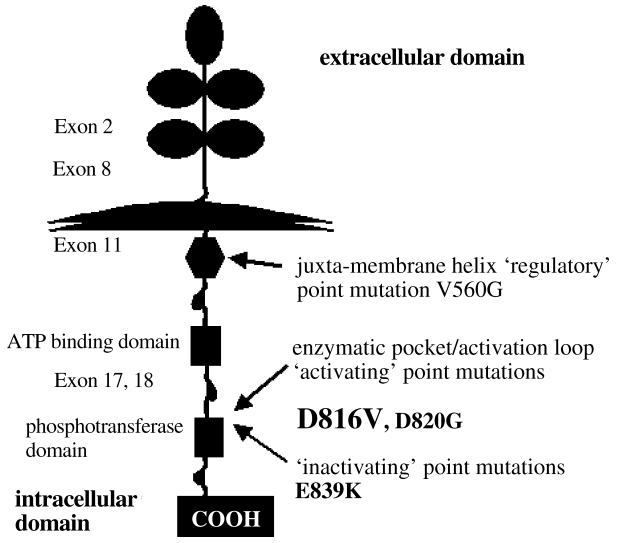

Fig. 1 Structure of c-kit receptor and localization of mutations. The c-kit receptor is composed of extracellular and intracellular domains. The most common mutation in c-kit, D816V, is located in the activation loop at the entrance to the enzymatic pocket of the c-kit kinase.

THE c-Kit MUTATION D816V AND ITS ROLE IN THE PATHOGENESIS OF SM

D816V is a point mutation in the c-kit codon 816 that leads to substitution of valine by aspartate and affects the activation loop at the entrance to the enzymatic pocket of the c-kit kinase (Fig. 1).[5] c-Kit D816V exhibits constitutive tyrosine kinase activity and leads to cytokine-independent growth of MCs.[21] Moreover, c-kit D814V (the murine homologue of D816V) transforms factor-dependent cell lines to growth factor independence and acts oncogenically in mice.[21] However, the exact mechanisms by which D816V leads to constitutive activation of c-kit are unknown. A number of previous and more recent studies support the notion that D816V alters several features of the c-kit receptor including dimerization and signaling.[21,22] One important mechanism appears to be an alteration in the activation of signal transduction pathways. Thus, recent data suggest that the signaling pathways activated by wild-type (WT) c-kit (in the presence of the c-kit ligand SCF) differ from the signaling pathways (constitutively) activated by c-kit D816V.[23] As a consequence, c-kit D816V may modulate the expression of molecules that are critical for transformation, although the identity of these genes remains largely unknown.

METHODS FOR DETECTION OF THE c-Kit MUTATION D816V

Several methods for the detection of c-kit mutations have been reported. The standard procedure for detection of c-kit D816V is restriction fragment length polymorphism (RFLP; Fig. 2).[24] In addition, direct sequencing of the c-*kit* gene can be performed[6] and may reveal additional c-kit mutations (apart from D816V). Recently, a novel

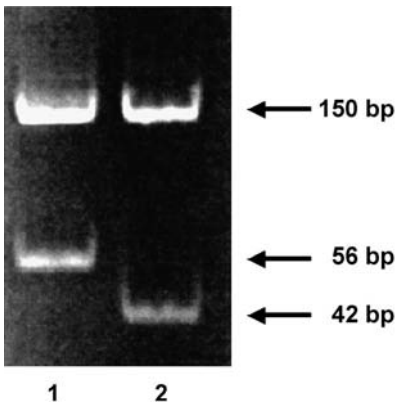

Fig. 2 RFLP analysis of c-kit. After amplification of the mutation-containing region of the c-kit cDNA, PCR products were digested with *Hin*fI and analyzed by electrophoresis on a polyacrylamide gel. Compared to WT c-kit (1), the c-kit D816V mutation (2) generates a second restriction site for the endonuclease *Hin*fI within the amplified region. Predicted sizes for the WT sequence are 150 and 56 bp, and are 150, 42, and 14 bp for the mutated sequence.

approach combining peptide nucleic acid-mediated polymerase chain reaction (PCR) clamping and detection of c-kit mutations with hybridization probes has been described.[25] The major advantage of this method is that the mutant allele is amplified selectively and can be detected in case of a more than 1000-fold excess of WT over mutated c-kit. In addition, sequence variations other than the D816V c-kit mutation can be detected within the region covered by the probes. However, all these techniques are not sufficient to identify the cell type (MCs vs. other cells in tissues or blood) in which the mutation is present. To address this subject, isolation of the cell type(s) of interest is required. One possible approach is to collect immunohistochemically defined subpopulations of cells from stained tissue sections by microdissection.[24] An alternative strategy is sorting of cell subpopulation from BM or peripheral blood (PB) by flow cytometry.[26] Using these techniques, even single cells can be isolated and analyzed for c-kit D816V.[24,26] However, these techniques are not used in the routine workup of patients with (suspected) SM. Rather, RFLP analysis of D816V is considered to be appropriate and sufficient for routine diagnostic purposes.

DETECTION OF c-Kit D816V IN VARIOUS SUBTYPES OF MASTOCYTOSIS

Detection of the D816V mutation in an extracutaneous organ is a minor criterion for the diagnosis of SM (SM criterion).[3] In the presence of other (i.e., one major or two minor) SM criteria, the final diagnosis SM can be established[3] (Table 1). Patients with cutaneous mastocytosis (CM) may also exhibit D816V (in their skin or even in BM), but other criteria for SM are not fulfilled.

In the diagnostic workup of suspected SM, analysis for the D816V mutation is routinely performed on BM and PB samples.[3–5,27] However, because SM can involve virtually all organs, the D816V mutation may be detected not only in BM and PB cells but also in other tissues such as the skin, liver, or gastrointestinal tract.[25] For most patients, it is recommended to isolate mononuclear cells (MNCs) from the BM and PB to seek for the c-kit mutation D816V.[3,27] Although c-kit D816V is detectable in BM MNC in the majority of all patients with ISM by RFLP, the organs affected and the distribution of the mutation in various hematopoietic cell lineages vary among patients.[3] In typical ISM, D816V is usually detectable in the BM, but not in unfractionated PB MNCs. By contrast, in smoldering SM, a novel subtype of (I)SM characterized by a high burden of MCs and multilineage involvement, the mutation is detectable in BM MNCs as well in unfractionated PB MNCs.[28–30] In these patients, the mutation appears to be present not only in MCs but also in monocytes and even in B lymphocytes.[26] By contrast, in typical ISM, the D816V mutation is only detectable in samples containing MCs.

In a group of patients with SM, an AHNMD is detectable.[3,9] In most cases, a myeloid neoplasm such as a myeloid leukemia or myeloproliferative disorder is found.[3,9] Similar to patients with smoldering SM (which can transform to SM-AHNMD), the c-kit mutation D816V is often detectable in unfractionated PB MNCs in these patients. Especially in patients with an associated chronic myelomonocytic leukemia (CMML), the D816V mutation was found to be expressed in leukemic cells.[24] In patients with an associated AML, leukemic blasts may also

Table 1 WHO classification of mastocytosis and typical patterns of expression of D816V in various organs

SM-AHNMD	+	±	∓
ASM	±	±	−
MCL	±	±	−

express the mutation. However, not all patients with SM and an associated AML exhibit c-kit D816V.

In patients with ASM and MCL, the D816V mutation has also been reported.[3] However, again, not all of these patients display this mutation.

MUTATED c-Kit AS A NOVEL TARGET OF THERAPY

Because the c-kit mutation D816V is a recurrent defect considered to be of pathogenetic significance, recent attempts have focused on agents that may be capable of inhibiting the kinase activity of D816V c-kit. A first promising observation has been that the tyrosine kinase inhibitor STI571 that is successfully applied in chronic myeloid leukemia (CML) is also capable of inhibiting the c-kit tyrosine kinase.[31,32] Moreover, it has been shown that STI571 downregulates (SCF-dependent) in vitro growth of human MCs at pharmacological concentrations.[33] However, unfortunately, the D816V-mutated form of c-kit is far less susceptible to STI571 compared to the WT receptor.[32,34] Therefore current research is focusing on novel inhibitory drugs that may counteract c-kit D816V.[35]

CONCLUSION

The c-kit D816V mutation is a pathogenetically important defect that is highly associated with the clinical picture of SM and has been proposed as a diagnostic criterion. Therefore much effort has been performed to standardize diagnostic procedures for the detection and analysis of the mutation. In addition, the mutated c-kit may be a novel promising target of therapy in SM.

Medullary Thyroid Carcinoma (MTC) and Multiple Endocrine Neoplasia (MEN 1, MEN 2)

M

Nader Hanna
University of Kentucky Medical Center, Lexington, Kentucky, U.S.A.

INTRODUCTION

Multiple endocrine neoplasia type 1 (MEN 1) and type 2 (MEN 2) are genetically and clinically distinct hereditary endocrinopathy syndromes with classical characteristics of early age of cancer onset, which is frequently bilateral or multifocal, multiple primary tumors, vertical transmission through either parent, frequent association with distinguished phenotypic stigmata, and occasional special pathological features. MEN 1-associated tumors, affecting mainly the parathyroid glands, the pancreatic-islet cells, and the anterior pituitary gland, are due to inactivation of the MEN 1 tumor suppressor gene located in 11q13, with no genotype–phenotype correlation. MEN 2-associated tumors, affecting mainly the thyroid parafollicular C cells, the parathyroid glands, and the adrenal medulla, are due to oncogenic point mutations of the *RET* proto-oncogene located in 10q11.2. There is a significant genotype–phenotype correlation in MEN 2 phenotypic variants, which has led to development of guidelines for the timing and extent of prophylactic surgery.

OVERVIEW

Medullary thyroid cancer (MTC) originates from the parafollicular calcitonin secreting cells of the thyroid gland and represents 5% of all thyroid cancers. Seventy-five to 80% of cases are sporadic and present in the fifth or sixth decade of life. Twenty to 25% of cases are hereditary, associated with multiple endocrine neoplasia (MEN) syndrome and characterized by younger age at presentation, and bilateral or multifocal tumors.[1] There are three phenotypic presentations of MTC in the MEN syndrome: MEN 2A, MEN 2B, and familial medullary thyroid carcinoma (FMTC) (Table 1). Other variants of MEN 2 are rare and include MEN 2A with cutaneous lichen amyloidosis often located over upper back, MEN 2A with Hirschsprung's disease, and FMTC with Hirschsprung's disease.[2,3] Medullary thyroid cancer is the first manifestation in most MEN 2 kindreds because of its higher penetrance. Average 5-year survival for MTC is 85% compared to 98% 5-year survival for papillary and follicular thyroid cancer. Survival is correlated with age, stage at diagnosis, familial vs. sporadic by biochemical screening vs. by symptoms.[4] The aggressiveness of MTC correlates with the MEN 2 variant syndrome and with the mutant *RET* codon. Most patients with MTC in MEN 2A will present with neck mass or neck pain at age 5–20 years; 30% will present with diarrhea and advanced disease. More than 50% will have cervical nodal metastasis. In MEN 2A syndrome, the biochemical manifestation of MTC with annual basal and stimulated calcitonin levels can be detected at a mean age of 5 years. In MEN 2B, MTC is very aggressive and presents early. Without prophylactic thyroidectomy, the average age of death in MEN 2B is 21 years. Parathyroid abnormalities are often found concomitantly with surgery for medullary thyroid carcinoma. MEN 2-related hyperparathyroidism (HPT) is rarely the first manifestation with a median age at presentation of 38 years. Pheochromocytomas in MEN 2 syndrome are characterized by high frequency of multiple tumors, which are often bilateral and extra-adrenal. The majority are benign (4% malignant). Other genetic disorders with heritable predisposition to pheochromocytoma include neurofibromatosis type 1, von Hippel–Lindau disease (VHL), hereditary pheochromocytoma, and the hereditary paraganglioma syndrome.

GENETIC ALTERATIONS IN MEN 2

MEN 2 is an inherited autosomal dominant disorder due to hereditary germline one amino acid point mutation in the *RET* gene (chromosomal locus 10q11.2).[5–7] It is a proto-oncogene composed of 21 exons over 55 kb of genomic material. It codes for a receptor tyrosine kinase receptor, termed ret, with extracellular, transmembrane, and intracellular domains. Recently, the glial cell line-derived neurotrophic factor (GDNF) has been identified to be a ligand for *RET*. Glial cell line-derived neurotrophic factor receptor (GDNFR)-alpha, a novel glycosylphosphatidylinositol-linked cell surface receptor, binds GDNF specifically and mediates the activation of the Ret protein-tyrosine kinase (PTK).[8] Ligand-independent homodimerization of the ret enzyme (cycteine-rich extracellular

domain mutants in most MEN2A) or activation of its catalytic site (intracellular domain mutants in MEN2B) results in inappropriate constitutive activation of the *RET* oncogene. Only one mutated copy of the oncogene is needed for a gain of function leading to uncontrolled proliferation and carcinogenesis.

CLINICAL DIAGNOSIS AND GENETIC TESTING

The diagnosis of the MEN 2 clinical subtypes relies on a combination of clinical findings, family history, and molecular genetic testing for *RET* gene mutation, which is recommended for all patients with sporadic MTC, pheochromocytoma (particularly if bilateral and/or before age 18), Hirschsprung's disease, and patients with physical features or gastrointestinal manifestation suggestive of MEN 2B. Genetic testing is also offered to first-degree relatives (before age 5 in MEN 2A and FMTC and before age 1 in MEN 2B) of *RET* mutation carriers to identify asymptomatic at-risk individuals for early prophylactic thyroidectomy, which could be curative when the disease is microscopic and localized to the thyroid gland. Genetic testing is generally done on DNA extracted from peripheral blood leucocytes for common mutations in exons 10 (codons 609, 611, 618, or 620), 11 (codon 634), and 16.[9] Because of the established genotypical–phenotypical correlation, *RET* mutation stratification has clinical and management implications.[10–13] Hyperparathyroidism is most commonly associated with mutations in codon 634, less frequent with mutations in codons 609, 611, 618, 620, 790, and 791. Individuals with MEN 2B (mutation in codons Met918 in exon 16, Ala883 in exon 15, or 922) do not develop HPT. Pheochromocytoma has been reported in all *RET* mutations except codons 768, Val804met, and 891 and is most commonly associated with mutations in codon 634 (in exon 11) and 918. Mutations in codons 609, 768, 790, 791, and 891 are associated with the lowest risk for MTC, whereas mutations in codon 611, 618, 620, or 634 are associated with high risk for MTC. Mutations in codon 883, 918, or 922 are associated with the highest risk for aggressive MTC. Mutations in codons 609, 618, and 620 in exon 10 are associated with MEN A2, FMTC, or Hirschsprung's disease. Therefore germline mutation analysis of *RET* exon 10 containing these codons is indicated in all children with Hirschsprung's disease.

Mutation detection rate is summarized in Table 1. Various molecular methods used to detect mutations in *RET* include DNA sequencing, restriction enzymatic analyses, chemical cleavage mismatch, single-stranded conformational polymorphism (SSCP), and denaturing gradient gel electrophoresis (DGGE). Most recently, a multiplex PCR assay to amplify exons 10, 11, and 13 of the *RET* proto-oncogene has been developed. The multiplex PCR product is then analyzed on a modified mutation detection enhancement (MDE) matrix for heteroduplex identification and visualized with ethidium bromide.[14] Confirmation of the specific mutation can be achieved by restriction enzymatic digestion (if feasible) or by DNA sequencing.

Genetic testing should always be done in the setting of pre- and post-test genetic counseling, as endorsed by the American Society of Clinical Oncology in its position statement on genetic testing for hereditary cancer.[15] The process of genetic counseling includes providing risk assessment, educating patients about testing options, discussing the implications for medical management, and providing supportive counseling to the individual and their family.

SURVEILLANCE

RET germline mutation testing has replaced biochemical screening with calcitonin to identify mutation carriers in MEN 2 families because calcitonin levels lack sensitivity and specificity, normal basal or stimulated calcitonin levels cannot exclude or predict development of MTC, pathological calcitonin levels cannot differentiate between chief cell hyperplasia and MTC, and stimulated calcitonin studies can occasionally produce false-positive results. Screening for pheochromocytoma and HPT is indicated in all variants of MEN 2 syndrome as some kindreds with MEN 2A syndrome manifest only MTC and thus incorrectly designated as FMTC. The presence of a functioning pheochromocytoma should always be excluded by appropriate biochemical screening before thyroidectomy in any patient with MEN 2. Annual screening for pheochromocytoma with 24-hr urinary levels of catecholamines and catecholamine metabolites should continue until age 35 in all phenotypical variants of MEN 2 syndrome. Because pheochromocytomas in MEN 2 syndrome are often multiple and extra-adrenal, MIBG (131I-metaiodobenzylguanidine) scintigraphy and MRI are needed for localization, only if the biochemical results are abnormal. Annual biochemical screening for HPT with serum parathyroid hormone (PTH) and ionized calcium is recommended for those patients who have not had parathyroidectomy and autotransplantation.

SURGICAL MANAGEMENT

Stratification of codon mutation has led to development of guidelines for the timing and extent of prophylactic total thyroidectomy, which is generally recommended before

age 5 years in MEN 2A and FMTC, and before age 1 year in MEN 2B.[12] Total thyroidectomy with central lymph node dissection and autotransplantation of parathyroid glands into the neck or nondominant forearm following positive testing for *RET* mutations is a preventive option for all subtypes of MEN 2. Postoperatively, all patients will need thyroid hormone replacement therapy and monitoring for possible hypoparathyroidism. Although thyroidectomy prior to biochemical evidence of disease may reduce the risk of recurrent disease, continued monitoring with calcitonin levels for residual or recurrent MTC is still recommended.

For HPT, surgical excision of only enlarged glands, similar to surgical management of primary sporadic HPT, is indicated.

For unilateral pheochromocytoma, adrenalectomy, preferably laparoscopic, is indicated. Cortical-sparing adrenalectomy to avoid adrenal insufficiency should be considered in patients with bilateral pheochromocytomas. Long-term follow-up, with periodic surveillance (serum or urinary catecholamine measurements), is recommended as contralateral pheochromocytoma or recurrence may develop many years after the initial operation.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1 (MEN 1 SYNDROME)

Multiple endocrine neoplasia type 1 (MEN 1) is an autosomal dominant endocrinopathy syndrome caused by mutations (mostly truncating) in the *MEN1* gene (chromosomal locus 11q13).[16] *MEN1* gene is a tumor suppressor gene that consists of 10 exons and its product is a 610-amino acid protein called menin.[16–18] MEN 1 syndrome is characterized by various combination of endocrine tumors involving the parathyroid glands (HPT is usually the first manifestation with near 100% penetrance by age 50), entero-pancreatic islet cell tumors (gastrinoma in 40%, insulinoma in 10%, nonfunctioning in 20%), and anterior pituitary adenomas (prolactinoma is the most common and occurs in 20% of patients).[12,19] Less prevalent tumors include adrenal cortical tumors, foregut carcinoid tumors, and lipomas. Pheochromocytomas are rare in MEN 1. Neuroendocrine tumors of the pancreas are often multifocal and malignant, and are the leading cause of mortality in patients with MEN 1. Genetic testing for MEN 1 is commercially available using single-strand conformation analysis (SSCA) and sequencing. It can identify mutation in the MEN 1 gene in approximately 80–90% of probands from well-defined MEN 1 families.[20–23] It is generally offered to patients with clinical criteria of MEN 1, their at-risk relatives, and to confirm diagnosis in cases with features atypical for MEN 1. Presymptomatic MEN 1 genetic testing for family members, while informative, its usefulness is controversial because it rarely mandates therapeutic intervention because of lack of consensus on prophylactic interventions and the inability to predict the extent, spectrum, or clinical onset of future disease.

CONCLUSION

Medullary thyroid carcinoma is the first neoplastic manifestation in MEN 2, the only consistently malignant neoplasm in all phenotypical variants, and the most common cause of death in affected patients. Recent advances in genetic profiling and stratification of RET codon mutations have contributed to accurate genotype–phenotype correlation, proper genetic counseling, targeted surveillance, and timing and extent of prophylactic thyroidectomy in accordance with the natural history of this hereditary syndrome. Genetic testing in high-risk family members is strongly recommended. The available current data indicate superiority of surgical prophylaxis compared with biochemical surveillance in reducing MTC risk in carriers of RET mutations.

Medulloblastoma—*MYC* Messenger RNA Expression

Michael A. Grotzer
University Children's Hospital, Zürich, Switzerland

INTRODUCTION

Cerebellar primitive neuroectodermal tumors/medulloblastomas (MBs) are the most common malignant brain tumors of childhood. Because of the high risk of leptomeningeal dissemination, standard postoperative treatment for MB includes craniospinal radiotherapy and chemotherapy. Such treatment causes long-term morbidity including endocrine and growth disturbances, as well as neurocognitive dysfunction, which is particularly severe in young children. Over the last years, oncogene *MYC* has been identified as one of the most important biological prognostic factors in MB. Assessment of *MYC* mRNA levels by quantitative RT-PCR is simple, rapid, and reproducible. It is therefore suitable for routine quantification of *MYC* mRNA expression in MB and will be a powerful tool in large prospective cooperative group trials. The goal of these important biological studies will be to evaluate whether *MYC* mRNA expression can be incorporated in future risk-classification systems for clinical use.

CHILDHOOD MEDULLOBLASTOMA

CNS primitive neuroectodermal tumors (PNETs), including cerebellar PNET (medulloblastoma, MB), are the most common malignant brain tumors in children and constitute 20–25% of all pediatric brain tumors. Because of the high risk of leptomeningeal dissemination, standard postoperative treatment for PNET includes not only local radiotherapy but also craniospinal radiotherapy and chemotherapy. Such treatment causes long-term morbidity, including endocrine and growth disturbances, and neurocognitive dysfunction, which is particularly severe in young children.

Clinical prognostic factors for PNET have been identified over the last two decades. These include metastatic stage, extent of tumor resection, tumor location, and age, and are currently used to distinguish a ''high-risk'' group of patients (M stage ≥ 1, residual tumor bulk ≥ 1.5 cm^2, age <3 years, supratentorial tumor location) from a ''standard-risk'' group. However, investigators have appropriately avoided the use of the term ''low risk'' or ''good outcome,'' because published survival rates in the 50–60% range do not justify such terms. At present, clinical prognostic factors cannot identify a good-outcome group of MB patients suitable for treatment with a substantially less toxic treatment strategy than the standard treatment. As it is unlikely that new clinical prognostic factors will be found, biological prognostic factors must be identified to further improve MB prognostic systems.

MYC PROTOONCOGENE

The *MYC* (*c-myc*) protooncogene, a member of a family of closely related genes that includes *MYCN* and *MYCL*, encodes a nuclear phosphoprotein involved in the transcription of genes central to regulating the cell cycle, cellular proliferation, apoptosis, embryonic development, and differentiation.[1,2] MYC proteins form heterodimers with Max, another helix–loop–helix leucine zipper protein. MYC/Max heterodimers bind to specific DNA sequences located in the transcriptional control region of target genes and alter the transcription of these target genes by transactivation or transrepression.

MYC expression is normally tightly regulated throughout the cell cycle, but may become deregulated or activated, thus contributing to malignant transformation.[3] Dysregulation of *MYC* has been implicated in the pathogenesis of a variety of human neoplasms. One important mechanism of *MYC* dysregulation is gene amplification. In childhood neuroblastoma, amplification of *MYCN*, a *MYC* family member, is found to occur in about 25% of primary tumors and is strongly associated with advanced-stage disease, rapid tumor progression, and poor prognosis.[4]

MYC GENE AMPLIFICATION IN MEDULLOBLASTOMA

MYC has been the subject of several published studies attempting to identify biological prognostic markers in human MB. Most show that *MYC* gene amplification is uncommon in MB, with an incidence of $\sim 8\%$ in primary tumors.[5,6] The incidence of *MYC* gene amplification in MB cell lines and xenografts may be as high as 67%,[7] suggesting that *MYC* gene amplification correlates with cell line establishment and tumorigenicity. *MYC* gene amplification has been suggested as an indicator of poor prognosis in some case reports and in a recently published

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020965

study of 29 MB patients.[5] In aggregate, however, published studies suggest that the frequency of *MYC* amplification is not sufficiently high to provide prognostic information of greater value than clinical variables.

MYC MESSENGER RNA EXPRESSION IN MEDULLOBLASTOMA

PNET cell lines show a wide range of *MYC* mRNA expression with lowest expression in DAOY PNET cells and highest expression in D425 PNET cells.[8–10] In DAOY, PFSK and UW288-2 PNET cell lines that do not have *MYC* gene amplification, *MYC* mRNA expression levels show a 10-fold difference. Mechanisms other than gene amplification that activate *MYC* are well recognized in various solid tumors. These include retroviral insertional mutagenesis, chromosomal translocation, somatic mutations, or activation by transcription factors (reviewed in Ref. [11]).

Our own studies demonstrate that MB primary tumors also show a wide range of *MYC* mRNA expression levels, with a 22-fold difference between the highest and lowest value.[8] Like the PNET cell lines, *MYC* mRNA expression is highly variable in those MBs with no *MYC* gene amplification (showing an 11.6-fold difference between the highest and lowest values).

Transcriptional regulation of *MYC* in MB may involve the adenomatous polyposis coli (APC) and β-catenin (CTNNB1) pathways. A subset of MB is associated with Turcot's syndrome,[12] in which colonic cancer is associated with primary brain tumors and which is characterized by germline mutations in the APC gene. While mutations of APC have not been detected in sporadic MB,[13,14] approximately 5% of sporadic MB have been reported to contain mutations in a second Wingless/Wnt pathway member, β-catenin.[15,16] Mutations in either APC or β-catenin act to stabilize β-catenin protein. Stabilized β-catenin protein accumulates and translocates into the nucleus where it forms a complex with Tcf4 and up-regulates the transcription of *MYC* and other target genes.[17,18] In a recent study, aberrant nuclear β-catenin staining was demonstrated in 18% of sporadic MB and in one MB from a Turcot's patient.[16] Therefore, mechanisms other than gene amplification may activate *MYC* transcription in MB.

MYC MESSENGER RNA EXPRESSION AND SURVIVAL

Performing univariate Cox regression analysis, high levels of *MYC* mRNA expression were found to correlate strongly with an unfavorable survival outcome in MB patients (Table 1). *MYC* mRNA expression levels did not correlate with metastatic stage, age, or sex of PNET patients. After correcting for these factors in multivariable analysis, the hazard ratio for *MYC* mRNA expression remained significant, indicating that *MYC* mRNA is of independent prognostic significance.[8] Accordingly, *MYC* mRNA expression represents one of four individual biological prognostic factors we have identified in PNET.[8,19–21] Of these, *TrkC* mRNA and *MYC* mRNA expressions seem to be the most potent prognostic factors when hazard ratios are compared and when the results of independent research groups are considered. Kim et al.[22] determined *TrkC* mRNA expression in 42 MB patients by Northern blot analysis and found that tumors with high *TrkC* mRNA expression were less likely to progress than tumors with low *TrkC* mRNA expression. Herms et al.[6] determined *MYC* expression in 72 MBs by in situ hybridization, and using their assay found that 30 patients with *MYC* mRNA-expressing MB had a worse survival outcome than 42 patients whose tumors did not express *MYC* mRNA.

PROGNOSTIC MODEL COMBINING *MYC* AND *TrkC* MESSENGER RNA EXPRESSION

It is well known that the regulation of tumorigenesis is multifactorial. Therefore, it is unlikely that any single biological prognostic factor will be sufficiently robust to segregate all MB patients optimally into risk-based

Table 1 Univariate analysis of clinical and laboratory variables and progression-free survival in 26 patients with medulloblastoma

Variable	Hazard ratio	(95% CI)	*P* value
MYC mRNA expression	10.89	(1.37–86.38)	0.024
TrkC mRNA expression	3.78	(0.92–15.51)	0.065
Age	20.35	(0.65–8.51)	0.19
Surgery	2.41	(0.60–9.75)	0.22
Therapy	2.40	(0.59–9.83)	0.22
Gender	1.99	(0.42–9.39)	0.39
Metastatic stage	0.88	(0.19–4.18)	0.88

The variables were compared in the following ways: *MYC* mRNA expression, high vs. low; *TrkC* mRNA expression, low vs. high; age, <3 years vs. ≥ 3 years; surgery, extent of resection $<90\%$ vs. $\geq 90\%$; therapy, radiotherapy, or chemotherapy alone vs. radiotherapy + chemotherapy; gender, male vs. female; metastatic stage, M1-3 vs. M0.
Source: Ref. [8].

strata. Accordingly, multiple factors of biological relevance are more likely to provide an accurate system of defining risk groups. We have demonstrated this by combining *MYC* and *TrkC* mRNA expression (Fig. 1). The group with low *MYC* and high *TrkC* mRNA expression had a 100% 5-year progression-free survival outcome after a median follow-up time of 55 months (range, 15–91 months). Notably, three patients in this group were infants who did not receive radiotherapy.[8] Although the number of patients is too small to draw firm conclusions, it is conceivable that for this age group, where the neurotoxic consequences of radiation therapy are greatest, a good-outcome group can be identified by biological factors and then treated using chemotherapy alone. The prognostic model using *MYC* and *TrkC* mRNA expression was superior to known clinical factors in identifying a good-outcome group of patients.

MYC QUANTITATIVE REAL-TIME RT-PCR

To optimize quantification of *MYC* mRNA expression, we developed a real-time quantitative RT-PCR assay based on TaqMan fluorescence methodology using 40 primary tumor and 7 normal brain samples. Isolation of total RNA and cDNA synthesis was performed as previously described.[9,23,24] Kinetic real-time PCR quantification of hTERT mRNA was performed using an ABI Prism 7700 Sequence Detection System (Applied Biosystems, Rotkreuz, Switzerland) as described previously.[25] For each PCR run, a master mix (Applied Biosystems) was prepared containing 200 nM of each primer and 400 nM probe. Thirty nanograms cDNA per RT sample was added to a final volume of 25 μL PCR master mix. The thermal cycling conditions comprised an initial denaturation step at 95°C for 10 min, and 50 cycles at 95°C for 15 sec and 60°C for 1 min. Experiments were performed in triplicate for each data point. Each PCR run included the five points of the standard curve (serially diluted DAOY PNET cell line cDNAs), a no-template control, the calibrator cDNA, and patient cDNAs.

The precise amount of total RNA added to each reaction mix (based on absorbance) and its quality are difficult to assess. We therefore also quantified transcripts of the *18S* rRNA housekeeping gene as endogenous control, and each sample was normalized on the basis of its *18S* rRNA content. The relative expression of *MYC* mRNA was calculated using the comparative C_T method.[26] The amount of *MYC*, normalized to *18S* rRNA and relative to the calibrator, is then given by $2^{-\Delta\Delta C_T}$, where $\Delta\Delta C_T = \Delta C_T$ (sample) $- \Delta C_T$ (calibrator), and ΔC_T is the C_T of the target gene (*MYC*) subtracted from the C_T of the housekeeping gene (*18S* rRNA). PCR efficiencies for *MYC* and *18S* rRNA were measured as previously described[27,28] and were found to be >95%. Thus, the $\Delta\Delta C_T$ method, in which the efficiency of PCR amplification of the target gene must be approximately equal to that of the housekeeping gene, is applicable.

We validated the method on a series of PNET cell lines with known *MYC* mRNA expression. *MYC* mRNA

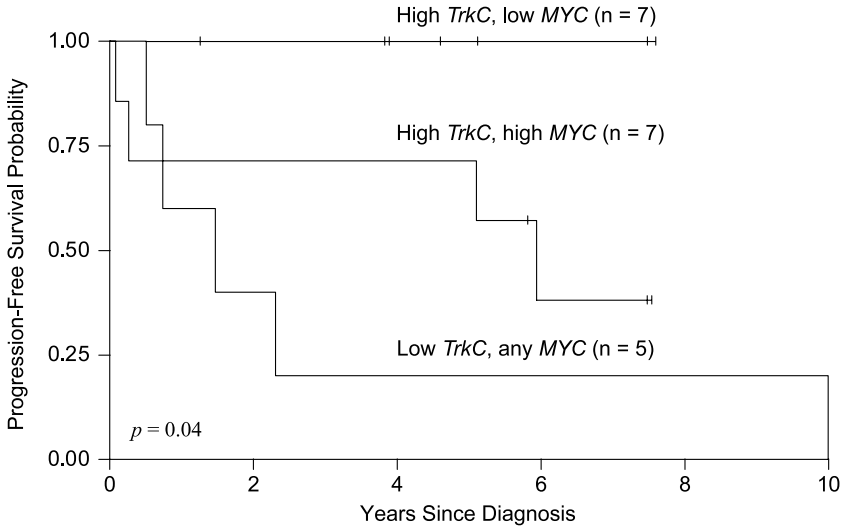

Fig. 1 Cumulative progression-free survival of patients with medulloblastoma, according to expression levels of both *MYC* mRNA and *TrkC* mRNA.

expression levels in primary PNET varied widely with >100-fold (*MYC*) differences between the highest and lowest values. This is higher than previously measured with less quantitative methods. Compared to normal cerebellum, *MYC* was overexpressed in 60% of the PNET samples evaluated.

CONCLUSION

We anticipate that biological prognostic factors, in addition to clinical factors, will define risk groups and help direct therapy decisions for children with MB. We therefore strongly recommend prospectively assessing *MYC* mRNA expression levels in future MB clinical trials in an effort to validate this model for future incorporation in risk-classification systems for clinical use.

INTRODUCTION

The incidence of cutaneous malignant melanoma is rising, and new clinical and histological variables that predict outcome have been identified. Cutaneous melanomas are also a tumor group, in which multiple new molecular profiling methods, such as DNA arrays, proteomics, and tissue microarrays (TMAs), have been extensively utilized to identify new prognostic factors and therapeutic targets. In this review we discuss how these new techniques may improve the diagnosis, prognosis, and therapy of malignant melanoma.

MELANOMA GENETICS

Altering the genetic message in cancer is essential for its development and can be caused by DNA mutations, chromosomal aberrations (CNAs), epigenetic modification, and protein–protein interaction.[1] Mutations in the genomic DNA can lead to alterations in gene expression and function. Multiple genetic alterations have been described during development and progression of cutaneous melanoma.[2] Investigation of primary melanomas by comparative genomic hybridization has resulted in detection of losses of chromosomes 6q, 8p, and 10 as well as increases in copy numbers of chromosomes 1q, 6p, 7, and 8.[2] DNA modification, mutation, and viral genome integration can lead to chromosomal instability, i.e., CNA, where particular regional amplifications and deletions of genes are found. Chromosomal aberrations have been found in genomes of multiple solid tumors. O'Hagan et al.[3] have been able to distinguish primary melanoma tumors with different etiology by using array-based comparative genomic hybridization analysis of genome-wide CNAs in a genetically modified mouse model.

There are also several specific gene mutations frequently found in cutaneous melanoma. Cyclin-dependent kinase gene *CDKN2A* is a tumor suppressor gene whose function is suppressed with malignant transformation.[4] *CDKN2A* encodes for p16 protein that binds and inhibits cyclin-dependent kinases, leading to cell-cycle arrest in G1 phase and continuous cell proliferation.[4] Mutations in genes, such as NRAS- and BRAF-encoding components of Ras–Raf–mitogen-activated protein kinase (MAPK) signaling pathway, have been found in nearly 90% of melanomas studied.[5] However, simultaneous mutation in both genes is rare.[5] These mutations cause uncontrolled activation of these genes, which mediate cellular responses to growth factor stimulation resulting in continuous growth signal.[5] Recent studies also show that there is a specific melanoma metastasis suppressor gene, which is located in chromosome 6.[6] Similarly, a mutation in the gene coding for tumor suppressor PTEN, a phosphatase, which opposes the action of PI-3-kinase, is found in late phases of melanoma progression.[7] In addition to alterations in individual chromosomes and genes, new array technology gives a possibility to detect multiple expression changes in thousands of specified genes simultaneously in a studied tumor model.

MELANOMA BIOMARKERS—HOW TO FIND THEM

Sample-based screening of melanoma tumors for desired markers can be performed with traditional immunohistochemistry (IHC) or with more sophisticated gene arrays, TMAs, or tumor protein lysate array.

Melanocytes and melanoma cells in vitro and in tumor samples from different stages of melanoma progression have been studied widely by immunohistochemistry to identify specific proteins to be used as biomarkers for prognosis. Markers which have shown prognostic value in restricted patient groups include S-100B, melanoma inhibitory activity protein (MIA), tyrosinase, certain matrix metalloproteinases, integrins, interleukin-8, and CD 44 (Ref. [8] and references therein). Some of these markers can also be measured in patient sera. The increased expression levels or bioactivity of these markers

DOI: 10.1081/E-EDGP 120030842

is usually associated with melanoma progression, recurrence, or poorer survival. However, the clinical use of these markers is limited to oncology departments with research activity.

In microarray studies thousands of marker genes can be simultaneously studied to diagnose melanoma, to classify patients into different prognostic subgroups, and to identify new targets for therapy.[9,10] DNA microarrays are based on high-density oligonucleotide or cDNA microarrays, which measure in parallel thousands of gene-specific mRNAs in a single RNA sample.[1] This kind of large-scale gene expression analysis has proved to be a valid strategy for developing sample-specific gene expression profiles.[1] DNA microarrays have potential application in clinical practice, but their application is limited by the requirement of fresh or frozen tissue for analysis (Fig. 1).

DNA microarrays determine the levels of target gene mRNA in studied tumors, but do not give information on gene function. Study of protein complement of the genome by functional proteomics can be used to screen for alterations in protein expression and posttranslational modifications under melanoma progression.[1]

Tissue microarrays are arrays in which hundreds of small core (0.6–2.0 mm) tissue sections are arrayed on a glass slide.[11] Tissue microarrays give a good impression of the whole tumor area and they can be used for IHC and in situ hybridization. Tissue microarrays are useful in screening of a desired marker rapidly in a large patient group.[11]

Tumor protein lysate array by proteomics is a new technique based on detection of a particular protein expression in patient samples. This array also requires frozen or fresh tissue samples.

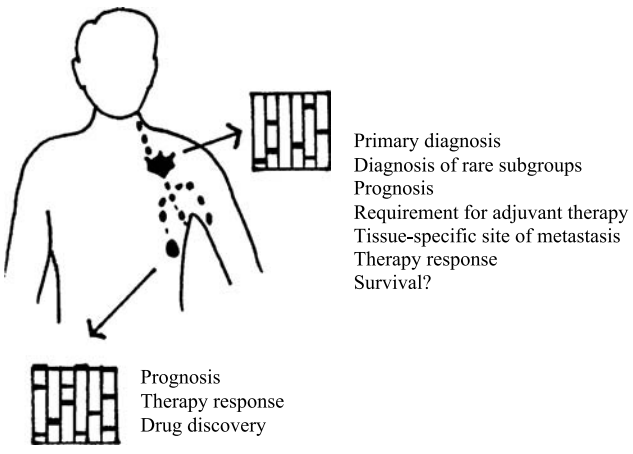

Fig. 1 Putative clinical value of DNA or tissue microarrays of primary or metastatic melanoma specimen.

Molecular Profiling of Cutaneous Melanoma

Molecular profiling of melanomas by gene expression analysis has emerged as a new possibility to predict melanoma prognosis and treatment planning. Detailed genetic profiles found by microarray analyses are available on the internet (http://www.nhgri.nih.gov). Bittner et al.[9] compared the tumor cell mRNA with a single reference probe, providing normalized measures of the expression of each gene in each sample relative to the standard. They found several genes whose expression levels were altered giving a possibility to discriminate studied genes into different clusters.[9] Interestingly, the melanoma cells studied belonging to different groups also had different biological properties, i.e., their ability to migrate, form tubular networks, and contract collagen gels in vitro was different.[9] It has become evident that there are genes whose expression levels are elevated in aggressive melanoma cell lines or tumors, as well as genes whose expression levels are downregulated. The expression of several extracellular matrix components, such as fibronectin, $\gamma 2$ chain of laminin 5, and $\alpha 2$ chain of collagen IV, is upregulated in aggressive melanoma cells,[9] suggesting that invasive tumors have increased capacity to regulate cytoskeletal organization, cell movement, and invasion by modifying the composition of the surrounding extracellular matrix. Similarly, the expression level of *Wnt5A*, a gene involved in melanoma cell motility and invasion, shows correlation with tumor grade while inversely correlating with survival.[12] In addition, several studies have shown upregulation of invasion-promoting matrix-degrading proteinases, such as cathepsin Z.[12] Melanocyte-specific markers, such as tyrosinase and melan-A, are downregulated suggesting that highly aggressive tumor cells undergo dedifferentiation into less melanocyte-like cells. Several markers of angiogenesis, such as endothelial protein receptor TIE-1, vascular endothelial growth factor-C (VEGF-C), and vascular endothelial cadherin (VE-cadherin) have been found to be overexpressed in melanomas.[10] The expression of these genes is related to a phenomenon called vascular mimicry, in which highly aggressive tumor cells are able to undergo a genetic reversion to a pluripotent, more embryonic-like phenotype, which may lead to the formation of new vessels by tumor cells themselves. Neovascularization by tumor cells may explain the aggressiveness of metastatic melanoma and provide a basis for therapy targeting angiogenic molecules and signal transduction pathways.

The possible clinical use of these arrays in diagnosis, prognosis, and treatment planning is further discussed by describing recent findings in in vitro models as well as in patient-derived sample analysis.

Molecular Profiling of Sentinel Nodes

The importance of sentinel node evaluation and detection of micrometastases in lymph nodes has been shown in a systematic evaluation of 17,600 patients with cutaneous melanoma.[13] Patients with detected micrometastases have less favorable prognosis than those whose nodes have been found to be unaffected.[13] However, this implication may change to a more detailed, molecular analysis of dissected lymph nodes.[14] Kuo et al.[14] have shown the feasibility of PCR-based molecular multimarker analysis of sentinel lymph nodes in the detection and prognostication of recurrence in patients with early-stage melanoma. The PCR-based multimarker analysis might even detect single metastatic melanoma cells in sentinel lymph nodes thought to be normal in microscopic IHC analysis.

CLINICAL IMPLICATIONS

Diagnosis

Detailed analysis of the expression patterns of thousands of genes simultaneously has made it possible to identify novel disease genes, such as *Wnt5A*, *RhoC*, and BRAF, for cutaneous melanoma.[12] De Wit et al.[15] have been able to identify new melanoma-specific antigens, such as MMA-1a and MMA-1b, by using oligonucleotide array-based analysis. In addition to diagnosis, gene expression profiling can be used in tumor classification. On the basis of melanoma-specific biomarker listing it would be possible to molecularly distinguish atypical melanomas from nonmelanoma skin cancers.

Gene array and cluster analysis might also help in the characterization of rare melanoma subgroups. Tschentscher and coworkers[16] have found new subtypes of uveal melanoma, and Segal et al.[17] have shown that clear-cell sarcoma is a distinct subtype of cutaneous melanoma.

Prognosis

Classification of tumors with similar histology into different prognostic subgroups is a clinically valuable benefit of DNA arrays. In a pronounced work by Clark et al.,[18] specific genes, such as *RhoC*, responsible for melanoma progression were identified. Alonso et al.[19] were able to identify distinct gene expression profiles distinguishing specific melanoma progression stages. Genes whose expression was reduced in advanced melanoma stages included *p16*, *p27*, and cyclin D, suggesting that losing cell-cycle control is essential in melanoma progression.[19] Previous work with primary breast cancer and its node-positive counterparts has suggested that gene expression pattern does not differ much between primary tumor and its node metastasis.[20] This may also be true in melanoma, as at least early mutation status of NRAS and BRAF is maintained from dysplastic nevi to primary melanomas and their metastases.[5] Thus detection of upregulation of genes responsible for dissemination in primary tumors would be clinically valuable as prognostic factor. Furthermore, DNA microarray analyses performed in murine melanoma models have even defined genes which are consistently elevated in pulmonary metastases,[21] suggesting that predictable, organ-specific metastasis gene expression profiles could be found and used in further patient surveillance. Similar hypothesis has been presented concerning breast cancer, where new findings suggest that primary tumors with metastatic capacity possess the signature for poor prognosis, but subpopulations of cells also display a tissue-specific expression profile predicting the site of metastasis.[22] According to these findings, the prevailing model of metastasis, where it is suggested to be a late and rare event in tumorigenesis, may change.

Direct analysis of melanocytic lesions by tissue microarrays has also helped in finding molecules which predict melanoma progression. Shen et al.[23] analyzed several benign and dysplastic nevi as well as different growth-phase melanomas to show that particular growth factor receptor tyrosine kinases are differently expressed in distinct stages of tumor development. They found that nearly 100% of dysplastic nevi and vertical growth-phase melanomas studied express c-kit and platelet-derived growth factor receptor β (PDGFR-β). Interestingly, metastases seemed to be associated with loss of c-kit and PDGFR-β expression, suggesting that patients with an earlier stage of disease might benefit from imatinib, a PTK inhibitor targeted toward these receptors.

Treatment

Different adjuvant treatment modalities, i.e., interferon-α (IFN-α) and vaccine therapy, have been extensively studied among melanoma patients. It is not known whether melanoma patients with high metastasis risk gain survival benefit from adjuvant therapy. Interferon-α is the most studied adjuvant therapy agent, although its routine use cannot be recommended in high-risk primary melanoma because of lack of phase III studies with evidence for survival benefit. Interferon-α exerts its effects through antiproliferative, apoptosis-inducing, and antiangiogenic effects in addition to immunological modulation. Certa et al.[24] have found differently regulated IFN-α responsive gene groups in IFN-α-

sensitive and -resistant melanoma cells. It is also clinically evident that an unidentified subpopulation of patients seems to benefit from IFN-α-based adjuvant therapy and thus array technology might help in identifying this population. Furthermore, microarray analysis may be used as a feasible test to identify patients who are cured by surgery alone and do not need any systemic adjuvant therapy.

Interleukin-2 (IL-2) is a cytokine which has been used in the treatment of metastatic melanoma. Panelli et al.[25] have shown that systemic IL-2 administration leads to gene expression changes in both blood mononuclear cells and melanoma metastases. The activation of genes was predominantly associated with monocyte function, but also genes responsible for secondary recruitment of immunological cells to the tumor site were upregulated.[25] Also, other types of immunotherapy have been studied in melanoma patients, especially in the form of different vaccines. Durable antitumor responses have been infrequent, which may be due to patient's specific lack of activation or trafficking of T cells. Wang et al.[26] examined gene profiles of melanoma metastasis samples and found a 30-gene cluster, which was predictive of clinical response to immunotherapy. Half of these genes are related to T-cell regulation.[26] Kershaw et al.[27] have shown in their model that melanoma cells express various chemokines, which might redirect the migration properties of activated T cells. Grolleau et al.[28] have made similar findings in their studies with dendritic cells (DCs), which can be used antigen-pulsed or -unpulsed in vaccine therapy of melanoma. They show that pulsing of DCs with tumor cell lysate leads to upregulation of genes important for DC effector function, but also induces macrophage receptor expression.[28] Differently regulated immunoresponse genes may explain some of the detected variations in the effectiveness of vaccines among individual patients. Microarray profiles might be useful when selecting between optimal therapy regimens, i.e., IFN-α, IL-2, or vaccination for a patient.

Neoangiogenesis is a pronounced phenomenon in melanoma progression and it is promoted by several factors including hypoxia. Upregulation of angiogenesis-related genes has been shown in several melanoma models, as discussed above. Specific genes involved in vascularization have been detected. In addition, progressing melanoma cells show molecular plasticity suggesting that they themselves are able to form new vessels via vascular mimicry, as discussed above. Targeting these factors might help in planning tailored therapy to each patient.

DRUG DISCOVERY

Drug discovery is an important area where gene arrays and proteomics might be used. Genomic studies that produce large databases of molecular information on cancers might be linked to patterns of drug activity. First, pharmacogenomic analyses, where genomic information is coupled with structure-based data to identify classes of compounds for which detailed experimental structure–activity studies might be used, have been performed.[29] Blower et al.[29] have identified two quinine subclasses, whose patterns of activity in tested cell lines (including melanoma) correlate strongly with expression patterns of particular genes.

Microarray studies on signaling molecules and transcriptional factors in melanocytes have identified potential therapeutic targets, such as bcl-2, which is known to rescue melanoma cells from apoptosis.[30] This antiapoptotic molecule was identified as the transcriptional target of the microphtalmia gene, *Mitf*, a transcription factor expressed in the majority of primary melanomas.[12] Bcl-2 has been used as a target of a new type of therapy, where inhibition of its expression by a specific antisense oligonucleotide has increased time to progression of metastatic melanoma patients when used together with DTIC.[31]

PERSPECTIVE

DNA and tissue microarrays have rapidly increased the molecular information on melanoma development and progression. However, there are several challenges left when different arrays are estimated in a clinical point of view. Why are the same markers measured in IHC and serum analysis assays only rarely upregulated in gene array-based analysis? There can be several explanations. The expression levels of studied ''traditional'' markers are usually estimated between different patients, thus there is always an artificial cut-off point, which is often more researcher-dependent than related to negative and positive controls. It is also evident that even if a gene is upregulated in an array analysis, it does not necessarily mean that there is an increase in the function of the protein which it codes. Comparison of results gained from distinct DNA microarray studies has brought specificity into array analyses. The function of a desired gene can be studied by RNA interference (RNAi) method, by specific gene knockdowns in mammalian cells. RNA interference analysis shows the biological effect of a specific inhibition of gene expression and thus suggests its therapeutic significance. However, there is no consensus at the moment on how to translate these microarray profiles into clinical utility.

Heterogeneity of gained gene profiles between different studies is a problem. Although several melanoma-''specific'' array results have been published there is still no melanoma-specific repeatable gene profile available. In in vitro studies with cultured cell lines this can be partly

explained by the heterogeneity of cellular subpopulations of the same pathological origin. However, clustering analyses also only rarely end up in a similar gene expression profile despite the fact that patients' clinical features between different studies have been quite homogeneous. Reliability of clustering results and profiles has been studied widely, and there are also possibilities of statistical errors. Pusztai et al.[32] have pointed out the importance of array standardization. Arrays can contain cDNAs of variable lengths or small oligonucleotide sequences leading to differences in signal intensity.[32] There is also variability in the control tissue and sampling method used. Symmans et al.[33] have clearly demonstrated that transcriptional profiles from the same tumor differ according to sampling method, i.e., fine needle aspiration and core needle biopsy yield different gene expression profiles.

There are also some ethical problems. Not all patients want to know their gene expression profile, although it would be worth assessing because of increased clinical risk factors. Similarly, it is not perfectly certain that gene profiles do not change during melanoma progression, and it is not always safe or even ethical to take serial biopsies during disease progression only to detect gene profiles. Detection of gene profile has been shown to have a survival value in breast cancer,[20] but, so far, there is no evidence supporting gene or tissue arrays or proteomics as a source of any information, which would increase the survival of melanoma patients. Furthermore, Ntzani and Ioannidis[34] have shown in their analysis that only a limited number of the DNA microarray studies performed to address cancer outcome actually had prognostic value.

CONCLUSION

Gene and tissue arrays have multiplied the genetic and molecular information on melanoma in a few years. It is probable that multimarker analysis of primary tumors and archival lymph nodes will lead to molecular staging of patients with primary melanoma. Marker assays will also lead to wide use of oncogenomics, i.e., molecular profiles will be incorporated into therapy and clinical trials. However, these functional arrays require fresh or frozen tissue samples and this implication may lead to a change in sampling for pathological diagnosis. Tissue banks containing frozen tumor samples may comprise the basics for future personalized medicine.

INTRODUCTION

To date, two high-penetrance melanoma predisposition genes have been identified, *CDKN2A* and *CDK4*. However, because only a small fraction of melanoma families can be explained by mutations in these genes, the search for additional melanoma susceptibility genes continues. Of particular clinical concern is the frequently reported increased risk of melanoma in nonmutation carriers in *CDKN2A* or *CDK4* mutation-positive families. Increasingly, a number of environmental, phenotypic, and other low-penetrance genetic risk factors for melanoma are being recognized. Hence, familial melanoma is a complex disorder with many aspects still to be unraveled. Therefore, the usefulness of diagnostic DNA testing is still being questioned.

CLINICAL DESCRIPTION AND PREVALENCE

The incidence of melanoma is rising faster than all other cancers except lung cancer in women, currently varying between 5 (Western Europe) and 20 (Northern Europe) to over 50 (Queensland, Australia) cases per 100,000 per annum.[1,2] Familial clustering of melanoma was first described by Norris in 1820,[3] but it was not until the second half of the 20th century before others documented the familial occurrence of melanoma. Across several population-based studies, 1–13% of melanoma cases reported the occurrence of melanoma in at least one first-degree relative.[4] Hence, it is commonly accepted that melanoma predisposition is hereditary in $\sim$10% of all cases. But even in high-sun-exposure areas such as Queensland, Australia, less than 5% of melanoma probands report two or more first- or second-degree relatives affected with melanoma.[5]

Whereas susceptibility in small numbers of highly selected multiple-case melanoma families is consistent with autosomal dominant inheritance of a single major gene, segregation analysis in a large population-based sample of families failed to show a single major gene being responsible for melanoma transmission, possibly because of relatives' risk factors not being included in this analysis.[6] Thus, the bulk of familial clustering of melanoma may be better ascribed either to a codominant, a polygenic, or a recessive mode of inheritance.

In the absence of a characterized mutation there are no clear-cut criteria for ''familial melanoma,'' but as a working definition clinicians and researchers generally use this term to describe families in which there are at least three cases of melanoma. However, in low-sunlight areas such as northern Europe, familial melanoma is often defined when melanoma occurs in as few as two first-degree relatives. Additionally, individuals in whom multiple melanomas occur in the absence of a family history of the disease are of concern, because many of these cases have been found to harbor mutations in *CDKN2A*.[7] As will be illustrated below, clinical suspicion of a hereditary component should also arise when pancreatic cancer, uveal melanoma, or nervous system tumors occur in conjunction with melanoma in the same family.

RISK FACTORS

Risk factors for melanoma in general (often termed ''sporadic melanoma'') have either proven, or are most likely, to be also risk factors for familial melanoma. Apart from a family history of melanoma, the best known environmental risk factor for melanoma is sunlight exposure. This risk factor can, to a large part, explain the increase in melanoma incidence over recent decades and most probably also explains the geographical variance in penetrance figures for mutation-positive melanoma families (discussed later).

The phenotypic characteristics of fair skin (inability to tan), light hair (especially red) and eye color, extensive freckling, and high number of nevi (moles, particularly atypical) are all well-recognized risk factors for melanoma. Many have been shown to be independent risk factors, but their relative risks vary considerably among different studies. This variation is most probably due to differences in phenotypic definition. Elucidation of the

DOI: 10.1081/E-EDGP 120025782

genetic variants underlying these complex characteristics should lead to an even better defined phenotypic risk profile. Molecular analysis of one pigmentation gene, *MC1R*, a regulator of melanin production, has led to the identification of a genetic risk modifier for melanoma. Beyond the finding that certain *MC1R* variants are linked to the melanoma risk phenotypes of red hair, freckles, and fair skin, these variants also confer melanoma risk irrespective of the pigmentation phenotype.[8] Furthermore, *MC1R* variants have been found to increase melanoma penetrance in *CDKN2A* mutation-positive individuals.[9,10]

Of all the above-mentioned risk factors for melanoma, nevi (especially atypical) have by far the greatest clinical implication. Also apparent as precursor lesions both in sporadic and familial melanoma, many groups have reported the co-occurrence of a nevus phenotype with familial melanoma. Throughout the years familial melanoma has been referred to by many different names, which may reflect the difficulty to reach consensus on defining the associated nevus phenotype: B-K mole syndrome (initials of described families); dysplastic nevus syndrome (DNS), familial atypical multiple mole melanoma (FAMMM) syndrome, and atypical mole syndrome (AMS). Each of these definitions includes atypical nevi as the most predominant feature of the phenotype. Atypical nevi are defined as nevi that have a size of 5 mm or larger, have a flat component, and fulfill at least two of the following three criteria: 1) variegated pigmentation, 2) ill-defined border, and 3) irregular shape. The photographs in Fig. 1 illustrate melanoma and atypical nevi. Although both phenotypes are commonly coexpressed in familial melanoma, they are not always transmitted together.

Fig. 1 Pigmented lesions on three different patients with familial melanoma or the atypical mole syndrome. The upper left picture shows several atypical nevi on the scalp, the lower picture shows the back of a patient with many common and atypical nevi, and the upper right picture shows a melanoma on the lower leg. DIFFERENTIAL DIAGNOSIS (OTHER RELATED SYNDROMES CONTAINING MELANOMA)

Melanoma/Pancreatic Cancer Syndrome

Melanoma susceptibility has also been reported in conjunction with gastrointestinal cancer and breast cancer, and an excess of pancreatic carcinoma is frequently being observed. Comparison of *CDKN2A* mutation-positive and -negative melanoma families showed an increased risk of pancreatic cancer in the mutation-positive group.[11] Interestingly, the increased risk for pancreatic cancer seems to be restricted to only some of the *CDKN2A* mutation-positive families, implying other genes and/or environmental factors are responsible for modifying the penetrance of this tumor type. Disentanglement of these issues is of utmost importance because of the high mortality associated with this cancer and the lack of routine surveillance for it. Whether the correlation with other cancers is restricted to pancreatic cancer only or also involves different cancers remains to be answered by large-scale analysis of cancer history in melanoma families.

Cutaneous Melanoma/Uveal Melanoma Families

Another tumor sometimes described in familial melanoma kindred is uveal melanoma. Although the first *CDKN2A* mutation in such a family was recently published,[12] up to then no underlying gene defect has been found in uveal/cutaneous melanoma families. Genome-wide linkage scans are currently under way to localize additional predisposition genes in such families.

Melanoma/Nervous System Tumor Syndrome

Nervous system tumors are sporadically being described in melanoma families and multiple melanoma cases. In most of these the underlying genetic defect affects the p14ARF transcript of the *CDKN2A* locus (see below),

either exclusively or concomitantly with the p16 transcript.[7]

MOLECULAR GENETICS

The first identified melanoma susceptibility gene, located on chromosome 9p21-p13, has been known by many different names: *MTS1*, *INK4A*, *CDKN2*. The currently accepted gene nomenclature is *CDKN2A*, which stands for cyclin-dependent kinase inhibitor 2A. This locus was mapped by linkage analysis in families in which melanoma was considered the sole phenotype, rather than including a nevus phenotype as well.[13] By using different first exons, exon 1α and 1β, respectively, *CDKN2A* encodes for two proteins, p16INK4A (commonly referred to as p16) and p14ARF (alternative reading frame). Both proteins are tumor suppressors involved in cell cycle regulation. p16 inhibits phosphorylation (and thereby activation) of the retinoblastoma gene product (pRb) by *CDK4* and *CDK6*. p14ARF inhibits HDM2 degradation of p53. Thus, loss of function of either protein drives cell cycle progression through deregulation of either the pRb or p53 pathways (Fig. 2).

Most germline mutations in *CDKN2A* are missense mutations found in exons 1α and exon 2, some of which are recurrent. Because of the low frequency of mutations detected in familial melanoma, mutation analysis has been extended and has led to the finding of mutations in the 5′ untranslated region and intronic regions, where they affect splicing (e.g., Refs. [14–16]). Where analyzed, all but one of the recurring mutations within *CDKN2A* have been shown to be founder mutations. The exception to this rule is a 24-base-pair duplication at the beginning of the coding region, which results in the addition (or in some cases the deletion) of one repeat unit of a naturally occurring 24-base-pair tandem repeat. Haplotype analysis of families carrying this duplication has indicated that the mutation has arisen multiple times, presumably as a result of replication slippage.

Because of the sharing of exon 2, many mutations affecting p16INK4A also affect p14ARF. However, gene defects affecting only p14ARF have been described in some melanoma families[7] thus indicating that the ARF locus is a melanoma susceptibility gene in its own right.

A candidate gene search led to the finding of a second melanoma susceptibility gene, *CDK4*, on chromosome 12q14.[17] *CDK4* mutations have been reported in only three families worldwide, but whereas its role in familial melanoma overall is low, mutations of this gene have similar impact to those in *CDKN2A*.[18] Phenotypic characteristics of the families carrying *CDK4* germline mutations do not differ from *CDKN2A*-affected families, similarly showing a high penetrance for melanoma in mutation-positive family members and no strong correlation between carrier status and nevus phenotype.

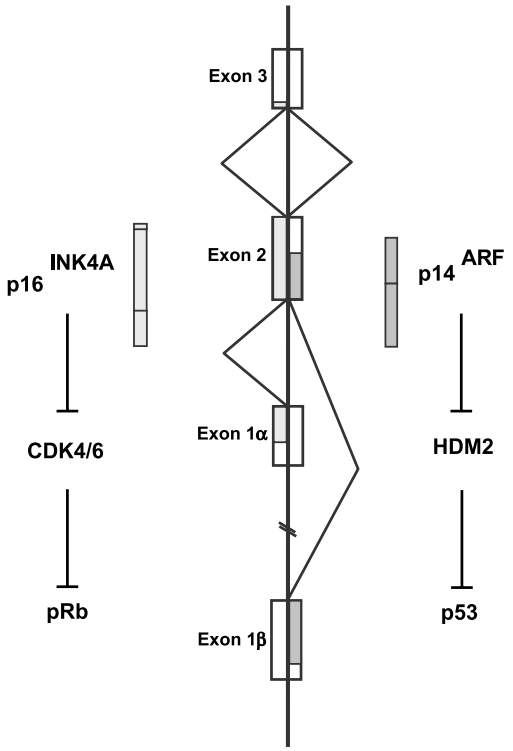

Fig. 2 The *CDKN2A* locus and its transcripts, p16 and p14ARF, generated by alternative splicing, along with their downstream targets. Boxes indicate exons, and colored sections the protein coding regions within them. (*View this art in color at www.dekker.com.*)

An on-line database[19] lists germline mutations of all disease loci implicated in familial melanoma.

Additional Melanoma Genes

Mutations in *CDKN2A* and *CDK4* account for only 5–50% of melanoma families. Many families in which no genetic defect has been found show linkage to chromosome 9p. Recent advances in mutation analysis of the *CDKN2A* gene suggest that some of these families will harbor mutations in the noncoding regions of the *CDKN2A* locus. However, several studies (including haplotype and loss of heterozygosity analyses) provide evidence for a second melanoma susceptibility gene residing centromeric of *CDKN2A*.

Considerable effort is being put into studies to identify other melanoma susceptibility genes. This effort has recently paid off with a publication showing convincing evidence for a melanoma susceptibility gene on chromosome 1p22.[20] Other nonreplicated linkage studies have

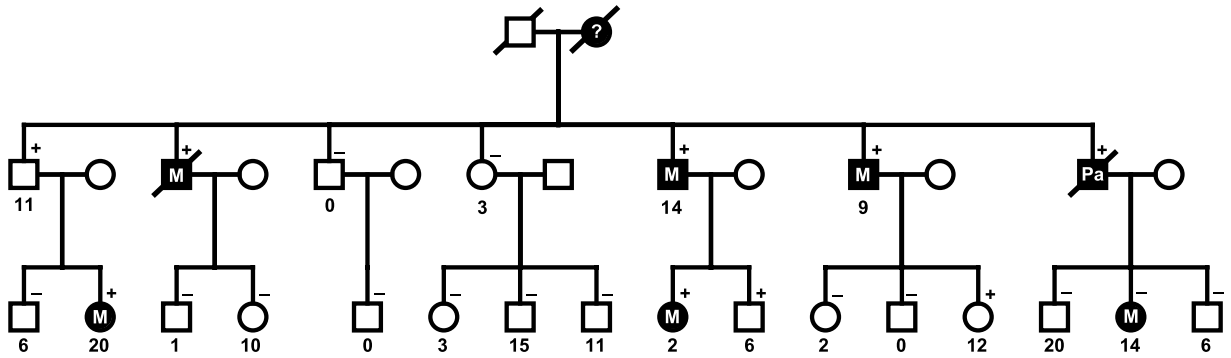

Fig. 3 Pedigree of a melanoma family, illustrating incomplete penetrance, the occurrence of pancreatic cancer, melanoma in a nonmutation carrier, and the lack of segregation of atypical nevi with carrier status. +=*CDKN2A* mutation-positive, −=*CDKN2A* mutation negative, M=melanoma, Pa=pancreatic carcinoma, ?=cancer of unknown origin. Numbers underneath individuals depict numbers of atypical nevi.

suggested the occurrence of melanoma predisposition genes on 1p36 and in the region of the HLA complex on 6p21.[21]

GENOTYPE–PHENOTYPE CORRELATIONS

The International Melanoma Genetics Consortium has estimated the penetrance of melanoma in *CDKN2A* mutation-positive family members between different geographical locations to range from 58% to 91% by the age of 80 years, with an average of 67%.[22] The broad confidence intervals make it impossible to provide precise melanoma risks. Mutations affecting only p16 compared to those affecting both p16 and p14ARF showed a trend (although not statistically significant) toward a higher penetrance in the latter.

Mutations affecting only p14ARF have been described in two melanoma families and an individual with multiple melanomas. Additionally, another multiple melanoma case and two other families have deletions of part of chromosome 9p that encompass both p16 and p14ARF coding sequences. Each of the latter and one of the p14ARF-only mutated families have cases of nervous system tumors.[7] These observations suggest that whereas both p16 and p14ARF predispose to melanoma, it is mutation of p14ARF that predisposes to nervous system tumors.

In families with an increased incidence of pancreatic cancer there is no clear correlation with the position or type of mutation in *CDKN2A*. Similarly, there is no obvious correlation between position (or type) of mutation within the gene and the development of nevi—this is particularly well highlighted by families with the same mutation being either extremely moley, or conversely, relatively free of nevi. One especially important observation is that abundance of nevi is not a predictor of *CDKN2A* mutation status. High numbers of nevi are also seen in nonmutation carriers within mutation-positive families (illustrated in the pedigree shown in Fig. 3).

MOLECULAR GENETIC TESTING, GENETIC COUNSELING, AND CLINICAL MANAGEMENT

Molecular genetic testing in familial melanoma is currently considered premature by the International Melanoma Genetics Consortium[23] for the following reasons. First, the mutation detection rate in melanoma families is very low. Second, risk estimates for mutation carriers are not well established (and have broad confidence intervals). In particular, the risk for other cancers, such as pancreatic cancer, is not clearly defined. Third, surveillance programs for mutation carriers have not yet been proven to be effective, questioning the medical benefit of the DNA test result. The last and most critical reason for not currently offering genetic testing in familial melanoma is the increased risk for melanoma in nonmutation carriers in *CDKN2A* mutation-positive families. Predictive DNA testing then should only be offered within the bounds of a clearly defined research protocol. In this setting, extensive genetic counseling addressing the limited value of testing in familial melanoma is a prerequisite. Such research protocols might offer possibilities to explore the still pending issues concerning the risk benefit and potential value of genetic testing for familial melanoma. They will need to address efficient screening protocols for melanoma and pancreatic cancer in the hope of leading to a decrease in mortality by earlier detection. Outside of such research investigations, clinical management of familial melanoma should be restricted

to recognition of high-risk individuals and subsequent yearly or half-yearly skin examination from age 10–12 onward. The strong decrease in life expectancy with increasing tumor thickness makes early recognition of melanoma through regular skin examinations the hallmark of clinical management.

CONCLUSION

Melanoma predisposition is hereditary in 10% of cases. Large international research projects have been set up to unravel many of the remaining issues concerning familial melanoma, which include the following:

- Identifying the causative gene defect in the majority of families.
- Determining precise risk estimates for melanoma and other cancers, especially pancreatic cancer, in mutation carriers.
- Attributing the degree and causes of the increased risk of melanoma in nonmutation carriers of mutation-positive families.
- Elucidating the underlying causes of the nevus phenotype and its risk implications.
- Assessing the efficacy of surveillance programs for melanoma and other cancers.

At present, the clinical management of familial melanoma should be restricted to recognition of the disease and subsequent regular skin examinations of high-risk individuals.

Metabonomics and Its Role in Disease Diagnosis

M

John C. Lindon
Jeremy K. Nicholson
Elaine Holmes
Imperial College London, London, U.K.

INTRODUCTION

The determination of the human genome generated much interest in using changes in levels of gene expression in individuals to discover the basis of disease and for the identification of new drug targets. Some significant advances have been made using this approach, and high-risk individuals can be identified. The ability to relate any changes seen to real conventional end points used in disease diagnosis remains elusive and much effort has been focused on the consequent protein level changes in tissues, cells, and biofluids (proteomics).

Metabonomics is another approach that provides data sets of similar high information content by systemic spectroscopic profiling of metabolites and metabolic pathways in whole organisms through study of biofluids and tissues. This results in complex multivariate data sets that require pattern recognition tools for interpretation, and the aim of these procedures is to extract biochemical information that is of diagnostic or other classification value. These identified substances become biomarkers that reflect actual biological events.

OVERVIEW

The main clinical and pharmaceutical areas where metabonomics is impacting include

- Validating animal models of disease, including genetically modified animals.
- Preclinical evaluation of drug safety, ranking of candidate compounds, assessment of safety in clinical trials and after product launch, evaluation of the effects of interactions between drugs, and between drugs and diet, and providing new measures of pharmaceutical efficacy.
- Improved diagnosis of human diseases, especially chronic and degenerative diseases.
- Better understanding of human population differences (epidemiological studies) and patient stratification for clinical trials and drug treatment (pharmaco-metabonomics).

Metabonomics yields time-dependent patterns of change in response to disease or drug effects. One role for metabonomics therefore is to direct timing of proteomic and genomic analyses to maximize the probability of observing ''omic'' biological changes that are relevant to functional outcomes.

Metabonomics, defined as the quantitative measurement of the dynamic multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification,[1,2] bridges the gap between other -omics measurements and real-world end points. Metabolites can easily be identified and quantified, and changes can be related to health and disease, and are changeable by therapeutic intervention. There have been a number of reviews of metabonomics recently.[3,4]

METABONOMICS DATA ACQUISITION METHODS

The two principal methods used comprise ^{1}H nuclear magnetic resonance (NMR) spectroscopy and liquid-chromatography mass spectrometry (LC-MS). Nuclear magnetic resonance spectroscopy is nondestructive and provides detailed information on molecular structure, molecular dynamics, and mobility, especially in complex mixture analysis. Mass spectrometry is more sensitive than NMR spectroscopy and is used extensively for molecule identification, but in complex mixtures of very variable composition, the separation step increases variability. Most published studies on mammalian biology have used NMR spectroscopy, but LC-MS techniques with electrospray ionization are increasing in usage.

Typically, metabonomics is carried out on biofluids as these provide an integrated view of systems biology. The biochemical profiles of the main diagnostic fluids reflect both normal variation and the impact of drug toxicity or disease on single or multiple organ systems.[3] Urine and plasma obtained essentially noninvasively are appropriate for clinical trials monitoring and disease diagnosis. However, there is a wide range of fluids that can be, and have been, studied, including cerebrospinal, seminal,

DOI: 10.1081/E-EDGP 120040392

amniotic, synovial, digestive, blister and cyst fluids, and lung aspirates and dialysis fluids.[3]

A ^{1}H NMR spectrum of urine contains thousands of sharp lines from predominantly low-molecular weight metabolites (Fig. 1). The position of each spectral band (its chemical shift) gives information on molecular group identity. The splitting pattern on each band (J-coupling) provides knowledge about through-bond connectivity to nearby protons and molecular conformations. The band areas relate to the number of protons giving rise to the peak and hence to the relative concentrations of the substances in the sample. Absolute concentrations can be obtained if an internal standard of known concentration is added to the sample.

Plasma and serum contain both low- and high-molecular weight components, and these give a wide range of signal line widths. Broad bands from protein and lipoprotein signals contribute strongly to the ^{1}H NMR spectra, with sharp peaks from small molecules superimposed. Standard NMR pulse sequences can be used for spectral editing experiments. These are based on molecular diffusion coefficients or on NMR relaxation times and can be used to select only the contributions from macromolecules or the signals from the small molecule metabolites, respectively.

Nuclear magnetic resonance spectra take only a few minutes to acquire using robotic flow-injection methods, with automatic sample preparation involving buffering and addition of D_2O as a magnetic field lock signal for the

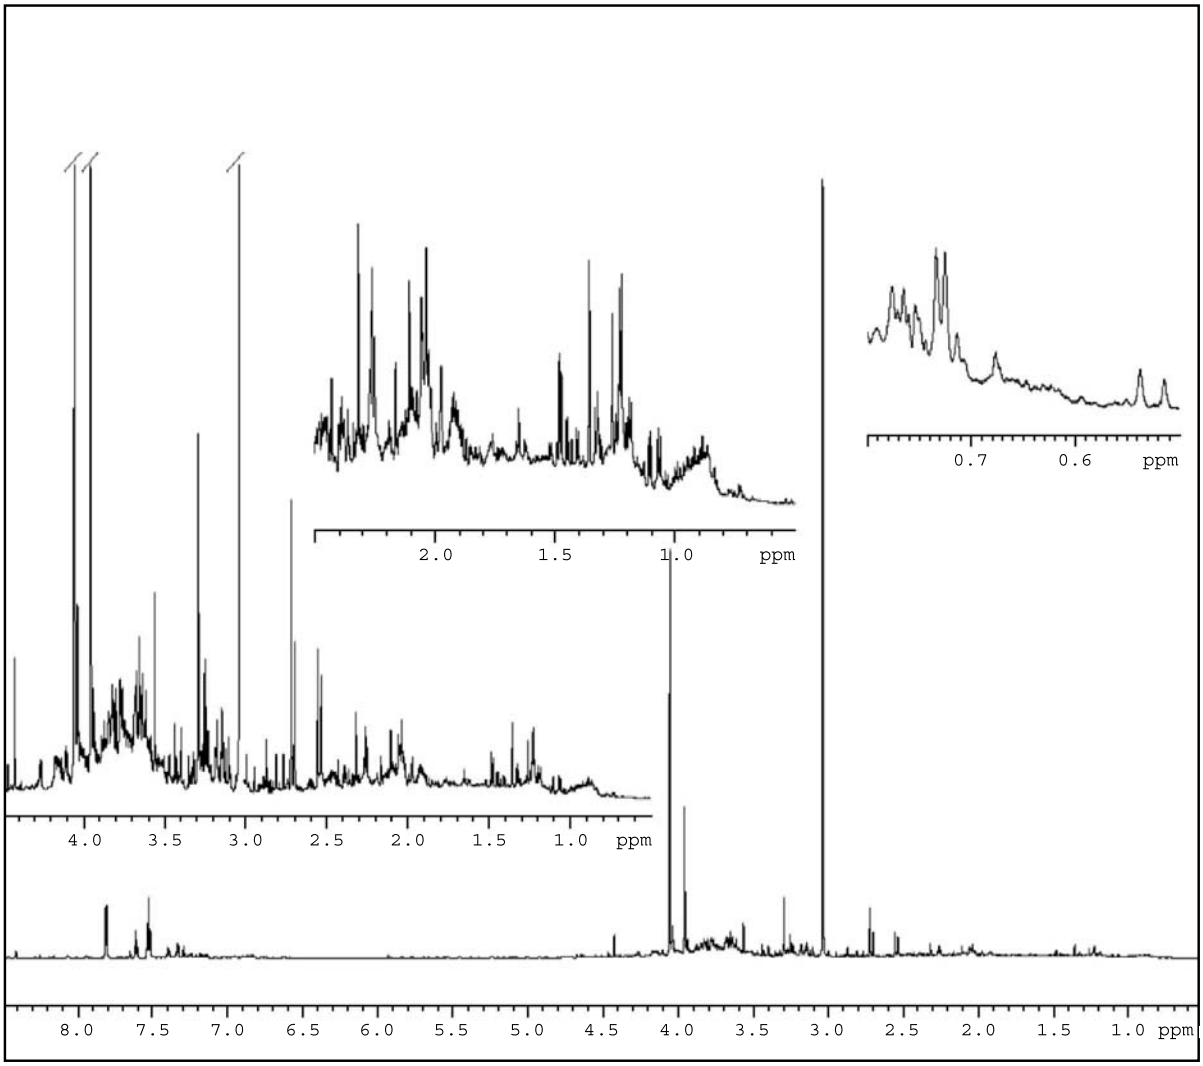

Fig. 1 ^{1}H NMR spectrum of human urine, with expansions showing the level of complexity. Peaks arise from different chemical types of hydrogen in the substances. The areas relate to molar concentrations, and the positions and splittings allow information to be obtained on molecular identity. The signal from water has been suppressed by an NMR procedure to avoid dynamic range errors in the detection process.

spectrometer. The large NMR signal from water is eliminated by the use of standard NMR solvent suppression methods. Using flow probes, the capacity for NMR analysis has increased and ~200 samples can be measured per day. Commercially available cryogenic NMR probes where the detector coil and preamplifier are cooled to around 20 K to provide up to a ×5 reduction in thermal noise. This has permitted the routine use of high-throughput natural abundance ^{13}C NMR spectroscopy of biofluids.

The use of mass spectrometry is increasing,[5] and for applications on biofluids, an HPLC chromatogram is generated with MS detection, using electrospray ionization (usually with both positive and negative ion chromatograms). At each point in the chromatogram, there is a full mass spectrum and so the data are three-dimensional (3-D), retention time, mass, and intensity, and this can be used as input to pattern-recognition (PR) studies.

The study of small pieces of intact tissues is possible using ^{1}H magic angle spinning (MAS) NMR spectroscopy.[6] Spinning the sample (~4–6 kHz typically) at an angle of 54.7° relative to the magnetic field reduces the line broadening effects seen in such heterogeneous, nonliquid samples. Studies have shown that diseased or toxin-affected tissues have characteristically different metabolic profiles to those taken from healthy organs. ^{1}H magic angle spinning NMR spectroscopy can also be used to probe metabolite dynamics and compartmentation. It can also be applied to in vitro systems such as tissue extracts or cell systems such as spheroids. A combined metabonomic analysis of different biofluids, tissue extracts, and intact tissues is possible, providing a comprehensive view of the biochemical responses to a pathological situation, an approach termed integrated metabonomics.

DATA ANALYSIS

The NMR spectrum of a sample can be considered an object in a multidimensional set of metabolic coordinates, the values of which are the spectral intensities at each data point. Similarity or differences between samples can then be evaluated using multivariate statistical methods or other pattern-recognition (PR) approaches.[7]

The general aim of PR is to classify an object based on identification of patterns in a set of experimental measurements or descriptors. It can also be used for reducing the dimensionality of data sets, e.g., using 2-D or 3-D mapping procedures, to enable easy visualization of any clustering of the samples. Data can be modeled using PR techniques so that the class of separate samples (a ''validation set'') can be predicted based on a series of mathematical models derived from original data or ''training set.''

Principal components analysis (PCA), one of the simplest techniques used extensively in metabonomics, allows the expression of most of the variance within a data set using a smaller number of factors or principal components. Each PC is a linear combination of the original data parameters with successive PCs explaining the maximum amount of variance possible, not accounted for by the previous PCs. Each PC is by definition independent of the other PCs. Conversion of the data matrix to PCs results in two matrices, scores and loadings. Scores are the new coordinates for the samples and may be regarded as the new variables, and in a scores plot, each point represents a single NMR spectrum. The PC loadings define the way in which the old variables are linearly combined to form the new variables and indicate which variables carry the greatest weight in transforming the position of the original samples from the data matrix into their new position in the scores matrix. In the loadings plot, each point represents a different NMR spectral region.

Unsupervised methods such as PCA are useful for comparing pathological samples with control samples, but supervised analyses that model each class individually are preferred where the number of classes is large. A widely used supervised method is partial least squares (PLS). This is a method which relates a data matrix containing independent (e.g., spectral) variables to a matrix containing dependent variables (e.g., variables describing the diagnosis) for those samples. Partial least squares can be used to examine the influence of time on a data set, which is useful for biofluid NMR data collected from samples taken over a time course of the progression of a pathological effect. Partial least squares can also be combined with discriminant analysis (DA) to establish the optimal position to place a discriminant surface which best separates classes.

BIOMARKER IDENTIFICATION

Identification of the metabolic biomarkers of a pathological situation can involve the application of the full range of analytical physical chemistry techniques, including mass spectrometry and NMR spectroscopy. The NMR spectra of urine and other biofluids, although they are very complex, allow many resonances to be assigned directly based on their chemical shifts, signal multiplicities, and by adding authentic material, and further information can be obtained by using spectral editing techniques.

Two-dimensional NMR spectroscopy can be useful for increasing signal dispersion and for identification of biomarkers. These include the ^{1}H–^{1}H 2-D J-resolved experiment, which yields information on the multiplicity and coupling patterns of resonances. Other 2-D experiments known as COSY and TOCSY provide ^{1}H–^{1}H

spin–spin coupling connectivities, thus giving information on which hydrogens in a molecule are close in chemical bond terms. Use of other types of nuclei, such as naturally abundant ^{13}C, ^{15}N, or ^{31}P, can help assign NMR peaks, and here 2-D correlation NMR experiments can also be obtained by the use of NMR pulse sequences that allow detection at the more abundant and sensitive ^{1}H nucleus. For example, these yield both ^{1}H and ^{13}C NMR chemical shifts of CH, CH_2, and CH_3 groups, useful again for identification purposes. There is also a sequence that allows correlation of protons to quaternary carbons.

It is also possible to separate substances of interest from a biofluid sample using solid-phase extraction or HPLC, and directly coupled chromatography-NMR spectroscopy methods can be used. The most powerful is HPLC-NMR-MS.[8] Other MS-based methods include MS^n for identification of fragment ions and FT-MS or TOF-MS for accurate mass measurement and derivation of molecular formulae.

APPLICATION TO PHYSIOLOGICAL EFFECTS

To understand biochemical alterations caused by disease, it is necessary to understand any underlying physiological sources of variation. Metabonomics has been used to determine the metabolic differences in cohorts of normal subjects and control laboratory animals. Many effects can be distinguished and characterized using metabonomics, including male/female differences, age-related changes, estrus cycle effects, diet, diurnal effects, interspecies differences and similarities, and the effects of gut microflora.[9]

Metabonomics has also been used for the phenotyping of mutant or transgenic animals that model human diseases and the investigation of the consequences of transgenesis such as the transfection process.[9] Metabonomic approaches can give insight into the metabolic similarities or differences between mutant or transgenic animals and the human disease processes that they are intended to simulate and hence their appropriateness for monitoring the efficacy of novel therapeutic agents.

APPLICATION TO DISEASE DIAGNOSIS

Many examples exist in the literature on the use of NMR-based metabolic profiling to aid human-disease diagnosis and most of the earlier studies have been reviewed[3] with a selection summarized below.

^{1}H NMR spectroscopy has been used to analyze the composition of the urine and plasma of a number of diabetic patients. There are marked elevations in the plasma levels of the ketone bodies and glucose, post-insulin withdrawal, and changes to lipoprotein composition. No other technique can provide a simultaneous assay on all three ketone bodies, glucose, the lipoproteins, and other important biochemicals in one fast and nondestructive test.

The levels of a variety of endogenous components in the synovial fluid aspirated from the knees of patients with osteoarthritis, rheumatoid arthritis, and traumatic effusions have been studied using NMR spectroscopy. The NMR spectrum of synovial fluid shows the signals of a large number of endogenous components, and correlations were reported between the disease states and levels of the *N*-acetyl signals from acute-phase glycoproteins and the levels and type of triglyceride.

The chemical composition of cerebrospinal fluid (CSF) gives a good indication of the health or otherwise of the central nervous system (CNS), and therefore biofluid NMR studies of CNS diseases have focused on CSF. Studies in this area include drug overdose, Reye's syndrome, and Alzheimer's disease.

A number of investigations involving kidney disease have been reported, including chronic renal failure, the uremic syndrome, glomerularnephritis, autosomal dominant polycystic kidney disease, and renal transplantation outcome.

Extensive biochemical assignments from the ^{1}H NMR spectra of seminal fluid and its component secretions, prostatic and seminal vesicle fluids, have been given, and the spectra derived from normal controls with those from patients with vasal aplasia (obstruction of the vas deferens leading to blockage of the seminal vesicles) and those with nonobstructive infertility have been compared.

One area of early use of biofluid metabolic profiling is in diseases caused by inborn errors of metabolism. Conventional diagnostic methods, including specific enzyme assays and gas chromatography/mass spectrometry, are sensitive but time-consuming. However, NMR spectroscopy of biofluids has been shown to be very powerful for the detection of inborn errors of metabolism. Most of the work has involved ^{1}H NMR studies on urine or serum.[10]

Metabonomics has been used to diagnose brain-tumor type based on NMR spectra of perchloric acid extracts of brain-tumor tissue,[11] classified as meningiomas, astrocytomas, glioblastomas, other glial tumors, medulloblastomas, metastases, and other tumors. Principal components analysis was used to reduce the data dimensionality and spectra were classified using neural networks. This gave $\sim$85% correct classification for meningiomas and nonmeningiomas. Classification of gliomas gave 62% correct within one grade. Other studies have used MAS NMR spectroscopy of involved and uninvolved tumor tissues, for renal cell carcinoma,[12] prostate,[13] and breast[14] tumors.

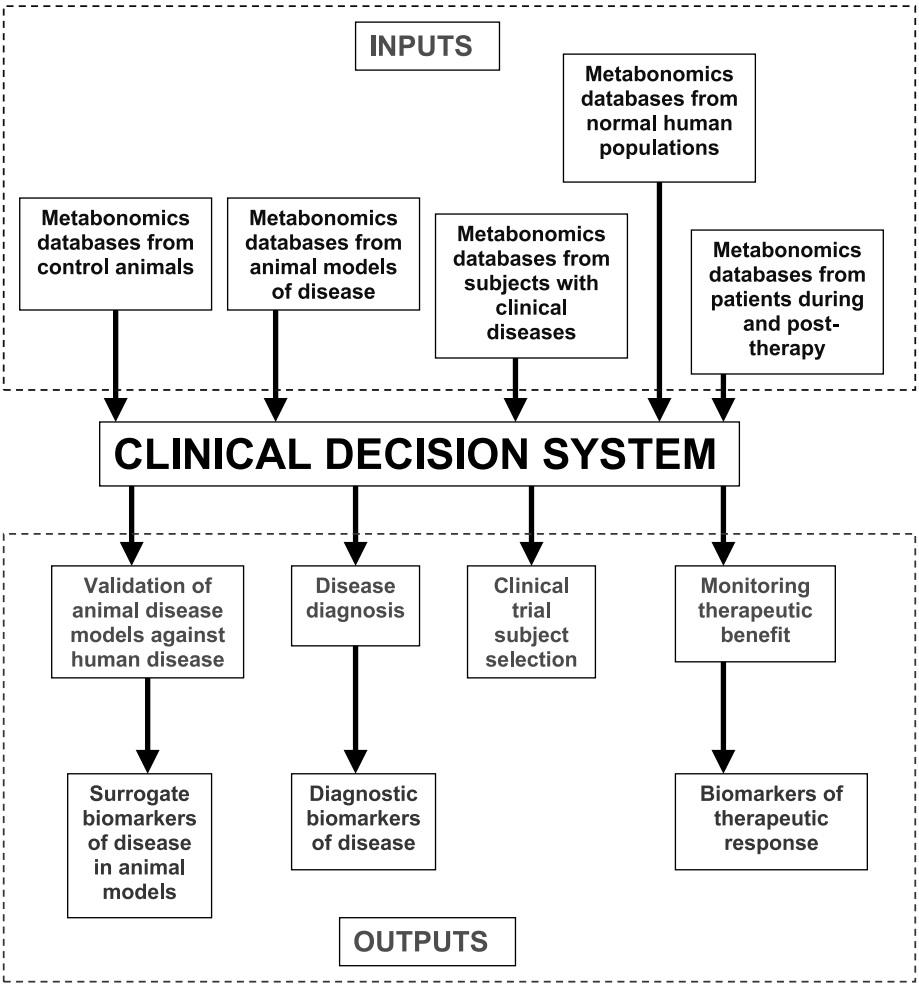

Fig. 2 Incorporation of metabonomics-based expert systems into clinical diagnosis for evaluation of disease models and the effectiveness of therapeutic procedures. (*View this art in color at www.dekker.com.*)

The ''gold standard'' diagnostic method for coronary heart disease (CHD) is X-ray angiography after injection of opaque dye into the blood stream. This is expensive and invasive with an associated 0.1% mortality and 1–3% of patients experiencing adverse effects. Recently, metabonomics has provided a method for diagnosis of CHD noninvasively through analysis of a blood serum sample using NMR spectroscopy.[15] Patients were classified, based on angiography, into two groups, those with normal coronary arteries and those with triple coronary vessel disease. Using a training set, the samples from the two classes were easily distinguished. The sample classes of a separate validation set were then predicted based on the model with a sensitivity of 92% and a specificity of 93%. The severity of the disease was diagnosed in patients with stenosis of one, two, or three of the coronary arteries. Separation of the three sample classes was evident although none of the wide range of conventional clinical risk factors that had been measured was significantly different between the classes.

CONCLUSION

There continues to be a need for advances in metabonomics analytical technologies both in NMR and MS. Nuclear magnetic resonance is likely to remain the method of choice for a broad impartial survey of metabolic profiles, especially given recent gains in sensitivity through the use of cryoprobe detectors. Mass spectrometry coupled to a separation stage is always likely to yield better detection limits for specific classes of metabolite.

It has proved possible to derive new biochemically based assays for disease diagnosis and to identify

combination biomarkers for disease, which can then be used to monitor the efficacy of drugs in clinical trials. Based on differences observed in metabonomic databases from control animals and from animal models of disease, diagnostic methods and biomarker combinations might be derivable in a preclinical setting. The use of databases to derive predictive expert systems for human disease diagnosis and the effects of therapy require compilations from both normal human populations and patients before, during, and after therapy. This approach is summarized in Fig. 2.

The ultimate goal of systems biology is the integration of data acquired from living organisms at all levels of molecular biology. In this respect, transcriptomics, proteomics, and metabonomics will all play an important role. Through the combination of these, and related approaches, will come an improved understanding of an organism's total biology, and with this better understanding of the causes and progression of human diseases, and the improved design and development of new and better targeted pharmaceuticals.

Microarrays—Confocal Scanning

M

Arthur E. Dixon
Savvas Damaskinos
Biomedical Photometrics Inc., Waterloo, Ontario, Canada

INTRODUCTION

Widefield confocal scanning is the imaging method of choice for microarrays. A confocal scanner rejects light from above and below the focal plane, thus rejecting fluorescence from the microarray substrate or from the aqueous buffer solution that is in contact with the array in some microarray formats. This article describes the principle of widefield confocal imaging and shows how this imaging technique fits the requirements for reading genetic and protein microarrays, and for tissue arrays. The sequence of events for reading arrays is described, and examples of both genetic microarray and tissue array images are presented.

CONFOCAL IMAGING

Three types of widefield confocal scanners are common for imaging microarrays. Scanning beam systems obtain a wide field of view using a telecentric f-theta laser scan lens combined with a slow-moving scanning stage;[1,2] scanning objective systems rapidly move a small objective lens across the width of the microarray while slowly moving the microarray in the perpendicular direction on a moving stage; and scanning stage systems use rapid stage motion to move the specimen under a stationary-focused laser beam. Confocal scanning laser microscopes can also be used, but their small field of view requires automated stage motion combined with image tiling to produce an image of the entire microarray. In addition to the problems of tiling separate subimages together, especially when the focus position may have changed from one subimage to the next, the boundaries of the subimages are exposed twice to the laser beam (and the corners four times), so that some fluorophore bleaching may occur at the edges of the images, resulting in poor quantification of probe spot intensity. The same problems arise in microarray readers based on CCD microscopes. Here the subareas are illuminated with a white light source, and nonconfocal images are collected using a CCD camera. A computer-controlled stage is used to move from one subarea to the next, and tiling is used to stitch the images together. In addition to multiple exposures of the fluorophores near the edges of the subareas, these systems have the additional disadvantages of collecting out-of-focus fluorescence from the glass substrate or an aqueous buffer solution (as they are not confocal).

Figure 1 shows a simple confocal microscope. Light from a point source (often a pinhole illuminated by a focused laser beam) passes through a beam splitter, expands to fill a microscope objective, and is focused to a tiny volume (at the focal point) inside the specimen (shown using solid lines). Light reflected (or emitted) from that point in the specimen is collected by the objective lens (a microscope objective) and is partially reflected to the right to pass through a pinhole to reach the detector. At the same time, light is reflected from parts of the specimen above the focal point (shown with dashed lines). This light is also collected by the objective lens and is partially reflected to the right, converging toward a focus behind the pinhole. Most of this light runs into the metal surrounding the pinhole and is not detected. Similarly, light reflected from parts of the specimen below the focal point (shown as dotted lines) converges toward a focus in front of the pinhole and then expands to hit the metal area surrounding the pinhole. Again, this light is blocked from reaching the detector. Thus the pinhole blocks light from above or below the focal point, so the detector output is proportional to the amount of light reflected back from only the parts of the specimen at the focal point. Images of the source pinhole and the detector pinhole formed by the objective lens are at its focal point (the source pinhole, detector pinhole, and the focal point are ''confocal'' with each other).

An image is collected by moving the specimen under the fixed laser beam in a raster scan (a scanning-stage microscope), by moving the beam using mirror scanners (a scanning-beam system), by moving the objective lens (a scanning-head system), or by moving the beam in one direction while moving the specimen in the perpendicular direction. Confocal images consist of sharp and empty areas; nonconfocal images consist of sharp and blurry areas. In a confocal microscope, light from out-of-focus parts of the specimen is rejected by the confocal pinhole, and it is this absence of out-of-focus information that allows three-dimensional images to be formed using a series of confocal slices.

DOI: 10.1081/E-EDGP 120020791

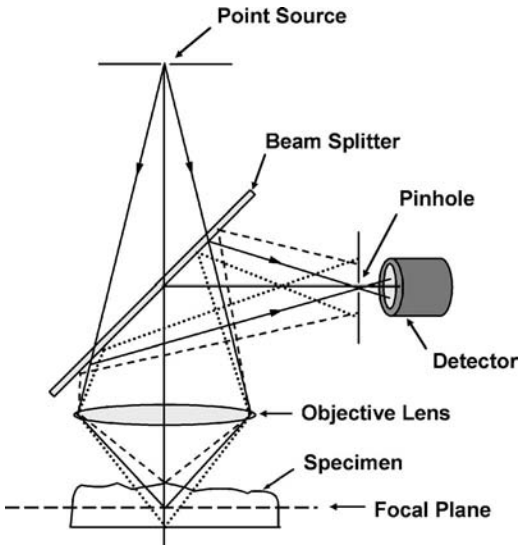

Fig. 1 Confocal laser microscope.

For many applications, an infinity-corrected confocal microscope is more useful than the simple microscope shown above. In an infinity-corrected mxicroscope (shown in Fig. 2), a parallel beam from a laser or other light source is focused by an infinity-corrected microscope objective onto a specimen at the focal plane. Light reflected from the specimen is collected by the microscope objective, and partially reflected by the beam splitter toward a detector lens that focuses the beam to pass through the detector pinhole to reach the detector. Just as before, light reflected (or emitted) from above or below the focal plane is rejected by the pinhole, and the microscope is confocal.

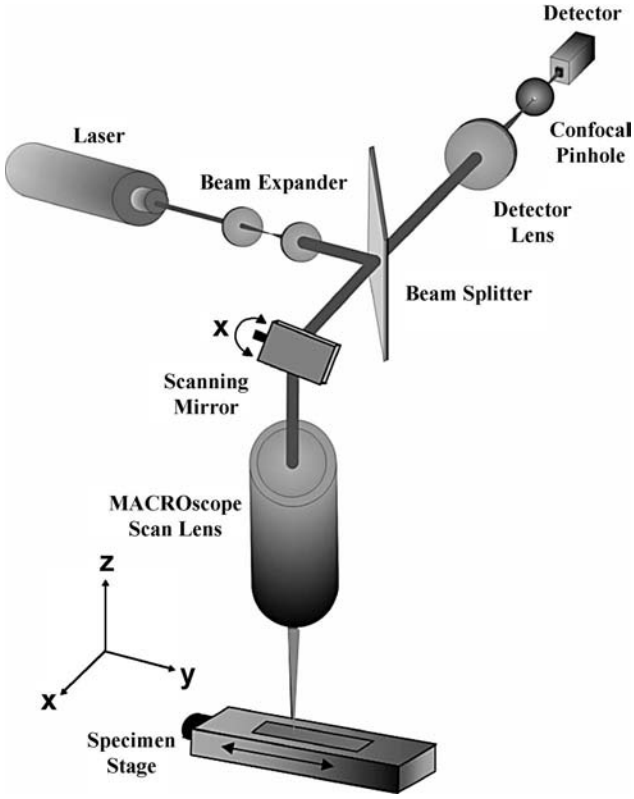

Fig. 3 Widefield confocal scanning laser MACROscope®.

A widefield scanning-beam confocal imaging system (MACROscope®) is shown in Fig. 3. Instruments based on this design behave very much like confocal scanning laser microscopes. All of the confocal scanning laser microscopy (CSLM) contrast mechanisms are available,

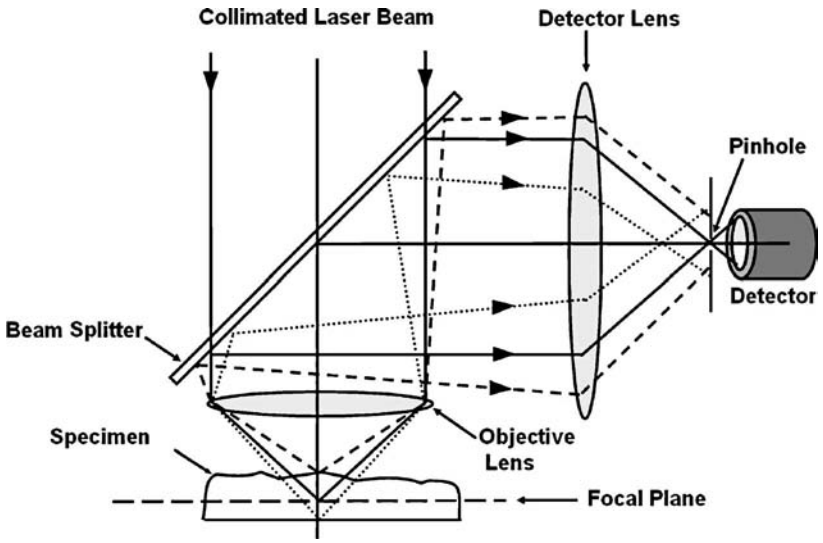

Fig. 2 Infinity-corrected confocal microscope.

but these instruments have a field of view that is about 20 times larger than a scanning laser microscope using a microscope objective with the same numerical aperture as the laser scan lens.

In Fig. 3, a beam expander expands the laser beam to match the diameter of the entrance pupil of the laser scan lens. This beam is reflected by a beam splitter toward a computer-controlled scanning mirror, situated at the entrance pupil position of a telecentric f-theta laser scan lens. The laser scan lens focuses the scanning beam on the specimen (usually on a microscope slide), which is mounted on a scanning stage. The scanning stage moves slowly in a direction perpendicular to the direction of the beam scan, such that the focused laser spot performs a raster scan across the specimen. Light reflected from, or fluorescence emitted by the specimen, is collected by the laser scan lens, passes back through the beam splitter, and is focused on a confocal pinhole in front of the detector. Light passing through the pinhole is detected. Photomultiplier tubes are often used as detectors because of their high speed, high sensitivity, and large dynamic range.

MICROARRAY IMAGING

For imaging DNA or protein microarrays in fluorescence, filters are added to the detection arm to block the reflected laser light, as well as fluorescence from other fluorophores on the specimen. For example, many microarrays use both Cy3 and Cy5. Cy3 is excited by a green laser (usually 532 nm), and Cy5 is excited with a red laser (often 635 nm). Although the red laser excites only Cy5, the green laser weakly excites Cy5 as well as strongly exciting Cy3. In addition, the emission spectra of Cy3 and Cy5 overlap slightly, so the reader manufacturer must choose filters carefully so there is no cross talk between detection channels. There may also be residual fluorescence from the substrate, which is minimized by confocal detection. Microarray scanners are available with up to four different laser sources, and multiple detection arms. Filter wheels containing a large number of filters allow sequential or simultaneous detection of several different fluorophores.

Several steps are required to image a microarray. First, the fluorophores used on the array are selected by the operator to enable the instrument to choose lasers and filter sets. A preview scan of the entire glass slide is performed for each fluorophore chosen, which allows the operator to choose the area to be imaged, and to set the detector gain and offset. The offset is set to minimize the background noise in the area of the image between the probe spots—this should be set to a small value, but not to zero. The gain is then usually set so that the brightest probe spots in the image are just below detector saturation. For some applications, the intensity of images from different fluorophores is adjusted by changing laser intensities. Finally, a high-resolution scan is performed on the area of the slide containing the microarray probe spots. For common microarrays with probe spots of 100 μm or more in diameter, a pixel setting of 5 μm works well. For best results, the pixel size should match the diameter of the focused laser beam. In some scanners, the smallest pixel size available is smaller than the focal spot diameter, so choosing this setting will not improve the image resolution, but it does act like frame averaging by making a larger number of overlapping intensity measurements inside the area of each probe spot.

The objective of these measurements is to analyze the fluorescence images to provide the user with a table of numbers (for each fluorophore) representing the integrated fluorescence intensity of all of the probe spots on the microarray. These numbers can then be transferred to an analysis program that matches the user's specific requirements. Image analysis comprises several steps. First, measurement circles in a grid pattern matching the microarray grid are placed around every probe spot in the image. Because the probe spots are not always centered exactly on the grid positions, the position of the measurement circles is adjusted to match the actual probe spot positions. The fluorescence intensity for each probe spot is calculated by integrating the fluorescence intensity of the pixels inside each measurement circle, and then subtracting the local background intensity calculated from pixels in the area just outside each circle. One number, representing the integrated fluorescence intensity for each probe spot and for each fluorophore, is stored in a table which is then available for the user's specific application software.

A trained operator can perform all of the steps described above to image a microarray like that shown in Fig. 4 in both Cy3 and Cy5, and analyze the images to produce tables of integrated intensities in an hour. A fully automated reader performs the same task in 10 min, and the only interaction with the operator is to load the microarray and specify which fluorophores are used. Ten minutes later, the operator can retrieve the output data files.

Figure 4A shows Cy3 and Cy5 images of a DNA microarray on a glass microscope slide, imaged with 5-μm pixels (and 5-μm focal spot size) on a DNAscope™ IV. The scan area was 20×70 mm. Figure 4B (left) shows a magnified image of one subgrid from the image in Fig. 4A, and Fig. 4B (right) illustrates the placement of measurement circles by the automated analysis routines in MACROview™. Note that the automated detection and placement algorithm has correctly ignored the smear of fluorescence at the edge of the picture and the dust particles in the image. Many grid placement algorithms require a bright fluorescent probe spot at the top left of

each subgrid (or at some other known position); this one does not.

Tissue microarrays and other tissue specimens on glass microscope slides are usually imaged in brightfield, using a white light source. These specimens require higher optical resolution than genetic microarrays on glass microscope slides, and in some cases submicron resolution is required. The tissue microarray shown in Fig. 5A was imaged on a DNAscope™ IV with a high-resolution (2-μm focal spot size) option, in a single scan. This is an epifluorescence image, excited by a green laser. Figure 5B is an expanded view of six of the tissue specimens.

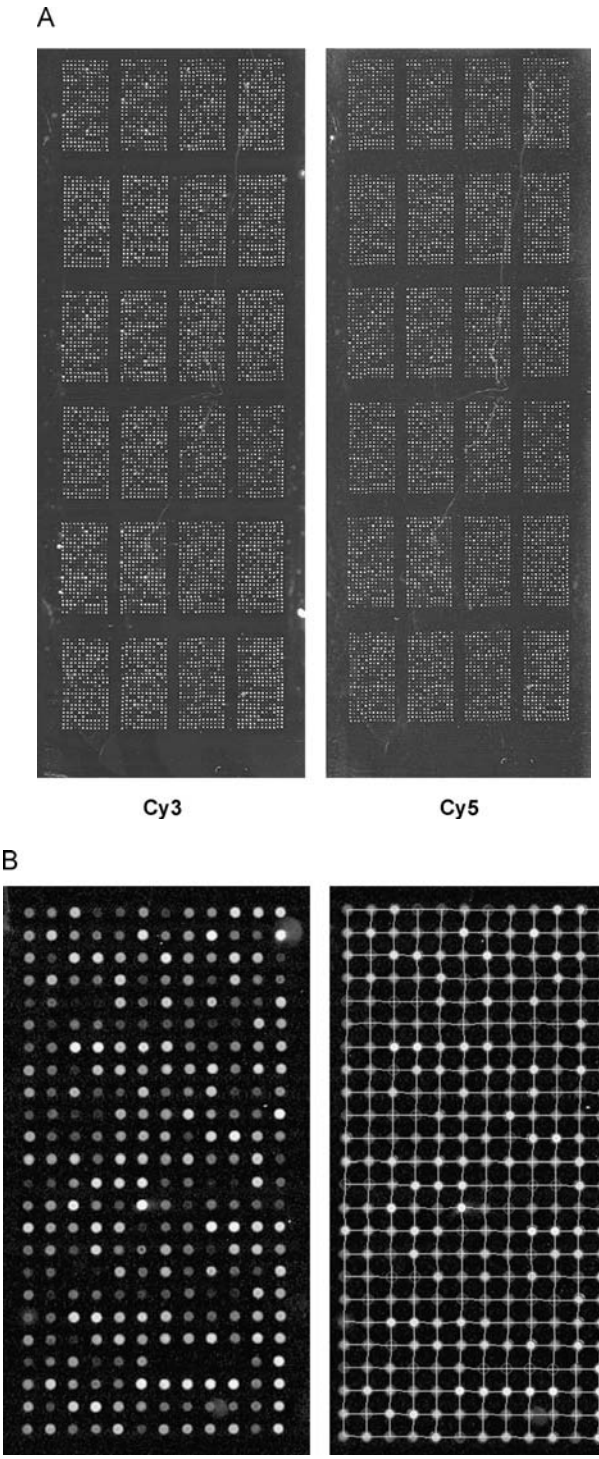

Fig. 4 (A) Fluorescence image of a genetic microarray on a glass microscope slide. Left is a Cy3 image; right is a Cy5 image. (B) Expanded view of one subarray from the image in (A). Measurement circles are shown around probe spots in the right image as placed by an automatic analysis algorithm.

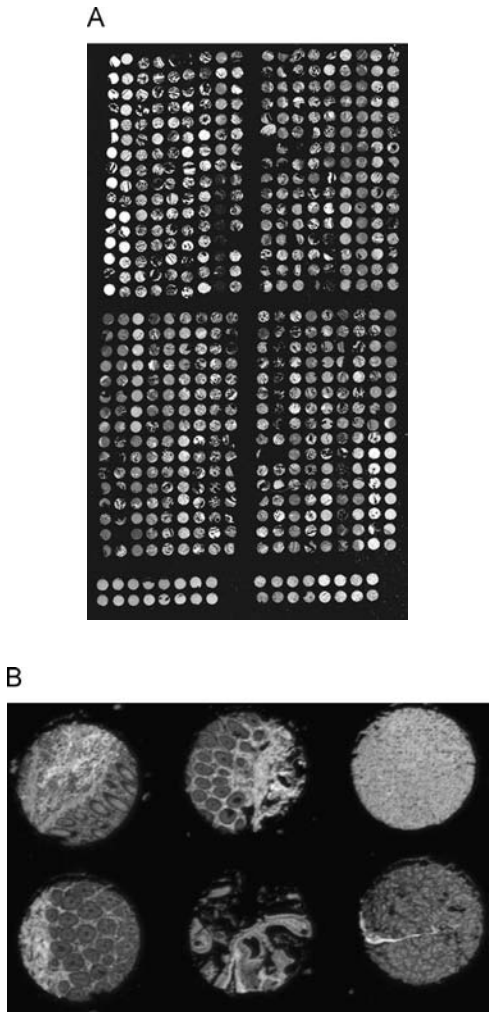

Fig. 5 (A) Epifluorescence image of a tissue array on a glass microscope slide. (B) Expanded view of six tissue specimens on the tissue array in (A).

CONCLUSION

Widefield confocal imaging provides the resolution, sensitivity, dynamic range, and background fluorescence rejection for fluorescence imaging of genetic and protein microarrays. The same instruments can also be adapted for imaging tissue arrays, both in brightfield and in fluorescence. We have reviewed the principles of confocal microscopy and the MACROscope® technology

on which the DNAscope™ is based. Images of DNA and tissue microarrays were shown, and the steps required to image and analyze a genetic microarray were described.

ACKNOWLEDGMENTS

We wish to thank our colleagues at the Institute for Biological Sciences at the National Research Council of Canada in Ottawa for providing the microarray shown in Fig. 4.

The tissue microarray shown in Fig. 5 was provided by Beecher Instruments, 820 Hummingbird Court, Sun Prairie, WI 53590, USA.

Microarrays—Detecting DNA Copy-Number Changes

Beatriz Carvalho
Marjan Marije Weiss
Bauke Ylstra
Gerrit A. Meijer
VU University Medical Center, Amsterdam, The Netherlands

INTRODUCTION

Gross chromosonal abnormalities leading to gains and losses of (parts of) chromosomes are frequent events in the majority of cancers, especially in solid tumors. Microarray-based comparative genomic hybridization (array-CGH) is the most versatile technique currently available for detecting DNA copy number changes. We will review the array-CGH technique that, as the conventional comparative genomic hybridization (CGH), is able to detect DNA copy number changes throughout the whole genome in one single experiment, but with much higher resolution. Applications and future developments of array-CGH will also be discussed.

WHAT IS MICROARRAY-CGH?

Genomic instability is a hallmark of cancer development, and in the vast majority of human malignancies overt instability at the chromosomal level exists, frequently giving rise to unbalanced chromosome copy-number changes. For long, the possibilities for detecting these DNA copy-number changes were limited. Karyotyping required living cells, which severely hampered wide-scale clinical application of the technique outside the fields of hematological malignancies and congenital disorders. Fluorescence in situ hybridization allowed the analysis of only a very limited number of targets at a time, whereas DNA cytometry could only disclose the presence of gross genomic aberrations without any further specificity.[1] This situation has dramatically changed with the introduction of comparative genomic hybridization (CGH). Comparative genomic hybridization is a molecular cytogenetic technique that allows the genome-wide analysis of alterations in DNA sequence copy number.[2] Differentially labeled tumor and reference DNAs compete for hybridizing to normal metaphase chromosomes. The ratio between the two labels along the chromosome axis allows the mapping of gains/amplifications and deletions throughout the whole genome of a tumor (Fig. 1). Because for CGH no cell culturing is required, and even formaldehyde-fixed paraffin-embedded material can be used, this technique has become one of the most popular genome scanning techniques and has contributed to an enormous progress in the analysis and knowledge of chromosomal changes in solid tumors.[3,4] However, CGH is limited by the poor resolution of the metaphase chromosomes. Genomic alterations smaller than 5–10 Mb are not detected.[3] The recently developed CGH microarray technique overcomes this limitation[5,6] as the metaphase chromosomes are replaced by an ordered set of DNA fragments (typically 100–200 kb) of which the precise chromosomal location is known (Fig. 2). In this case the resolution is limited by the insert size and density of the DNAs spotted on the glass slide.[5–7] Thus, microarray-CGH has the ability of detecting small amplicons and deletions that potentially harbor specific oncogenes and tumor suppressor genes. As in conventional CGH, microarray-CGH allows the measurement of DNA copy-number aberrations by means of hybridization of two differentially labeled DNAs (the DNA to be tested against reference DNA). However, in array-CGH, because of the nature of the DNA spotted on the glass slides, it is possible to map the copy-number aberrations directly onto the genomic sequence. The DNA fragments spotted on the slide can be either large-insert genomic clones (cosmids, BACs, or PACs) or cDNA clones.[5,6,8] The last one identifies directly of which genes the chromosomal copy number has changed and allows the parallel comparison of the alterations in DNA copy number and gene expression in the same sample.[8] However, with cDNA clones fluorescent ratios do not reflect the chromosomal copy-number changes as precise, possibly due to cross hybridization effects.[8] Initially, arrays were spotted with fragmented DNA from the BACs/PACs.[5,6] As BACs are single-copy vectors, the yield of DNA obtained in culture is low, and for that reason big culture volumes were needed, and DNA density on the spotted arrays was low. Nowadays, PCR representations of the clones are spotted on the slide. This process fragments the DNA, allows small-scale

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020799

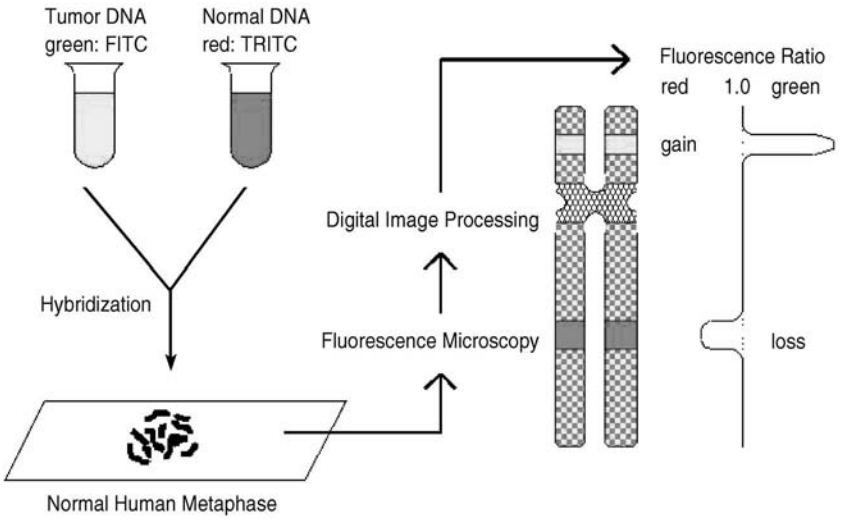

Fig. 1 Schematic representation of the comparative genomic hybridization (CGH) technique. Test and reference DNAs are differentially labeled and hybridized to metaphase spreads. After hybridization, the slide is washed and scanned. Images obtained are processed and ratios calculated.

DNA isolations, and allows high spotting concentration, which simplifies the process and enhances sensitivity.[9,10] Currently, genome-wide CGH arrays comprise generally about 3000 BAC and PAC clones, yielding a resolution of 1 to 1.5 Mb.[9,10] Just very recently, the first results of a 30-kb whole genome tiling path BAC array have been presented.[11] For cDNAs the number of clones is finite and will never be genome covering. Alternative strategies use arrays with spotted oligonucleotides (see below).

APPLICATIONS OF MICROARRAY-CGH

Array-CGH is nowadays the method of choice for studying DNA copy-number changes and has been successfully applied in the study of several tumor models.[12–25] Albertson et al.[26] showed how accurately array-CGH can define amplicon boundaries and identify peaks within the amplified regions, which lead to the localization of oncogenes involved in oncogenic process. In this way, CYP24 was identified as a candidate

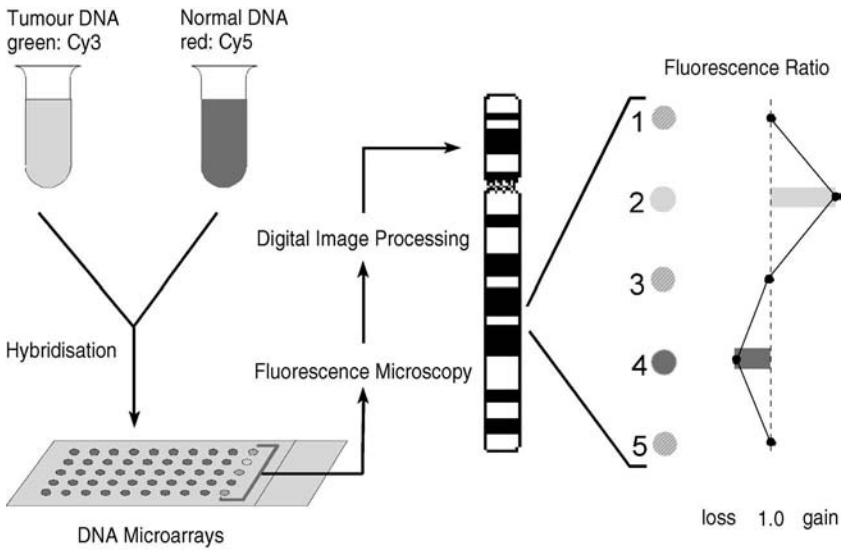

Fig. 2 Schematic representation of the microarray-CGH technique. Test and reference DNAs are differentially labeled and hybridized to genomic clones spotted on a slide. After hybridization, the slide is washed and scanned. Images obtained are processed and ratios calculated.

oncogene mapping to the amplified region at 20q13.2 in breast tumors.[26] This amplicon was also analyzed in stomach tumors by array-CGH, as 20q amplification is a frequent event in gastric carcinoma, and was narrowed down to a 800-kb segment.[27] Also, in a study of alterations of mouse islet carcinomas, which progress in a similar way as in human tumors, regions of LOH were further narrowed and new regions of copy-number loss and gain were defined.[28] The analysis of human genome sequences syntenic to the defined regions suggested several candidate tumor suppressor genes and oncogenes.[28] These studies show how powerful array-CGH can be in identifying the underlying genetic events of the chromosome aberrations, because of its high resolution and sensitivity.

Array-CGH is a strong technique for cancer diagnosis, prognosis, and therapy strategies.[29] In a study of 40 renal tumors, Wilhelm et al.[20] were able to correctly diagnose 33 of 34 malignant tumors and group together the benign lesions, showing that array-CGH is a feasible approach for cancer diagnosis. Cluster analysis of the microarray-CGH data in gastric cancer correlated with clinical parameters, e.g., lymph node status and survival,[17] which is important for prognosis and for decision in therapy strategies, as preoperative needle biopsies can be used diagnostically for the isolation of DNA for array-CGH. Analysis of the genome of occult micrometastatic cells was possible by array-CGH, leading to the identification of regions critically involved in metastasis, and thus providing means to identify in the future, patients who will benefit from therapies directed toward the eradication of occult micrometastatic tumor cells.[15] Array-CGH has been applied in the analysis of epigenetic alterations of tumors, by using CpG island microarrays,[30] and in the evaluation of the effect of mismatch repair competence on genomic alterations in cells that undergo selection for resistance to drug treatment.[31]

Array-CGH has also shown to be useful for diagnosis of other genetic diseases such as neurofiromatosis-2[7,32,33] and congenital aural atresia,[34] and for screening and detection of subtelomeric chromosome rearrangements in individuals with mental retardation or congenital anomalies.[35]

The applications of microarray-CGH are broad and will still increase as the need to understand diverse biological questions will continue to drive development of new uses of genomic arrays. Lin and collaborators[36] developed a physical mapping method based on radiation hybrids together with array-CGH that increases the speed and efficiency of positional cloning in somatic cell genetics. Array-CGH has also been applied in evolution studies by comparing DNA copy-number variation between humans and great apes.[37] Also, comparison of closely related

mycobacterium strains, by array-CGH, helps in the design of improved diagnostics and vaccines.[38] Moreover, array-CGH is sensitive enough to study dynamic processes, such as DNA replication. Khodursky et al.[39] traced the progression of the replication fork along the bacterial chromosome by using the relative abundance of replicated DNA over unreplicated DNA.

FUTURE DEVELOPMENTS

Developments and improvements of the array-CGH technique are taking place in order to have a robust technique that can be used in a regular basis in clinical applications. Algorithms that help to accurately define the breakpoints of chromosomal aberrations[40] as well as a fully automated quantification of the image data obtained in microarray experiments[41] have already been developed. Also, array-CGH using spotted oligonucleotides instead of BACs/PACs or cDNAs is currently being approached.[42] These oligos, which are currently used in expression profiling,[43] have the advantage of shortcutting the array production as there is no need for culturing and amplifying. Oligo-CGH has high accuracy in detecting amplifications, as with BAC-arrays (Fig. 3). It is also able to detect single-copy alterations, although with less accuracy, which requires further optimization.[42]

Finally, as the ultimate goal is to arrive to the gene that is affected by the chromosomal aberration, it is important to merge the array-CGH data with the expression data. Together, these two pieces of information will give a more complete picture of which genes and pathways are involved in the development of the disease.

CONCLUSION

In the past decade we have witnessed a fast evolution of comparative genomic hybridization as the tool for genome-wide analysis of DNA copy-number changes. Starting off as a research tool for cancer genetics mainly, it has now entered the field of clinical applications, a step facilitated by the arrival of microarray-based CGH.

Microarrays—Electronic Microarrays

Elaine M. Weidenhammer
Jay Shaw
Nanogen, Inc., San Diego, California, U.S.A.

INTRODUCTION

DNA microarrays represent a novel technology that incorporates elements from the fields of microfluidics, microfabrication, molecular biology, chemistry, and bioinformatics. High-density arrays have changed the scope of genetic analysis by allowing researchers to examine thousands of genes in parallel, enabling whole-genome analysis in a single experiment. DNA microarrays, manufactured using photolithographic combinatorial synthesis techniques[1–4] or physical deposition,[5–7] have proven to be invaluable for gaining a genome-wide perspective for genotyping, haplotyping, and gene expression profiling experiments.

Test sites on high-density arrays are defined by the sequence of the DNA probe that is spotted or synthesized at a particular location. Target hybridization is mediated by controlling the temperature and salt concentrations of the hybridization and wash buffers. In contrast, active electronic microarrays are composed of individually controlled microelectrodes (test sites). These arrays use electric field control to drive the transport of charged molecules from the bulk solution to activated test sites, allowing addressing and hybridization reactions to occur within seconds.[8–10] Nucleic acids will concentrate only at the activated test sites; the remaining sites are unaffected and available for subsequent use. In addition to concentrating nucleic acids, electronic control can also be utilized to denature double-stranded DNA and to discriminate single base mismatches between target molecules and reporter probes. Electronic microarrays thus provide flexibility, enabling multiplexed analysis of different targets from multiple samples, and are particularly well suited to clinical diagnostics laboratories where flexibility, reproducibility, and accuracy are critical.

ELECTRONIC MICROARRAYS

Nanogen has commercialized a 100-test site array, the NanoChip® microarray, housed in plastic cartridges (NanoChip cartridge) that provide fluidic, electronic, and optical interfacing. A platinum microelectrode underlies each test site (Fig. 1A). An electrophoretic field is generated by applying a positive direct current (DC) bias to one or more microelectrodes and a negative bias to counter electrodes; negatively charged DNA molecules in the bulk solution are electronically transported, or addressed, to the activated test sites. By applying a negative DC bias to the microelectrodes, denaturation of double-stranded DNA and removal of mismatched or weakly hybridized reporter oligonucleotides can be achieved. Independent control of the test sites enables the user to electronically address samples in any configuration, allowing complete flexibility in assay design.

A gel permeation layer containing streptavidin is present over the array surface. This layer protects the DNA from electrochemical by-products during activation and enables retention of biotinylated target DNA sequences. Electronic activation not only concentrates the target over the test site, but also provides an electrochemical environment conducive to attachment of the biotinylated DNA to the activated test site. These features of the electronic microarray ensure that the biotinylated DNA will be present only at the designated sites, and allow sequential addressing of biotinylated DNA targets from multiple samples onto different test sites of an array without carry-over (Midwest Research Institute and Nanogen, internal results).

The NanoChip Molecular Biology Workstation is the instrument system in which NanoChip electronic microarrays are processed. Electronic addressing of samples is done in the ''loader'' component, which can process up to four NanoChip cartridges simultaneously. Fluorescent signal detection occurs in the ''reader'' component. Both the loader and reader are capable of performing fluidic and thermal processes. A computer interface controls the workstation and provides software for data analysis and management.

GENOTYPING ON ELECTRONIC MICROARRAYS

Detection of single-nucleotide polymorphisms (SNPs) on electronic microarrays is achieved via hybridization of allele-specific probes to biotinylated, amplified target DNA. Genomic DNA is extracted from the sample, and

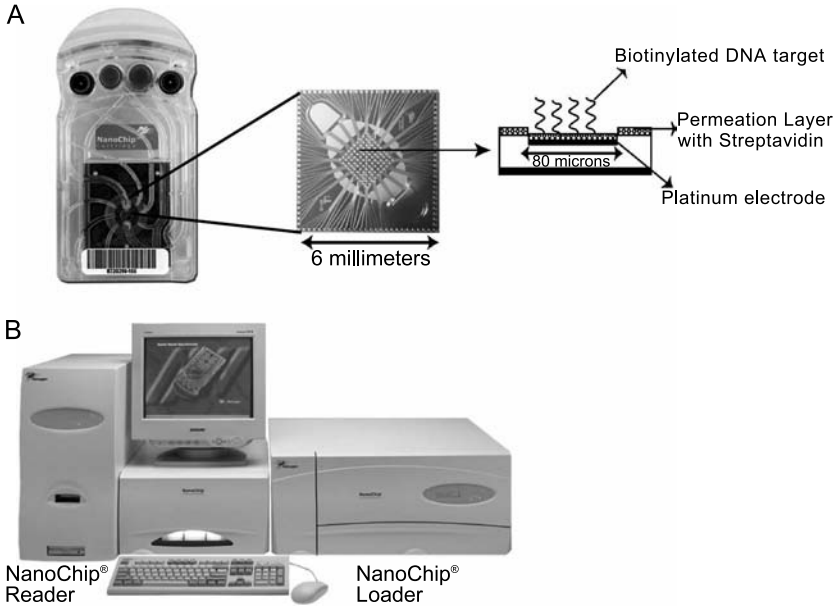

Fig. 1 (A) The NanoChip cartridge, NanoChip electronic microarray, and schematic cross section of an individual test site (not to scale). The NanoChip cartridge contains the microarray, fluidic channels and ports for automated addition of samples and reagents, and electronic interfaces. As depicted in the drawing of the test site, a permeation layer containing streptavidin covers the surface of the microarray, which enables attachment of biotinylated DNA targets. (B) The NanoChip molecular biology workstation. (*View this art in color at www.dekker.com.*)

the target sequence containing the region of interest is amplified by PCR. The use of one biotinylated amplification primer and one unmodified amplification primer generates a product that is biotinylated on one strand. A wide range of target size (from <100 base pairs to >1000 base pairs) can be accommodated on electronic microarrays. For genotyping analysis of two or more targets from a sample, multiple oligonucleotide primer pairs can be used in a single amplification reaction, which will generate multiple biotinylated DNA targets.

After the amplification reaction, desalting with size exclusion membranes is performed to facilitate electronic transport and remove unincorporated amplification primers. The biotinylated targets are then electronically addressed onto NanoChip cartridges. Software on the workstation enables the user to designate the test sites to be addressed for each sample. Electronic activation concentrates the biotinylated DNA in the sample to the test sites, where the DNA remains anchored via interaction with the streptavidin in the permeation layer. Unbound nucleic acids are removed by a series of fluidic washes before addressing the next sample. When multiple NanoChip cartridges are processed in a single loader run, cartridges are loaded in parallel, minimizing the time required for electronic addressing.

One method for sample genotyping uses fluorescently labeled reporter probes specific for the wild-type and variant sequences (Fig. 2). For target sequences containing significant secondary structure near the SNP, an unmodified ''stabilizer'' oligonucleotide can be used; this oligonucleotide hybridizes to the target sequence immediately adjacent to the nucleotide of interest (Fig. 2). Hybridization of the stabilizer next to a perfectly matched reporter probe generates a base-stacking energy component that, added to the Watson–Crick base-pairing energies, further stabilizes the reporter/target interaction. An alternative method utilizes chimeric ''discriminator'' oligonucleotides that contain a target-specific region, complementary to the wild-type or variant alleles, and one of two universal tail sequences. Two fluorescently labeled universal reporter probes, each complementary to one of the tail sequences, are used to detect the bound discriminators.

Whether allele-specific reporter probes or allele-specific discriminator oligonucleotides/universal reporter probes are utilized, genotype determination is achieved by monitoring the fluorescent signal remaining on each test site after the mismatched allele-specific oligonucleotides have been destabilized. Mismatched probes are removed by increasing the stringency of the environment, either thermally or electronically; perfectly matched probes will remain hybridized under the more stringent conditions. The NanoChip reader uses a two-laser system to detect the fluorescent signal remaining at each test site.

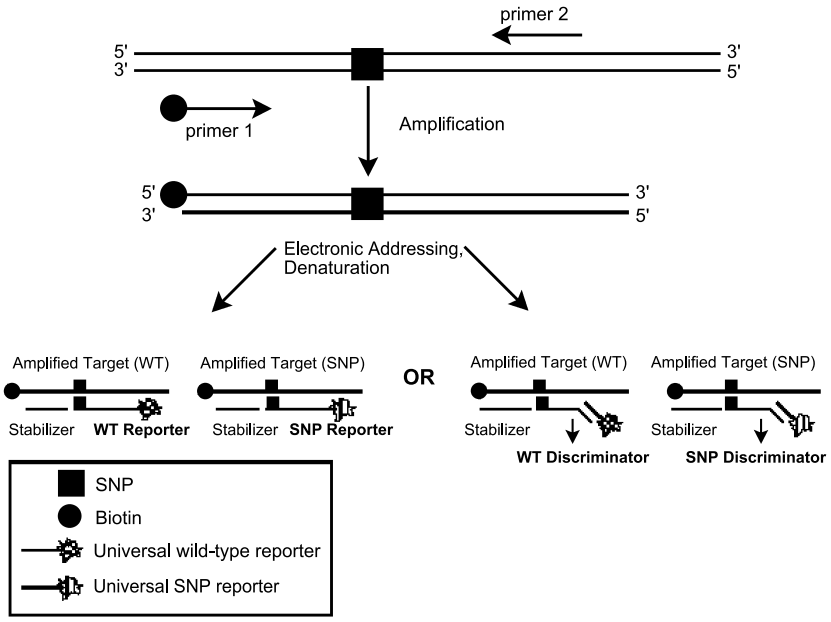

Fig. 2 Genotyping on electronic microarrays. The region of interest is amplified from genomic DNA by using one biotinylated amplification primer. After electronic addressing and denaturation, allele-specific reporter probes or allele-specific discriminator oligonucleotides/universal reporter probes are used for genotype determination (see text for detail). The use of stabilizer oligonucleotides is optional.

Predominance of fluorescent signal from one labeled reporter indicates a sample that is homozygous for the corresponding allele, whereas equivalent levels of fluorescent signal from both reporter oligonucleotides indicate a heterozygous genotype.

For multiplex genotyping, locus-specific discriminator (or reporter) pairs can be hybridized and discriminated sequentially (S.A. Williams, Children's Hospital of Orange County, personal communication).[11] Such analyses can be performed on a single DNA target containing multiple SNPs or on different DNA targets amplified from a single sample. As many as seven genotyping assays have been performed on a single 1.2-kb target (Dr. Dennis O'Kane, Mayo Clinic, personal communication). The ability to perform multiplex genotyping analyses greatly increases the capacity of the 100-site array, such that hundreds of genotypes can be generated without having to perform separate amplification and addressing reactions.[12–14]

CLINICAL DIAGNOSTIC APPLICATIONS

As correlations between genetic polymorphisms and disease are established, the need arises for robust, accurate methods to test for the presence of clinically relevant SNPs. Such testing may be performed to confirm the genetic cause of a clinical indication, establish risk profiles for specific diseases, or determine carrier status for heritable disorders in couples contemplating pregnancy. As the genetics underlying more complex disorders are understood, effective testing will require analysis of panels of SNPs. Electronic microarrays can be formatted to analyze multiple loci from multiple samples, and can be altered to incorporate new or different sets of markers as additional information becomes available. These features will be increasingly valuable in clinical research and clinical diagnostic laboratories as complex genetic diseases are assessed.

Several published reports provide examples of the utility of electronic microarrays for clinical diagnostics. Genotyping has been performed on the *TNFα* and *IL-4* cytokine genes;[15] on the prothrombin[16,17] and Factor V gene mutations,[17,18] which can lead to venous thrombosis; and on the *NAT1* and *NAT2* genes, which are involved in drug metabolism.[11,19] In addition, the NanoChip microarray has been used to genotype 362 samples for eight common mutations in the *MeCP2* gene, associated with RETT syndrome,[14] and to analyze 940 samples for 11 SNPs in the Factor VII, β-globin, and *RET* genes.[20] These studies demonstrate the flexibility and multiplexing capacities of NanoChip microarrays; they also illustrate the benefits of an open platform that enables researchers to tailor the arrays to their own experiments.

INFECTIOUS DISEASE APPLICATIONS

Microarray technology can have a broad range of applications in infectious disease. For example, Bekal

et al. examined the pathogenic potential of different *Escherichia coli* strains using conventional microarrays.[21] The DNA products from the PCR amplification of 105 virulence factors were spotted onto glass slides. Fluorescently labeled genomic DNA from different strains was hybridized to the arrays, allowing the detection of virulence genes and the potential to identify emerging pathotypes. In addition, detection and genotyping of rotaviruses have been performed with genotype-specific oligonucleotides immobilized on glass slides.[22] Standard microarrays have also been effective in the detection and subtyping of influenza viruses.[23,24]

These standard microarray experiments demonstrate the ability to query a sample against multiple strain- or genotype-specific probes—a primary goal in epidemiological studies. In the clinical laboratory setting, however, the testing situation may differ slightly. Patients typically present with symptoms that could be indicative of any one of a defined set of pathogenic agents. The goal of the clinical laboratory is to quickly identify which pathogen is responsible for the symptoms and to determine whether the pathogen is resistant to standard antibacterial or antiviral treatments. The number of patients to be examined varies seasonally and can be quite large in some months. For clinical testing of these patients, the ideal tool would enable the screening of multiple patient samples for a specific panel of pathogens, e.g., those causing respiratory illness. Electronic microarrays provide the flexibility required to perform these types of assays—multiple samples can be analyzed for the presence of a panel of pathogens, and genes conferring resistance can be analyzed simultaneously. The specific infectious agents being tested can be varied as necessary by substituting the amplification primers and reporter probes. Multiplex experiments using electronic microarrays have differentiated samples containing *E. coli*, *Pseudomonas aeruginosa*, or *Staphylococcus aureus*,[25] and have differentiated 12 species of mycobacteria in 270 patient samples (M. Sanguinetti et al., Universita Cattolica del S. Cuore, unpublished observations). The ability to use electronic microarrays to amplify and detect a panel of organisms and to quickly assess resistance should provide the clinical laboratory with a powerful tool for identifying the causative agents of a wide range of infectious diseases.

PHARMACOGENOMIC APPLICATIONS

Several benefits arise from incorporating genotyping analysis in pharmacogenomics studies. Genotyping results are not affected by diet, drug–drug interactions, or disease progression. Unlike phenotyping, test accuracy is not dependent on steady-state metabolism of the therapeutic. In addition, genotyping results are not dependent on the methodology used. By genotyping individuals suffering adverse drug reactions, specific genetic profiles associated with risk can be identified. Optimizing drug selection and dosing for poor and ultra metabolizers will not only result in increased effectiveness of treatment, but also reduce the need for multiple phenotypic evaluations.

The overall effectiveness of a given therapeutic will be determined by a combination of genetic loci encoding transporters, receptors, and metabolizing enzymes. The use of electronic microarrays to analyze panels of SNPs in such genes will allow greater accuracy in determination of the therapeutic effect and potential toxicity of therapeutics. Such a personalized panel represents the ultimate goal and promise of pharmacogenomics. Electronic microarrays can provide a valuable tool in the efforts to facilitate development of such panels and incorporate them into clinical practice.

CONCLUSION

Achieving maximum efficiency and cost-effectiveness on microarrays requires that all test sites provide useful information. Standard high-density arrays are, therefore, best suited for research studies requiring analysis of very large numbers of SNPs. Such discovery efforts provide valuable insight into markers of potential clinical utility. Those markers must then be clinically validated and, ultimately, incorporated into panels for diagnostic or prognostic use. The demands in a clinical environment differ from those in a research setting: multiple samples must be analyzed in a cost-effective, time-efficient way, and the methods used must be highly accurate and robust. Electronic microarrays are ideally adapted to these clinical applications.

Individual control of each test site allows DNA from different samples to be analyzed simultaneously on a single microarray. Unused test sites remain available for subsequent addressing, allowing utilization of all microarray sites regardless of the number of markers and samples being interrogated in any one experiment. The ability to analyze multiple SNPs from each sample provides the capacity necessary for development of complex genetic panels. Nanogen's open platform provides unique flexibility in assay design, allowing the user to reconfigure the panel of SNPs as additional information becomes available regarding the clinical utility of particular markers. The unique features of an electronic microarray not only provide the cost and time efficiencies required in a clinical laboratory setting, but also enable the validation and incorporation of new molecular diagnostic tests as new data are generated.

INTRODUCTION

In 1987, Augenlicht et al. published the first paper on arrays and the use of gene expression profiles in typing cancers.[1] Almost two decades later, microarrays have been used as a tool in defining expression profiles in diseases as well as in compound discovery and development. Previous reviews have discussed the history and the application of microarrays.[2,3] This paper will cover printing microarrays, including the variety of printing surfaces, the immobilization techniques, the types of molecules printed, and the printing process itself. Topics which will not be covered will be other methods used in the microarray process: sample preparation, array hybridization, array scanning, image analysis and data analysis, and mining.

Microarrays are described as arrays of macromolecules (including proteins), tissue slices, cells, chemicals, or nanomaterials printed on a surface to mimic a ''micro'' environment. Typically, the materials are printed in hundreds or thousands covering 1–2 cm^2 of surface area. The advantage is that this large number of materials can be screened all at once. An investigator can sometimes repeat in one experiment what took other investigators years to evaluate. In addition, microarrays lend themselves well to producing data which allow the investigator to piece together a ''systems'' answer to the hypothesis. Many mathematical modeling algorithms and methods are now being used to try to ''reverse engineer'' a biological system or remap what pathways are involved based on the expression profiles obtained from microarrays.

MICROARRAYS

Traditionally, arrays have been categorized into different formats: conventional (cDNA and oligonucleotide), electrokinetic, fiberoptic, microfluidic, and more recently, applications in the nanotechnology field. The most popular format today is the conventional arrays, which will be discussed in detail here (Fig. 1). Within this paper, ''probe'' will refer to the macromolecule printed on the array surface and ''target'' will refer to the macromolecule derived from the sample and hybridized to the array. The other array formats have just recently been commercialized or are in development.

The conventional array format involves either printing macromolecules onto a surface or synthesizing the macromolecules in situ one building block at a time. The first technique, usually referred to as ''cDNA microarrays,'' is the printing of DNA onto a substrate. The initial papers describing this technique were derived from collaboration between the laboratories of Ron Davis and Pat Brown at Stanford University.[4] The second technique, usually referred to as ''oligonucleotide arrays,'' builds the macromolecular sequence in situ or at a specific location on the surface. Early applications used photolithography. A mask is put over the array surface to allow chemical reactions to take place only at specified sites. The reactions involve photolabile groups activated by light to free hydroxyl groups. The hydroxyl groups were then covalently bound with phosphoramidite-activated deoxynucleosides. The bound molecule is capped and oxidized. After rinsing, a new mask covers the array surface and a new set of reactions occur. With each round of reactions, an activated nucleoside is added and the oligonucleotide (''oligo'') is synthesized to approximately 25 nucleotide oligomers or ''25-mers.'' This method was originated by Stephen Fodor and David Lockhart at Affymetrix.[5] Two newer in situ methods have been developed: one which uses a digital micromirror to create a virtual mask for the photolithographic manufacturing process of microarrays[6] and another allows parallel synthesizing of several different types of molecules.[7] The first technology was initially developed at Texas Instruments and is being commercialized by NimbleGen and the second is being commercialized by Xeotron.

If an investigator wishes to set up his/her own arraying facility, cDNA microarrays are the easiest methodology to start with. (Here the authors are referring to printing microarrays of cDNAs or oligos by methods other than photolithography.) However, before starting, several choices of materials and processes are required.

The first choice is to decide which substrate the array will be printed on. Current choices are listed in Table 1

DOI: 10.1081/E-EDGP 120020787

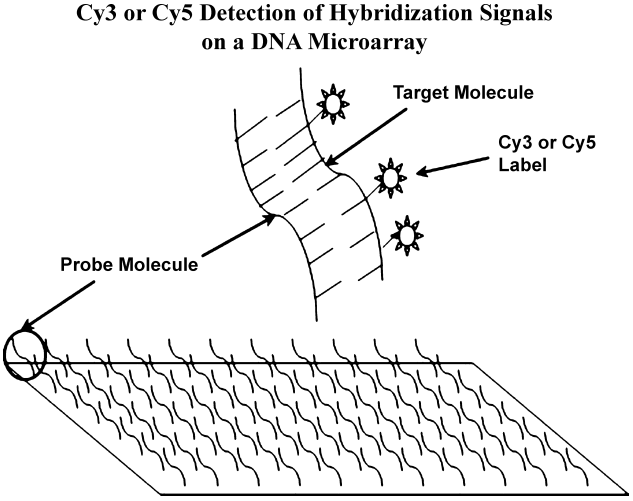

Fig. 1 The schematic depicts the hybridization reaction for cDNA or oligonucleotide microarrays. Briefly, the probes are oligonucleotides or expressed sequence tags (ESTs, actual form of cDNA used) printed onto a glass slide. The target molecule is the cDNA (fluorescently labeled with either Cy3 or Cy5) present in the hybridization solution. During the reaction, the fluorescently labeled cDNA in solution will hybridize to the probe on the glass surface with a homologous sequence.

and, traditionally, the most common substrates used are glass slides and nylon filters. Because of their larger surface area (several square centimeters), nylon filter arrays are sometimes referred to as ''macroarrays.'' Other surfaces listed in Table 1 are being used by formats just recently commercialized or in development, such as microfluidic arrays. Today, most conventional arrays use glass; however, it is extremely important that glass surfaces are cleaned prior to printing. Some preferred methods include ultrasonication[23] or washing with acid[10,12] or alkali.[24]

Table 1 Microarray substrate choices

Substrates	References
Beads	[8]
Compact discs	[9]
Fused silica slides	[10]
Gel pads (fixed to glass)	[11]
Glass slides	[4,5,12]
Nylon filters	[13,14]
Polypropylene film	[15]
Polystyrene microwell plates	[16]
Silicon wafer	[17–20]
Waveguides, planar	[21,22]

Table 2 Derivatizing agents for microarray surfaces

Modifications	Derivative	References
Agarose film	–	[27]
Gold substrates	–	[28]
Poly-lysine	–	[4]
Microporous polymer	Nitrocellulose	[24]
Silane	Aldehyde	[29]
Silane	Amine	[30,31]
Silane	Amine/diazotization	[32]
Silane	Amine/epoxy	[23]
Silane	Epoxy	[12,18–20]
Silane	Polyethylenimine	[25]
Silane	Self-assembly; aminosilanes	[10]
Silane	Self-assembly; alkylsiloxanes	[17]
Silane	Semicarbazide	[33]
Silane	Thiol	[34]

The second choice is whether or not to treat the substrate surface to further enhance the binding of the macromolecule or substance. Table 2 lists a variety of modifications which have been used and range from simply coating with poly-lysine[4] or using a multistep procedure with polyethylenimine.[25] The most common method is silanization and several silane derivatives are listed in Table 2. Some unique slide coatings are the use of microporous polymer, agarose file, and a deposition of gold substrates. Glass slides coated with amine, aldehyde, epoxy, thiol, or gold derivatives as well as a plain silylated form (CEL slides) are commercially available through TeleChem International, Inc.[26]

The third choice is a form of macromolecule to print. In the past, some investigators chose to print whole bacterial plasmids containing the cDNA insert.[1,13] More commonly today, cDNA is printed started with its double-stranded purified form. Recent references refer to the printing of long vs. short oligos; short oligos being 25-mers or less and long oligos being 40-mers or longer. Although factors, such as GC content and overall sequence similarity, are important and need to be considered for designing oligos to be printed,[35] several references have shown long oligos to be comparable in sensitivity and specificity to cDNA probes.[36,37]

Once the type of macromolecule is chosen, the quality of the printed macromolecules should be checked. One method is to check the PCR products (cDNA probes) by agarose gel electrophoresis. Any product which shows more than one band or does not show any product at all is not arrayed and can be substituted with a ''cleaner'' alternative product corresponding to the same gene. Also,

Fig. 2 Experimental prototype of a DNA Microarrayer: a Hamilton Microlab 2200 (Reno, Nevada) modified with a 32 Stealth printhead and SMP3 Micro Spotting Pins (TeleChem International, Inc., Sunnyvale, CA). Metal platters (Machine shop at HARC) have been fashioned to hold five slides during attachment, and will be set on top of the platform. The platform is capable of holding one microtiter plate and seven of these platters, allowing 35 slides to be printed in each round. (*View this art in color at www.dekker.com.*)

it is necessary to obtain an accurate quantification of the molecule to be arrayed. Yue et al. describes using an assay with PicoGreen.[38]

The fourth choice is whether to modify the macromolecule. Most cDNA probes are modified by adding an amino group at either the 3′- or 5′-ends.[4,12,19,20] Other modifications have included thiol,[10,28,31] disulfide,[34] or benzaldehyde groups;[33] although unmodified DNA probes have shown equal success.[32,37] In addition, some investigators have used chemical linkers to connect the modified surface with the modified probe. Yang et al. used a maleic anhydride linkage between a thiol-modified oligo and an aminosilane-modified surface.[31]

The fifth choice is the type of printing method to use. Printing methods have been divided into contact and noncontact methods.[39,40] The contact method uses microspotting devices to deliver the macromolecular solution to the printing surface. An example is depicted in Figs. 2 and 3. These devices deliver the solution by capillary action and tips are either disposed of or washed thoroughly before the next printing. Initial devices were hand-built using an *xyz*-axis gantry robot with the macromolecular solutions being delivered through stainless steel printing pins (Stanford University, National Institutes of Health). Pin heads are now available in ceramic (Apogent Discoveries, Hudson, NY) and tungsten (Point Technologies, Boulder, CO). Other delivery methods are capillaries, tweezers, or quills, and Holloway et al. describes several commercially available arrayers.[40]

Noncontact methods include inkjet printers which disperse solutions of macromolecules onto the array surface without the dispensing tool touching the array surface. Many of these devices use piezoelectric technology where an electrical current controls droplet formation to precise measurements.[19,41] Two current commercial vendors include Shimadzu Biotech (Pleasanton, CA) and PerkinElmer (Boston, MA).

After printing, several investigators recommend treating the printed surface to ensure a tight covalent bond and to lessen nonspecific binding during hybridization. The most common method is to cross-link the macromolecules to the surface with UV light.[32,37] This method has been used with glass slides as well as nylon filters. Other protocols bake the slides in a vacuum oven[4] and/or treat with succinic anhydride[4] or just treat with a mixture of succinic anhydride and acetic anhydride.[42]

Finally, it is recommended that a set of protocols be instituted to assess the quality of the printed slides. Microscopic examination of the slides with food coloring or hybridizing the slides with a labeled PCR primer (used to make the arrayed PCR products) has been used with random sampling, but these agents can destroy the active sites on the probes.[43] Other investigators have successfully used nondestructive means to assess quality, such as dCTP-Cy3 or SYBR Green dyes.[44,45]

Fig. 3 Experimental prototype of the DNA microarrayer: a close up view of a 32-pin dry station (Die-tech, San Jose, CA) that has been mounted to a specially designed wash station (Machine shop at HARC) secured to the base of the MicroLab 2200 between the two platforms. (*View this art in color at www.dekker.com.*)

CONCLUSION

Microarrays vary from the conventional formats of cDNA and oligonucleotide arrays to arrays now incorporating nanotechnology. The types of molecules and substances printed onto arrays also vary, and examples are cDNA probes, proteins, chemicals, cells, tissue slices, and nanomaterials. The easiest format for any investigator to use in their own laboratory from start to finish is the cDNA microarrays, which has been described in detail here. Several options need to be considered before starting and these choices include the printing substrate and its modification, the type of macromolecule and its modification, and the actual printing process. Very soon the newer formats of arrays may supercede the conventional ones emphasizing the need for more efficiency and less cost and continuing the revolution of compound discovery and development and finding disease cures.

ACKNOWLEDGMENT

This work was supported in part by the funding from the U.S. Department of Commerce/National Institutes of Standards and Technology/Advanced Technology Program Cooperative Agreement No. 70NANB3H1364. A special thanks to HARC and its primary contributor, the Mitchell family, for their continuing financial support.

Microarrays—Standard Operating Procedures

Thorsten Forster
Peter Ghazal
The Scottish Centre for Genomic Technology and Informatics, University of Edinburgh Medical School, Edinburgh, U.K.

INTRODUCTION

Microarrays, or generally bioarrays, can be defined as the simultaneous assaying of a biological target sample interacting with a large number of biomolecule probes positioned in a gridlike layout on a physical substrate.

Like its forerunners dot blotting and cDNA filter arrays, microarray technology exploits complementary binding properties of biomolecules. As opposed to these forerunners, microarray technology is highly parallel in terms of the number of bioprobes that can be assayed simultaneously under a given experimental condition, and provides high throughput in terms of the number of experimental conditions that can be investigated in a relatively short time. The current level of microarray technology has been enabled through the combined use of robotics, miniaturization, labeling approaches, and image processing hardware and software.

Microarrays are redefining vast areas of experimental and applied sciences, from gene expression analysis to combinatorial chemistry and protein expression analysis. Although DNA microarray technology is now relatively mature and gene expression analysis a more widely used tool than protein expression analysis, it involves the assumption that mRNA levels correlate well with protein expression levels. However, because a gene may transcribe multiple mRNA sequences depending on splicing, polyadenylation or editing, and because translation of a sequence can lead to protein, which undergoes a variety of posttranslational modifications (such as phosphorylation, glycosylation, or lipidation), predictions of protein expression levels from mRNA expression are subject to some restrictions. Consequently, there has been an increasing interest in the direct, systematic measurement of protein expression levels.

DESCRIPTION OF TECHNOLOGY

Common features for all variations on this technology are the following:

- Large numbers of distinct probes are bound to a substrate in a gridded layout on a solid substrate.
- The level of abundance of each test analyte (target) can be assessed by the amount of labeled analyte specifically bound to its cognate probe on the surface of the chip.
- In general, target sample materials are labeled (there are direct and indirect methods), but in some cases the probe may contain the label.
- One target sample is labeled and assayed against one array, or two target samples are differently labeled and assayed against one array.
- After hybridization or other interaction, arrays are scanned to obtain images showing the amount of bound, labeled material for each probe on the array.
- Array images are subjected to image processing algorithms, which convert them to numerical signal levels for each probe.
- Signal correction and systematic adjustments (normalization algorithms) for nonbiological effects are performed before data analysis.
- Basic analysis of these data provides absent/present calls, semiquantitative levels of abundance or expression, and differential abundance or regulation between different experimental conditions.

Figure 1 shows a typical workflow for a cDNA microarray experiment, and Fig. 2 the most relevant differences when using protein microarrays.[1] A good overview can be found in Ref. [2].

VARIATIONS ON MICROARRAY TECHNOLOGY

The microarray platform used can be defined by the following factors:

- Probes can be double-stranded DNA (usually several thousand bases), single-stranded oligonucleotide sequences (~20–75 bases), antibodies, other proteins or biomolecules, chemical entities, and even tissue slices.
- Probes can be deposited robotically or by fluid mechanics; oligonucleotide sequences can also be

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120027892

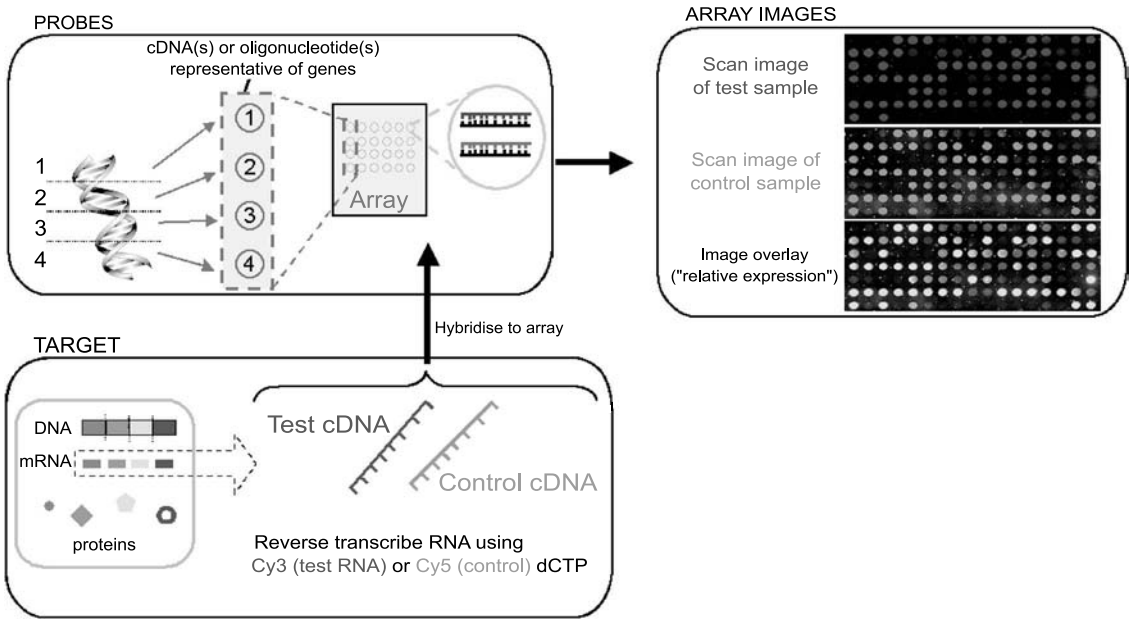

Fig. 1 Typical workflow for a cDNA microarray experiment. This example is based on oligonucleotide gene probes on a custom spotted array, using dual-dye cohybridization of two different samples on each array. Based on a genome of interest, probes are selected and synthesized. Using a robot, one can then arrange these probes into a grid on the substrate (in this case, a glass slide), where they remain bound to the surface by electrostatic forces, covalent cross-linking, or other means of attachment. On the other side of the process, biological samples are obtained from tissues or cell lines, followed by the extraction of total RNA and reverse transcription to cDNA. The last step also includes the dye-labeling step, and the sample is now referred to as target sample. In this case, a target sample from a control or reference condition has been dye labeled with Cy5, a target sample from an experimental or test condition with Cy3. These samples are then mixed and cohybridized to one array. This is followed by scanning the array at frequencies corresponding to both dye labels. The resulting false-color images can be obtained separately or as a composite image. Probes appearing red are more abundant (or higher expressed) in the experiment sample, probes appearing green are more abundant in the reference sample, and probes appearing yellow are equally abundant in both samples. (*View this art in color at www.dekker.com.*)

assembled in situ (e.g., using lithography methods) on the array.

- The most common protein/DNA array formats are glass slides (standard microscopy size) with various coatings or fully encapsulated cartridges containing the array.
- For single-target arrays, one target sample is labeled and assayed against one array. For dual-target arrays, two target samples are differentially labeled and assayed against one array.
- Labeling approaches include dyes, reflective or light-scattering particles, antibodies, or radioactive material.

ESSENTIAL ASPECTS OF MICROARRAY TECHNOLOGY

Laboratory Standards

Microarray experiments—both custom spotted and commercially available arrays—are susceptible to failure or data bias introduced by laboratory procedures. A very high level of laboratory protocols is therefore required. It has now frequently become a prerequisite for publication to record these steps at minimum information about a microarray experiment (MIAME) level set by the Microarray Gene Expression Data society (http://www.mged.org).

Laboratory protocols should cover precise instructions for sample acquisition and processing, array production and processing, the selection and synthesis of probes, labeling steps, the hybridization process, posthybridization processes, and storage. It is highly recommended that rigorous standard operating procedures be applied for both benchwork and data capture.[3]

Data Acquisition

Scanning and the conversion of resulting images (Fig. 3) into numerical data (‘‘quantification’’) is a source of technological data variability. Depending on the system used, scanning any array with inappropriate parameter values will either cause signal saturation or miss out low expressed probes. It is therefore better to scan each array more than once, with different parameter values, and to

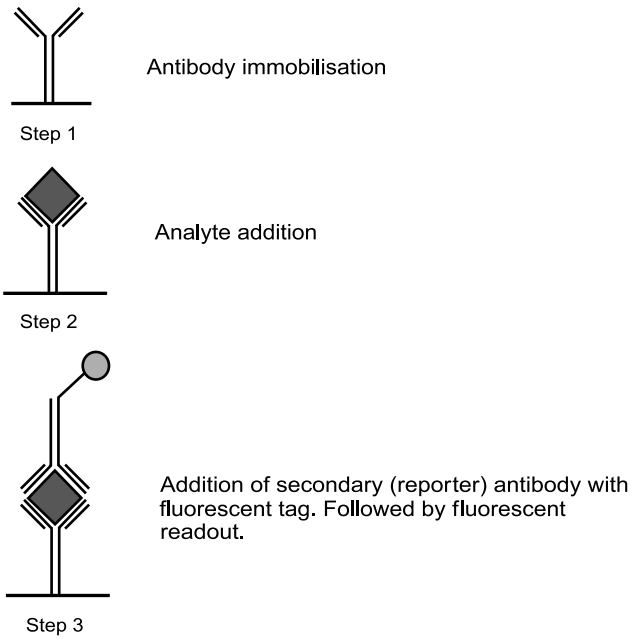

Fig. 2 Deposition and detection of a single probe on a protein array. The general concept of probe selection, probe deposition, target labeling, binding, and scanning are comparable to DNA microarrays, the main differences lying in the specific method of depositing and labeling proteins. In this case, the target sample or analyte is incubated onto the array before labeling the target by means of a specific antibody with a fluorescent tag. The analyte could also be labeled before incubation; this depends on user preference and the biological system under investigation. (*View this art in color at www.dekker.com.*)

select a best scan or use statistical approaches to combine the information from multiple scans. A standard protocol must be associated with this approach. This needs to cover suitable scanning parameters, a consistent quantification method, recommended level of manual fine-tuning for the grid alignment, and quality control steps such as the assessment of background noise.

Data Processing

It is most likely that despite use of stringent laboratory and data acquisition protocols, there are still systematic sources of variation or noise in the data that cannot be attributed to the biological sample differences under investigation. The use of data processing techniques[4–6] is not optional but required. Image data is associated with background noise (specks of dust, uneven hybridizations, etc.), which needs to be adjusted. Most array data are assumed to be on a scale that benefits from prior transformation of the data values. The term ''normalization'' in relation to microarray data is best defined as a collection of mathematical methods that are used to make target samples comparable by removing systematic effects introduced by dye-label incorporation differences, hybridization differences resulting in overall image ''brightness'' differences, and differences across an individual array caused by deposition of probes by different robotic print tips.

Background measured by the image processing software is usually removed by subtracting individual probe background from the probe signal value or by subtracting a local average background from each individual probe signal value. It is also recommended to define a detection-threshold limit for each array, which is the mean plus two standard deviations of negative control probes on the array, or another robust estimate for theoretically nonexpressed probes on the array.

On-chip signal ratios are most often log-transformed to base 2, which symmetrizes the distribution. To stabilize variance, transformations such as arc sinh are still being evaluated. For dual-target arrays, the currently most common method of normalization is the locally weighted scatterplot smoother (LoWeSS), which adjusts for the nonlinear differences between two dye labels on an array.[5] The effect of this can be seen in Fig. 4.

In many cases, the normalized log ratio is still subject to different levels of variance, and to make them comparable across a number of arrays, a second step can be included in the normalization, which adjusts variance rather than location of log ratios. One such method is the median absolute deviation scaling.[6]

Single-target arrays do not normally require any on-chip normalization like the above. The center (median) of the absolute signal intensities on the array is often scaled to match other arrays. Other common forms of normalization take into account specific print tip groups; that is, standard normalization methods are performed on physical subsets of the array rather than on the array as a whole. For further analysis, in particular cluster analysis, normalization also occurs on a per-gene level, which means that each gene's values across a number of arrays are adjusted to have a mean of 0 and a standard deviation of 1.

A special case of normalization is one that estimates the size of an effect rather than correct for it. Given a high enough level of replication, analysis of variance (ANOVA) can provide estimates for each effect (hybridization, dye label, print tip group, etc.) that has been included in the model; that is, the observed signal value is described by the level of signal that is due to unwanted sources of data variation and the signal differences that are due to real biological effects.[7]

Data Analysis

Microarrays produce an amount of data that has rarely been seen before in biological research. It is common to

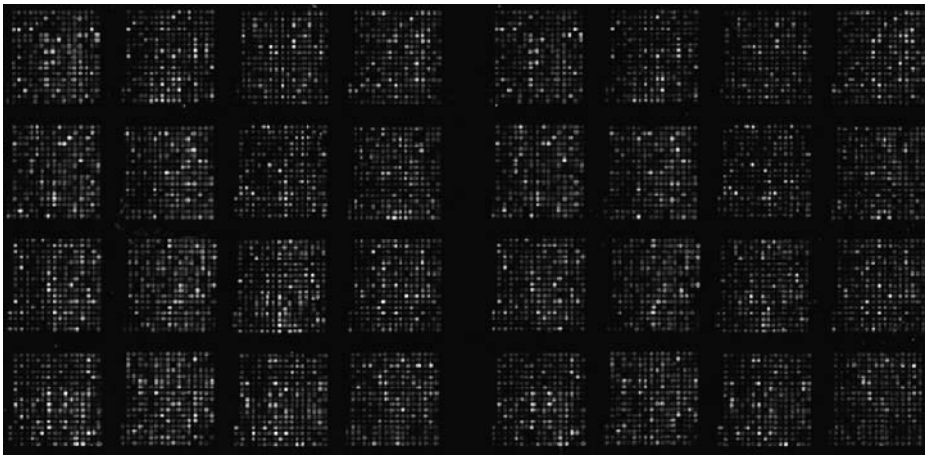

Fig. 3 Example of a false-color array scan image. The image is a composite of the image scanned for cy3 and the image scanned for cy5, resulting from the cohybridization of two target samples to one array. The original scan images are 16-bit grayscale; that is, signal intensities can range from 0 to 65536, and software converts this to color levels for display purposes. Each separate smaller grid within the entirety of the array consists of probes deposited by one of many robotic print tips. The ''gap'' in the middle of the array indicates that all probes have been printed onto the array twice. (*View this art in color at www.dekker.com.*)

use arrays containing 10,000–30,000 genes, and the use of multiple experimental conditions and replicate samples can easily produce millions of data points for an experiment. Analysis of the data is further complicated by the dimensionality of the data; that is, compared to ''normal'' data with many observations (e.g., patients) and few variables (e.g., weight and blood pressure) there are few biological samples and a large number of response variables—the probes. This poses statistical problems with analysis approaches.

Inference statistics such as *t* tests or Mann–Whitney *U* tests on a gene-by-gene basis effectively means hundreds or thousands of tests performed in parallel, which introduces a multiple-testing problem.[8] A proportion of all tests performed is liable to contain false positive results. This can be counteracted by adjustments to the computed *p* values; common approaches include, but are not limited to, Bonferroni and false discovery rate method.[8]

Following basic inference approaches to discover significant differentially expressed genes, the most common second form of analysis is exploratory, and a large part of this consists of a variety of clustering and classification algorithms.[9] These methods are statistically less rigorous, but often very relevant to the biologist. Interpretation of such results must be made with care, and subsequent result validation is required for hypothetical models of genetic regulation to stand.

The great potential of microarray technology is matched by potentially complicated experimental designs. This applies to statistical experiment design as well as experiment logistics. Experiment design[10–12] for microarray studies tends to be based on the principle of cohybridizing an experimental sample with a common reference sample (Reference Design). As opposed to a ''loop design'' where experimental samples are cohybridized in pairs, this provides less statistical power for the analysis, but better flexibility and extensibility of the study design. Studies designed around single-target platforms trade in reduced problems with differential label properties against error caused by different hybridization qualities and spot morphologies across arrays. Experiment design can also be driven by interest in either hypothesis- or data-driven approaches to analysis. The former requires high levels of biological replication to provide reliable results; the latter requires new mathematical approaches and potentially the integration of other sources of data.

Postanalysis Validation

Many microarray studies rely on a total of only tens of arrays to determine differences between multiple experimental conditions, and although the use of microarray technology as an ''interest filter'' for genes is perfectly valid, it needs to be supplemented[13] by follow-up studies with single-gene methods to confirm findings for individual genes or entire predicted genetic pathways.

APPLICATIONS

Microarray technology has proliferated into most areas of life sciences. It has found application in multiple organisms, multiple experimental conditions, and different biological or medical areas of interest such as cancer, immunology, or neurology. Microarrays enable researchers to identify genes that are differentially regulated in

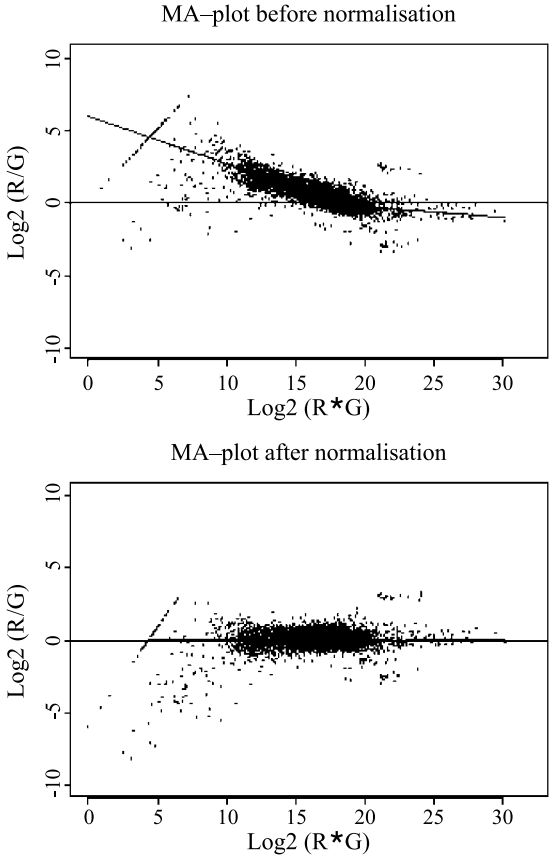

Fig. 4 MA plots before and after LoWeSS normalization. Before normalization, a systematic difference between the two dye labels on one array (R for ''red'' and G for ''green'') can be seen by the general shape of the data cloud diverging from the central line. In most experiments, one would expect only a subset of genes to be affected by different treatment conditions, and the most genes should therefore be centralized around zero in the horizontal (i.e., log ratio). The LoWeSS normalization adjusts the data cloud to match this assumption; the data cloud is straightened and centered around zero.

different experimental target samples, to semiquantitatively profile any experimental target sample, and to predict or diagnose disease by discovering new marker genes.[14,15] Microarrays also throw open the door to identifying cyclic behavior in time series experiments or to relate genes to one another based on similarities in their expression profiles across multiple conditions.[16] Special arrays for identifying splice variations[17] or single nucleotide polymorphisms[18] have also been used, and the number of practical applications for protein arrays[19] is increasing.

Looking at microarray data in isolation provides information on individual important genes and proteins in disease diagnostic and prediction, potential networks of gene interaction, new drug targets, and biological development. This is often enhanced by combining data from multiple sources; for example, using protein array data and cDNA microarray data from the same system can ultimately provide a systems-level understanding. Host and pathogen genomes can be interrogated simultaneously to gain a better understanding of their interactions.

DEVELOPMENTS AND CHALLENGES

There are a number of future key areas for this technology, some of which involve the maturing of this technology, and others that will likely lead to entirely new applications and discovery. Below are brief outlines for some of these developments.

System-level understanding is of course the ultimate goal, and requires building an understanding of how biological processes work from the molecular to organism level, and how changing factors (e.g., drugs) in the process may affect key pathway processes. Both DNA and protein microarrays provide only partial information, and there is a distinct need for a greater level of data *integration*.[20] This must combine data from various biological techniques, clinical data, and demographic data, as well as make better use of existing data of the same type, i.e., microarray data and gene/protein annotation data. The means to facilitate this are better *databases* and *ontologies*,[21] allowing one to directly link and analyze data from multiple formats and sources. *GRID technology* (sometimes referred to as ''Internet Version 2'') may be the technological base to accomplish this by providing data exchange formats and the required software and hardware architecture.

Microarray technology will also move further toward *miniaturization*, and ''nanoarrays'' for the detection of single molecules are a possibility, as are the deposition of entire genomes on smaller surface areas or the deposition of multiple probe/target combinations on one array substrate.

Irrespective of the substrate dimensions, there has also been a move toward using arrays for very *specialized applications*, such as the detection of splice variants or the fabrication of diagnostic chips containing only probes relevant for disease patterns, or selective neurological chips.

The current state of hybridize-now-analyze-later could soon be superseded by *real-time platforms*, which allow simultaneous hybridization events and data readout from the chip, which is closely coupled with conventional microelectronics. These platforms will be closer to point-of-care applications than current microarrays. They will almost certainly not rely on microscopy slides as substrates, but incorporate etched/channeled patterns in

materials with different properties. Despite these differences, they will still share purpose and gridlike layout with the current technology, and are likely to have a large impact in *chip*-based *medicine* of the future.

A further drive is toward more elaborate and good-quality *protein arrays*, which requires improvements in purification methods, spatial orientation on a substrate, and substrate adherence.[22,23] This is being researched, and protein arrays are getting ever closer to the level of comprehensiveness achieved by DNA microarrays, although they themselves are not faultless.

Independent of the technology used, methods of statistical and exploratory analysis are continuously being expanded, creating more powerful and, importantly, more robust results for biological interpretation. Machine learning, genetic networks, Bayesian methods, artificial intelligence, and other established mathematical approaches of analysis and *data mining* are being investigated for use in microarray research.

CONCLUSION

Independent of the platform used, microarray technology exhibits properties that cause complications in the analysis and interpretation of data. Data dimensionality as defined by large numbers of variables (probes) for small numbers of biological replicate samples is one such aspect, and the relative amount of technical and unwanted biological data variation is another. For these reasons, every aspect of a microarray experiment needs to be tightly controlled from the experiment design to laboratory work and data analysis. Standard operating procedures are a necessity, and where such methods exist and are adhered to, microarray technology is a very powerful tool opening new and promising avenues for further research.

Microduplication Syndromes—17p11.2 Duplications, Proximal 15 Duplications, and Cat Eye Syndrome

M

Heather E. McDermid
University of Alberta, Edmonton, Alberta, Canada

INTRODUCTION

The human genome contains numerous sites where the presence of complex low-copy repeated sequences leads to recurrent chromosomal rearrangements resulting in recognizable syndromes. Typically, mispairing and crossing over between adjacent direct repeats, resulting in the deletion of the intervening DNA, cause these syndromes. Such microdeletion syndromes include deletions of 22q11 (DiGeorge/velocardiofacial syndromes or DGS/VCFS), 7q11 (Williams syndrome), and 15q11–q13 (Prader–Willi/Angelman syndromes or PWS/AS) (reviewed in Ref. [1]). Theoretically, such nonallelic homologous recombination between repeats should also result in an equivalent number of reciprocal microduplications. However, microduplication syndromes are less well known, probably due to a combination of milder, less distinct phenotype which may be unrecognized as a particular syndrome, and the difficulty of detecting microduplications compared to microdeletions.

The classic case of reciprocal microdeletion/microduplication syndromes is that of the peripheral neuropathies of 17p12.[2] Deletion of a 1.5-Mb segment results in ''hereditary neuropathy with liability to pressure palsies'' (HNPP), whereas duplication of the same region results in Charcot–Marie–Tooth disease Type 1A (CMT1A). The rearrangements involve the 24-kb CMT1A-REP repeats and the change in dosage of the central gene PMP22 is thought to cause the peripheral neuropathies typical of both disorders. Details of these syndromes are covered elsewhere. Below are reviewed other microduplication syndromes, which include interstitial duplications such as CMT1A, as well as duplication through the presence of a supernumerary chromosome. The phenotype associated with such microduplication syndromes presumably arises due to the overexpression of one or more genes in the duplicated regions.

DUPLICATIONS OF 17p11.2

Recombination between a set of low-copy repeats in 17p11.2 causes the microdeletion syndrome known as Smith–Magenis syndrome (SMS). This disorder, with an estimated prevalence of 1/20,000, is characterized by mental retardation, neurobehavioral abnormalities, sleep disorders, speech and motor delays, midface hypoplasia, short stature, and brachydactyly.[3] The same deletion is seen in 90% of patients. Only recently has it been recognized that a reciprocal duplication also exists. The dup(17)(p11.2p11.2) syndrome is characterized by borderline to mild mental retardation, behavioral problems, short stature, dental anomalies, normal facies, and lack of major organ malformations[4,5] This syndrome typifies a milder phenotype that was not recognized as a syndrome until connected to the microduplication.

Nonallelic homologous recombination is thought to occur between the 200-kb SMS-REPs, which are direct repeats separated by $\sim$4 Mb.[6] A third SMS-REP exists with the SMS region, but because of its inverted orientation it does not usually participate in deletion/duplication formation. Interchromosomal and intrachromosomal exchanges appear to occur with equal frequency, as determined by microsatellite analysis of 16 dup(17)(p11.2p11.2) syndrome patients.[5] There appears to be no significant parent-of-origin bias among these 16 patients. The gene or genes involved in the dup(17)-(p11.2p11.2) syndrome are unknown. Recently, chromosome engineering in mice has resulted in mouse models for both deletion and duplication syndromes of the equivalent murine region of conserved synteny.[7]

DUPLICATIONS OF PROXIMAL 15Q

The region of chromosome 15q11–13 has long been known to be chromosomally unstable, being the site of deletions, duplications, triplications, translocations, inversions, and the breakpoints for supernumerary chromosomes. The resulting phenotype of such rearrangements is further complicated by the abundance of imprinted genes in the region. Thus, paternal deletions of the region result in Prader–Willi syndrome (PWS), whereas maternal duplications of the exact same region cause the phenotypically unrelated Angelman syndrome (AS) (both syndromes are described elsewhere). A series of complex low-copy repeats exist within the region and mark breakpoint sites.[8] The two most centromeric breakpoints,

DOI: 10.1081/E-EDGP 120020618

BP1 and BP2, form the proximal breakpoint of the PWS or AS deletions, and the common distal deletion breakpoint is known as BP3. Between the BP1/BP2 and BP3 breakpoints lies the PWS and AS critical region, or PWACR. The prevalence of this deletion is estimated at 1/10,000.

Duplications of this region take several forms. Interstitial duplications usually include the entire PWACR. Most paternal duplications are associated with normal phenotype, whereas maternal duplications are usually associated with developmental delay, delayed speech, autistic-like and other behavioral problems, and few or no dysmorphic features.[9] Interstitial duplications appear to share the same breakpoints with deletions, spanning the region between BP1/BP2 and BP3.[10] Both intrachromosomal and interchromosomal exchanges have been reported.

Interstitial triplications are also known to occur,[10,11] and may result in a more severe phenotype. Some triplications use some of the PWS/AS breakpoints, but they also break within and distal to the PWACR, implying that they may arise by a different mechanism than duplications. The duplication of the region distal to the PWACR may also contribute to the severity of the triplication phenotype.

Supernumerary marker chromosomes (SMC) represent a second basic type of duplication. The most common SMC is a bisatellited, isodicentric chromosome (Fig. 1) derived from proximal 15q and usually referred to as an inverted duplication 15 or inv dup(15). Because one centromere is usually inactivated, these chromosomes are more properly termed pseudodicentric. The inv dup(15) chromosomes are thought to arise through a U-type exchange between low-copy repeats present in opposite orientation. The inv dup(15)s exist in two basic sizes, although specific breakpoints may vary.[12] ''Small'' inv dup(15)s do not include the PWACR, break at BP1 or BP2, and are usually associated with normal phenotype, although some male carriers have been found to be infertile with azoospermia.[13] Such chromosomes are often familial and detected during routine prenatal diagnosis. ''Large'' inv dup(15)s include the PWACR, break at BP3 or more distally, and are associated with mild to severe mental retardation, autistic-like behavior, seizures, hypotonia, poor motor coordination, abnormal dermatoglyphics, and dysmorphic features such as strabismus. They are usually symmetrical (Fig. 1a), resulting in the presence of four copies of the PWACR [two on normal chromosome 15s, two on the inv dup(15)], and thus are more like the interstitial triplications. However, rare asymmetrical inv dup(15)s (Fig. 1b) have been reported,[12] resulting in only three copies of the PWACR.

It should be noted that there have been difficulties in the interpretation of some patients' karyotypes in the past, as duplications and triplications can be difficult to distinguish using microsatellite markers. Some patients with supernumerary chromosomes have also been found to have uniparental disomy of the normal 15s, leading to a PWS or AS phenotype. Many genes in the region have been well characterized, but while many duplication studies have determined the duplication size, few have determined whether these genes are actually overexpressed.

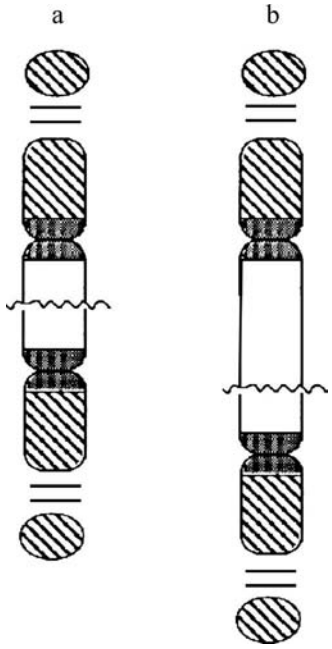

Fig. 1 Supernumerary bisatellited chromosomes, representing either inv dup(15) or inv dup(22). Such chromosomes can be symmetrical with the same breakpoint for each half (a) or asymmetrical with different breakpoints for each half (b). (Modified from Mears: Molecular Characterization of Duplications Associated with Cat Eye Syndrome. Ph.D. thesis; University of Alberta, 1995.)

The clinical features of the proximal 15q duplications are highly variable. Some of this variability may result from the form the duplication takes. It is possible that an interstitial duplication and duplication through a supernumerary chromosome of a similar region may not give the same phenotype. This could be due to possible differences in position effect (for instance, distance from a centromere) or changes in global imprinting of the region.

DUPLICATION OF 22Q11—CAT EYE SYNDROME

The inv dup(22), or CES chromosome, is associated with the clearly delineated disorder cat eye syndrome or CES (MIM #115470).[14] This syndrome is characterized by a

variety of congenital defects including ocular coloboma, anal atresia, preauricular tags/pits, heart defects (particularly the relatively rare total anomalous pulmonary venous return or TAPVR), kidney and skeletal defects, dysmorphic facial features, and mild mental retardation.[15] Cat eye syndrome is highly variable in severity and the number of features expressed, even within families, can range from severe to essentially normal. Cat eye syndrome is rare, with an estimated frequency in the range of 1/50,000 to 1/150,000 live births.

The typical CES karyotype is 47,+idic(22)(pter→q11.2), resulting in the presence of four copies of the CES critical region or CESCR. However, interstitial duplications of 22q11.2 have also been associated with CES.[16–18] Because of the small sample size of interstitial duplications and the extreme variability of the syndrome, it is unclear whether three copies of the region give a less severe phenotype than four.

The CESCR does not overlap with the DGS/VCFS deletion syndrome of 22q11, and thus they are not reciprocal syndromes (Fig. 2). However, the CES chromosome exists in several discrete sizes, some of which do include the DGS/VCFS critical region.[20] The CES region extends ~3 Mb from the centromere and is present in two copies in all inv dup(22). Some CES chromosomes also contain one or two copies of the adjacent 3-Mb region deleted in DGS/VCFS. The recurrent CES breakpoint regions occur in the same intervals as the proximal and distal 3-Mb VCFS/DGS deletion breakpoints.[20,21] Thus a Type I CES chromosome is symmetrical with two proximal breakpoints and no DGS/VCFS material (Fig. 2). Type II CES chromosomes contain one proximal and one distal breakpoint (Type IIa, asymmetrical) or two distal breakpoints (Type IIb, symmetrical), resulting in an additional one or two copies of the VCFS/DGS region. Interestingly, most reported Type II inv dup(22)s are asymmetrical, whereas most reported inv dup(15)s are symmetrical. An additional, less-frequent 22q11 breakpoint exists in the middle of the DGS/VCFS, which can also be used as a distal breakpoint.[22] All three breakpoint regions, each 1.5 Mb apart, harbor a similar low-copy repeat or LCR22.[23] The size of the inv dup(22) does not appear to have an obvious correlation to the severity of the phenotype, despite the fact that dosage-sensitive gene(s) must be present in the DGS/VCFS region.[20] However, the sample size of this study was small (10 patients).

The CESCR was further defined by studying a child with an unusual supernumerary double-ring chromosome 22 and all major physical features of CES.[24] The duplication extended from the centromere to the gene *ATP6E*, a distance of approximately 2 Mb (Fig. 2). Fourteen transcripts have been identified in the CESCR, as well as 12 mouse homologues in the region of conserved synteny on murine chromosome 6.[25,26] It is not yet known whether one or multiple genes are involved in CES. Unlike the inv dup(15), the study of the inv dup(22) is not complicated by the presence of imprinting.[27–29]

Like the inv dup(15), there are also inv dup(22)s that are associated with normal phenotype. These chromosomes presumably do not contain euchromatin, although their cytogenetic appearance is often not distinguishable from the CES chromosome. This is especially problematic when an inv dup(22) is found during prenatal testing, as there are currently no commercial fluorescence in situ hybridization (FISH) probes available to distinguish between the benign and CES chromosomes.

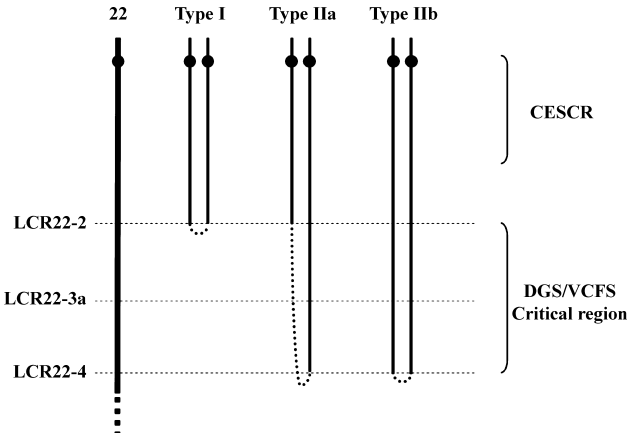

Fig. 2 Different types of inv dup(22), which contain no (Type I), one (Type IIa), or two (Type IIb) copies of the DGS/VCFS critical region. Breakpoints for both inv dup(22)s and the DGS/VCFS deletions are found in regions of low-copy LCR22 repeats. (Redrawn from Ref. [19].)

DIAGNOSIS OF MICRODUPLICATIONS

Microduplications in the form of SMCs can be identified by karyotyping followed by the identification of the chromosomal origin using FISH. However, interstitial microduplications are technically difficult to detect. Using FISH, a microdeletion can be detected as the absence of probe signal over the deleted chromosome. However, microduplications typically result in two superimposed signals, which are difficult to distinguish from a single signal. Confirmation of a microduplication usually requires analysis of FISH signals over high-resolution chromosomes or interphase nuclei. Commercial probes for microdeletion syndromes SMS and PWS/AS can be used to detect microduplications of these regions; however, no commercial probe is currently available for the CES-specific region. Other techniques such as microsatellite and dosage analysis are difficult to do in a clinical setting. The prevalence of both microduplications and

microdeletions in individuals with developmental delay and/or congenital malformations may soon become clearer, as quantitative analysis of the whole genome via comparative genomic hybridization (CGH) arrays becomes clinically applicable (reviewed in Ref. [30]). In this technique, fluorescently labeled DNAs from a patient and a normal individual are competitively hybridized to CGH arrays containing genomic clones from various regions of the genome, allowing differences in copy number of these regions to be detected.

CONCLUSION

The existence of reciprocal microdeletion/microduplication syndromes of 17p12 (HNPP/CMT) and 17p11.2 [SMS/dup(17)(p11.2p11.2) syndrome] suggests that other such reciprocal microduplication syndromes may exist but remain unrecognized. As more individuals are carefully checked for microduplications with more sophisticated techniques such as CGH arrays, the prevalence of such possible syndromes will become clear. It is particularly interesting to speculate for the DGS/VCFS region of 22q11, the site of the most common of the microdeletion syndromes with an incidence estimated at 1/4000 live births. The fact that a reciprocal 22q11 microduplication syndrome has so far gone unrecognized suggests that it is mild and highly variable. Considering the variability of the DGS/VCF deletion phenotype, which is currently recognized as at least three different syndromes, variability in the reciprocal duplications is highly likely. A mild and nondistinct phenotype is also suggested by the fact that the presence of the DGS/VCFS region on the CES chromosome does not appear to have an obvious effect on top of the CES phenotype. The one case reported to date with duplication of the DGS/VCFS region showed developmental delay and hypotonia, but the mother and grandmother with the same duplication appeared normal.[21]

Microduplications, like microdeletions, can shed light on developmental processes by revealing dosage-sensitive genes critical in developmental pathways. To this end, the genes in microduplication regions are being characterized and mouse models are being produced.

ACKNOWLEDGMENT

Microplate Array Diagonal Gel Electrophoresis for SNP and Microsatellite Genotyping and for Mutation Scanning

INTRODUCTION

Electrophoresis continues to be widely used for diagnostic applications in molecular genetics, although many efforts are being made to develop liquid-phase and closed-tube systems. Throughput requirements are increasing in proportion to the number of diagnostically relevant genes, mutations, and polymorphic variants known. Many tests are polymerase chain reaction (PCR) based. The well-known industry-standard 96-well microplate has evolved to form the basis of many high-throughput approaches in the biosciences over the past 30 years and such 96 (and 384)-well formats are now frequently used for PCR. However, microplates are only permissive of liquid-phase reactions or solid-phase (binding) separations, whereas electrophoresis can derive information about parameters such as size, shape, and charge of molecular moieties as well as acting as a highly resolving separation approach for complex mixtures. In 1994, we described an electrophoresis system, microplate array diagonal gel electrophoresis (MADGE), which enables the simple conjunction of polyacrylamide or agarose gel electrophoresis in an open-faced 96-well microplate-compatible format. This permits checking of PCRs, allele-specific PCRs, and enzyme digests of PCRs. We have since developed 192-, 384-, and 768-well versions, ''dry'' formats, high-resolution formats for microsatellite analysis (''stretchMADGE''), and a thermal ramp (''meltMADGE'') approach for scanning for unknown mutations. Analysis software is also available. These developments are outlined below. Protocols and further links are available on our laboratory web server (Southampton Genetic Epidemiology Laboratories—http://www.sgel.humgen. soton.ac.uk).

MICROPLATE ARRAY DIAGONAL GEL ELECTROPHORESIS

In 1807, Ferdinand Frederic Reuss observed under a microscope the migration of colloidal particles in an electric field, perhaps the first electrophoretic separation. During the early 1970s, both agarose and polyacrylamide electrophoresis gel usage evolved to slab gel formats[1,2] much as they are still found in the laboratory today. Throughput requirements were not an issue at that time. Indeed, slabs were an advance from tube gels. For both tubes and modern capillaries, each ''lane'' is separate from any other and cross-referencing requires reliance on either an external frame of reference (e.g., time of elution) or an internal frame (e.g., coelectrophoresed mobility standards). Slabs give convenient alignment of tracks. Microplate array diagonal gel electrophoresis, in the process of achieving microplate compatibility, uses 96 (higher density in newer formats)-track origins (wells) with 8×12 array locations at the 9-mm pitch identical with microplates devised 30 years ago by Dynatech and now a highly established industry standard for liquid-phase operations.

The Original 96-Well Format

The original MADGE format[3] uses a two-dimensional plastic former in conjunction with one glass plate coated with gamma-methacryloxypropyltrimethooxysilane (sticky silane). The plastic former contains a 2-mm-deep, 100×150-mm rectangular ''swimming pool.'' Within the pool, there are ninety-six 2-mm cubic ''teeth'' (well formers) in an 8×12 array with 9-mm pitch directly compatible with 96-well plates. The array is set on a diagonal of 18.4° relative to the long side of the ''pool,'' which is parallel to the eventual direction of electrophoresis, giving gel track lengths of 26.5 mm (Fig. 1A). The gel former is placed horizontally, acrylamide mix poured into the pool, and the glass plate overlaid (Fig. 1B). After the gel has set, the glass plate is prized off, bearing its open-faced 96-well gel. It should be noted that although the diagonal-array approach may appear complex, many users have noted that this is the simplest gel preparation and sample tracking system they have ever used. Additionally, the human eye/brain is extremely good at pattern recognition and the small-scale user, once accustomed, is not obliged to use image

analysis software. A 26.5-mm track length (2×4 diagonal of array) such as in Fig. 1A or greater such as the 2×6 diagonal in Fig. 3 (see section below on higher-resolution MADGE), using polyacrylamide gel matrix, is efficient for many post-PCR analyses involving simple band pattern recognition. We also use agarose MADGE gels anchored on a hydrophilic plastic such as GelBond for checking long PCR products. Polyacrylamide MADGE gels are robust, reusable, directly stackable for storage or use, and fully compatible with industry-standard PCR microplates, thus minimizing procedural information transfers and enabling direct 96-channel pipetting. However, considerable advantage is gained even with 8- and 12-channel pipettes.

Short track length/run time, compactness, and scalability with hand-sized robust slab gels accessible for direct human interaction are additional benefits of MADGE. Startup costs are minimal, so ''third-world'' laboratories can also apply the system. Essentially, any analysis which can be reduced to short tracks (e.g., <3 cm) gains the throughput advantages. One technician can process

10–100 gels (960–38,400 tracks) per day according to the application and the MADGE implementation in use. Typical applications, in many laboratories worldwide, have been for allele-specific PCR and restriction digest checking post-PCR, for single-nucleotide genotyping in many samples in parallel in genetic epidemiological (''DNA bank'') research. Such MADGE-based approaches have been used extensively in our own laboratory (e.g., Ref. [4]) and in other laboratories (e.g., Refs. [5,6]). Another laboratory implemented complete genome mapping using high-throughput PCR from radiation hybrid cell lines combined with 96-well reusable MADGE-checking gels.

192-Well MADGE

For checking one or two bands, much of the usual MADGE track length remains unused. One general approach to single nucleotide polymorphism (SNP) calling is to use allele-specific PCR such as amplification refractory mutation system (ARMS):[7] one simple robust format uses two separate allele-specific amplifications, one testing for each allele, with a control (unlinked) amplicon also included in each reaction as a positive control. In this case, it is easiest to load one gel and recombine the two tracks of information about a given template into one ''virtual'' software track. This can be readily achieved by locating a second well halfway along the ''original'' MADGE track, giving two concatenated tracks of 12.25 mm (for 2×4 diagonal MADGE) in a 192-well gel.[8]

384-Well MADGE and 768-Well MADGE

384-well microplates have become an established new standard in higher-throughput genomics research laboratories for clone operations (arrayed libraries, gridding, spotting, storage, etc.) and for PCR. The difficulties in thin-walled plastics manufactured for the latter have been solved. 384-well microplates have wells in a 16×24, 4.5-mm pitch array. A diagonal turn of this array would result in MADGE wells and tracks too narrow (<1 mm) for manual access, but we have devised a 384-well MADGE format which combines four 96-well arrays in a linear (rather than tetradic) overlay. The 384-format locates the long axis of the array at 11.3° relative to the direction of electrophoresis and respectively give track lengths of 9.98 and 4.24 mm and track width of 1.5 mm. The $1.5 \times 1.5 \times 1.5$-mm wells can be accessed by human hand. However, the array is dense and confusing for 8- or 12-channel loading, but 96-pin passive or air displacement transfer is not a problem for human hand and eye. We have also derived a 768-well format from 384[9] in the same way that the 192-well format was derived from the original 96-well format (see above). Protocols for setting up 768-well gels are identical with those for 384-well gels. Unlike 96- and 192-well protocols, the 384-well protocol depends on the use of oil-free PCR, 96-pin manual transfers from 384-well PCR plate to gel, and use of dry rather than submerged gels to enable the use of passive pin transfers. However, this approach is also considerably more convenient. Combined with direct electrode contact in ''dry'' clamshell electrophoresis boxes which plug directly into contacts in a powered stacking frame and using 5–10 min electrophoresis times, very much higher throughputs can be achieved than with 96-well submersible systems. Components of this system are shown in Fig. 1C and D and a typical result from a 384-well gel is shown in Fig. 2. The present approach to machining of the gel formers is near its limit because the space between ''teeth'' is small, but other arrangements of teeth, or other approaches to gel former production, may enable yet higher densities. However, it is likely that this would force the transition from economy of startup and versatility of

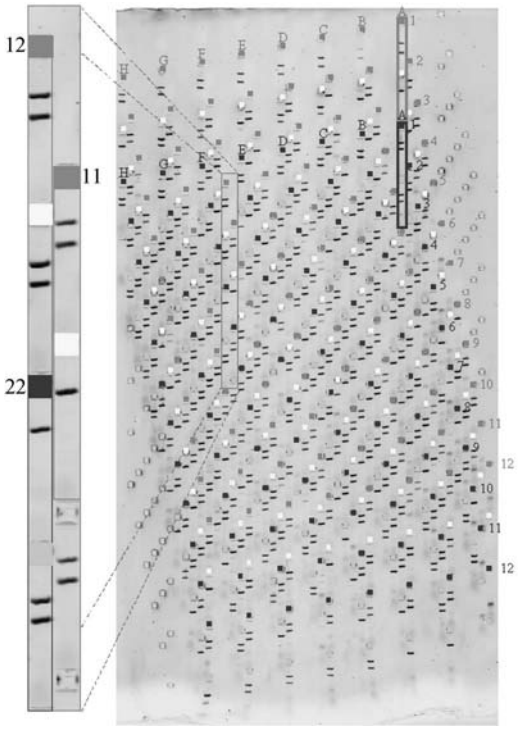

Fig. 2 384-well MADGE gel used for dual-reaction ARMS assay. On the main gel image the red rectangle indicates reactions a and b for sample A1, array 1, whereas the blue rectangle indicates reactions a and b for sample A1, array 2. The enlargement shows the three possible genotype calls as pairs of lanes with either two bands in each heterozygote or two bands in one and one in the other (for each category of homozygote). (*View this art in color at www.dekker.com.*)

the human operator to expensive hardware configured around a core mini–microscale format, and at this level, complete departure from industry-standard microplate format may be appropriate.

High-Resolution 96-Well MADGE (StretchMADGE) for Sizing Microsatellite Alleles

The following modifications enable resolution of bands with small (e.g., 1.5–5%) mobility differences (Fig. 3A):

- Increased track length on 2×6 diagonal instead of 2×4 diagonal.
- Introduction of internal molecular weight markers in every track.
- Sample dilution to avoid salt artefacts in the electrophoresis.
- Use of better resolving acrylamide derivatives such as duracryl.
- Thermostatic control of the electrophoresis.

This has enabled calling of minisatellite[10] and tetranucleotide and trinucleotide repeat multiallelic microsatellite polymorphisms.[11] We have been interested in using such sites *within* genes as linkage disequilibrium markers in association studies and wider utility can be anticipated. In our system, microsatellite amplicons are electrophoresed double stranded and there is the possibility that not only length polymorphic information but also internal sequence variation will be accessible by examining heteroduplex mobility.

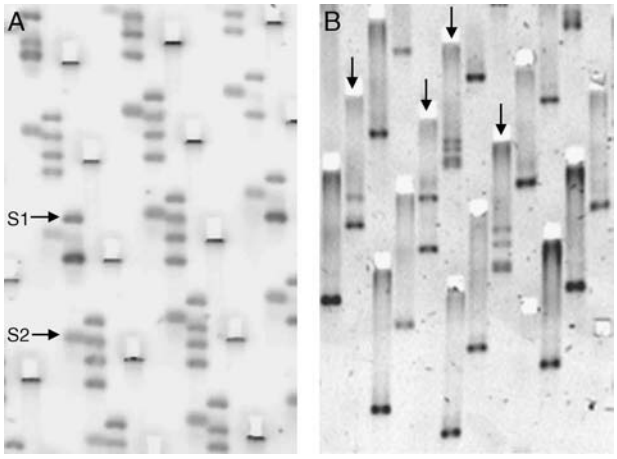

Fig. 3 StretchMADGE and meltMADGE. (A) StretchMADGE resolution of homoduplexes and heteroduplexes of a tetranucleotide microsatellite amplicon with five main alleles. Except in homozygotes, two resolving homoduplexes and two resolving or corunning heteroduplexes are observed. Homoduplexes are sized relative to flanking size markers (arrows) introduced into every track. Amplicon size is $\sim$260 bp, so one repeat size difference corresponds with approximately 1.5% band mobility difference. (B) MeltMADGE scanning of an amplicon for identification of unknown mutations. As explained in the text, heterozygotes for a mutation show a set of bands (tracks marked by arrows) instead of a single band, representing differential melting and hence differential mobilities during thermally ramped electrophoresis.

Temporal Thermal Ramp MADGE Electrophoresis (MeltMADGE) for Identification of Unknown Mutations

As MADGE involves a complex spatial configuration of sample wells and tracks, electrophoresis methods involving spatial gradients would be difficult to establish. Denaturing gradient gel electrophoresis,[12] which is used for identification of unknown mutations, involves a spatial gradient of denaturant. Polymerase chain reaction products heterozygous for a base change possess four moieties resolvable as separate bands. Consider a G to A transition. The homoduplex with a G–C base pair will migrate furthest in the gel because it will be the last moiety to denature with consequent reduction of migration velocity. The homoduplex with an A–T base pair will migrate almost as far. The heteroduplex with the relatively stable G–T mismatch will show a band of lower mobility. The heteroduplex containing the relatively unstable A–C mismatch will appear as the band nearest to the well. A thermal ramp in time can achieve a similar effect to a denaturing gradient in space and has the advantage of spatial homogeneity and hence applicability to the MADGE (or other array) formats. This forms the basis of our meltMADGE invention[13] and an early proof of principle example is shown in Fig. 3B.

We have previously described (for other use than meltMADGE) a purpose-built programmable real-time thermoregulated electrophoresis apparatus.[14] In brief, a $10 \times 10 \times 15$-cm electrophoresis tank contains buffer which is continuously mixed to ensure spatial thermal homogeneity, and the temperature is varied real-time by programmable software controlling heating and cooling systems and receiving feedback from temperature sensors in the tank. Overall, this is little more complex than a PCR machine, although for PCR low thermal mass for rapid temperature shifts is the objective, whereas for meltMADGE, the aim is high thermal mass for stability of small temperature shifts. The initial prototype accommodates 10–12 horizontal MADGE gels spaced in a carrier stack. Each 2-mm-thick gel is adherent to and supported by a 2-mm glass plate and is also covered by 2-mm glass, with spacing between each glass/gel/glass sandwich for buffer circulation. As buffer and hence thermal circulation is vigorous and the glass is both a good thermal conductor

and also quite thin, and the thermal ramps are relatively shallow, reasonable spatial thermal homogeneity is achieved, at least to within 0.1°C as determined by a reference platinum resistivity thermometer. Alternately, an electrophoresis box with a fast impellor, a rack for the gels, and a glass serpent taking the input from a programmable, recirculating water bath can be used. The latter are commercially available and the remainder is simple to build. At 10 MADGE gels per tank (96-well or 192-well) and 1–4 hr run time (faster if powerful cooling is available to counteract amperometric heating), it is feasible for one worker to optimize a number of amplicon assays in parallel, or to run several thousand scans (either of thousands of subjects for one amplicon or of several amplicons of matched melting characteristics for a few hundred subjects) per day. Assay optimization tends to be the limiting factor.

The reconfiguration of the denaturing gradient to have temperature as the dependent variable and time as the independent (controlled) variable opens a range of significant advantages:

1. It creates the option for high density arraying of wells and tracks (e.g., MADGE arrays), hence enabling high throughput of analyses.
2. Programmability of the gradient, which can be arbitrary and uses temperature rather than chemicals, is achievable easily in time. Arbitrary ramps (rather than simple linear gradients) would be very difficult in space. Gradients as an integral feature of the gel demand special gels. Programmability gives flexibility and convenience.
3. Potential for arbitrary ramps enables very short track lengths, and short run time (e.g., 1 hr) further enables high track density and hence throughput.
4. The use of ordered arrays (e.g., microplate format of MADGE) greatly simplifies data handling.
5. Arbitrary programming enables arbitrary resolution, thus reducing the analysis to simple pattern recognition rather than detailed relative mobility measurements. Pattern recognition evades the need for closely juxtaposed tracks or for internal markers. By contrast, the resolution of single-stranded conformation polymorphism (SSCP) is often small, cannot be programmed, and hence cannot be arbitrarily great. Thus advantages 1–4 cannot be realized with SSCP.

We have applied this system to a number of human genes both for studies of large case collections and for epidemiological research in population samples (BRCA1 in breast cancer risk; LDLR in familial hypercholesterolemia; MC4R-population research in obesity; APOE). Other assays relevant to the diagnostic laboratory are under development.

Identification of unknown mutations is an important aspect in genetic diagnostics. For mutations not known in advance, the choice at present is between direct sequencing, de novo scanning techniques to target sequencing more efficiently to appropriate regions, and ''chip'' technologies equivalent with direct resequencing by multiple parallel oligonucleotide hybridization.[15] For the identification of rare variants, important criteria are the degree of parallelism of samples possible, the number of bases analyzed per ''run,'' and the total number of bases an individual can scan per day. For heterozygote sequencing in humans, the difficulties of accurate base calling (essential for every base to avoid excessive numbers of false positive calls) may restrict sequencing as a first-line approach.[16] Even as sequencing improves, reagent requirements and need for high-resolution electrophoresis introduce significant cost issues. Chip technologies, while promising, have low capability for sample parallelism; a chip is expensive ($5000–10,000) for any selected sequence and also requires an optimization process; and the approach will demand high capital expenditure on chip-reading hardware. Scanning technologies are much used, but intense activity to develop improved approaches reflects the importance and shortfalls in this field. Such technologies generally rely on electrophoresis and give some information about the mutation from the resultant band pattern. MeltMADGE enters the field alongside SSCP,[17] denaturing gradient gel electrophoresis (DGGE),[12] and denaturing HPLC.[18] Sensitivity to all base changes has been a concern with SSCP. Denaturing gradient gel electrophoresis, although used in diagnostics laboratories on account of good sensitivity to most if not all base changes, is laborious and has low throughput. Denaturing HPLC has recently become prevalent but incurs high capital costs and high consumables costs, both tenfold greater than for the other techniques. In effect, meltMADGE should be considered as a convenient, high-throughput format of DGGE. Our comparisons with other techniques (to be published) show good sensitivity to most base changes, given appropriately planned and optimized assays.

CONCLUSION

There is intense activity to systematize the genomic, genetic, transcriptomic, and proteomic descriptions of organisms. A supplement to *Nature Genetics* ''The Chipping Forecast'' considered in detail the shift from hypothesis-led to descriptive hypothesis-forming research in the biosciences.[19] The systems that we have described here incur no substantial capital costs. Reagent costs are minimal and, in general, gel-based assays represent well-understood, widely available, adaptable methods. The

system is thus readily accessible to almost any standard laboratory. With a capacity up to 1 million tracks per day for minimal investment, the achievable throughputs for low-resolution electrophoresis by ''dry'' gel PAGE MADGE match the current shift of philosophy in biosciences research toward higher throughput, systematic description. Similarly, the throughputs with meltMADGE are two orders of magnitude greater than the currently favored approaches of SSCP and denaturing HPLC. Microplate array diagonal gel electrophoresis and melt-MADGE may meet the criteria of economy, sample parallelism, convenience of setup, and accessibility to large and small laboratories alike, and may thus find an important role in diagnostic, as well as research, applications. Future applications might also include enzyme, protein, RNA, protein–DNA, and other categories of biomolecular analysis.

Microsatellite Instability

INTRODUCTION

Microsatellites (MS) are repetitive stretches of genomic DNA consisting of mono-, di-, tri-, tetra-, and pentanucleotide repeats. Tens of thousands of MS are distributed throughout the genome. The length of MS repeats in individuals of a species tends to be highly polymorphic making them suitable as genetic markers. For this reason, MS analysis has become a valuable tool in forensic medicine, paternity testing, tissue typing, and molecular diagnostics. Because of their simple sequence structure, MS are usually located in regions of DNA that are not transcribed or translated. However, a growing number of coding mono-, tri-, and tetranucleotide repeats are reported to be involved in cancer or neurodegenerative disorders. Because of their repetitive nature, MS sequences are prone to alteration during DNA replication as a result of polymerase slippage and/or misalignment of template strands. In normal cells the mismatch repair (MMR) system detects and repairs small DNA alterations such as missense mutations and small insertions and deletions. A defective MMR system may result in shortened or extended microsatellite sequences (microsatellite instability, MSI), ultimately accumulating genomewide mutations affecting fundamental cellular processes such as signal transduction, cell growth, apoptosis, or DNA repair.

Microsatellite instability occurs in about 15% of all colorectal cancers (CRC) and is a hallmark of the hereditary nonpolyposis colorectal cancer (HNPCC) syndrome. Inactivating germline mutations in MMR genes will predispose patients of HNPCC families to colorectal and other cancers (e.g., tumors of the endometrium, ovary or upper urinary tract). Promoter hypermethylation of MMR genes may epigenetically cause MSI in sporadic CRC. Microsatellite instability tumors exhibiting such ''mutator phenotype'' differ from microsatellite-stable (MSS) tumors in their molecular, histopathological, and clinical characteristics. Microsatellite-stable tumors are characterized by aneuploidy and frequent large chromosomal deletions or amplifications, a feature referred to as chromosomal instability (CIN). In contrast, colorectal MSI tumors are commonly diploid with few chromosomal alterations. They typically arise in the right colon, are poorly differentiated, are of mucinous type, and show extensive intra- and peritumoral lymphocytic infiltration. Patients with MSI CRC tend to have a favorable clinical prognosis and are reported to respond better to chemotherapeutical treatment than patients with MSS CRCs.

DIFFERENT TYPES OF MSI

Microsatellite instability was first described nearly simultaneously by three groups in 1993.[1–4]

There are two types of MSI in colorectal tumors: highly frequent MSI (MSI-H) is defined by a MSI frequency of >40% using a specified microsatellite marker panel. In contrast, tumors with a frequency of MSI of <40% are referred to as MSI-low tumors (MSI-L).[5] Mononucleotide markers such as BAT25, BAT26, and BAT40, which are almost monomorphic in germline DNA, show the highest mutation rates in tumors of the HNPCC spectrum. Alterations in these markers are associated very specifically with deficient MMR genes *MSH2*, *MLH1*, *MSH6*, and *PMS2* in CRC. In contrast, the MSI-L phenotype is mostly restricted to dinucleotide markers and those with longer repeat units. A standardized, sensitive, and specific marker panel for detection of MSI in CRC was recently defined[5] and is currently recommended as the consensus marker panel for molecular HNPCC diagnostics in CRC.[6]

The mutation spectrum (e.g., *KRAS* mutation, *TP53* mutation, LOH at 5 q, 17 p, and 18 q) and the clinicopathological features of MSI-L and MSS tumors are quite similar but differ from that in MSI-H cancers which show relatively open mutations in genes with coding repetitive sequences (e.g., *TGFBR2*, *BAX*). It has recently been suggested that MSI-L arises as a consequence of epigenetically silencing the *O*-6-methylguanine DNA methyltransferase (*MGMT*) gene through promoter hypermethylation leading to promutagenic methylguanine adducts which are not sufficiently eliminated and thereby overcharging the MMR system.[7]

DOI: 10.1081/E-EDGP 120020962

MICROSATELLITE INSTABILITY IN HNPCC AND IN SPORADIC CRC

The MSI-H phenotype is a defining feature of HNPCC patients and is a result of predisposing constitutional mutations in the MMR genes *MSH2*, *MLH1*, *MSH6*, *hPMS2*, and *hMSH3*.[8] Most mutations were found in *MSH2* and MLH1 and less frequently in *MSH6, hPMS2*, and *hMSH3*. Germline mutations in MMR genes predispose not only to CRC but also to endometrial, upper urinary tract, and ovarian malignancies. Small intestinal and gastric cancers as well as tumors of the biliary tract are also seen in HNPCC, but they are relatively rare events. Highly frequent MSI is not restricted to HNPCC but occurs in approximately 12% of sporadic CRC with epigenetically and biallelically silenced MLH1 genes through promoter methylation in the vast majority of cases.

Hereditary and sporadic MSI-H CRCs share several clinicopathological characteristics. These include right-sided location, poor differentiation, a medullary or mucinous phenotype, and extensive lymphocytic tumor infiltration, but specific characteristics for HNPCC and sporadic tumors exist as well.[9–12] Hereditary nonpolyposis colorectal cancer is more common in males and occurs in younger patients compared to sporadic MSI-H colorectal carcinomas. Hereditary nonpolyposis colorectal cancers show more frequently Crohn's-like lesions and peritumoral lymphocytes than sporadic MSI-H CRCs. In contrast, sporadic CRCs are more likely to show two or more tumor subclones with diverse grades of differentiation than HNPCC tumors.[10] Adenomas from HNPCC patients are more often of the MSI-H phenotype than sporadic adenomas.

In addition, different molecular pathways seem to be involved in the carcinogenesis of sporadic and familial CRC. There are disruptions of the *wnt* pathway and frequent *KRAS* mutations in HNPCC cancers and/or cell lines, whereas sporadic MSI-H tumors show little evidence of *APC*-mutation, *CTNNB1* (beta-catenin) mutation or abnormal CTNNB1 immunolocalization, and *KRAS* mutation.[13–16] Little evidence, however, exists regarding these alterations in sporadic MSI-H CRC.[15,16]

CLINICAL OUTCOME OF PATIENTS WITH MSI-H COLORECTAL TUMORS

Considering the different molecular and histological features of tumors with microsatellite instability and chromosomal instability (see introduction) one could expect that cancers emerging from MSI-H and CIN pathways would also differ in clinically relevant characteristics. Several studies investigating MSI-status and prognosis show that survival of patients with the MSI-H phenotype is longer than that of patients with MSS cancers. However, some conflicting reports let the National Cancer Institute workshop conclude that MSI-H has not been demonstrated to be an independent predictor of prognosis.[6] These results may be due to both inconsistent definitions of MSI before 1998 and retrospective investigation of small patient cohorts. In a relatively large population-based study, the clinical outcome of MSI-H and MSS patients was assessed and associated with classic clinical prognostic factors. Highly frequent MSI was independently associated with prolonged survival in patients without adjuvant chemotherapy.[17] In another study, MSI-H correlated with lower tumor stage indicating that either MSI-H contributes to improved survival independently of other prognostic factors or MSI-H is independently predictive of lower pathological stage, thus contributing to the improved survival through tumor downstaging.[18] The reason why MSI-H improves clinical outcome is not clear yet. One can assume that the MSI-H typical mutation spectrum, i.e., small genomewide mutations, leads to mutation within coding repeats in genes of cell surface proteins thereby provoking an intense lymphocytic infiltrate and attack of the tumor.[19]

MICROSATELLITE INSTABILITY—PREDICTOR OF ADJUVANT TREATMENT RESPONSE

The different tumor characteristics could be used to develop improved and more individualized chemotherapy in the future. There are promising data that MSI-H and MSS CRC respond differently to specific classes of chemotherapeutic agents. There is evidence that the effective treatment with methylating agents such as *N*-methyl-*N*′-nitro-nitrosoguanidine, *N*-methyl-*N*-nitrosourea, and their chemotherapeutic analogs, streptozocin and temozolomide, requires functional MMR. Tumor cell lines with defective *MSH2*, *MSH6*, *MLH1*, or *PMS2* genes as well as *MSH2*-deficient mouse embryonic cells are highly resistant to these drugs compared to the corresponding MMR-proficient cell lines. It is suggested that the absence of MGMT alkylated guanine will lead to incorrect incorporation of thymine into the newly synthesized strand. This mismatch will be recognized by MMR proteins, which, after a further replication round, leads to apoptosis by a not-yet-understood mechanism. This process seems to be interrupted in MSI-H tumors with inactivated MMR resulting in ''damage tolerance'' which should be considered in therapy stratification.

Another widely used chemotherapeutic drug targeting DNA is cisplatin leading to intrastrand DNA cross-links between adjacent purines and activation of DNA repair.

As the nucleotide excision repair (NER) system is an important part of this cellular response, it is suggested that a highly effective NER system leads to resistance or reduced sensitivity of tumors to cisplatin treatment by efficient removal of DNA adducts. Mismatch repair also seems to affect the sensitivity of tumors to cisplatin treatment, but in a different way. Cell culture experiments revealed that tumor cell lines with defective MSH2 or MLH1 proteins show a twofold resistance to cisplatin compared to MMR proficient cell lines.[20] There are several clues that MMR may contribute to the toxicity of cisplatin in the same way it mediates the action of methylating agents. It has been shown that MMR proteins (MSH2/MSH6, MLH1) can be recruited by cisplatin adducts,[20–22] and MSH2 specifically recognizes 1,2-intrastrand cross-links between two adjacent guanine residues which are induced by cisplatin treatment. It has been shown in vitro that MutS-alfa binds to duplex oligonucleotides containing a 1,2-diguanyl intrastrand cross-link with a thymine opposite to 3′-guanine in the cross-link. This situation corresponds to O^6-methylG-T mismatch activating MMR processes and activation of apoptosis if MMR proteins are intact. Thus MSI-H tumors will respond neither to alkylating nor to platinating agents and should be treated by different drugs.

The value of MSI-H as a molecular predictor of response to 5-fluorouracil (5-FU)-based adjuvant chemotherapy has recently been addressed in several studies. The first indication of the importance of MSI-H in the response to 5-FU-based agents came from in vitro studies showing that colon cancer cell lines with defective MMR were more resistant to 5-FU.[23]

Interestingly, clinical studies showed controversial results regarding the response of MSI-H tumors to adjuvant 5-FU treatment. A clear benefit of 5-FU treatment in stage III CRC (Dukes C) with MSI-H phenotype was shown in a retrospective, nonrandomized, hospital-based cohort of 656 CRC patients.[24] A striking survival benefit from adjuvant chemotherapy for patients with right-sided tumors and patients with MSI-H tumors was found. Highly frequent MSI was an independent predictor of improved survival in multivariate analyses. This finding was confirmed by another study demonstrating a favorable outcome in patients treated with adjuvant fluorouracil-based chemotherapy for stage III CRC with MSI-H and retention of heterozygosity of chromosome 18 q.[25,26] An even more significant benefit of adjuvant chemotherapy was demonstrated in MSI-H cancers carrying mutations in the transforming growth factor β1 receptor type II gene (*TGFBR2*). The TGFB1 pathway plays an important role in tumor suppression, because it leads to inhibition of tumor proliferation by blocking the cell cycle in late G1. The TGFB1 pathway is also known to be inactivated in most MSI-H tumors as a consequence of mutations within a coding repeat, and unregulated cell proliferation may thus lead to increased susceptibility to chemotherapy. However, an adverse effect of MSI on the response to adjuvant 5-FU treatment was recently reported. This study showed that randomized patients with stage II or stage III MSI-H colon cancer do not benefit from 5-FU-based adjuvant treatment and may even be harmed.[17] Further prospectively controlled and population-based studies are needed to clarify whether MSI will affect the response to adjuvant chemotherapy.

CONCLUSION

Highly frequent MSI (MSI-H) as a result of defective MMR affects about 15% of all CRC. Highly frequent MSI tumors differ from microsatellite-stable tumors in a number of molecular and clinicopathological features. Approximately 3% of CRC show MSI-H due to predisposing constitutional mutations in MMR genes. This group of patients is referred to as hereditary nonpolyposis colorectal cancer, HNPCC. Familial and sporadic MSI-H tumors are largely similar in their molecular characteristics, but differ in some clinicopathological features. Patients with MSI-H cancers respond differently to various chemotherapeutic treatment regimens compared to MSS CRC patients. Further prospective and population-based studies are needed for a better and individualized therapy stratification of CRC.

Molecular Beacons and Other Hairpin Probes

Natalia E. Broude
Boston University, Boston, Massachusetts, U.S.A.

INTRODUCTION

Stem-loop (hairpin) DNA oligomer probes provide increased specificity of target recognition as compared with linear DNA probes. Invention of molecular beacons, a variant of stem-loop oligonucleotides, which are able to fluoresce upon hybridization but are ''dark'' in the absence of the target, made possible real-time monitoring of hybridization process. A variety of robust assays using diverse, structurally constrained oligonucleotides have been developed that exploit endless number of formats and detection methods.

Hairpin DNA oligonucleotides are also used as different components in many DNA amplification methods providing higher specificity and lower background. Thus, these structured probes are an indispensable tool in modern biotechnology and diagnostics.

ENHANCED SPECIFICITY OF HAIRPIN DNA PROBES

Specificity of probe/target hybridization is a crucial factor determining efficiency of most nucleic acid-based methods used in diagnostics and biotechnology. Hybridization specificity is determined as a match-versus-mismatch discrimination: binding to sites that differ from the perfectly complementary sequences even by a single base pair substitution is characterized by a substantial free-energy penalty.[1] If the free-energy penalty is high enough, a set of conditions (so-called stringency conditions) can be found where perfect complexes will be considerably more stable than the complexes containing mismatches.

Stem-loop DNA probes are single-stranded oligonucleotides containing a sequence complementary to the target that is flanked by self-complementary target-unrelated termini. Thermodynamic analysis of hybridization characteristics of linear and stem-loop DNA probes proved that it is a general feature of structurally constrained probes to distinguish mismatches over a larger range of temperatures or other experimental parameters comparing to unstructured probes.[2,3] Thus, stem-loop DNA probes allow for a wider window of stringency conditions, which provide better match/mismatch discrimination.

MOLECULAR BEACONS

Molecular beacon (MB) is a stem-loop DNA oligonucleotide, which carries a fluorophore and a quencher at the 3′- and 5′-ends[4,5] (Fig. 1A). In the absence of the target, these molecules form closed stem-loop structures in which fluorophore and quencher are in close proximity—this results in fluorescence quenching. In the presence of the DNA or RNA target, molecular beacon forms a complex with it, which brings apart the fluorophore and the quencher. Once the fluorophore and quencher are spatially separated, the fluorescence develops under illumination and quantitatively reports on the presence of the target (Fig. 1A).

Molecular beacons, being inactive in absence of the target, do not require purification of the hybridization product from the excess MB and thus provide simple, homogeneous (close-tube) format of the assay and, consequently, a possibility of real-time hybridization monitoring. This feature of MBs made them a tool of choice in many applications. They were used for detection of single nucleotide polymorphisms, in quantitative PCR, in isothermal amplification, as DNA microarray-immobilized probes and biosensors, and as antisense probes for detecting RNAs in vivo (for reviews, see Refs. [6,7]). Recent developments were directed toward simplification of the MB approach and creation of the ''label-free'' optical biomolecular sensors. For example, immobilization of fluorophore-labeled MBs on a gold surface allowed using the surface as a quencher, thus eliminating the need in quenching moiety in the beacon structure.[8] Fully unlabeled stem-loop DNA probes were used as electrochemical DNA sensors capable of detecting femtomoles of DNA by electrochemical signal rather than by optical signal.[9]

Fluorescence monitoring allows quantitative kinetic analyses of the conformation changes of molecular beacons. Therefore they have also become a useful tool in studies on conformational changes of DNA under various conditions or caused by various types of reagents

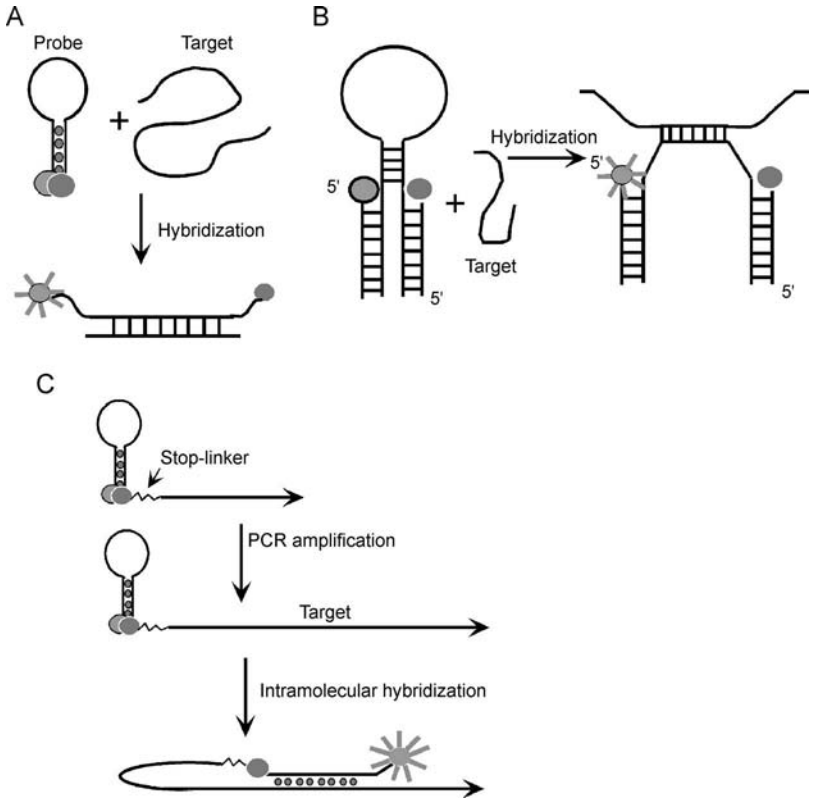

Fig. 1 Outline of different assays using molecular beacons. (A) Molecular beacon is in a closed (''dark'') form in the absence of the target, and a fluorophore (red) and a quencher (gray) are in a close proximity, which quenches fluorescence. Upon hybridization with the target, the beacon changes its conformation, which results in spatial separation of the fluorophore and quencher. As a result, bright fluorescence reveals the presence of a target. (B) Tripartite molecular beacons with universal arms and varying loop provide flexibility in design and reduced cost. (C) Schematics of the beacon-like Scorpion probe approach. Incorporation of a stem-loop-shaped probe into the PCR primer allows unimolecular target detection, which ensures faster kinetics and higher stability of the complex as compared with bimolecular reaction. interacting with nucleic acids. These studies include real-time monitoring of DNA cleavage caused by enzymes or chemicals, protein–DNA interaction studies, and studies of various dye interactions with duplex DNA. Conformational studies of single-stranded DNAs as well as kinetic and thermodynamic characteristics of triplex formation have also been performed using molecular beacons.[6]

Structural Variants of Molecular Beacons

There are several derivatives of ''classical'' MBs, which differ from the conventional stem-loop DNA oligonucleotides. First, it was shown that the linear DNA oligonucleotides without self-complementary termini (stemless) but bearing fluorophore and quencher at the 5′- and 3′- ends could work as MBs.[10] Later, the same was reported for the peptide nucleic acid (PNA) oligomers.[11] PNAs are DNA mimics with pseudopeptide (polyamide) backbone instead of sugar–phosphate one in DNA. Apparently, the flexibility of the sugar–phosphate and polyamide backbones of DNA and PNA, respectively, in combination with a strong hydrophobic interaction between the fluorophore and the quencher, keeps these structures preferably in a closed form in the absence of a target.[11,12]

Specificity, Sensitivity, and Reproducibility

Molecular beacons exhibit exceptional sequence specificity because of the favorable structure energetics. They are used in combination with different amplification technologies, such as polymerase chain reaction (PCR) and rolling circle amplification (RCA), which allows real-time amplification monitoring. Fluorescence detection is very sensitive: an increase of a signal over the background in the presence of the target up to two orders of magnitude can be achieved. Thus sensitivity of PCR and RCA in the presence of molecular beacons can be as high as single molecule in case of PCR and 10–100 molecules in case of RCA. Another important feature of MBs is the

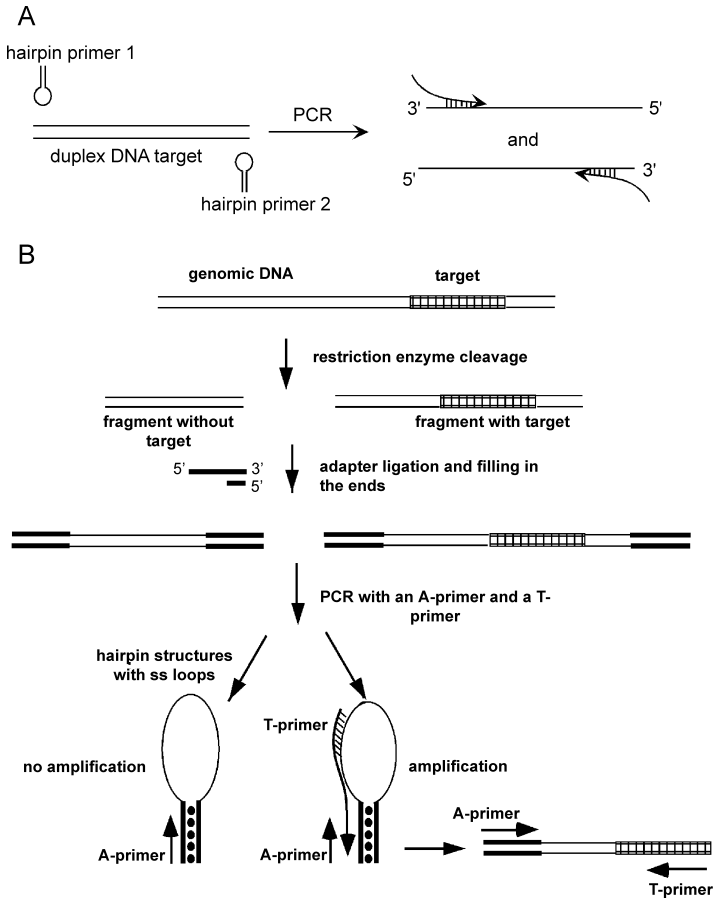

Fig. 2 Examples of application of stem-loop DNA structures in amplification methods. (A) Hairpin-shaped primers allow hot-start PCR because they anneal to the target only at high temperature upon denaturing of the stem. (B) The PCR suppression approach. Genomic PCR is digested with a restriction enzyme and ligated with specially designed adapters. During the PCR, only the DNA fragments containing the target are efficiently amplified, while the vast number of the target-unrelated fragments remains intact.

possibility of multiplex analysis by using MBs with different fluorophores.

Advantages and Limitations

The major advantage of MBs is the possibility of real-time hybridization monitoring. This provides simple close-tube format of the assay, which reduces chances of contamination and false positives. Among other advantages of hairpin probe application in biotechnology and diagnostics are an endless number of formats and detection methods.

Current limitations of MB technology include the high cost of MB synthesis and their instability in the presence of DNA polymerases with exonuclease activities. The efforts, therefore, in this respect are directed toward simplification and/or generalization of the beacon design. An example of simplification of MB design is the use of MBs immobilized on a gold surface, which serves as a quencher.[8] Tripartite MBs with universal parts carrying fluorophore and quencher and sequence-specific oligonucleotides allow flexibility in MB design[13] (Fig. 1B). This approach also brings down the MB cost. Application of chemically modified MBs, which are not cleavable by exonucleases (e.g., PNA beacons or 2-*O*-methyl-deoxy containing MBs), is a way to overcome instability of MBs in the presence of exonucleases.[11,14]

Combination of Molecular Beacon Approach with Other Technologies

Molecular beacons have been incorporated in many detection techniques using DNA amplification with the aim of real-time process monitoring. However, the area of MB applications is much wider and is not limited by DNA amplification methods. Catalytic MBs represent a next generation of molecular probes with the potential to amplify signals and thus to detect nucleic acid targets without PCR amplification.[15] These MBs are DNA constructs that combine the features of molecular beacons and hammerhead-type deoxyribozymes with RNase

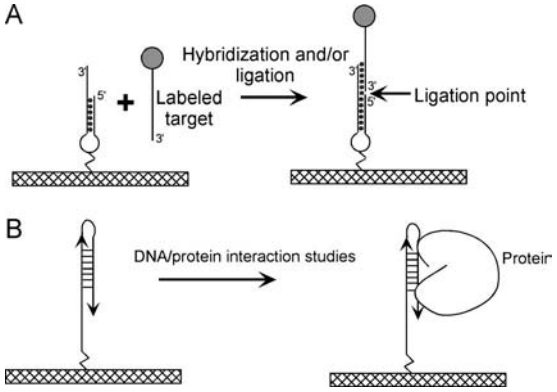

Fig. 3 Outline of two major approaches for application of immobilized stem-loop DNA oligonucleotides. (A) Sequence-specific capturing and mutation detection using immobilized stem-loop probes. (B) DNA microarrays with hairpin probes for DNA/protein interaction studies. (*View this art in color at www.dekker.com.*)

activity, which are located on two different modules.[15] In the absence of a target, the beacon hybridizes with the deoxyribozyme module. When the target is present, the beacon changes its conformation and allows the substrate (a stemless fluorogenic oligonucleotide) to hybridize with the deoxyribozyme module. The deoxyribozyme cleaves the substrate, which results in increasing fluorescence, substrate dissociation, and beacon hybridization with the deoxyribozyme. Thus, the cycle is repeated. This approach is just in the development stage, but in the proof-of-principle experiments, it was shown that it initiated catalytic events.[15]

The combination of PNA-based technology with molecular beacons opened the possibility of targeting duplex DNA without prior denaturation. PNA openers are short PNA oligomers, which invade duplex DNA and locally expose a single-stranded region within duplex DNA forming a P-loop complex. Locally denatured DNA region serves as a unique target for sequence-specific binding of DNA or PNA probes forming PD- or PP-loops, respectively.[16] If the probes are DNA or PNA beacons, they are capable of real-time reporting on cognate targets located within the preopened double-stranded DNA.[11,12]

USE OF STEM-LOOP OLIGONUCLEOTIDES IN DNA AMPLIFICATION AND MICROARRAY TECHNOLOGY

Stem-Loop Structures in DNA Amplification

Stem-loop DNA constructs are also used for different purposes in both thermocycling and isothermal DNA amplification (Fig. 2). For example, stem-loop primers allow hot-start PCR and thus increased specificity of amplification.[17,18] Scorpion probes are designed to serve simultaneously as a PCR primer and as a molecular beacon.[19] During PCR, when the primer is extended and the target is synthesized, the stem loop unfolds and the loop sequence hybridizes intramolecularly with amplified target, thus developing fluorescence (Fig. 1C). The scorpion primer approach uses a unimolecular mechanism of probe–target hybridization, which ensures faster kinetics and higher stability of the probe–target complex.[19]

Design of the large stem-loop constructs from DNA restriction fragments by ligation of special GC-rich adapters forms the basis of the PCR suppression (PS) technology (Fig. 2B). To perform suppression PCR, genomic DNA is digested with a restriction enzyme and ligated with an adapter with a high GC content.[20,21] As a result, long self-complementary ends flank each single-stranded DNA fragment. These self-complementary termini form duplexes during each PCR annealing step, so that the fragments adopt large stem-loop structures, which makes PCR with the adapter–primer (A-primer) alone relatively inefficient. This effect is called PCR suppression (PS). However, the PCR is efficient with two primers, A-primer and target-primer (T-primer). In this case, only DNA fragments with the target are efficiently amplified on the background of all other fragments without a target. Several variants of PS approach were used in subtractive hybridization, cDNA and genomic differential displays, and in multiplex PCR (see Ref. [6] for a review). Hairpin structures were also used for elimination of PCR errors from amplified DNA.[22] Specially designed primers forming stem loops allow also isothermal amplification of DNA; this method is designated as loop-mediated amplification (LAMP).[23,24]

Stem-Loop Structures in DNA Microarray Technology

Hairpin DNA probes can be immobilized on the surface of microarrays and used in hybridization experiments for mutation detection (Fig. 3A)[25] and DNA/protein interaction studies (Fig. 3B).[26] Kinetic analysis confirmed better performance of stem-loop structures as compared with linear oligonucleotides.[27]

CONCLUSION

Stem-loop oligonucleotide constructs are widely used in molecular biology, genomics, and diagnostic biotechnology. Two major factors are responsible for such broad applications of these DNA constructs: 1) enhanced specificity of the probe–target interaction and 2) the possibility of close-tube real-time monitoring formats.

There is no doubt that many new applications of hairpin probes will be developed in the future. Especially useful will be the methods that may allow direct detection of target molecules without prior amplification.

Mucopolysaccharidosis Types IIIA and IIIB

M

Clare E. Beesley
University College London, London, U.K.

INTRODUCTION

Mucopolysaccharidosis (MPS) type III or Sanfilippo syndrome encompasses a group of four lysosomal storage disorders that are characterized by the inability to breakdown the glycosaminoglycan (GAG), heparan sulfate. Glycosaminoglycans are complex polysaccharides that are an important component of connective tissues and the extracellular matrix and heparan sulfate is an integral part of cell surfaces. Deficiency of one of the degradative enzymes results in the accumulation of partially degraded GAGs inside lysosomes, which leads to cell death and ultimately organ dysfunction. Each of the four Sanfilippo subtypes, A, B, C, and D, is caused by the deficiency of a different enzyme in the same degradative pathway for heparan sulfate: heparan-*N*-sulfatase (EC 3.10.1.1), alpha-*N*-acetylglucosaminidase (EC 3.2.1.50), acetyl-CoA *N*-acetyl transferase (EC 2.3.1.3), and *N*-acetylglucosamine-6-sulfatase (EC 3.1.6.14), respectively. The incidence of MPS III has been estimated to be approximately 1 in 58,000 live births. All four Sanfilippo subtypes are autosomal recessive disorders but the genes have only been identified in types A, B, and D. The acetyl-CoA *N*-acetyl transferase enzyme that is deficient in type C patients is membrane-bound and this property has hindered its isolation and subsequent cloning. For subtype D, a total of 14 patients have been described worldwide and genetic defects have only recently been reported. The majority of Sanfilippo patients have subtypes A or B and it is these subtypes that will be focused on in this article.

CLINICAL DESCRIPTION AND DIAGNOSIS

Clinical Description

Clinical symptoms are similar in both Sanfilippo subtypes. They usually occur after 2 years of apparently normal development and include hyperactivity, aggressive behavior, delayed development (particularly in speech), sleep disturbances, coarse hair, hirsutism, and diarrhea. There are only relatively mild non-CNS manifestations and this may be the reason why Sanfilippo patients present later than other MPS patients. Following the hyperactive and aggressive phase there is then a period of progressive mental retardation with death usually between the second and third decade of life. In both Sanfilippo A and B a small number of more slowly progressive forms with later onset have been described.[1,2] An adult Sanfilippo A patient was recently described who presented with cardiomyopathy at 45 years and, interestingly, had no neurological symptoms.[3]

Biochemical Diagnosis

A deficiency of heparan-*N*-sulfatase (HNS) or alpha-*N*-acetylglucosaminidase (NAGLU) in Sanfilippo A and B patients, respectively, leads to the accumulation of partially degraded heparan sulfate inside lysosomes. This accumulation is progressive and leads to hypertrophy of the lysosomal system and subsequent urinary excretion of GAGs. Quantitative analysis of urinary GAGs by precipitation with dimethylmethylene blue[4] is the initial step in the biochemical diagnosis, followed by two-dimensional electrophoresis to identify the individual GAGs.[5] Patients with Sanfilippo syndrome show a raised urinary GAG level and abnormal excretion of heparan sulfate and heparin-like component. It is impossible to differentiate between the four Sanfilippo subtypes by the urinary GAG pattern so specific enzyme assays are carried out on leukocytes or fibroblast cells,[5,6] to determine the subtype and make a definitive diagnosis.

MOLECULAR GENETICS

Sanfilippo A

The gene encoding HNS is situated on chromosome 17q25.3, contains eight exons and extends over 11 kb of DNA. It produces a mRNA transcript of $\sim$3.1 kb, which encodes a protein of 502 amino acids with a predicted molecular mass of 54.67 kDa.[7,8] The reaction catalyzed by HNS is the removal of the *N*-linked sulfate group from the nonreducing terminal glucosamine residues of heparan sulfate. Recombinant HNS produced in Chinese hamster ovary (CHO) cells exists in two forms, a major species of 62–64 kDa (precursor) and a minor species of 56–58 kDa

DOI: 10.1081/E-EDGP 120027812

(mature). Both forms have the same size and N-terminus as the comparable forms isolated from liver.[9] The native molecular mass of HNS as determined by fast-performance liquid chromatography (FPLC) is 115 kDa so it exists as a dimer inside lysosomes.[10] Heparan-*N*-sulfatase has five potential *N*-glycosylation sites and all are used, with three high mannose or complex oligosaccharide chains and two with tri- and/or tetracentenary complex-like and biantennary chains.[11] At least one mannose group will be phosphorylated because mannose-6-phosphate groups on all soluble lysosomal enzymes are used to transport the enzymes from the *trans* Golgi to the lysosome via mannose-6-phosphate receptors. Heparan-*N*-sulfatase is a member of a highly conserved group of sulfatases that undergo a common and unique posttranslational modification necessary for catalytic function. This process involves the conversion of an active site cysteine residue to formylglycine and is catalyzed by the C(alpha)-formylglycine generating enzyme (FGE). The gene for FGE (*SUMF1*) was recently cloned and shown to be defective in multiple sulfatase deficiency patients, in whom the activity of all sulfatases is reduced.[12,13]

Sanfilippo B

The gene encoding NAGLU is situated on chromosome 17q21.1, extends approximately 8.2 kb, and contains six exons. The cDNA is 2.7 kb long and encodes a protein of 743 amino acids that has a predicted molecular mass of 82 kDa.[14,15] Alpha-*N*-acetylglucosaminidase acts as an exoglycosidase on the nonreducing end of alpha-*N*-acetylglucosaminide residues of heparan sulfate. Two forms of NAGLU have been purified from human placenta with apparent molecular weights of 77 and 80 kDa, representing the mature and precursor forms, respectively.[14] There are seven potential glycosylation sites and it has been predicted that the site at residue 272 is occupied and carries a phosphorylated carbohydrate side chain necessary for lysosomal targeting.

Mutation Analysis

Following the characterization of the *HNS* and *NAGLU* genes, many mutations have been identified in Sanfilippo A and B patients. The initial step is to perform polymerase chain reaction (PCR) amplification on the coding exons and intron/exon boundaries and numerous sets of primers have been published. Initially single-stranded conformation polymorphism (SSCP) analysis was used to screen the PCR products for possible mutations. Nowadays, all of the PCR fragments are purified and sequenced directly, either by radioactive methods or by fluorescent sequencing technology. Many different mutations have now been identified and both disorders show extensive genetic heterogeneity.

Sanfilippo A

To date, 70 mutations have been identified in Sanfilippo A patients. These consist of 50 missense, 4 nonsense, 8 deletions, 7 insertions and 1 splice site mutation. Some mutations have been found in more than one patient whereas others are unique to individual families. Some mutations have been found at high frequencies in particular populations. The R245H, R74C, 1079delC, and S66W were the most frequent mutations in the Dutch (56.7%),[16] Polish (56%),[17] Spanish (36.5%),[18] and Italian (33%)[19] populations, respectively. Several non-disease-causing polymorphisms have been identified including R456H, which has a high frequency of 55% in the normal Australian population.[20] A study of four polymorphic markers in the Spanish Sanfilippo A patients with the 1079delC mutation showed that they had a conserved haplotype, suggesting a common origin for this mutation.[18]

Sanfilippo B

To date, 99 mutations have been identified in Sanfilippo B patients. These consist of 60 missense, 8 nonsense, 16 deletions, 12 insertions and 2 splice site mutations. Again some mutations have been found in more than one patient whereas others are unique to individual families. In contrast to Sanfilippo A, common mutations have not been identified in patients of different national origins. However, in a recent study of Greek Sanfilippo B patients, three mutations were found at a high frequency, with mutations Y140C, H414R, and R626X accounting for almost 70% of the mutant alleles.[21]

Genotype/Phenotype Correlation

The relationship between the severity of a monogenic disorder and the mutations is called the genotype/phenotype correlation. If the mutation causes the production of a truncated protein either by a nonsense mutation or by a deletion or insertion (frameshift), this is predicted to be severe and the protein nonfunctional. Patients homozygous for these types of mutations are predicted to be severely affected and this is true in both Sanfilippo A and B. The effect of missense mutations on the protein is more difficult to predict because some will allow the production of functional enzyme albeit at lower levels and

others will not. It depends on the function of a particular amino acid within the protein as some will have a more critical role than others. This can only be investigated by expression studies where the mutation is generated in a normal copy of the gene, transfected into mammalian cells, such as CHO, and the resulting enzyme assayed for activity. All missense mutations should be investigated in this way, firstly to confirm their pathogenicity and secondly to determine which ones produce residual activity. Without performing such a procedure it is possible that a rare polymorphism could be reported as a mutation. By carrying out further studies such as immunoprecipitation of mutant enzyme and cellular localization by confocal microscopy, more information can be obtained about the effect of the mutation on the processing and transport of the enzyme. This will increase our understanding of the effect of the mutation on enzyme function and further our knowledge of the disease process. The majority of missense mutations reported in Sanfilippo A and B have been found in severely affected patients either in homozygous form or in combination with a truncating mutation so it can be deduced that they have a serious effect on enzyme function. Only a small number of attenuated, late onset patients have been described in Sanfilippo A and B, and, as predicted, they all have at least one missense mutation, which will be responsible for the residual enzyme activity. The effect of polymorphisms on enzyme activity still requires investigation in Sanfilippo A and B.

TREATMENT

As previously mentioned, soluble lysosomal enzymes are synthesized in the *trans* Golgi network and transported via mannose-6-phosphate receptors to the lysosome. Research into the process has enabled this sorting mechanism to be utilized to target recombinantly expressed replacement enzyme to deficient lysosomes. This treatment is now available for some lysosomal storage disorders, such as Fabry and MPS I, but recombinant enzyme is unable to cross the blood–brain barrier. As neurological disease is the major symptom in Sanfilippo patients, this form of treatment is unsuitable. Bone marrow transplantation has been performed in a few Sanfilippo A and B patients but has proven unsuccessful, even when carried out before development of clinical symptoms.[22] Gene therapy is currently being investigated using a variety of viral vectors and a number of animal models exist for Sanfilippo A and B including mice (IIIA, IIIB), dogs (IIIA, IIIB), and emu (IIIB). Such models can be used to investigate different viral vectors and different methods of delivery such as direct injection into the brain. However, many problems need to be overcome before gene therapy becomes a viable form of treatment for single gene disorders. One of the major problems of introducing recombinant enzyme, however it is produced, into patients that have no functional enzyme is the immunological response to the ''foreign'' protein. This may be worse in those patients who have no cross-reactive material. Most patients with missense mutations will probably produce full-length protein that is nonfunctional, so will not develop antibodies to the recombinant protein. Therefore it is a prerequisite that the genotype of all patients undergoing treatment is known. At present, the only form of treatment for Sanfilippo patients is palliative care.

CONCLUSION

Over the last 8–9 years, there have been major advances in understanding the genetics of Sanfilippo A and B. Many mutations have been described, some of which are common, but the majority of which are unique to individual families, making both Sanfilippo A and B genetically heterogeneous. The disease-causing mutations can be identified in the majority of patients diagnosed with Sanfilippo A and B, and accurate carrier detection is available for other family members. Mutation screening in several countries has highlighted the prevalence of particular mutations in different populations and this is important in initial screening programs. By characterizing the genotype in many patients we are able to understand more about the genotype/phenotype correlation in Sanfilippo disease. By analyzing the mutations we can learn more about the function of the enzyme and understand more about the pathogenesis of Sanfilippo disease. Knowing the genotype will be a prerequisite for any form of future therapy and we may be able to predict from the genotype whether there is likely to be any adverse reaction to recombinant enzyme. However, no treatment will be available for Sanfilippo A and B until there is a means by which replacement enzyme can cross the blood–brain barrier in order to treat the major neurological symptoms.

Multiplex Real-Time PCR

M

Maurice M. Exner
Quest Diagnostics Nichols Institute, San Juan Capistrano, California, U.S.A.

INTRODUCTION

The polymerase chain reaction (PCR) has been adapted for a myriad of applications involving the amplification of nucleic acid sequences. This technology often involves a specific detection methodology to analyze the products of a reaction. The advent of real-time detection systems, which detect amplified products concurrently with the amplification process of the reaction, has enabled the creation of a system that can provide accurate, quantitative results without cumbersome post-amplification steps. Multiplex real-time PCR technology is simply a variation of the standard reaction methodology in which there are multiple amplification reactions that take place in a single reaction vessel. The ability to combine reactions together provides a number of benefits. Not only does it allow for multiple target detections, which saves time, effort, and money, but it also provides a means for enhanced experimentation. For instance, with the ability to discriminate different targets in a reaction, comparative or relative quantitation of targets can more accurately be achieved, and positive controls can be coamplified with targets of interest to monitor the efficiency of each individual reaction. There are a number of different chemistries available that allow for multiplex real-time amplification and discrimination of targets. Each chemistry and each multiplexing strategy has its advantages as well as its own technical challenges. However, if these challenges can be overcome, this ''simple'' variation of a standard PCR reaction turns into an extremely powerful tool for clinical diagnostics.

MULTIPLEX REAL-TIME POLYMERASE CHAIN REACTION METHODOLOGY

Multiplex PCR is the amplification of multiple targets, or the capability of a system to amplify multiple targets, within the same reaction vessel. ''Real time'' refers to the fact that the detection of the amplified product is taking place in real time or during the actual process of the amplification reaction. Therefore multiplex real-time PCR involves the simultaneous amplification, detection, and discrimination of multiple amplified targets in a single reaction. Real-time PCR and multiplexing methodologies, when combined, provide a flexible research or clinical tool that can be specifically tailored to interrogate nucleic acid sequences and to provide a researcher with experimental answers to a variety of questions. Flexibility is a product of the variety of chemistries available to perform real-time PCR, in conjunction with the numerous strategies available to combine reactions in a multiplexed fashion.

The detection of real-time PCR products is based on increases in fluorescence that are apparent only when amplified products are present. Real-time PCR instrumentation uses a light source to produce an excitation wavelength that activates fluorescent molecules within the reaction. Following the interaction between the fluorescent molecule or probe and the target amplicon, fluorescent emissions can be observed and monitored. The specific method by which products in a reaction are discriminated depends on the particular detection chemistry being utilized. Some of the most commonly utilized chemistries or fluorescence detection schemes for real-time PCR detection include: 1) 5′ nuclease or ''TaqMan'' probes;[1] 2) hybridization probes or fluorescence resonance energy transfer (FRET) probes;[2] 3) molecular beacons;[3] 4) minor groove binding probes;[4] and 5) double-stranded DNA binding dyes (SYBR green).[5]

Each different detection chemistry has specific characteristics that lend to different multiplexing strategies. Multiplexing is generally achieved by using multiple primer and/or probe sets in a reaction, although there may also be cases where a single primer set is used with multiple probes, or a single probe could be used with a number of different primer sets. The amplified products generated can be discriminated by means of melting curve analysis,[6] by an analysis and discrimination of fluorescent emissions,[7] or by a combination of the two. When the different strategies are combined with the variety of available chemistries, a vast number of permutations and possibilities are created. The strategy utilized will depend on the information desired by the researcher.

DISCRIMINATION OF POLYMERASE CHAIN REACTION PRODUCTS

Fluorescent Emission Discrimination

The discrimination of multiple targets that are amplified within a reaction can be performed using a differential color analysis; that is, multiplexing is accomplished by using a different ''color'' fluorophore for each particular probe.[7] By scanning the fluorescence emission wavelengths observed in a reaction vessel, and by separating the observed emissions according to the discrete wavelengths produced by each particular fluorophore, PCR products can be selectively identified. The number of different targets that can be discriminated in a single reaction is dependent on the excitation and emission wavelengths that the instrumentation is able to produce and monitor, along with the availability of fluorophores with distinct emission spectra.

Melting Temperature Analysis

A melting temperature (Tm) analysis measures the dissociation rates of hybridized nucleic acids, and there are two main methods by which this technique can be used to differentiate PCR products. Either the dissociation of a specific probe molecule from a target strand can be analyzed[8] or the temperature at which an entire amplicon molecule denatures can be determined.[6] When using specific probes (hybridization probes or minor groove binding probes), Tm discrimination is achieved based on the hybridization affinities of the probes for the target amplicon. Following thermocycling, the probes are allowed to anneal to the target amplicons. Upon hybridization of the probes to their specific targets, fluorescence is produced. The reaction temperature is then gradually increased, and fluorescence emissions are continually monitored. When a probe reaches its Tm, it dissociates from the amplicon and fluorescence ceases. Probes used for multiplexing can be designed with different lengths and different GC contents such that each has a distinguishable melting temperature. Besides being used to differentiate completely different targets, Tm analysis using specific probes can also be used to interrogate single nucleotide polymorphisms (SNPs). Targets with a single base pair mismatch with a probe sequence can readily be distinguished from targets with complete homology to the probe. The combination of colorimetric differentiation with Tm analysis creates the potential for multiplex detection and analysis of a large number of SNPs in a single reaction.

Melting temperature (Tm) analysis that does not involve the use of specific probes is based on the Tm of an entire double-stranded amplicon. In this case, fluorescence is a product of molecules such as SYBR green that bind to double-stranded DNA and fluoresce when they are bound to the DNA double helix. Therefore at relatively low temperatures that permit DNA duplexes to remain stable, fluorescence will be observed, but when temperatures are increased and the double-stranded DNA molecules denature, the SYBR green will no longer bind to the nucleic acids, and fluorescence is no longer detectable. This strategy for Tm analysis will produce a characteristic melting curve that is based on the length, sequence, and GC content of each amplified product. However, it should be noted that using SYBR green lacks specificity because sequence-specific probes are not utilized. Consequently, genetic variability of target sequences from different patients makes identification of an amplified product, based on Tm of the amplicon, somewhat inconsistent.

MULTIPLEX ASSAY DESIGN

There are a number of inherent challenges involved in designing and running multiplex real-time PCR assays. First and foremost is the problem with unequal amplification efficiencies for different products. This may be a result of differences in primer and probe binding affinities for their targets, different primary and secondary structures of target regions, and interaction or cross-reactivity between oligonucleotides within a reaction. These differences lead to competition for reagents such as nucleotides and the DNA polymerase, and this competition will lower the reaction sensitivities of the less efficient reactions. One simple way to decrease competition is to increase the concentrations of reaction components, such as dNTPs or the polymerase.[9] Choosing primers and probes with very similar length, GC content, and hence Tm values can also minimize variation in reaction efficiencies. Competition can be further abrogated by using limiting amounts of primers, such that the primer supply for a reaction is exhausted before the amplification is able to outcompete less efficient reactions and consume a majority of the reagents. This technique is very successful when using a controlled reaction, such as when an internal positive control amplification is multiplexed in the reaction. However, for other target amplifications, especially with unknown or low concentrations of target, a decrease in primer concentration may decrease the reaction efficiency and sensitivity.

Another form of cross-reactivity that exists in multiplexing, besides interactions between oligonucleotides, is with respect to overlap in the fluorescent spectra of the fluorophores being used. Fluorophores must carefully be chosen such that there are sufficient discrete wavelengths

Table 1 Examples of multiplex real-time PCR methodologies and corresponding applications

Chemistry	Target differentiation method	Application	Ref.
5′ nuclease probe	Color	Pathogen detection/differentiation	[10]
5′ nuclease probe	Color	Genotyping/allelic discrimination	[11]
5′ nuclease probe	Color	Normalization of pathogen concentration to human genomic DNA concentration	[12]
5′ nuclease probe	Color	Detection of sarcoma specific fusion transcripts	[13]
Hybridization probes	Tm analysis	Pathogen detection/differentiation	[14]
Hybridization probes	Color	Relative quantitation of tumor marker gene expression	[15]
Hybridization probes	Color	SNP detection/genotyping	[16]
Molecular beacons	Color	Pathogen detection/differentiation	[7]
Molecular beacons	Color	Pathogen detection/differentiation with the inclusion of an internal positive control	[17]
SYBR green	Tm analysis	Pathogen detection/differentiation	[18]
SYBR green	Tm analysis	Detection of leukemia specific fusion transcripts	[19]
Minor groove binding probes	Color	SNP detection/genotyping	[20]

that separate the emission spectra. This is particularly critical with increasing degrees of multiplexing in a single tube. The constant generation of new fluorescent dyes, as well as the use of nonfluorescent quenchers (used with 5′ nuclease probes, molecular beacons, or minor groove binding probes), has increased the number of different targets that can be discriminated in a reaction. However, considering that there is significant crossover in wavelengths of the emission spectra for most commonly used fluorophores, it is currently practical to distinguish only three or four different colors within a reaction.

When distinguishing between amplified targets on the basis of melting temperatures, salt and magnesium concentrations must be optimized, and Tm values of the probes must be carefully chosen. Because secondary structures and interactions between reaction components cannot always be accurately predicted using computer programs, optimization of reaction conditions and the choice of a proper probe sequence must often be determined empirically. Despite the fact that in theory, dozens of different products can be discriminated in a single reaction by Tm, in reality, for routine clinical assays, a maximum of three or four products is all that can easily be discriminated. This is because of the overlap in Tm ranges; Tm values are relatively consistent, but nevertheless, run to run reaction variability makes it such that a range of at least $\pm 2^{\circ}C$ must be allowed between products to ensure that no cross-reactivity is observed.

APPLICATIONS

There are a multitude of different uses for which multiplex real-time PCR can be employed. In a clinical setting, this technology has been most prominently used in the infectious disease field, in which case it is highly beneficial to be able to simultaneously identify and detect multiple pathogens from a single specimen. This approach has become commonplace in many laboratories, with assays that can be designed to be qualitative or quantitative. Quantitative multiplex reactions may involve amplification of multiple targets that are quantified using external calibration curves. Alternately, relative quantification can be calculated using products that are coamplified in the same reaction. This method typically compares or normalizes the target of interest to a calibrated standard or to a housekeeping gene. This relative quantitation is also an example of another separate use for multiplexing. With respect to relative quantitation, greater accuracy is achieved using multiplexing because identical reaction conditions are present for both targets being compared (they are in the same reaction tube).

The addition of an internal positive control (IPC) to a reaction is another common use for multiplexing in a clinical setting. The inclusion of an IPC monitors the efficiency of each individual PCR reaction. The IPC can be included at the point of specimen collection to monitor sample stability, it can be added just prior to nucleic acid extraction to monitor extraction efficiency, or it can be added solely to the PCR mastermix to determine whether inhibitory substances are present following extraction.

In addition to infectious disease applications, multiplex real-time PCR is also extensively used in the fields of molecular genetics and oncology. For instance, multiplex techniques are used to detect multiple SNPs in a single reaction and to do allelic discrimination experiments. In

addition, relative quantitation is used for gene dosing determinations, and it is also used to monitor gene expression; reverse-transcriptase PCR can be used on mRNA to determine the expression levels of tumor markers or to determine the response of specific genes to drug therapy. Some examples of real-time PCR applications are listed in Table 1. This is but a small sampling of the many uses for multiplex PCR, but a more complete listing and description is beyond the scope of this work.

CONCLUSION

Although multiplex real-time PCR can generally be described as the amplification and detection of multiple targets in a single reaction tube, there is tremendous variation with respect to the methods used to perform this technique and how the experimental data are utilized. By combining different available chemistries and different multiplexing strategies, the technique can be tailored for use in a number of different applications, from SNP analysis to multiple pathogen detection, and from oncology and molecular genetics to infectious disease uses. Presently, multiplex real-time technologies are limited only by the available instrumentation and chemistries, and it is currently practical to discriminate three to four targets in a single multiplex reaction. The combination of Tm determinations and multiple-colored fluorophores gives the potential for the discrimination of many more targets, and this could be further expanded using technology such as microarrays. However, the expansion to microarrays and to greater degrees of multiplexing has yet to be achieved on a level that is satisfactory for routine clinical testing. Nevertheless, multiplex real-time methods that are currently available are already changing the diagnostic field, as they are providing more rapid and accurate results, and they are allowing scientists to answer clinical questions that were unable to be answered before the arrival of this technology.

INTRODUCTION

Murray Valley encephalitis virus (MVEV) is a member of the Japanese encephalitis serocomplex of the genus *Flavivirus* of the family Flaviviridae and is closely related to both Japanese encephalitis (JEV) and West Nile (WNV) viruses. It is endemic in tropical areas of Australia and causes severe encephalitis with high mortality and morbidity. The earliest recorded outbreaks of arboviral encephalitis occurred along the east coast of Australia between 1917 and 1925, and was then given the name Australian X disease. It was not named Murray Valley encephalitis until an outbreak occurred in that region in 1951, at which time MVEV was isolated. A major outbreak centered on the Murray Valley region then occurred in 1974, with cases subsequently being identified in all mainland states of Australia. Although the vast majority of these cases were due to MVEV, some were found to have been caused by another flavivirus, Kunjin (KUNV). The term Australian encephalitis was coined to include disease caused by either virus, but due to confusion over that terminology, it is now preferred that they are called MVEV encephalitis or KUNV encephalitis.

NATURAL HISTORY

The incubation period is not well established, but is in the range of 1–4 weeks.[1,2] The majority of infections are asymptomatic or nonspecific. Very few cases of non-encephalitic illness have been described, as it is likely that most are undiagnosed or unreported. Two cases were identified during an epidemic in Western Australia (WA) in 2000. The illness consisted of headache, myalgia, and backache with or without recorded fever.[3] Both had a spontaneous recovery.

Only about 1:500 to 1:1000 infected individuals develop encephalitis.[2] In children, MVEV encephalitis presents as fever of 1–2 days duration, almost always with convulsions.[2,4] Reduction of mental state and respiratory failure may follow. Some recover rapidly, whereas others progress to more severe disease characterized by involvement of central brain structures, brain stem, and, possibly, the spinal cord. In adults, the encephalitis begins with headache, fever, and altered mental state.[2,4] Tremor may be apparent on examination and cranial nerve palsies may develop.[4] The course varies from rapid recovery to a prolonged illness with respiratory paralysis or even death.[2–4] Mortality is about 12% in adults, confined to those aged 50 years or over, compared with about 25% in children, particularly those aged less than 2 years (Table 1). Approximately 40% of survivors have neurological residua varying from mild cranial nerve palsies to spastic quadraparesis. Severe residua are much more likely in those over 50 or under 2 years old. Long-term follow-up is available for only a small number of cases, so other late sequelae may not be recorded.

The CT scan is usually unremarkable or shows nonspecific cerebral edema, and EEGs show nonspecific changes.[2,4] MRI scans in late disease have been reported to show thalamic or gray-matter destruction.[5] The CSF shows a variable leukocyte pleocytosis, usually with lymphocyte predominance and a raised protein.[2,4]

TREATMENT

Treatment is supportive, and access to respiratory support is important in the survival of severe cases, which is believed to account for the improvement in outcomes between the outbreaks in the 1950s and 1974.[2] There are no data on specific interventions for MVEV encephalitis. However, the disease and pathology are very similar to encephalitis due to JEV and WNV virus, and it is reasonable to extrapolate from those. Based on the experience with JEV encephalitis,[6] steroids are unlikely to be of

value, although dexamethasone can be used to reduce intracranial pressure if needed. Alpha-interferon showed some promise for JEV encephalitis, but a recent placebo-controlled trial did not find any benefits in children.[7] There has been interest in intravenous immunoglobulin for treatment of WNV encephalitis, but there is limited human experience.[8]

ECOLOGY OF MVEV

The virus is maintained in a cycle involving water birds and mosquitoes (primarily *Culex annulirostris*) in enzootic foci within the north of WA and adjacent area of the northern half of the Northern Territory (NT).[9] Surveillance using sentinel chicken flocks has demonstrated MVE activity during the tropical wet season (February to July) in these areas in most years.[9] There is some evidence to suggest that the incidence of MVEV has increased in recent years which may be associated with dam building on the Ord River in the Kimberley region and the establishment of large water impoundments.[10]

Activity outside the enzootic areas follows heavy rainfall and flooding, although not invariably, indicating that other factors are also important.[11] When spread occurs, infected migratory water birds or possibly wind-blown infected mosquitoes carry the virus into the flooded areas and set up local epizootic mosquito–bird cycles of infection.[12] A subsidiary mechanism for generating epizootic activity is reactivation of vertically transmitted MVEV that survives in desiccation-resistant eggs of species such as *Ochleratus tremulus* (formerly called *Aedes tremulus*).[13] Spread can be extensive and lead to introduction or reintroduction of MVE into normally arid areas further south in WA or in Central Australia.[3,13] This mechanism is believed to have been the source of the epidemics that occurred in the heavily populated areas of southeastern Australia in 1974,[14] and for the temporary reintroduction of the virus into that area in 2001.[13,15] Little is known about the role of tropical areas of northern Queensland in the maintenance of MVEV in Australia, but virus has been recovered from mosquitoes in this area.[9,16] It has also been isolated from mosquitoes and a fatal human case in Papua New Guinea (PNG).[9,17]

EPIDEMIOLOGY OF MVEV INFECTION IN AUSTRALIAN POPULATIONS

In the endemic areas in the north of WA and the NT, seropositivity rates are very high among indigenous communities, with most being infected before the age of 10 years,[18] indicating that there is often sufficient activity to lead to human infections. In areas of regular epizootic activity, seroprevalence is lower but very high seroconversion rates may occur across epidemic seasons.[19] Areas with uncommon or rare epidemic activity have very low population infection rates, being less than 5% in the Murray Valley area 7 years after their last epidemic.[20]

Cases of MVEV encephalitis occur in most years in the enzootic areas of northern WA and the NT.[2,9] (Fig. 1). There is no evidence to indicate that there is any age difference in susceptibility to infection,[19] and patterns of clinical disease reflect the risk of exposure and susceptibility. Therefore in the endemic areas, encephalitis most often occurs in young indigenous children or in adults who are new residents or tourists in the area.[2,4] Epidemic activity causes occasional encephalitis cases further south in WA in the Pilbara and Gascoyne regions,[2] as well as northern Queensland.[9] Rarely, wider spread results in human cases in the southern half of WA and normally arid areas of inland WA and Central Australia.[3,21] Encephalitis in these epidemic areas mainly occurs in adults, presumably reflecting their higher risk of mosquito exposure.

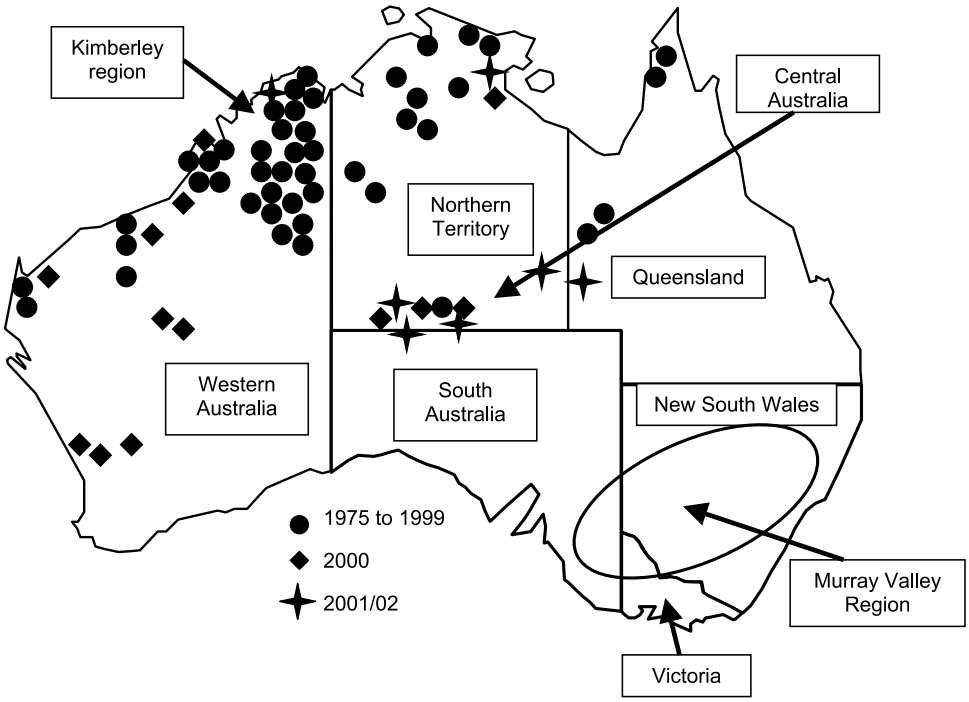

Fig. 1 The distribution of reported cases of encephalitis due to MVEV acquired in Australia between 1975 and 2002. This only includes cases where a definite or likely location of infection could be determined. Most cases occurred in the Kimberley region of Western Australia (WA) and the top end of the Northern Territory. In 2000 and 2001, there was southerly spread in WA and reappearance of disease in Central Australia. Sentinel chicken surveillance picked up MVEV activity in the Murray Valley area of New South Wales in 2001, but without human cases.

MOLECULAR GENETICS

There are two genetic lineages of the virus in Australia. The first includes the original isolate of MVEV, and that lineage is thought to have caused the epidemics on the east coast (including part of the 1974 epidemic) after which it disappeared. The second lineage appeared in the north of WA in 1969 and was responsible for part of the 1974 outbreak. Since then this lineage has been responsible for nearly all MVEV activity in Australia, with less than 2% sequence divergence across time and geographic areas in the NS5 region.[9] However, recent data based on the E gene sequence do indicate that there are minor strain variations over time, but not across different geographical areas (Johansen, C.A., personal communication). This is consistent with there being a single enzootic focus, most likely in the north of WA, which is the source of MVEV throughout Australia, and that evolution of the virus occurs within that enzootic focus.

One early isolate (OR156) from the north of WA contained additional uridine residues resembling two PNG isolates[22] from 1956 and 1966, suggesting that other

Table 2 Yield of diagnostic tests for MVE encephalitis for human cases tested at the Western Australian Centre for Pathology and Medical Research between 1978 and 2001

	Proportion positive for samples collected at the following days after onset of symptoms			
	≤3	4 to 7	>7	All
Serum IgM	6/9	12/14	14/14	32/37
CSF IgM	7/8	3/6	3/3	13/17
CSF PCR	3/5	0/2	0/1	3/8

IgM in serum and cerebrospinal fluid (CSF) detected by indirect immunflourescent antibody method. Polymerase chain reaction (PCR) was a nested reverse transcription PCR directed at 3′ noncoding region sequence.

lineages exist in PNG and possibly the eastern Indonesian archipelago. The E gene sequence data show that recent PNG isolates cluster with isolates from the Kimberley region of WA prior to 1984, but are different from the more recent Australian isolates. Therefore, there may be regular movement of the virus between the north of WA and PNG. Little is known about the distribution of MVEV in PNG and its role in human disease.

DIAGNOSIS

The virus has rarely been cultured from human material, and the viremia is likely to be short-lived. Therefore, while MVEV will grow in mosquito cell lines and suckling mouse brain, cell culture methods have not been useful in diagnosis of infections.

Most diagnoses are made serologically. Paired sera taken in the first few days after onset and 2–3 weeks later will show rising antibody by HI test, EIA, or IFA, although the HI is the least sensitive and may rise late or, rarely, not at all. IgM is present in nearly all patients at the time of presentation. In the WA series, IgM was detected in serum in most cases within 1 week of onset of illness, and in all cases beyond that, whereas CSF IgM was positive in about 75% (Table 2). Following infection serum IgM may remain positive for months, so that the presence of IgM, in the absence of virus detection of a rise in IgG, can only be taken as possible evidence of recent infection.

Antibody will cross-react with other flaviviruses, particularly Kunjin and JE which may also cause encephalitis in the same geographical area. The specificity of antibody can be determined by neutralization tests or epitope-blocking EIA.[23] However, even with specific tests, misleading results may occur in patients who have had a previous flavivirus infection. In these circumstances, antibody to the previously infecting flavivirus may rise before antibody to the currently infecting virus.[24]

Detection of MVEV-RNA in CSF can be achieved using a nested PCR directed to the 3′ untranslated region of the genome, and it is a useful investigation where early samples are available at a time when serology may still be negative (Table 2).

MOLECULAR METHODS FOR MVE SURVEILLANCE

Traditionally, flavivirus surveillance has been carried out by mosquito trapping using carbon dioxide light traps, transport of the trapped mosquitoes to a central laboratory on dry ice, and then speciating, counting, and processing of mosquitoes for virus isolation. This produces excellent information about vector species, infection rates, and the types of viruses they carry[16] provided it is practical to perform this at a time when MVE is likely to be active. Unfortunately, MVE activity occurs over large and sparsely populated areas of Australia, and peak activity occurs during the wet season when flooding may restrict access to many areas. This has meant that mosquito trapping for virus isolation is often not achievable during periods of high virus activity. Sentinel chicken surveillance, using fortnightly or monthly bleeds to check for seroconversion, has proven to be valuable in monitoring MVEV activity within endemic and epidemic areas.[15] However, it does not provide data about virus strains and is not useful for some other flaviviruses of interest such as JEV and dengue virus. It has been shown that a seminested RT-PCR was able to reliably detect JEV in dead mosquito pools,[25] and this is likely also to be suitable for MVEV. This shows considerable promise as a robust surveillance technique that can detect multiple flaviviruses quickly, using dried mosquitoes that can be sent by routine transport mechanisms or by post.

CONCLUSION

Murray Valley encephalitis virus is an important virus that causes serious disease within Australia and has the potential to lead to major epidemics in heavily populated areas, as has occurred in the past. Molecular studies have supported epidemiological data indicating that it exists in an enzootic focus in the north of Western Australia and that this acts as a source for MVEV throughout Australia. Polymerase chain reaction-based methods are valuable in supplementing serological diagnosis and are now being developed as tools for identification and characterization of flaviviruses in mosquitoes.

Mycobacteria, Atypical

M

Chand Wattal
Sangeeta Joshi
Sir Ganga Ram Hospital, New Delhi, India

INTRODUCTION

Mycobacterial disease, an ancient scourge of mankind, still remains an enigma to medical world. The scourge, once thought to have been conquered with the advent of BCG vaccine, is still desired a lot to be known. Its atypical variety known as nontuberculous mycobacteria (NTM) has come to the fore as the burden of geriatric population is increasing because of diseases such as AIDS and various modern treatment modalities for organ transplant or oncology therapies, which are being used more frequently, creating a pool of immunocompromised population susceptible to this infection. Besides this, minimal-access laparoscopic surgeries have exposed our population to the hazards of the infections caused by the environmental microbes earlier unknown to cause fulminant infections. Similarly, waterborne NTM, once thought to be of no consequence, is increasingly recognized as a cause of various skin/soft tissue infections following a surgical procedure.

Currently, more than 80 species of NTM have been described. If an organism takes 7 days or more to grow, it is slow growing (types 1, 2, and 3), whereas the ones growing in <7 days are rapid growers (type 4).

EPIDEMIOLOGY AND PREVALENCE

Most of the NTM have been isolated from water and soil,[1] e.g., species of the *Mycobacterium avium* complex, *Mycobacterium marinum*, *Mycobacterium kansasii*, *Mycobacterium xenopi*, *Mycobacterium simiae*, and rapid growers (Table 1).[2] Most common NTM associated with nosocomial disease are *Mycobacterium fortuitum*, *Mycobacterium chelonae*, and *Mycobacterium abscessus*. *M. xenopi* requires a temperature of 28°C or more to grow and has been recovered from hot water and hot water taps within hospitals.[3]

Airborne environmental NTM may result in respiratory disease, whereas ingestion may be the source for cervical lymphadenitis and, in AIDS patients, may lead to a disseminated disease. Soft tissue and skin infections are likely a result of direct inoculation of NTM. It is not known whether NTM disease has a latent period or not. Because NTM disease is not notifiable, the worldwide estimates of incidence and prevalence may not be accurate. A study conducted by Centers for Disease Control and Prevention (CDC, Atlanta, GA 30333, U.S.) from 1991 to 1992[4] demonstrated a dramatic increase in numbers of NTM, especially *M. avium* complex.

CLINICAL PRESENTATION

Nontuberculous mycobacteria are classified depending on the clinical syndrome associated with it (Table 2).[5]

Pulmonary Disease

Predisposing factors[6] for the development of pulmonary disease include alcoholism, bronchiectasis, cyanotic heart disease, cystic fibrosis, prior mycobacterial disease, pulmonary fibrosis, smoking, and chronic obstructive lung disease. Radiological features include thin-walled cavities, parenchymal infiltrates, and pleural involvement. High-resolution computed tomography of the chest shows a combination of multifocal bronchiectasis and nodular parenchymal disease.[7]

Lymphadenitis

In children (1–5 years), localized nontender lymphadenitis is seen involving the submandibular, submaxillary, cervical, or preauricular lymph nodes[8] which may enlarge, rupture, and form sinuses. Almost 80% NTM lymphadenitis are due to *M. avium* complex.

Localized Skin and Soft Tissue Infection

Most species of NTM have been described causing cutaneous disease[9,10] (Table 2) or nosocomial skin and soft tissue infection, postinjection abscess, surgical wound infections, and infections because of long-term intravenous or peritoneal catheters. *M. chelonae* causes disseminated nodular skin disease in immunocompromised patients. *M. marinum* causing ''swimming pool granuloma'' or ''fish tank granuloma'' gets implanted while cleaning fish tanks or handling fish. Solitary papules get

DOI: 10.1081/E-EDGP 120020883

Table 1 Runyon's classification of NTM

Type	Characteristics	Common organisms
Type 1	Slow grower, photochromogen	*M. kansasii*, *M. marinum*, *M. simiae*, *Mycobacterium asiaticum*
Type 2	Slow grower, scotochromogen	*Mycobacterium scrofulaceum*, *Mycobacterium szulgai*, *Mycobacterium gordonae*, *M. ulcerans*
Type 3	Slow grower, nonchromogen	*M. avium–intracellulare*, *Mycobacterium malmoense*, *Mycobacterium terrae*, *Mycobacterium haemophilum*, *M. ulcerans*, *M. xenopi*
Type 4	Rapid grower	*M. fortuitum*, *M. chelonae*, *M. abscessus*, *Mycobacterium smegmatis*

formed that progress to ulceration and scar formation. *Mycobacterium ulcerans* causes disease in children and young adults, producing necrotic lesions of skin and underlying tissue.[9] In our experience, five cases (four wound infections following a laparoscopic surgery and one injection abscess) of *M. chelonae* (three isolates) and *M. fortuitum* (one isolate) were isolated which were sensitive to imipenem, amikacin, and ciprofloxacin.

Infections of Bursae, Joints, Tendon Sheaths, and Bones

Most of the NTM[9] can cause chronic granulomatous infection of the tendon sheaths, bursae, joints, and bones (Table 2). *M. abscessus* is a common cause of posttraumatic wound infection.[10]

Disseminated Disease

In immunosuppressed patients (AIDS with CD4 cell count <50 cells, posttransplant, long-term steroid use, malignancies), disseminated disease because of various NTM has been described (Table 2).[9,10] The disease can present as fever of unknown origin in case of *M. avium* complex[11] or as multiple localized abscesses or nodules. The organism can be isolated from blood or bone marrow more so if *M. avium*.

DIAGNOSIS

There are no specific skin tests standardized for NTM.

Microscopic Examination

Because nontuberculous mycobacteria are transiently present in the sputum, three or more sputum samples should be evaluated for acid-fast bacilli. Bronchial washing is a better sample. A fine needle aspiration performed from the lymph nodes may yield NTM on cultures and show granulomatous changes on cytology. The two commonly used stains are the Ziehl–Neelsen stain (sensitivity 50–60%) and auramine–rhodamine (sensitivity 80%).

Culture

Culture still remains the gold standard in diagnosing mycobacterial infections,[12] which, besides being more

Table 2 Clinical syndromes associated with NTM

Syndrome	Common	Less frequent
Pulmonary disease	*M. avium* complex, *M. kansasii*, *M. abscessus*, *M. xenopi*, *M. malmoense*	*Mycobacterium celatum*, *M. simiae*, *M. smegmatis*
Lymphadenitis	*M. avium* complex	*Mycobacterium scrofulaceum*, *M. malmoense* (in Europe), *M. abscessus*, *M. fortuitum*
Skin soft tissue disease	*M. marinum*, *M. ulcerans*, rapid growers	*M. haemophilum*, *M. smegmatis*, *M. kansasii*
Bone and joint infection	*M. avium* complex, *M. marinum*, rapid growers, *M. kansasii*	*M. haemophilum*, *M. smegmatis*, *M. scrofulaceum*

Table 3 Culture methods for mycobacteria

Method	Medium	Manufacturer
Conventional methods		
Egg-based solid media	Lowenstein Jensen medium	
Agar-based media	Middlebrook 7H10, 7H11 medium	
Broth media	Middlebrook 7H9, Dubos Tween albumin broth	
Automated/semiautomated methods		
Biphasic medium	Septichek system	Becton Dickinson
Radiometric	BACTEC 460 system	Becton Dickinson
Nonradiometric	MB/BacT system	BioMerieux
Fluorescence	MGIT, BACTEC 9000MB	Becton Dickinson

sensitive than staining techniques, also allows identification and antimicrobial sensitivity known.[13] The decontamination methods used for processing samples for *Mycobacterium tuberculosis* (MTB) can also be used for NTM. Commonly used media and automated and semiautomated methods are mentioned in Table 3. For maximal recovery within 4–6 weeks, one liquid and one solid media are recommended. In general, recovery rate does not differ considerably among the different automated systems but is higher and shorter (10–14 days) than the solid media.

Identification

Species identification is performed by conventional biochemical tests along with their growth characteristics.[14] The ρ-nitro-α-acetylamino-β-hydroxy propiophenone (NAP) test can be used to differentiate NTM from the MTB complex directly from the BACTEC broth. High-performance liquid chromatography and gas–liquid chromatography can be used to speciate and analyze the mycobacterial cell wall fatty acids. Nucleic acid probe kits have been used to directly amplify *M. tuberculosis* and *Mycobacterium avium intracellulare* from MB/BacT and BACTEC cultures using nucleic acid sequence-based amplification assay (NASBA, bioMerieux)[15] and acridinium–ester-labeled DNA probes[16] with a sensitivity and specificity of nearly 100%. The biomass obtained in MB/BacT is superior to BACTEC for direct molecular assays.

MOLECULAR METHODS

For rapid diagnosis, two nucleic acid amplification tests (NAA), the amplified *M. tuberculosis* direct test (MTD) (bioMerieux) and AMPLICOR (Roche) *M. tuberculosis* test, have been cleared by the Food and Drug Administration (FDA) for direct use in smear-positive respiratory samples, whereas enhanced MTD (Genprobe, bioMerieux) is also approved for smear-negative respiratory cases. A number of molecular methods have been used to differentiate between *M. tuberculosis* and NTM and also for speciating NTM.

Nucleic acid sequence-based amplification assay, a MTD type of assay, has been used for the detection of *M. avium*, *Mycobacterium paratuberculosis*, and *Mycobacterium intracellulare* using a set of primers and probes[15] directly on sputum sample. Restriction enzyme analysis of the amplified segment of the gene encoding for the 650 kDa mol. wt. heat shock protein and polymerase chain reaction with single universal primer was used to identify MTB complex and species identification of NTM.[17] Bhattacharya et al.[18] have developed a multiplex PCR based on amplification of 165-, 365-, and 541-bp target fragments to distinguish between strains of MTB complex and NTM.

Hall et al.[19] evaluated the Microseq 500 system and could identify 98.3% of the ATCC strains and 90.1% of the clinical isolates to the species/group level. The 5′ exonuclease fluorogenic PCR assay[20] had a 100% positive predictive value to detect mycobacteria in clinical samples. Smear-positive samples had a sensitivity of 90.3% as compared with smear-negative (49.2%). The INNO-LiPA Mycobacteria and GenoType Mycobakterien (Hain Diagnostica) are DNA strip assays and have identified 89.4% and 95.1% of mycobacterial isolates, respectively.[21]

A new technology involving high-density oligonucleotide arrays or ''DNA chips'' can be used to examine large amount of DNA sequences. The nucleotide sequence diversity in 10 mycobacterial species from 121 mycobacterial isolates was examined by Gingeras et al.[22] by analyzing the rpoB oligonucleotide array hybridization patterns. The use of this array allowed simultaneous detection of mutations that confer rifampicin resistance as well as species identification.

DRUG SUSCEPTIBILITY OF NONTUBERCULOUS MYCOBACTERIA

Drug susceptibility methods for NTM are not standardized. However, MB/BacT and radiometric BACTEC method, agar proportion method, broth microdilution, and E test have been used for this purpose. Standard first-line antitubercular agents are tested along with clarithromycin, amikacin, streptomycin, quinolones, and sulfonamide.

M. avium Complex

M. avium complex (MAC) is usually resistant to the first-line antituberculous agents. Patients with previous exposure to macrolides and those who develop MAC while receiving macrolides for its prophylaxis should have their initial isolate tested for macrolide susceptibility. Minimal inhibitory concentration (MIC) of >32 μg/mL is the recommended breakpoint for resistance.[6]

M. kansasii

All initial isolates should be tested against rifampicin. Resistance usually develops during treatment. A resistant isolate could be tested against ciprofloxacin, ofloxacin, clarithromycin, ethambutol, streptomycin, and sulfonamide.

Routine antituberculous agents are not tested for rapidly growing mycobacteria. The drugs tested include amikacin, cefoxitin, fluoroquinolones, doxycycline, clarithromycin, tobramycin, imipenem, and sulfonamides. Susceptibility tests for other slow-growing NTM may include isoniazid, rifampin, ethambutol, ciprofloxacin, and clarithromycin. Analysis of mutations in the emb B region could predict intrinsic and acquired resistance to ethambutol in case of NTM.

TREATMENT

M. avium Complex

The newer macrolides are the mainstay of therapy for MAC pulmonary and disseminated disease (Table 4). Intermittent streptomycin for the first 2–3 months of therapy for the first 8 weeks has also been used. For disseminated disease in AIDS, treatment regimens should include clarithromycin or azithromycin and ethambutol and a third agent rifabutin can be used, but drug interactions exist between rifabutin and protease inhibitors. Prophylaxis for MAC, with either azithromycin (1200 mg once weekly) or clarithromycin (500 mg twice daily, BD), is now recommended for all AIDS patients with CD4 cell counts <50 cells/mm^3.[23] Rifabutin (300 mg/day) or a combination of azithromycin (1200 mg once weekly) plus rifabutin (300 mg/day) has been proven to be effective.

M. marinum

Surgical excision of the skin lesions or electrodessication with or without adjuvant ATT is the most common treatment. The organism is uniformly resistant to isoniazid. Other drugs have been referred to in Table 4.

Rapidly Growing Mycobacteria

M. fortuitum, *M. chelonae*, and *M. abscessus* are resistant to the antituberculous agents. Depending on the susceptibility pattern, treatment with amikacin, ciprofloxacin, cefoxitin, and clarithromycin is recommended (Table 4).

For treatment of pulmonary disease because of other NTM, see Table 4.

Table 4 Treatment of NTM

Species	Drug	Duration
M. avium complex	Clarithromycin (500 mg, BD)+ethambutol (15 mg/kg)+rifampicin (600 mg) or rifabutin (300 mg)	Culture-negative for 12 months. In HIV-positive patients, treatment is for life.
M. kansasii	Rifampicin (600 mg)+isoniazid (300 mg)+ethambutol (15 mg/kg)	18 months, culture negative for 12 months
M. marinum	Clarithromycin (500 mg, BD) or minocycline or doxycycline (100 mg) or rifampicin (600 mg)+ethambutol (15 mg/kg)	3 months
M. fortuitum, *M. chelonae*, and *M. abscessus*	Amikacin (10–15 mg/kg)+cefoxitin (12 mg/day) or clarithromycin (500 mg, BD)	Cutaneous and disseminated—6 months; pulmonary—2 weeks
M. malmoense	Clarithromycin (500 mg, BD)+ethambutol (15 mg/kg)+rifabutin (300 mg)+streptomycin	18–24 months
M. szulgai, *M. xenopi*, *M. simiae*	Isoniazid, rifampicin, ethambutol, and streptomycin	18–24 months

CONCLUSION

To conclude, atypical mycobacteria have come to stay with us and it is important to keep a high index of suspicion. To do so, it becomes mandatory to isolate and identify. The role of molecular assays is clearly defined as a supportive one and cannot be viewed in isolation as the only evidence of infection. Molecular assays cannot be recommended as the first-line routine assays for the diagnosis of mycobacterial disease because of its cost and exacting technique implications.

Mycobacterium leprae

Diana L. Williams
Thomas P. Gillis
National Hansen's Disease Programs, Baton Rouge, Louisiana, U.S.A.

INTRODUCTION

Advances in molecular technologies have brought forth new diagnostic procedures for rapid, specific, sensitive, and cost-effective identification of *Mycobacterium leprae* and drug-resistant strains. These tools have made possible the specific and early diagnosis of leprosy which is critical for initiating appropriate treatment to hasten a cure and prevent progressive nerve damage. Genomics of both man and *M. leprae* are providing new information regarding disease susceptibility as well as markers for strain typing *M. leprae*. Annotation of *M. leprae*'s genome has provided insight into why the leprosy bacillus is an obligate intracellular parasite and has provided the basis for future experimentation to better understand its pathogenicity.

LEPROSY

Leprosy (Hansen's Disease) is a chronic infectious disease caused by infection with *Mycobacterium leprae* affecting the skin, mucous membranes, and peripheral nerves.[1] The predilection of *M. leprae* for peripheral nerves can result in nerve damage leading to sensory and motor paralysis which in turn can cause deformities of the hands and feet and blindness. It is estimated that 2–3 million patients suffer from irreversible nerve damage as a long-term consequence of *M. leprae* infection and that approximately one-fourth of the 621,000 new cases in 2003[2] will suffer from some form of nerve damage.

Leprosy exhibits a spectrum of clinical forms resulting from the infected patient's ability to attack and destroy *M. leprae*.[1] At one extreme of the spectrum is the localized form of disease, tuberculoid leprosy (TT), in which very few bacteria are observed in infected tissues as a result of partially effective cell-mediated immunity (CMI). At the opposite end of the spectrum is the disseminated form of the disease, lepromatous leprosy (LL), in which large numbers of *M. leprae* are observed due to ineffective CMI. Patients whose disease appears neither TT nor LL fall in an intermediate category called borderline leprosy. In approximately 50% of leprosy patients under treatment, acute inflammatory reactions develop that are immunologically mediated responses to *M. leprae*.[1] Type 1 reactions are seen in patients with significant T-cell immunity to *M. leprae* and in extreme cases may result in necrosis with abscess formation in nerve trunks with irreparable loss of nerve function. Type 2 reactions, or erythema nodosum leprosum (ENL), are characterized histologically by a vasculitis and a neutrophilic infiltrate superimposed on a lepromatous infiltrate. Chronic episodes of ENL can lead to nerve damage and eventual loss of nerve function. Both reactions can be managed with anti-inflammatory agents such as steroids or in the case of ENL, thalidomide.

Identification of the host genes that influence host susceptibility/resistance enables a greater understanding of disease pathogenesis. Genetic linkages with leprosy have been recognized for years.[3,4] For example, twin studies in India demonstrated higher concordance rates for leprosy among monozygotic twins (60–85%) than dizygotic twins (5–20%).[3] Recent developments in genome-wide linkage analysis have identified three major susceptibility loci that are linked to and associated with leprosy susceptibility.[4] Fine mapping of these chromosomal regions is now required to better understand the contribution derived from these putative susceptibility genes.

ETIOLOGICAL AGENT

M. leprae is a nonmotile, nonspore-forming, microaerophilic, acid-fast-staining bacterium that usually forms slightly curved or straight rods. *M. leprae* has never been grown on artificial media but can be maintained in axenic cultures in a metabolically active state for a few weeks.[5] As a result, propagation of *M. leprae* has been restricted to animal models including the armadillo, normal, and athymic rodents.[1] These systems have provided the basic resources for genetic, metabolic, and antigenic studies of the bacillus. Growth of *M. leprae* in mouse foot pads also provides a tool for assessing

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020885

viability and for testing drug-susceptibility of clinical isolates.[5,6]

Genome and Transcriptome

Annotation of *M. leprae*'s genome has rekindled basic investigations into aspects of metabolic, biochemical, and pathogenic potential of this obligate intracellular pathogen of humans. Comparison of *M. leprae*'s genome with that of its close relative *Mycobacterium tuberculosis* suggests that *M. leprae* has undergone an extreme case of reductive evolution.[7,8] This is reflected in its smaller genome (3.3 Mb for *M. leprae* vs. 4.4 Mb for *M. tuberculosis*) and a major reduction in G+C content (66% for *M. tuberculosis* to 58% for *M. leprae*). *M. leprae* contains 1605 open reading frames (ORFs), encoding potentially functional proteins compared to 4000 ORFs in *M. tuberculosis*. Proteomic studies, using two-dimensional SDS polyacrylamide gel electrophoresis analysis, with *M. leprae* predict 391 proteins[9] as compared to approximately 1800 proteins in *M. tuberculosis*.[10] One of the most striking features of *M. leprae*'s genome is that it possesses 1116 inactivated genes, genes lost through mutation (pseudogenes), compared to six pseudogenes in *M. tuberculosis*.[7] In addition, a large number of genes have been entirely deleted from the genome. The result of this massive gene loss leaves *M. leprae* with only 50% of its genome encoding functional genes as compared to 90% functional genes in *M. tuberculosis*.

The largest functional groups of genes in *M. leprae* were found to be involved in the metabolism and modification of fatty acids and polyketides, transport of metabolites, cell envelope synthesis, and gene regulation.[7,8,11] Downsizing of the genome has resulted in the elimination of entire metabolic pathways, their regulatory circuits, and accessory functions, resulting in a pathogen with very specific growth requirements.

While comparative genome analysis provides useful clues to identify deficits in general cellular metabolic potential and cellular composition, it offers only a starting point from which functional studies can ensue. Because of the inability to cultivate *M. leprae* axenically, purification of large quantities of bacterial proteins for analysis is extremely limited. Transcriptional analysis of *M. leprae* genes provides a perspective that is complementary to protein analysis by identifying actively transcribed genes and therefore those genes essential for optimal growth during infection in the host. Therefore an efficient method for purifying *M. leprae* RNA has been developed and transcripts for several genes have been identified directly from skin biopsy tissues of multibacillary leprosy patients.[12] With the development of a complete genomic array for *M. leprae*, the elucidation of the functional transcriptome should be forthcoming.

A major limitation exists for studying the impact of specific genes on *M. leprae*'s metabolism and pathogenesis. Because of the inability to cultivate *M. leprae* axenically, genetic systems for creating gene knockout mutants have not been developed. To overcome this limitation, mycobacterial surrogates such as, *Mycobacterium smegmatis*, have been used to test the function of several *M. leprae* genes.[13,14] While this is a powerful approach for studying *M. leprae* genes, caution must be taken in interpreting data generated using surrogate genomics because *M. leprae* genes are being expressed in a mycobacterial system that has a wealth of other genes not found in *M. leprae*.

Metabolism and Physiology

The primary reasons for investigating the metabolic aspects of *M. leprae* has been to determine whether special media could be formulated to support in vitro growth of the bacilli and to learn more about metabolic pathways that could potentially be exploited for developing new antileprosy drugs. Early work provided a picture of a bacterium with some basic anabolic and catabolic pathways needed for survival in the host, but a thorough assessment of *M. leprae*'s metabolic potential was still lacking.[15] With the completed sequencing and annotation of *M. leprae*'s genome, an improved version of *M. leprae*'s metabolic capabilities exists.[7,8]

Annotation of the genome identified genes showing that *M. leprae* has the capacity to generate energy by oxidizing glucose to pyruvate through the Embden–Mayerhoff–Parnas pathway supporting earlier biochemical observations. Acetyl-CoA from glycolysis enters the Krebs cycle producing energy in the form of ATP. In addition to glycolysis for energy production, genome analysis as well as biochemical studies in *M. leprae* and *M. tuberculosis* suggests that these organisms rely heavily upon lipid degradation and the glyoxylate shunt for energy production. In this regard *M. leprae* contains a full complement of genes for B-oxidation but very few genes as compared to *M. tuberculosis* capable of lipolysis. Acetate as a carbon source has been lost to *M. leprae* as genes such as acetate kinase, phosphate acetyltransferase, and acetyl-CoA synthase are pseudogenes. Overall, *M. leprae* has much fewer enzymes involved in degradative pathways for carbon and nitrogenous compounds as compared to *M. tuberculosis*. This is reflected in the paucity of oxidoreductases, oxygenases, and short-chain alcohol dehydrogenases, and their probable regulatory genes. Other major

problems associated with metabolism for *M. leprae* exist in that the bacilli have lost anaerobic and microaerophilic electron transfer systems, and the aerobic respiratory chain is severely curtailed making it impossible for *M. leprae* to generate ATP from the oxidation of NADH. In contrast to the reduction in catabolic pathways, anabolic capabilities of *M. leprae* appear relatively unharmed. For example, complete pathways are predicted for synthesis of purines, pyrimidines, most amino acids, nucleosides, nucleotides, most vitamins, and cofactors. The maintenance of these anabolic systems suggests that the intracellular niche that *M. leprae* finds itself may be highly restrictive for these compounds or transport systems for them do not exist.

Cell Wall Chemistry and Related Genes

A great deal has been learned about the nature of the mycobacterial cell wall through biochemical and genetic manipulation of cultivable strains such as *M. tuberculosis*, *Mycobacterium avium*, *M. smegmatis*, and *Mycobacterium bovis* BCG. Similar approaches with *M. leprae* have been meager by comparison, but basic chemical studies have concluded that the cell wall is a covalently linked peptidoglycan–arabinogalactan–mycolic acids complex similar in composition to all mycobacterial cell walls.[16,17] The peptidoglycan of *M. leprae* contains meso-diaminopimelic acid as do other mycobacteria; however, *M. leprae* contains the unusual substitution of glycine for alanine in the bridging tetrapeptide. The muramic acids of the peptidoglycan in *M. leprae* are modified with *N*-glycolyl as opposed to the more common *N*-acetyl substitution. Coupled to the peptidoglycan through a disaccharide linkage is the arabinogalactan component of the outer cell wall. Linear arrays of D-arabinose–D-galactose polymers with appendages of D-arabinose make up this layer lying external to the peptidoglycan. Mycolic acids are esterified to the terminal arabinoses of the arabinan chains completing the bulk of the cell wall. A rich array of intercalating lipoglycans, phosphotidylinositol mannosides (PIM), lipomannans (LM), and lipoarabinomannans (LAM) are also present. Finally, the dominant lipid in the cell wall which engenders *M. leprae* with immunological specificity is phenolic glycolipid I (PGL-I). Recent studies suggest that PGL-1 is involved in the interaction of *M. leprae* with the laminin of Schwann cells suggesting a role for PGL-1 in peripheral nerve/bacilli interactions.[18]

Annotation of the *M. leprae*'s genome and comparative genomic studies with other bacterial genomes has produced insight into the putative genes needed to direct the synthesis of this complex biopolymer.[11] Most of the genes necessary to build the peptidoglycan–arabinogalactan–mycolate polymer appear to be present in the *M. leprae* genome and fit a reasonable strategy for its construction. A few exceptions are two genes involved in polyprenyl–phosphate synthesis (*dxs-II*, *idi*), a gene (*fabH*) involved in meromycolate synthesis, and a glycosyltransferase gene (*pimB*) involved in the biosynthesis of PI, PIM, LM, and LAM. It should be noted that much of this comparative work, while speculative, provides an important framework from which to investigate the authenticity of these putative pathways.

MOLECULAR TOOLS

Diagnosis of Leprosy

Early diagnosis and effective treatment of leprosy are essential for reducing the risk of neurological complications resulting in progressive and irreversible nerve damage. Confounding the diagnosis is the increased presence of other mycobacterial infections of the skin. As *M. leprae* is not cultivatable, culture amplification with subsequent phenotypic identification of *M. leprae* is not feasible. In addition, there are no approved blood tests or skin test reagents for leprosy diagnosis that are used on a routine basis. Therefore differentiation of leprosy from other cutaneous granulomatous diseases is routinely based on characteristic histopathological features and demonstration of acid-fast bacilli by microscopy.[1]

Rapid molecular-based assays have been developed for detection of *M. leprae* directly from patient specimens using available genetic data (for review, see Ref. [19]). These assays have been based primarily on the use of polymerase chain reaction (PCR) amplification of an *M. leprae*-specific gene fragment and identification of the *M. leprae* DNA fragment in the lesion. Many different genes (e.g., *hsp18*, *ag36*, and *groEL1*), noncoding repetitive sequences (RLEP), and 16S rRNA (DNA or RNA) of *M. leprae* have been utilized in these assays. On the basis of extensive assessment of these tests in field studies, PCR-based techniques have shown a specificity of essentially 100% and a sensitivity ranging from 34% to 74% in patients with paucibacillary forms of the disease to greater than 90% in patients with multibacillary forms of the disease. Automation of PCR-based techniques has allowed their implementation in many reference laboratories, chiefly in leprosy endemic countries. Therefore PCR can provide an excellent adjunct to clinical and histopathological diagnosis of leprosy. It is anticipated that information gained from these tests will be useful to

the overall public health strategy for identifying and treating early leprosy.

Diagnosis of Drug-Resistant *M. leprae*

Treating infectious diseases with combinations of effective antibiotics is a proven method of limiting the emergence and spread of new or existing antibiotic-resistant pathogens. Current multidrug therapies (MDT) formulated for leprosy[1] are based on this principle and appear to be effective at both minimizing the development of drug resistance and reducing the prevalence of leprosy in many areas of the world.[2] However, over the last several years, drug resistance has been observed for *M. leprae* (for review, see Ref. [20]). Leprosy presents a very special problem for the detection of resistance because of the inability to culture *M. leprae* axenically. The current method for determining the activity of drugs against *M. leprae* is the mouse foot pad inoculation assay.[6] While this assay gives definitive information pertaining to the susceptibility of an *M. leprae* isolate to standard antileprosy drugs, it is cumbersome, requiring up to a year to obtain results.

Mutations in *M. leprae* genes associated with the development of resistance to key antileprosy drugs, including rifampin, dapsone, and ofloxacin, have been identified.[20] The β-subunit of the RNA polymerase, encoded by *rpoB*, is the target for rifampin, a derivative of rifamycin S. Missense mutations within an 81-bp region of *rpoB*, referred to as the rifampin resistance determining region (RRDR), have been associated with rifampin resistance in *M. leprae*. The dihydropteroate synthase, encoded by *folP-1*, is the target for dapsone, a sulfone. Missense mutations within a region of *folP-1*, referred to as the sulfone resistance determining region (SRDR), have been associated with high-level dapsone resistance in *M. leprae*. The GyrA subunit of the DNA gyrase, encoded by *gyrA*, is the target for ofloxacin, a fluoroquinolone. Mutations within a region of *gyrA*, referred to as the quinolone resistance-determining region (QRDR), have been associated with ofloxacin resistance in *M. leprae*. Mechanisms of resistance to the other effective antileprosy drugs including clofazimine and minocycline have not been elucidated primarily because of the inability to isolate sufficient numbers of resistant organisms for investigation.

The above information has been used as the basis for development of rapid, molecular assays for detecting mutations associated with rifampin-, dapsone-, or ofloxacin-resistant *M. leprae* directly from patient's specimens.[20] These assays are based on the use of PCR to amplify a fragment of an *M. leprae* drug target gene (RRDR, SRDR, or QRDR) and identification of missense mutations associated with drug resistance in these fragments using mutation detection methodologies. Polymerase chain reaction-based mutation detection assays which have been developed for drug susceptibility testing of *M. leprae* in clinical specimens include PCR-direct DNA sequencing, PCR-single-strand conformation polymorphism analysis (PCR-SSCP), PCR-heteroduplex analysis (PCR-HDA), and PCR-solid phase reverse-hybridization analysis. These assays demonstrate high specificity and sensitivity for detecting drug-susceptibility patterns of *M. leprae* from clinical specimens. The use of these molecular assays for limiting the spread of drug-resistant *M. leprae* is currently being evaluated as an integral component of an overall public health strategy for controlling leprosy.

Strain Identification

Understanding the epidemiology of leprosy is a prerequisite for effective control of the disease. As *M. leprae* cannot be cultured in vitro, it has been virtually impossible to assess exposure, onset of infection, and various aspects of disease progression. As a consequence, the sequence of events which must occur for successful transmission of leprosy is poorly understood. Genetic markers may hold the key to establishing species and strain-specific markers for assessing exposure to *M. leprae* and tracing transmission patterns. These tools should be helpful for improving our understanding of the epidemiology of leprosy. Over the last two decades, a wide range of molecular tests have been applied to reveal genotypic variation of *M. leprae*. Results of initial studies suggested that the genome of *M. leprae* was highly conserved based on restriction fragment length polymorphism (RFLP) analysis of *M. leprae* isolates using a combination of restriction enzymes and probes, and sequencing the internal transcribed spacer region of the 16S–23S rRNA operon yielded no polymorphic DNA sequences.[21–23] A polymorphic structure in the *pol*A gene[24] and variation in a GACATC repeat in the *rpo*T gene[25] have been described, but the value of these elements for differentiating *M. leprae* appears to be limited. In completing the sequence of the *M. leprae* genome, Cole et al.[7] identified several tandem repeats that could prove useful for discriminating *M. leprae* strains. Recently, Shin et al. reported evidence for diversity among *M. leprae* obtained from several patient biopsy samples in the Philippines, based on the frequency of TTC repeats located downstream of a putative sugar transporter pseudogene.[26] In addition to the TTC locus, in silico analysis of the genome sequence indicates that *M. leprae* has several other tandem repeat loci which may provide the genetic diversity necessary for creating a typing scheme capable of answering important questions related to the epidemiology of leprosy.

CONCLUSION

Over the past several years, *M. leprae*'s genetic information has been used to identify markers for the development of rapid, highly specific, and sensitive assays for the diagnosis of leprosy and drug-resistant leprosy directly from patient specimens. Genetic markers for susceptibility to leprosy have been identified, making the development of molecular assays for assessment of risk to this disease feasible. In addition, molecular markers for strain identification have been identified. Together, these assays will potentially aid in the elimination program by providing rapid diagnostic and epidemiological tools for leprosy. In addition, the availability of genomic information has opened new areas of leprosy research that will increase our knowledge of the metabolic, physiological, and pathogenic lifestyle of *M. leprae*, and aid in the identification of novel targets and skin test reagents for early diagnosis of leprosy.

Mycoplasma spp. and *Ureaplasma* spp.

Florian Daxboeck
University of Vienna, Vienna, Austria

INTRODUCTION

Mycoplasma spp. belong to the class of mollicutes (derived from the Latin mollis=soft and cutis=skin, indicating that these organisms lack a cell wall). Mollicutes have evolved regressively from gram-positive bacteria (*Clostridia*). Within the class of mollicutes, the family Mycoplasmataceae includes the genera *Mycoplasma* and *Ureaplasma*, which represent the most important mollicutes in human medicine. The genome size of Mycoplasmataceae is small, ranging from 577 to 1380 kbp (*Mycoplasma* spp.) and from 760 to 1140 kbp (*Ureaplasma* spp.). The limited genomic information implies the extensive nutrient requirements of the organisms when cultured in vitro and the inability to survive outside their natural hosts. To date, complete genomes of *Mycoplasma pneumoniae*, *Mycoplasma genitalium*, *Mycoplasma penetrans*, and *Ureaplasma urealyticum* have been sequenced.

Although some *Mycoplasma* spp. are capable of invading human cells, close attachment to the host cells without invasion is typical. Diagnosis of infections with Mycoplasmataceae is challenging because of their fastidious growth in vitro. Standard single-step polymerase chain reaction (PCR) assays have been established for most human-pathogenic Mycoplasmataceae (Table 1). In addition, for the most clinically relevant species, advanced PCR-based methods such as real-time PCR or nucleic acid sequence-based amplification (NASBA) have been constructed.

When *Mycoplasma* spp. or *Ureaplasma* spp. cause infections in their main mucosal habitat (e.g., respiratory tract or urogenital tract), copy numbers above the sensitivity level of a standard single-step PCR are expectable. When a screening for colonization is performed, and notably when the pathogens are to be detected in other anatomical sites, methods providing superior sensitivity should be applied.

M. PNEUMONIAE

M. pneumoniae is an important causative agent of upper and lower respiratory tract diseases. The most frequent extrapulmonary manifestations include encephalopathy, Guillain–Barré syndrome, perimyocarditis, and arthritis. Overall, these manifestations occur in less than 10% of patients, mostly in association with respiratory tract disease. There is no evidence of a predisposition of immunocompromised patients for severe or extrapulmonary *M. pneumoniae* infection.

When diagnosis of *M. pneumoniae* infection is based on serology from serum, assays (e.g., ELISAs) for separate detection of the early-appearing IgM (children) or IgA (adults) should be combined with the detection of all specific antibodies (microparticle agglutination assay). The most important antigen of *M. pneumoniae* is the attachment protein P1 (169 kDa). In patients with respiratory tract disease, molecular methods are useful to assist serological diagnosis. Molecular detection of *M. pneumoniae* is especially useful in patients with suspected mycoplasma central nervous system disease, perimyocarditis, arthritis, and other extrapulmonary manifestations. With the exception of the urogenital tract, detection of *M. pneumoniae* by PCR from sites outside the respiratory tract is always diagnostic. Because of the possibility of immunologically mediated disease, negative PCR results must be interpreted with caution. Detection of low quantities of *M. pneumoniae* in the throat can reflect a past illness.

It is important to note that 1 cfu (colony forming unit) or 1 ccu (color changing unit) of *M. pneumoniae* does not correspond to one genome equivalent, e.g., one single organism. In contrast, 1 cfu is estimated to be 10–1000 bacterial cells, and 1 ccu is estimated to be 10–100 organisms.[1] Importantly, formation of conglomerates of the bacteria in biological samples can limit the sensitivity of ultrasensitive detection methods.

Polymerase chain reaction was first applied for *M. pneumoniae* diagnosis in 1989 by Bernet et al. (target sequence: ATPase operon gene). To date, a variety of additional primer pairs targeting the genes encoding for the P1 protein and the 16S rRNA have been published.[2,3] A kit for PCR detection of *M. pneumoniae* is commercially available. Single-step PCR assays usually have a sensitivity of 10^2–10^3 genome copies/ml when applied to clinical samples.[4] Hybridization of PCR products is generally thought to increase the sensitivity of PCR compared with gel electrophoresis and ethidium bromide staining alone, but discordant findings have been pub-

DOI: 10.1081/E-EDGP 120021493

lished.[5] The sensitivity can be increased by 10^2 using nested PCR. However, false positive results because of cross-contamination remain a major concern when this method is applied. From a technical point of view, nested PCR has been overcome by real-time PCR assays.[6] The advantages of real-time PCR include high sensitivity, monitoring and semiquantitative assessment of the amplified product during PCR, and a reduction of hands-on time. Quantification of mycoplasmas in the respiratory tract may be useful because recent work has shown that patients with acute infection harbor greater quantities of the pathogen in respiratory secretions (10^2 and 10^4 ccu/mL) than convalescent patients. Low (and unpredictable) copy numbers may be present in nonrespiratory sites.

RNA amplification techniques are a promising perspective in *M. pneumoniae* diagnosis. The theoretical advantage of RNA-based mycoplasma diagnosis is the higher sensitivity because a large number of rRNA copies ($>10^3$) is present in each cell. In addition, the detection of this nucleic acid is indicative of the presence of viable mycoplasmas. A reverse transcriptase (RT-) PCR for detection of *M. pneumoniae* has been developed.[7] In addition, the nucleic acid sequence-based amplification technique (NASBA) has been applied to the pathogen both in a conventional and in a real-time format.[8] The sensitivity of these assays is indicated with 5–50 ccu. A NASBA kit for detection of *M. pneumoniae* is commercially available.[9] In one case, amplification of eubacterial 16S rDNA and subsequent sequencing of the amplicon enabled diagnosis of *M. pneumoniae* infection in a case of osteomyelitis, in which pus cultures had been repeatedly negative.[10]

An ELISA kit for direct antigen detection and a hybridization assay using a ^{125}I-labeled DNA probe complementary to the rRNA of *M. pneumoniae* are commercially available. These methods show a sensitivity of 10^4 cfu/mL and have been replaced by amplification-based methods.

MYCOPLASMA HOMINIS

M. hominis is a common inhabitant of the urogenital tract of healthy adults, with colonization rates of up to 20%. The pathogen is associated with pelvic inflammatory disease (PID), bacterial vaginosis, spontaneous abortion, and postpartum fever. In addition, *M. hominis* can cause posthysterectomy wound infections, endocarditis, abscesses, septic arthritis, and suppurating infections of hematomas. Immunocompromised patients are at higher risk for extragenital infection. Kits for the isolation of this species and *U. urealyticum* (including antibiotic susceptibility testing) are commercially available, but PCR is more sensitive. A PCR assay targeting the 16S rDNA has been shown to provide a sensitivity of 10–100 genome copies (under optimized conditions).[11]

M. GENITALIUM, *MYCOPLASMA FERMENTANS*, AND *M. PENETRANS*

M. genitalium is associated with nongonococcal urethritis (NGU), cervicitis, and endometritis. The pathogen has also been recovered from joints (in patients with arthritis) and from the respiratory tract, whereby the pathogenetic role in the latter site is uncertain. Like *M. fermentans* and *M. penetrans*, *M. genitalium* has been investigated intensively in the early 1990s because of its suspected role in the pathogenesis of AIDS. This ability of *Mycoplasma* spp. could not be demonstrated unequivocally, but immunocompromised patients are at risk for colonization and infection with these mycoplasmas. *M. genitalium* shows a high degree of similarity with *M. pneumoniae* with regard to cell morphology (flask shape and the terminal tip-like attachment structure) and antigens. These two pathogens may be present concomitantly in respiratory, urogenital, and synovial fluid samples. In these cases, isolation of the pathogen is problematic because *M. pneumoniae* shows a similar colony morphology and the same susceptibility to antimicrobial agents (except thallium acetate, which inhibits selectively the growth of *M. genitalium*). Primer pairs targeting the sequences encoding for the MgPa protein and the 16S rRNA have been published, whereby the latter assay has been shown to be more sensitive.[12] A real-time PCR assay based on amplification of the *M. genitalium* 16S rRNA gene with a sensitivity of 10 copies/reaction has been developed.[13]

M. fermentans has been shown to cause arthritis and acute respiratory distress syndrome (ARDS). The pathogenic potential of *M. penetrans* is not fully elucidated; however, bacteremia in an immunocompetent patient has been described. Both pathogens have been implicated in the pathogenesis of chronic fatigue syndrome. PCR primers targeting the 16S rDNA (*M. fermentans*) and the 16S–23S rDNA spacer region (*M. penetrans*) have been described.[14,15]

U. UREALYTICUM AND *UREAPLASMA PARVUM*

U. urealyticum causes nongonococcal urethritis (NGU) and septic arthritis in immunocompetent and immunocompromised patients. The pathogen is of special importance in newborns, where it may cause bloodstream infection, pneumonia, and central nervous system disease. The clinical significance of *U. parvum*, the

second human-pathogenic member of the genus established in 2002, remains to be determined. PCR primer targeting the 16S rDNA of *U. urealyticum* (which show no cross-reaction with the *U. parvum* genome) has been described.[11]

SIMULTANEOUS DETECTION OF SEVERAL MOLLICUTE SPECIES

As mollicutes usually cause diseases of the respiratory or the urogenital tract, where the spectrum of pathogens to be considered is large, considerable interest has been focused on the simultaneous detection of several mollicutes, or mollicutes and other pathogens, by the same assay. Although the regions V2 and V3 of the 16S rDNA display sufficient interspecies differences for species-specific detection, conserved sequences of the 16S rDNA gene enable detection of most *Mycoplasma* spp., *Ureaplasma* spp., *Spiroplasma* spp., and *Acholeplasma* spp. by a single assay using the primer pair GPO-1/MGSO.[9] All mollicutes, which have been isolated from humans, are listed in Table 1.

A recently described seminested PCR based on this assay using the additional primer My-ins provides improved sensitivity. This assay has been shown to allow amplification of *M. genitalium*, *M. hominis*, *Mycoplasma faucium*, *U. urealyticum*, and *U. parvum* specific sequences.[16]

A variety of assays for simultaneous detection of mollicutes and other pathogens have been described, e.g., a multiplex real-time PCR assay to detect *M. pneumoniae*, *Chlamydia pneumoniae*, and *Legionella pneumophila* in respiratory samples.[17] In addition, a multiplex RT-PCR for the detection of *M. pneumoniae* and eight additional respiratory pathogens has been constructed.[18] Simultaneous detection of *M. hominis* together with the bacterial vaginosis-associated pathogens *Lactobacillus* spp. and *Gardnerella vaginalis* by real-time PCR has been described.[19]

When cell cultures are to be tested for mycoplasma contamination, a convenient alternative to PCR (using GPO-1/MGSO) is a commercially available ELISA kit for antigen detection.

MOLECULAR TYPING OF *MYCOPLASMA* SPP. AND *UREAPLASMA* SPP.

Molecular typing of *Mycoplasma* spp. and *Ureaplasma* spp. is rarely indicated, but outbreaks of respiratory

Graduation of clinical relevance: •—anecdotal reports; ••—human infection is rare and/or restricted to patients at risk; •••—well-established, frequently encountered pathogen.

[a]Primer sequences for in vitro studies have been constructed but not applied to clinical specimens.

[b]*Ureaplasma parvum* has been described only recently (2002), so that a considerable clinical relevance cannot be ruled out.

Source: Ref. [22].

disease because of *M. pneumoniae* or *M. hominis* infections following surgery may warrant the application of these techniques. Pulsed field gel electrophoresis (PFGE) is regarded as gold standard in molecular typing. The disadvantages of PFGE are that the method is time-consuming and cost-intensive. More convenient alternatives, which have been applied to *M. pneumoniae*, include random amplification of polymorphic DNA (RAPD) and restriction fragment length polymorphism (RFLP) analysis.[20] In addition, serological typing has been applied to this pathogen. Arbitrarily primed (AP-) PCR has been used to investigate the transmission of *M. hominis* and *U. urealyticum*.[21]

CONCLUSION

Although all human-pathogenic mollicutes are cultivable using special media, PCR provides superior diagnostic accuracy. Diagnosis of *M. pneumoniae* infection can be based on serology, whereas PCR is preferable for other *Mycoplasma* spp. and *Ureaplasma* spp. When these pathogens are to be detected in their natural mucosal habitat, copy numbers above the sensitivity level of standard single-step PCR assays can be expected, especially when they cause clinically significant infection. PCR-based methods of superior sensitivity (e.g., real-time PCR and NASBA assays) are useful for detection of low copy numbers of the pathogen in atypical sites. Common methods for molecular typing (PFGE, RAPD, and AP-PCR) have been applied to some *Mycoplasma* spp. and to *U. urealyticum*, whereby these versatile techniques can be applied to any human-pathogenic mollicutes.

INTRODUCTION

Myelodysplastic syndromes (MDS) are clonal disorders characterized, initially, by ineffective hematopoiesis and, subsequently, by frequent development of acute myeloid leukemia (AML). Peripheral blood cytopenias, in combination with a hypercellular bone marrow exhibiting dysplastic changes, are the hallmarks of MDS. In 1982, the French–American–British (FAB) Cooperative Group classified five subentities of MDS: refractory anemia (RA), refractory anemia with excess of blasts (RAEB), refractory anemia with excess of blasts in transformation (RAEB-T), refractory anemia with ringed sideroblasts (RARS), and chronic myelomonocytic leukemia (CMML). This classification based on morphological criteria was recently revised, resulting in the World Health Organization (WHO) classification that includes, in addition, specific chromosomal changes.

In addition to FAB and WHO classifications, the initial chromosomal aberration, the age of patient, and the number and severity of cytopenias are most important to evaluate the prognosis of MDS as summarized in the International Prognostic Scoring System (IPSS). The median survival of MDS patients according to this classification ranges from 6 years for low-risk patients to 6 months for high-risk patients. The value of IPSS for assessing individual prognosis in patients with MDS has been demonstrated in several further studies.

OVERVIEW

The recently available microarray technology is a powerful new tool to assess the expression of a large number of genes in a single experiment. The most important use of array technology in medical science is to characterize global gene expression profiles, which are specific for disease subgroups or have prognostic value (e.g., for disease progression). The aim of those studies is to accelerate the identification of diagnostic and prognostic markers, and to identify novel tumor-specific markers for certain malignant diseases.

One of the groundbreaking studies[1] using oligonucleotide microarrays showed that global gene expression analysis can distinguish with high accuracy between leukemic blasts from patients with either AML or acute lymphoblastic leukemia (ALL). Subsequently, a number of studies[2–4] analyzing different kinds of tumor entities including malignant lymphomas or solid tumors (e.g., breast cancers carrying mutations of *BRCA1* and *BRCA2*) were performed by demonstrating the power of microarray analyses to correlate specific gene expression profiles with well-established classification/prognostic systems.

TECHNIQUE OF GLOBAL GENE EXPRESSION ANALYSIS

$CD34^+$ Cell Selection and Nucleic Acid Preparation

Fresh bone marrow is processed immediately after aspiration to select the $CD34^+$ cells within the next 2 hr. $CD34^+$ cells are purified by high-gradient magnetic cell separation (MACS) using superparamagnetic streptavidin microparticles. Yield and purity of the positively selected $CD34^+$ cells are evaluated by flow cytometry.

Total RNA is extracted using TRIzol (Life Technologies, Grand Island, NY) according to the manufacturer's protocol with minor modifications. In addition, RNA is purified by the RNeasy system (Qiagen, Inc., Valencia, CA) following the manufacturer's advice. The quality of RNA is critical for any microarray experiment. To assure that the gene expression measured by microarray assay is not affected by degradation of the RNA extracted from the purified $CD34^+$ cells, the Bioanalyzer system (Agilent, Waldbronn, Germany) is used to evaluate the quality of the RNA. Figure 1 shows the Bioanalyzer pattern of a high-quality RNA compared with a pattern that is related to degradation of RNA.

DOI: 10.1081/E-EDGP 120020964

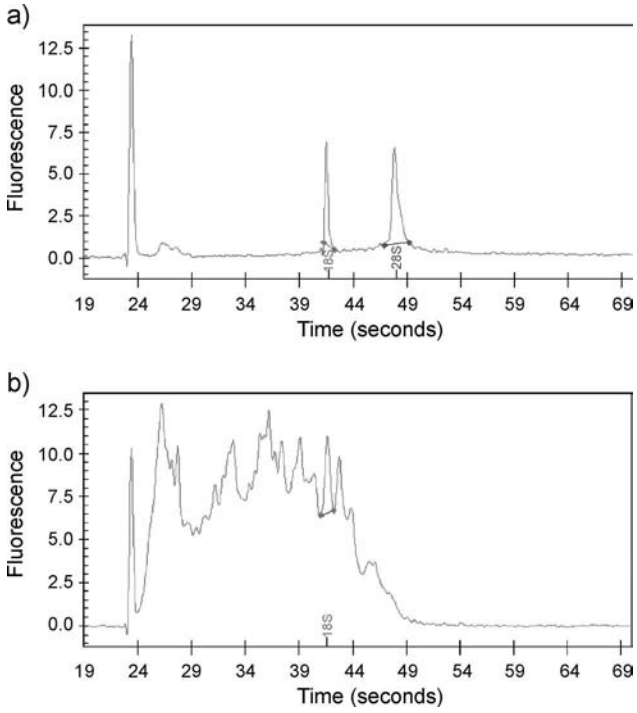

Fig. 1 Quality of RNA from $CD34^+$ cells as determined by the Bioanalyzer system. (a) Analysis image of a high-quality total RNA extracted from $CD34^+$ cells. Beside the marker spike (left), the 18S and 28S spikes (right) are clearly separated. There is no significant degradation of RNA. (b) Image of a degraded total RNA. Beside the marker spike, there is no clear separation of the 18S and/or 28S fraction demonstrating the high level of RNA degradation. (*View this art in color at www.dekker.com.*)

Oligonucleotide Microarrays and Data Analysis

The GeneChip system (Affymetrix, Inc., Santa Clara, CA) can be used for oligonucleotide microarray analysis of $CD34^+$ MDS cells. The detailed protocol for sample preparation and microarray processing is available from www.affymetrix.com. Because of the limited number of $CD34^+$ cells and the low content of RNA in these hematopoietic stem cells, a double in vitro transcription technique (''nanogram-scale assay'') has been established. To assay 50 ng of total RNA, the standard Affymetrix target amplification protocol has been modified by using first-round cRNA product to generate a double-stranded cDNA that is then used for a second round of in vitro transcription for synthesis of the biotinylated cRNA. GeneChip image analysis is performed using the Microarray Analysis Suite 5.0 (Affymetrix). Data are analyzed by the GeneSpring™ software version 5.1 (Silicon Genetics, Inc., San Carlos, CA).

Class membership prediction[5,6] refers to the process of statistically dividing clinical samples (e.g., bone marrow cells) into reproducible classes that have similar gene expression behaviors or properties. Using a ''training set'' a list of predictive genes that can be used to discriminate one group from other groups of samples (diseases) exclusively according to their gene expression profile is selected. In a second analysis, the predictive genes are used to analyze a ''test set'' of additional samples whose classes are currently not known to place such samples into already known classes.

PREDICTION OF DISEASE RISK USING $CD34^+$ CELLS FROM PATIENTS WITH MDS

The clinical diagnosis of typical MDS according to FAB/WHO[7,8] criteria is often straightforward and presents no difficulty. Although the diagnosis may be suspected based on the history and the peripheral blood findings, morphological examination of the bone marrow and cytogenetics are essential to establish the final diagnosis and to estimate the prognosis of the disease. The latter may be difficult and requires additional genetic information, which can hopefully be obtained from global gene expression data in MDS.

We and others[9,10] have shown that characterizing the cellular and molecular defects of clinical samples from patients with MDS by global gene expression analysis requires the analysis of a freshly isolated and homogenous population of bone marrow cells. Because expression of CD34 is a marker for hematopoietic stem cells, experiments to detect abnormalities have focused on $CD34^+$ cells from patients with MDS. The first description of MDS-specific genes that were found to be overexpressed in $CD34^+$ cells from patients with MDS compared with leukemic cells from patients with AML was published in 2001.[10] Twenty genes [including delta-like 1 (DLK1), a secreted protein that has epidermal growth factor motifs] were selected by direct comparison of expression data in MDS vs. AML. By hierarchical cluster analysis, it could be demonstrated that the selected genes can be used to clearly distinguish the MDS samples from the AML samples.

We have used two independent data sets created from a total of 19 patients with MDS to predict the risk groups of those patients at the time of initial diagnosis. Using the first data set (11 patients, samples 275–286; Fig. 2a), we identified by class membership prediction 11 genes whose expression can be used to differentiate with high accuracy between low-risk MDS, high-risk MDS, and normal individuals (samples 271–274; Fig. 2a).

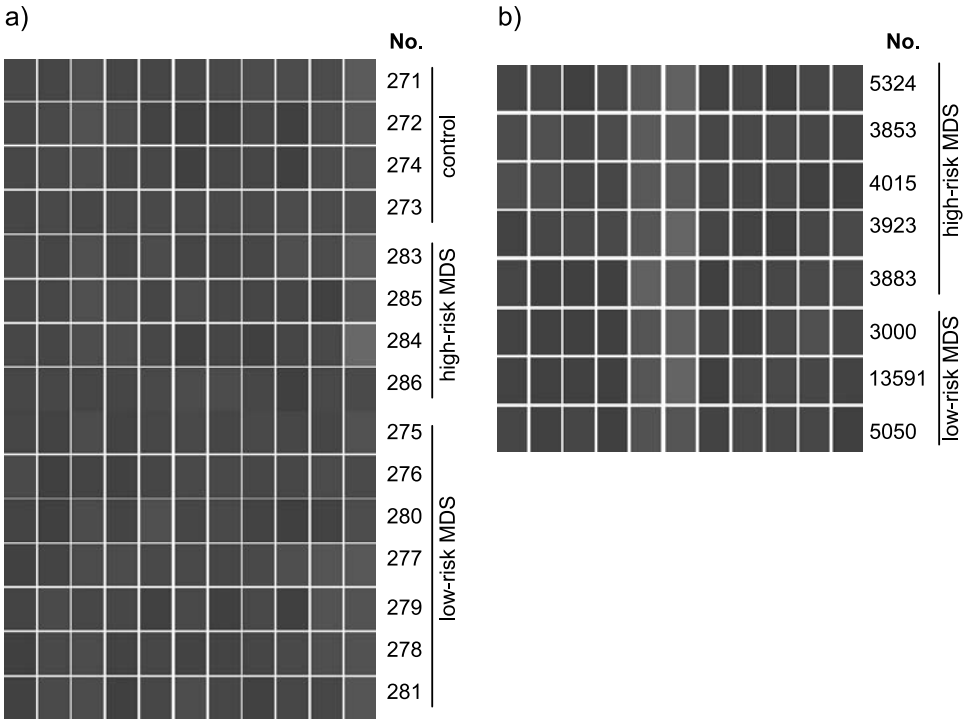

Fig. 2 Identification of genes expressed in $CD34^+$ marrow cells, which can distinguish between low-risk MDS, high-risk MDS, and healthy individuals. (From Ref. [9].) (a) Results represent the analysis by hierarchical clustering with Spearman's confidence correlation of 15 samples of $CD34^+$ bone marrow cells. Eleven genes were selected to predict the class membership of each of the samples. Vertical: Each of the samples. Horizontal: Each of the 11 predictive genes. (b) Validation of the 11 predictive genes used to distinguish between high-risk and low-risk MDS by gene expression profiling. The 11 predictive genes were used for clustering analysis in a second data set obtained from $CD34^+$ cells from patients with low-risk and high-risk MDS (test set). Two clusters corresponding to the IPSS classifications of ''high risk'' and ''low risk'' were found. No misclassification of any of the samples of the test set occurred, demonstrating the power of the selected genes for risk group prediction. No., sample number. Color code: blue, low expression; red, high expression. The intensity of the color reflects the reliability of the expression data. (*View this art in color at www.dekker.com.*)

To verify the power of the genes selected by class membership prediction, we used the 11 genes for hierarchical clustering with Spearman's confidence correlation (Fig. 2a). We generated three clusters. All of the controls (normal $CD34^+$ cells) were in one cluster (with a maximum of two subclusters). Furthermore, all of the high-risk MDS and low-risk MDS were separated in different clusters with a maximum of three subclusters.[9]

In a second experiment, we have used the 11 predictive genes to do clustering analysis in a independent data set obtained from $CD34^+$ cells from patients with low-risk and high-risk MDS (samples 3000–13591; Fig. 2b). The aim of this additional experiment was to evaluate the predictive power of the 11 selected genes in new series of patient samples. As shown in Fig. 2b, we found two clusters corresponding to the IPSS[11] classification ''high risk'' and ''low risk.'' No misclassification of any of the samples of the test set occurred, demonstrating the power of the selected genes for risk group prediction.

CONCLUSION

Microarray analysis can detect gene expression profiles that are strongly associated with different risk groups in MDS. Therefore we believe that the prognosis of this disease may be predicted by using gene expression analyses of purified $CD34^+$ cells. We have shown that microarray analysis can be used with small amounts of RNA, which can be obtained from cells during routine diagnostic bone marrow aspiration. This method may facilitate the making of therapeutic decisions in cases where the diagnosis and/or risk evaluation is not possible based on morphological and classical cytogenetic data. The results from a number of studies using $CD34^+$ cells as well as other cell types (e.g., granulocytes) from patients with MDS are pending. Furthermore, such analysis of global gene expression provides new insights into alterations of cellular pathways in early hematopoietic stem cells in MDS.

Myotonic Dystrophy

M

Josef Finsterer
Krankenanstalt Rudolfstiftung, Wien, Austria

INTRODUCTION

Myotonic dystrophy, also termed dystrophia myotonica (DM), is an autosomal dominant, progressive, multisystem, myotonic disorder, of which the key feature is delayed muscle relaxation (clinical myotonia) because of muscle fiber hyperexcitability from spontaneous or induced runs of repetitive muscle fiber action potentials (electrical myotonia).[1] DM is genetically heterogeneous and is subdivided into type-1 (DM1) and type-2 (DM2). Although there are aspects that differentiate DM1 and DM2, many features overlap, so that only molecular genetic investigations unambiguously distinguish them (Table 1).[2]

CLINICAL DESCRIPTION

DM1

Ninety percent of DM1 patients present at adulthood with delayed muscle maturation, distal muscle weakness, wasting, myotonia, cataracts, cardiac abnormalities, smooth muscle dysfunction, insulin resistance, daytime sleepiness, testicular atrophy (low reproductive fitness), ''difficult'' personality, neuropsychiatric disturbances, and frontal balding.[1] Ten percent of the patients present at infancy with hypotonia (floppy infant), oromotor dysfunction, tent-shaped mouth, feeding and respiratory insufficiency (diaphragmatic hypoplasia), arthrogryposis, and mental retardation in those who survive until adulthood (congenital DM).[1] All manifestations show a progressive course. Usually, creatine kinase is elevated. Muscle biopsy shows type 1 predominance, centrally located nuclei, severe fiber atrophy with nuclear clumps, hypertrophic and angulated fibers, and occasionally, necrotic fibers, fibrosis, or fat deposits. Cardiac involvement comprises conduction defects (mostly HV prolongation) and, less frequently, primary cardiomyopathy (wall thickening, hypertrabeculation, dyskinesia, and reduced myocardial tissue velocities). Cerebral MRI shows large Virchow–Robin spaces, white matter lesions, and atrophy. There may also be megacolon, megarectum, and delayed gastric emptying without dyspeptic symptoms. Some patients have hypo-IgG and, in some cases, thyrotropin deficiency. Phenotype severity and age at onset vary greatly between patients.

DM2

Although less severe, DM2 closely resembles adult-onset DM1 with common features, including progressive weakness, myotonia, cardiac arrhythmias, cataract, male hypogonadism, insulin insensitivity, and hypogammaglobulinemia.[2] The most frequent manifestations are muscle pain, muscle stiffness, myotonia, and weakness.[2] Muscle pain is frequently fluctuating or episodic. Weakness characteristically affects the neck flexors, elbow extensors, deep finger flexors, hip flexors, and hip extensors. Facial and ankle dorsiflexion weakness is uncommon. Mild muscle wasting occurs in -10% of the cases.[2] Creatine kinase is typically mildly elevated. Muscle biopsy shows similar features as in DM1, but preferentially type 2 fiber atrophy. Cataracts of the posterior, subcapsular, and iridescent type develop between age 30 and 50 years.[2] Cardiac manifestations comprise palpitations, intermittent tachycardia, and episodic syncope, which frequently increase with age. Frequent ECG abnormalities are atrioventricular or intraventricular block. Some patients develop fatal arrhythmias. Idiopathic cardiomyopathy is rare. Cerebral MRI may demonstrate atrophy but less severe than in DM1. γ-Glutamyltransferase may be elevated.

MOLECULAR GENETICS

DM1

DM1 is caused by an unstable CTG expansion in the 3′ untranslated region of the dystrophia myotonica protein kinase (*DMPK*) gene on chromosome 19q13.3 (Table 1).[1] Affected subjects are usually heterozygous for the expansion. Only six homozygous subjects have been reported.[2] In affected subjects the repeat length varies between 50 and 5000. Alleles with 50–80 repeats are

DOI: 10.1081/E-EDGP 120025801

Table 1 Genetic differences/similarities between DM1/DM2

Genetic aspects	DM1	DM2
Transmission	Autosomal dominant[a]	Autosomal dominant[a]
Gene locus	19q13.3	3q21.3
Mutated gene	*DMPK*	*ZNF9*
Gene product	Protein kinase	Zinc finger protein 9
Function	Signal propagation[b]	RNA-binding protein[b]
Type of mutation	CTG expansion	CCTG expansion
Number of expanded repeats	50–5000	75–11000
Localization of mutation	3′ Untranslated region	Intron-1
Gene dosage	Hetero/homozygous	Homozygous
Somatic cell heterogeneity	+	++
Congenital cases	+	−
Intergenerational repeat-size variation	+	++
Anticipation	+	−
Reversions in offsprings	+	++
Increase of repeat size with age	+	+
Transcribed into RNA	+	+
Translated	−	−
Intranuclear RNA-foci	+	+
Premutation differences mother/offspring	+	Unknown
Premutation differences father/offspring	+	Unknown

[a]Disease despite normal allele.
[b]Assumed.

classified as protomutation with a mild or asymptomatic phenotype.[3] Alleles between 38 and 49 repeats, designated as premutation, do not manifest clinically, but may expand to the full mutation range in subsequent generations. In the normal population the repeat length ranges between 4 and 37. The normal allele is usually stable upon transmission. Occasionally mutations occur, causing a transition from a large normal allele to a small, expanded allele (transition mutation). One factor that prevents DM1 from dying out is segregation distortion (alleles with 19–37 repeats are preferentially transmitted to offsprings than alleles with 4–18 repeats). The expanded *DMPK* allele is transcribed but not translated. It produces RNA transcripts containing long tracts of CUG repeats, but no dysfunctional protein. Mutant mRNA is not exported to the cytoplasm but retained within multiple nuclear foci. The amount of *DMPK* in the cytoplasm is presumably reduced, as it can be translated only from the normal allele (haploinsufficiency).

A hallmark of the CTG expansion is its high intra-individual, interindividual and intergenerational variability in somatic and germline cells. Expansion instability is thought to arise from its capacity to form long hairpin loops during replication, leading to folded structures, and the involvement of various DNA-repair mechanisms. Several models try to explain how an encounter between folded structures and the replication apparatus leads to expansion, including the following: Rad52 and Rad54, involved in DNA strand break repair (homologous recombination), strongly destabilize long CTG repeats, enabling expansion. Msh2 (major component of the mismatch repair system) stabilizes anomalous slipped strand or loop end structures thereby promoting incorporation of further repeats.[4] DNA Pkcs is involved in nonhomologous end joining.[4] So far, however, it remains unknown how these mechanisms affect repeat instability.[4] Once in the disease-associated range, the expansion size progressively increases in subsequent generations (anticipation), although reversion back to a normal size may also occur (retraction). The CTG expansion continues to expand throughout life, causing age-dependent somatic mosaicism. During embryogenesis the CTG expansion remains fairly equal in various tissues, but postnatally marked variability emerges in different tissues. CTG expansions appear to continue to increase even in non-dividing cells. The repeat instability is tissue specific, with muscle cells and myocardiocytes containing larger expansions than blood leukocytes. Premutation alleles are generally more stable during transmission through the female than the male germline.[3] Small protomutations are very unstable in the male germline and highly biased toward expansion.[3] Congenital DM patients have CTG expansions >1000 and inherit the disease almost invariably from their mother, reflecting a sex difference in the dynamics of the repeat instability during gametogenesis. Rarely, fathers transmit congenital DM1. When the repeat

size varies between sibs, differences tend to be greater when the affected parent is the father.

Immunohistological investigations localize *DMPK*, an 80-kDa protein kinase, most highly expressed in the skeletal muscle and heart, to the neuromuscular junction, terminal cisternae of the sarcoplasmic reticulum, and gap junctions. *DMPK* consists of a leucine-rich repeat, a catalytic domain, an α-helical coil-coiled region, and a transmembrane-spanning tail.[5] The *DMPK* function is not yet fully understood.[6] *DMPK* has been implicated in modulating calcium homeostasis and initial events concerning excitation–contraction coupling and was associated with the heat shock protein myotonic dystrophy protein kinase-binding protein.[6] Additionally, the specific regulation of *DMPK* expression and activity during myocyte differentiation suggests a functional implication of *DMPK* in the generation or maintenance of myotubes.[6] *DMPK* is reduced in the DM1 muscle.

Mechanisms to explain the deleterious effect of mutant *DMPK* are the following:

1. Chromatin conformation alteration in the vicinity of the *DMPK* gene, resulting in partial suppression of neighboring genes, like the dystrophia myotonica-associated homeobox protein (DMAHP or SIX5) or immunodominant peptide N59. Suppression of DMAHP may contribute to the development of cataracts.[7]
2. Haploinsufficiency, resulting in shortage of the functionally available enzyme.
3. Altered cellular *DMPK* location.
4. Disturbed distribution and transport of the expanded mRNA transcripts.
5. Toxic effect of mutant mRNAs by sequestering essential RNA-CUG-binding proteins.There is evidence that rather a gain of function for RNA than haploinsufficiency plays the prominent pathogenetic role.[7] Gain of function involves a transdominant effect (both alleles are poorly processed) on RNA-CUG-binding proteins, such as CUG-binding protein 1 (CUGBP1), elav-like RNA-binding protein 3 (ETR3), muscleblind proteins (MBNL, MBLL, and MBXL), and PKR.[7] Gain of function is substantiated by recruitment of muscleblind proteins into ribonuclear inclusions in fibroblasts and muscle cells from DM1 and DM2 patients, which clearly interact with expanded CUG repeats. mRNA accumulation presumably skews alternative splicing also of unrelated specific pre-RNAs,[8] because RNA CUG induces reiteration of and reversion to embryonic splicing patterns, mediated by CELF proteins. CUGBP1 does not extensively bind expanded CUG repeats in vitro, although some studies detected CUGBP1 within ribonuclear inclusions.

Targets of abnormal splicing are mRNAs for:

1. The insulin receptor. Insulin resistance may be due to missplicing of exon 11 skipping isoform pre-mRNA.
2. Cardiac troponine-T. Splicing regulation of troponine transcripts is abnormal.
3. Tau protein. Altered stoichiometry of the exon 2 skipping tau protein isoform could explain behavioral and cognitive alterations.
4. Myotubularin-1. Muscle-specific isoform is reduced and an abnormal transcript appears in differentiated DM1 myocytes.
5. Muscle-specific chloride channel ClC-1. Loss of ClC-1 mRNA and protein after inappropriate regulation of ClC-1 alternative splicing because of CUGBP-1 overactivity results in hyperexcitability as a result of reduced transmembrane chloride conduction.[7]
6. MyoD. This transcription factor, required for the differentiation of myoblasts during muscle regeneration, by activating differentiation-specific genes via binding E-boxes, is reduced in cells containing mutant *DMPK* transcripts.[8] All these findings suggest abnormal regulation of alternative splicing to be fundamentally involved in the pathogenesis of DM1. There is also evidence for a delay in muscle maturation, possibly because of a retarded rate of myoblast fusion to multinucleated myotubes.[6]

DM2

DM2 is caused by an unstable CCTG expansion in intron-1 of the *ZNF9* gene.[9] Allele expansions range from 75 to 11,000 repeats (mean 5000; (Table 1). Because the CCTG repeat is too large to amplify by PCR, all expansion-positive individuals appear to be homozygous and are thus indistinguishable from unaffected truly homozygous controls. Family studies may distinguish true homozygotes from expansion carriers. Failure of the expanded allele to amplify, also referred to as ''blank allele,'' suggests a non-Mendelian inheritance pattern and provides evidence that a family carries a DM2 expansion or that paternity was misinterpreted.[2] Expansion sizes in the blood of affected children are usually shorter than in their parents. Most affected American families can trace an affected ancestor to Germany or Poland and all are of European descent.[2]

ZNF9, also referred to as cellular nucleic acid-binding protein, contains 7 zinc-finger domains and is thought to be an RNA-binding protein. It is broadly expressed, with the highest expression in heart and skeletal muscle. Mutant *ZNF9* RNA accumulates in numerous nuclear foci, similar to those in DM1, but with lower stability of the probe–target complex. Whether nuclear RNA foci contain the entire unprocessed *ZNF9* transcript is unknown. As in

DM1, intranuclear foci bind specific RNA-binding proteins, leading to altered splicing of the insulin receptor and CLC1.[2]

MOLECULAR GENETIC TESTING

DM1

Small expansions are determined by standard PCR. Large expansions are refractory to PCR and are traditionally identified by Southern blotting by hybridization of restriction-digested genomic DNA. For Southern blotting, genomic DNA is digested with *Eco*R1 and then separated according to size by agarose gel electrophoresis. After denaturation and neutralization, DNA fragments are transferred onto a membrane, which is then randomly probed with ^{32}P-labelled cDNA25. Blots are then washed and exposed at -80°C for 5–10 days.

DM2

In a first step, PCR amplification is performed across the CCTG repeat.[9] For genomic Southern analysis, DNA is digested with *Bso*B1 or *Eco*R1.[2] Because of the size and somatic instability of the CCTG repeat, Southern analysis fails to detect expansions in 20% of the known carriers.[2] Expanded alleles appear as single discrete bands, multiple bands, or smears. Contrary to other expansion disorders, *ZNF9* expansions are almost always less intense than normal alleles.[2] To improve detection of CCTG repeat expansions, a repeat assay has been developed, amplifying the region containing the CCTG expansion by use of the primers CL3N58-D R (5′-GGCCTTATAACCATG-CAAATG-3′), JJP4CAGG (5′-TACGCATCCGAGTTT-GAGACGCAGGCAGGCAGGCAGGCA-GG-5′), and JJP3 (5′-TACGCATCCGAGTTTGAGACG-3′) followed by Southern analysis of the PCR products probed with an internal probe. By using a PCR primer that primes from multiple sites within the CCTG repeat, expansions are detected by the presence of a smear of products with a molecular weight higher than in control lanes.[2] To ensure specificity, repeat assay PCR products are transferred to a nylon membrane and probed with an internal oligonucleotide probe.[2] The repeat assay cannot be used to determine the CCTG repeat length.

GENOTYPE–PHENOTYPE CORRELATION

DM1

Conflicting results indicate a generally poor genotype–phenotype correlation.[3] Only disease severity and age at onset correlate positively with the CTG expansion size.[1] At least in patients with CTG expansions > 1000, the risk of intraventricular conduction delay increases with increasing expansion size. Various other measures of disease severity correlate positively with the CTG repeat size in leukocytes, although the range of disease severity associated with a particular repeat size is broad.

DM2

Because of the somatic instability of the expansion (-9000 repeats in the blood of a single patient), a final assessment of phenotype–genotype correlations is not possible. At least the CCTG expansion size increases with age and age at onset.[2]

PREVALENCE

DM1

DM1 is one of the most common inherited neuromuscular disorders with a worldwide prevalence of 2.1–14.3 per 100,000.[1] The prevalence is unexplainably increased in isolates in Canada (Saguenay—Lac-Saint-Jean region, prevalence: 189 per 100,000), Sweden, and Iceland. The worldwide incidence of DM1 is 1:8000.

DM2

By pooling the data of all publications since 1994, approximately 500 DM2-patients have been identified. Although the exact incidence and prevalence is unclear, it is considered to be similar to DM1, based on the clinical similarity between DM1/DM2. The incidence of DM2 is estimated to be 1:20000. DM2 is equally frequent in both genders.

DIFFERENTIAL DIAGNOSES

Differential diagnoses that have to be considered before diagnosing DM are other myotonic syndromes, facioscapulohumeral muscular dystrophy, oculopharyngeal muscular dystrophy, limb-girdle muscular dystrophy, congenital muscular dystrophy, distal muscular dystrophy, hereditary inclusion body myositis, congenital myopathy, endocrine myopathy, motor neuron disease, and mitochondrial encephalomyopathy.

MANAGEMENT

So far, there is no causal treatment. Physiotherapy is recommended as soon as weakness or myotonia occurs. Orthoses may be helpful to stabilize knees or ankles. Treatment with nonsteroidal antiinflammatory drugs, carbamazepine, or corticosteroids ameliorates muscle pain in single DM1 patients. If myotonia predominates in DM1, mexiletine, phenytoin, or carbamazepine may be beneficial, but no data supporting its effectiveness in DM2 are available. For muscle cramps, quinine sulfate may be tried. However, if cardiac conduction defects are present, antiarrhythmic medication should be avoided. Modafinil reduces daytime sleepiness and improves mood in DM1 patients. Testosterone or growth hormone increases muscle mass but fails to improve muscle strength. As soon as the diagnosis is established, patients should undergo cardiological examinations. Reinvestigation is indicated if baseline investigations are highly abnormal or if patients become cardiologically symptomatic. At least an ECG should be recorded annually. In case of arrhythmias, appropriate therapy is essential. Patients should be regularly evaluated for thyroid dysfunction. If indicated, hormone replacement therapy should be initiated. Diabetes requires adequate therapy. Cataracts may require surgical treatment at some point. Noninvasive ventilatory support is effective in nocturnal hypoventilation. Because single DM1 patients experience respiratory depression in response to benzodiazepines, opiates, or barbiturates, aggravation of myotonia by depolarizing muscle relaxants or malignant hyperthermia-like manifestations during anesthesia, general anesthesia should be carried out with caution and the postoperative period needs careful attendance. In DM1 patients, survival to higher ages is markedly reduced. In DM2, progression is slow, and prognosis and life expectancy are more favorable than in DM1. Life expectancy may be reduced only in single cases, mainly if there are malignant rhythm abnormalities.

GENETIC COUNSELING

DM1

Genetic counseling of an affected proband or an asymptomatic mutation carrier aims to clarify their genetic status and relies on the family history and genetic testing. In case of an affected proband it is essential to investigate the parents, sibs, and offsprings of the proband. Offsprings of a DM1 patient carry a 50% chance of inheriting the mutant allele. The chance of a female DM1 patient of having an affected child increases with the severity of the maternal phenotype. A mother who has had a previous child with congenital DM has 20–40% risk to have another affected child. Before prediction testing of an at-risk asymptomatic adult is carried out, an affected family member should be tested. Asymptomatic children at risk for adult-onset DM1 should not be tested. In counseling a person with DM1 it is prudent to mention the small possibility of transmitting congenital DM. Genetic counseling is generally hampered by the high instability of the CTG expansion and the poor genotype–phenotype correlation.

DM2

Generally, genetic counseling is complicated by the highly unstable CCTG expansion and the uncertain genotype–phenotype correlation. CTG expansions in the blood of affected children are usually shorter than in their parents.[9] Males have a minor probability than females to transmit the mutation to their offspring. If DM1 is suspected, probands should undergo genetic testing as the golden standard of diagnosing this condition. DNA analysis is also applicable in prenatal testing. However, if abortion is not desired, prenatal testing should not be performed.

CONCLUSION

DM is genetically heterogeneous and comprises at least two disorders (DM1 and DM2). DM1 and DM2 are clinically similar, progressive multisystem, myotonic disorders due to a CTG repeat expansion in the *DMPK* gene (DM1) or to a CCTG repeat expansion in the *ZNF9* gene (DM2). Both expansions show high somatic, interindividual, and intergenerational instability and uncertain genotype–phenotype correlation. Both expansions are transcribed but not translated. Transcripts of the mutant alleles, harboring large CUG and CCUG expansions, are retained within nuclear foci. Suggested pathomechanism is considered to be a transdominant effect on the function of RNA-binding proteins, rather than haploinsufficiency. CUG-binding proteins regulate alternative splicing of proteins such as troponine-T, insulin receptor, ClC-1, myotubularin-1, tau protein, myo-D, and presumably various other mRNAs. Genetic counseling is hampered by the high expansion variability. Therapy of DM1 and DM2 is symptomatic. Preliminary results show that ribozyme-mediated cleavage of mutant *DMPK* mRNA reduces nuclear foci and partially restores function of the insulin receptor.[10] Other promising therapeutic concepts rely on the delivery of antisense RNA, which is capable of inhibiting mutant *DMPK* transcripts. Paralleles between the *ZNF9* gene mutation and the *DMPK* gene mutation indicate that RNA microsatellite expansions in a noncoding portion of a gene,

transcribed but untranslated, are pathogenic and cause multisystem disease.

Nanotechnology-Based Lab-on-a-Chip Devices

N

K. K. Jain
Jain PharmaBiotech, Basel, Switzerland

INTRODUCTION

Scientists and engineers have borrowed miniaturization, integration, and parallel-processing techniques from the computer industry to develop laboratory devices and procedures that fit on a wafer or microchip. Biochip is a broad term indicating the use of microchip technology in molecular biology and can be defined as arrays of selected biomolecules immobilized on a surface. A microarray is a collection of miniaturized test sites arranged on a surface that permits many tests to be performed simultaneously, or in parallel, in order to achieve higher throughput. The sample spot sizes in microarray are usually less than 200 μm in diameter. The trend to miniaturization continued with the introduction of microfluidic technology. To meet the increasing needs, the density and information content of the microarrays is being improved. One approach is fabrication of chips with smaller, more closely packed features—ultra-high-density arrays, which will yield:

- High information content by reduction of feature size from 200 to 50 nm.
- Reduction in sample size.
- Improved assay sensitivity.

NANOTECHNOLOGY

The process of miniaturization in biochip technology has been revolutionized by the introduction of nanotechnology—a term used for the creation and utilization of materials, devices, and systems through the control of matter on the nanometer-length scale, i.e., at the level of atoms, molecules, and supramolecular structures. The term is applied for the construction and utilization of functional structures with at least one characteristic dimension measured in nanometers (a nanometer is one billionth of a meter (10^{-9} m). Nanotechnology is applied for healthcare when it is referred to as nanobiotechnology. The topic is discussed in more detail elsewhere.[1] Nanobiotechnology has also been applied to molecular diagnostics and referred to as nanodiagnostics.[2] The assigned title of the article ''lab-on-a-chip'' indicates focus on nanofluidics. However, several nanotechnologies shown in Table 1 are used for molecular diagnostics and some of these can be applied in the form of nanochips.

Microarrays and Nanoarrays

Nanoarrays are the next stage in the evolution of miniaturization of microarrays. Whereas microarrays are prepared by robotic spotting or optical lithography, limiting the smallest size to several microns, nanoarrays require further developments in lithography strategies used in nanotechnology and include the following:

- Electron beam lithography.
- Dip-pen nanolithography (DPN).
- Scanning probe lithography.
- Finely focused ion beam lithography.
- Nanoimprint lithography.

Protein Nanoarrays

High-throughput protein arrays allow the miniaturized and parallel analysis of large numbers of diagnostic markers in complex samples. This capability can be enhanced by nanotechnology. Dip-pen nanolithography technique has been extended to protein arrays with features as small as 45 nm, and immunoproteins as well as enzymes can be deposited. Selective binding of antibodies to protein nanoarrays can be detected without the use of labels by monitoring small (5–15 nm) topographical height increases in atomic force microscopy (AFM) images.

Protein Nanoarrays (BioForce Nanosciences, Ames, IA, USA) contain up to 25 million spots per square centimeter. They can be used to detect protein–protein interactions. BioForce's NanoReader uses a customized AFM to decipher molecules on a NanoArray chip. The company was awarded a grant in 2002 by the U.S. Department of Defense for breast cancer research titled, ''Protein Nanoarrays for Studying Malignant Progression in Breast Cancer Cell Lines.'' The project constructed a nanoscale protein array platform and used it as a basic research tool to study alterations in cellular signaling pathways that accompany breast cancer disease progression.

Microfluidics and Nanofluidics

Microfluidics is the handling and dealing with small quantities (e.g., microliters, nanoliters, or even picoliters) of fluids flowing in channels the size of a human hair (approx. 50 μm thick) or even narrower. Fluids in this environment show very different properties than in the macro world. This new field of technology was enabled by advances in microfabrication—the etching of silicon to create very small features. Microfluidics is one of the most important innovations of biochip technology. Typical dimensions of microfluidic chips are 1–50 cm^2 and have channels 5–100 μm. Usual volumes are 0.01–10 μL but can be less. Microfluidics is the link between microarrays and nanoarrays as we reduce the dimensions and volumes.

Microfluidics is the underlying principle of lab-on-a-chip devices, which carry out complex analyses, while reducing sample and chemical consumption, decreasing waste and improving precision and efficiency. The idea is to be able to squirt a very small sample into the chip, push a button and the chip will do all the work, delivering a report at the end. Microfluidics allows the reduction in size with a corresponding increase in the throughput of handling, processing, and analyzing the sample. Other advantages of microfluidics include increased reaction rates, enhanced detection sensitivity, and control of adverse events.

Drawbacks and limitations of microfluidics and designing of microfluidic chips include the following:

- Difficulties in microfluidic connections.
- Because of laminar flows, mixing can only be performed by diffusion.
- Large capillary forces.
- Clogging.
- Possible evaporation and drying up of the sample.

Applications of microfluidics include the following:

- DNA analysis.
- Protein analysis.
- Gene expression and differential display analysis.
- Biochemical analysis.

NANOTECHNOLOGY-BASED LAB-ON-A-CHIP

Nanotechnology on a chip is a new paradigm for total chemical analysis systems. The ability to make chemical and biological information much cheaper and easier to obtain is expected to fundamentally change healthcare, food safety, and law enforcement. Lab-on-a-chip technology involves micrototal analysis systems that are distinguished from simple sensors because they conduct a complete analysis; a raw mixture of chemicals goes in and an answer comes out. Sandia National Laboratories (Albuquerque, NM, USA) is developing a handheld lab-on-a-chip that will analyze for airborne chemical warfare agents and liquid-based explosives agents. This development project brings together an interdisciplinary team with areas of expertise including microfabrication, chemical sensing, microfluidics, and bioinformatics. Although nanotechnology plays an important role in current efforts, miniaturized versions of conventional

architecture and components such as valves, pipes, pumps, separation columns are patterned after their macroscopic counterparts. Nanotechnology will provide the ability to build materials with switchable molecular functions which could provide completely new approaches to valves, pumps, chemical separations, and detection. For example, fluid streams could be directed by controlling surface energy without the need for a predetermined architecture of physical channels. Switchable molecular membranes and the like could replace mechanical valves. By eliminating the need for complex fluidic networks and microscale components used in current approaches, a fundamentally new approach will allow greater function in much smaller, lower-power total chemical analysis systems.

A new scheme for the detection of molecular interactions based on optical readout of nanoparticle labels has been developed. Capture DNA probes were arrayed on a glass chip and incubated with nanoparticle-labeled target DNA probes, containing a complementary sequence. Binding events were monitored by optical means, using reflected and transmitted light for the detection of surface-bound nanoparticles. Control experiments exclude significant influence of nonspecific binding on the observed contrast. Scanning force microscopy revealed the distribution of nanoparticles on the chip surface.[3]

BioForce Nanosciences has taken the technology of the microarray to the next level by creating the ''nanoarray,'' an ultraminiaturized version of the traditional microarray that can actually measure interactions between individual molecules down to resolutions of as little as 1 nm. Here 400 nanoarray spots can be placed in the same area as a traditional microarray spot. Nanoarrays are the next evolutionary step in the miniaturization of bioaffinity tests for proteins, nucleic acids, and receptor–ligand pairs. On a BioForce NanoArrayT, as many as 1500 different samples can be queried in the same area now needed for just one domain on a traditional microarray.

Microfluidic Chips for Nanoliter Volumes

Nanoliter implies extreme reduction in quantity of fluid analyte in a microchip. The use of the word ''nano'' in nanoliter (nL) is in a different dimension than in nanoparticle, which is in nanometer (nm) scale. Diagnostic companies with ''nano'' in their name may have other technologies. For example, Nanolytics Inc. with lab-on-chip based on nanoliter microfluidics and Nanogen with NanoChip based on microelectronics.

Chemical compounds within individual nanoliter droplets of glycerol were microarrayed on to glass slides at 400 spots/cm^2 in another technique.[4] Using aerosol deposition, subsequent reagents and water were metered into each reaction center to rapidly assemble diverse multicomponent reactions without cross contamination or the need for surface linkage. This proteomics technique allowed the kinetic profiling of protease mixtures, protease–substrate interactions, and high-throughput screening reactions. From one printing run that consumes <1 nmol of each compound, large combinatorial libraries can be subjected to numerous separation-free homogeneous assays at volumes 103–104 smaller than current high-throughput methods. The rapid assembly of thousands of nanoliter reactions per slide using a small biological sample (2 mL) represents a new functional proteomics format implemented with standard microarraying and spot-analysis tools.

NanoChip

NanoChip (Nanogen, Inc., San Diego, CA, USA) is a microelectronic chip format suitable for rapid single nucleotide polymorphism (SNP) analysis and genetic dissection of complex phenotypes. In beta testing, the NanoChip system has been shown to provide accuracy equal to or better than DNA sequencing and other methods for SNP confirmation. Unlike other systems, the NanoChip system uses electronically accelerated hybridization under very low-salt conditions, potentially avoiding problems with DNA conformation and secondary structures, whereas most sequencing and primer extension technologies require high-salt conditions. The NanoChip system allows the user to array and analyze DNA on its NanoChip cartridges in user-selected formats in a single day with walkaway automation. The NanoChip system integrates advanced microelectronics and molecular biology into a platform technology with broad commercial applications in the fields of biomedical research, genomics, medical diagnostics, genetic testing, and drug discovery.

NanoPro™ System

The NanoPro™ System (BioForce Nanosciences, Inc.) consists of three separate components:

1. The NanoArrayer™ embodies proprietary instrumentation and methods for creating a broad spectrum of NanoArray™-based biological tests. This device places molecules at defined locations on a surface with nanometer spatial resolution. The arrays of molecules (NanoArrays™, see below) are unique to BioForce and can only be created with a NanoArrayer™.
2. NanoArrays™ are ultraminiaturized biological tests with applications in many areas. The company's first NanoArray™ products are presently being evaluated for commercial utilization by potential users and are

targeted toward the proteomics/genomics and diagnostics markets. These products include a custom nucleic acid NanoArray™ for RNA expression profiling as well as virus detection NanoArray™ called the ViriChip™. NanoArray™ chips are for protein expression profiling and immunodiagnostics.
3. The NanoReader™ is a customized AFM optimized for reading NanoArray™ chips. Using the AFM as a readout method optimizes analysis, including no requirement for secondary reporter systems (no fluorescence, radioactivity, or enzyme-linked detection), reductions in materials used (several thousand molecules per test), and increased sensitivity (ultimately single molecule detection).

Use of Nanotechnology in Microfluidics

Techniques such as nanoimprinting are used to construct large arrays of nanoscale grooves with efficiency and speed. Now such grooves can be sealed with similar ease to form nanofluidic channels. Laser-assisted direct imprint technique has been described by scientists at Princeton University that allows the construction of millions of enclosed nanofluidic channels side by side on a single substrate, which is ideal for such parallel processing.[5] By sputter-depositing silicon dioxide at an angle onto an array of prefabricated nanochannels imprinted into the surface of a biopolymer substrate, not only is an effective and uniform seal formed over the entire array, but the channels are further narrowed down to 10 nm, from an initial width of 55 nm. The authors point out that this process could be easily used for narrowing and sealing micro- and nanofluidic structures formed by other patterning techniques. By minimizing the hollow space in such structures, it could help surpass existing limitations in the spatial resolution of these techniques.

A chip-scale maze for combing out strands of DNA and inserting them into nanoscale channels was made using standard, inexpensive lithographic techniques.[6] Their ''gradient nanostructure'' might be used to isolate and stretch DNA molecules for analysis, e.g., to look for bound proteins such as transcription factors along the strand. Such molecules would be obscured in normal solution because DNA, like any other linear polymer, collapses into a random coil as a featureless blob. The strands can, in principle, be straightened by feeding them into channels just a few tens of nanometers wide, using nanofluidic techniques.

Researchers from Oak Ridge National Laboratory (Oak Ridge, TN) have found a way to fabricate flexible tubes whose diameters are 100 nm, i.e., 10 times narrower than those used in today's microfluidic systems.[7] The tubes could be used to make stacked, interconnected fluidic networks designed to shunt fluids around biochips that sense and analyze chemicals. The researchers discovered the method when they noticed that depositing a certain type of polymer into tiny silicon grooves caused the polymer at the tops of the grooves to close across the gaps, forming tubes. They realized the process could be used to make tiny networks of tubes for use in microfluidics. The method is also compatible with conventional processes for making chips and can be used to integrate the networks with electronic chip components.

Nanoparticle Protein Chip

At the Fraunhofer Institute for Interfacial Engineering and Biotechnology IGB (Stuttgart, Germany), a new type of protein chip is being developed based on protein-binding silica-nanoparticles. The surface of this minute particle with a diameter of less than one ten-thousandth of a millimeter can be configured with many different capture proteins. The particles configured in this way are then applied to silicon carriers in thin, even layers. After contact is made with a sample, the chips can be analyzed using state-of-the-art mass spectrometry, MALDI-TOF mass spectrometry. Knowing the masses of the bound proteins provides a direct indication of their identity.

Biosensor Nanochips

Biosensors incorporate a biological sensing element that converts a change in an immediate environment to signals that can be processed. Nanotechnology-based biosensors have been reviewed elsewhere.[8] Nanomaterials are exquisitely sensitive chemical and biological sensors. As their surface properties are easily modified, nanowires can be decorated with virtually any potential chemical or biological molecular recognition unit, making the wires themselves analyte independent. The nanomaterials transduce the chemical binding event on their surface into a change in conductance of the nanowire in an extremely sensitive, real-time, and quantitative fashion. Boron-doped silicon nanowires (SiNWs) have been used to create highly sensitive, real-time, electrically based sensors for biological and chemical species.[9] The sensors can be electronically gated to respond to the binding of a single molecule. Prototype sensors have demonstrated detection of nucleic acids, proteins, and ions. These sensors can operate in the liquid or gas phase, opening up an enormous variety of downstream applications. The detection schemes use inexpensive low-voltage measurement schemes and detect binding events directly so there is no need for costly, complicated, and time-consuming labeling chemistries such as fluorescent dyes or the use of bulky and expensive optical detection systems. As a result, these sensors are inexpensive to manufacture and

portable. It may even be possible to develop implantable detection and monitoring devices as biochips based on these detectors.

CONCLUSION

It is now obvious that direct analysis of DNA and protein could dramatically improve speed, accuracy, and sensitivity over conventional molecular diagnostic methods. However, DNA, RNA, protein, and their functional subcellular scaffolds and compartments are in the nanometer scale, the potential of single molecule analysis approach would not be fully realized without the help of nanobiotechnology. Advances in nanotechnology are providing nanofabricated devices that are small, sensitive, and inexpensive enough to facilitate direct observation, manipulation, and analysis of a single biological molecule from a single cell. This opens new opportunities and provides powerful tools in fields such as genomics, proteomics, molecular diagnostics, and high-throughput screening. Given the inherent nanoscale of receptors, pores, and other functional components of living cells, the detailed monitoring and analysis of these components will be made possible by the development of a new class of nanoscale probes. The most important area of application will be in point-of-care diagnostics. Important indications will include cancer diagnosis and detection of infectious disease agents, particularly in bioterror attacks. Future trends in diagnostics will continue in the miniaturization of biochip technology to nano range. There is also a trend to build the diagnostic devices from bottom up starting with the smallest building blocks.

NEBcutter—A Program to Cleave DNA with Restriction Enzymes

Janos Posfai
R. J. Roberts
Tamas Vincze
New England Biolabs, Inc., Beverly, Massachusetts, U.S.A.

INTRODUCTION

NEBcutter is a computer program offering services to research laboratories that employ nucleic acid technologies. The software provides bioinformatics tools for experiments where DNA molecules are manipulated with restriction enzymes. Type II restriction enzymes recognize specific four- to eight-nucleotide-long patterns in DNA, and introduce cuts into the strands at predictable positions.[1,2] The specificity and precision of cleavage make these enzymes useful in a wide array of applications. Gene cloning, detection of point mutations, probing of repeat sequences, genome mapping, and characterization of genetic variations[3–5] are a few of these. The NEBcutter program supports such applications by providing routines for the systematic analysis of restriction site distributions within defined DNA sequences. The service is accessible over the web, through a link on http://www.neb.com.

The discovery of restriction enzymes and the accumulation of significant amounts of sequenced DNA prompted the development of the first restriction digest analysis computer programs.[6,7] Since then, hundreds of new restriction enzymes have been characterized. Today, the authoritative restriction enzyme database, REBASE,[8] lists over 3500 type II entries, with almost 250 different specificities. The amount of sequenced DNA has expanded equally rapidly. The GenBank[9] collection of DNA sequences now contains over 30 billion bases, including complete genome sequences of dozens of species (human, mouse, fruitfly, yeast, bacteria, and so on). Substantial changes in computer power and computing environments occurred during this time as well. Advanced algorithms,[10] network access, linked databases, and graphic presentations have become standard. In this new environment, NEBcutter provides tools for state-of-the-art restriction enzyme digest analysis.

METHODS

Analysis starts by specifying a target DNA sequence. Many popular vector and phage sequences (such as pBR322, lambda, T7, and so on) are directly accessible for processing. Alternatively, DNA sequences can be pasted into an entry form, or uploaded from local user files. Sequences of GenBank entries can also be loaded simply by specifying their accession numbers. The program distinguishes between linear and circular sequences, and handles them according to their topology. Occasional ambiguities in the input sequence are permitted; these are resolved by putting special marks on hits that are conditional on the specific sequence. Analyzing inputs with runs of N-s would be meaningless because the runs could be sites for any enzyme, and so such inputs should be avoided. Sizes of target sequences are currently limited to 300 kb.

The program determines the cut sites for a repertoire of restriction enzymes. This repertoire is selectable and may be New England Biolabs-marketed enzymes, all commercially available specificities or all specificities ever characterized. Users can add hypothetical enzymes with fictitious sites to the list manually. NEBcutter keeps its internal data structures up to date by connecting daily to REBASE and by fetching the latest information about restriction enzymes and specificities.

Results from a digest are presented in schematic figures, summary tables, and detailed textual pages. In the default setting, the site distribution of enzymes with single cuts is displayed (Fig. 1). One-click options can bring up the distributions of double or triple cutters. One can also switch to a display of custom digests with particular enzyme(s). Cut sites sensitive[11] to the mammalian CpG methylation, or to typical *E. coli* methylation are highlighted on the output. Color-coded symbols distinguish cuts with blunt ends from cuts with 5′ and 3′ extensions. The user can zoom on selected regions, all the way to the actual sequence. Circular sequences need to be linearized (with a single click) before engaging this zoom option.

In many applications, locations of gene flanking cut sites are of particular interest. To find them, NEBcutter places arrows on the output to indicate where the genes of the input sequence are, assuming that GenBank-style coordinate annotations are available. When the input is a plain, unannotated sequence, NEBcutter displays open reading frames (ORFs) according either to its own internal

DOI: 10.1081/E-EDGP 120030819

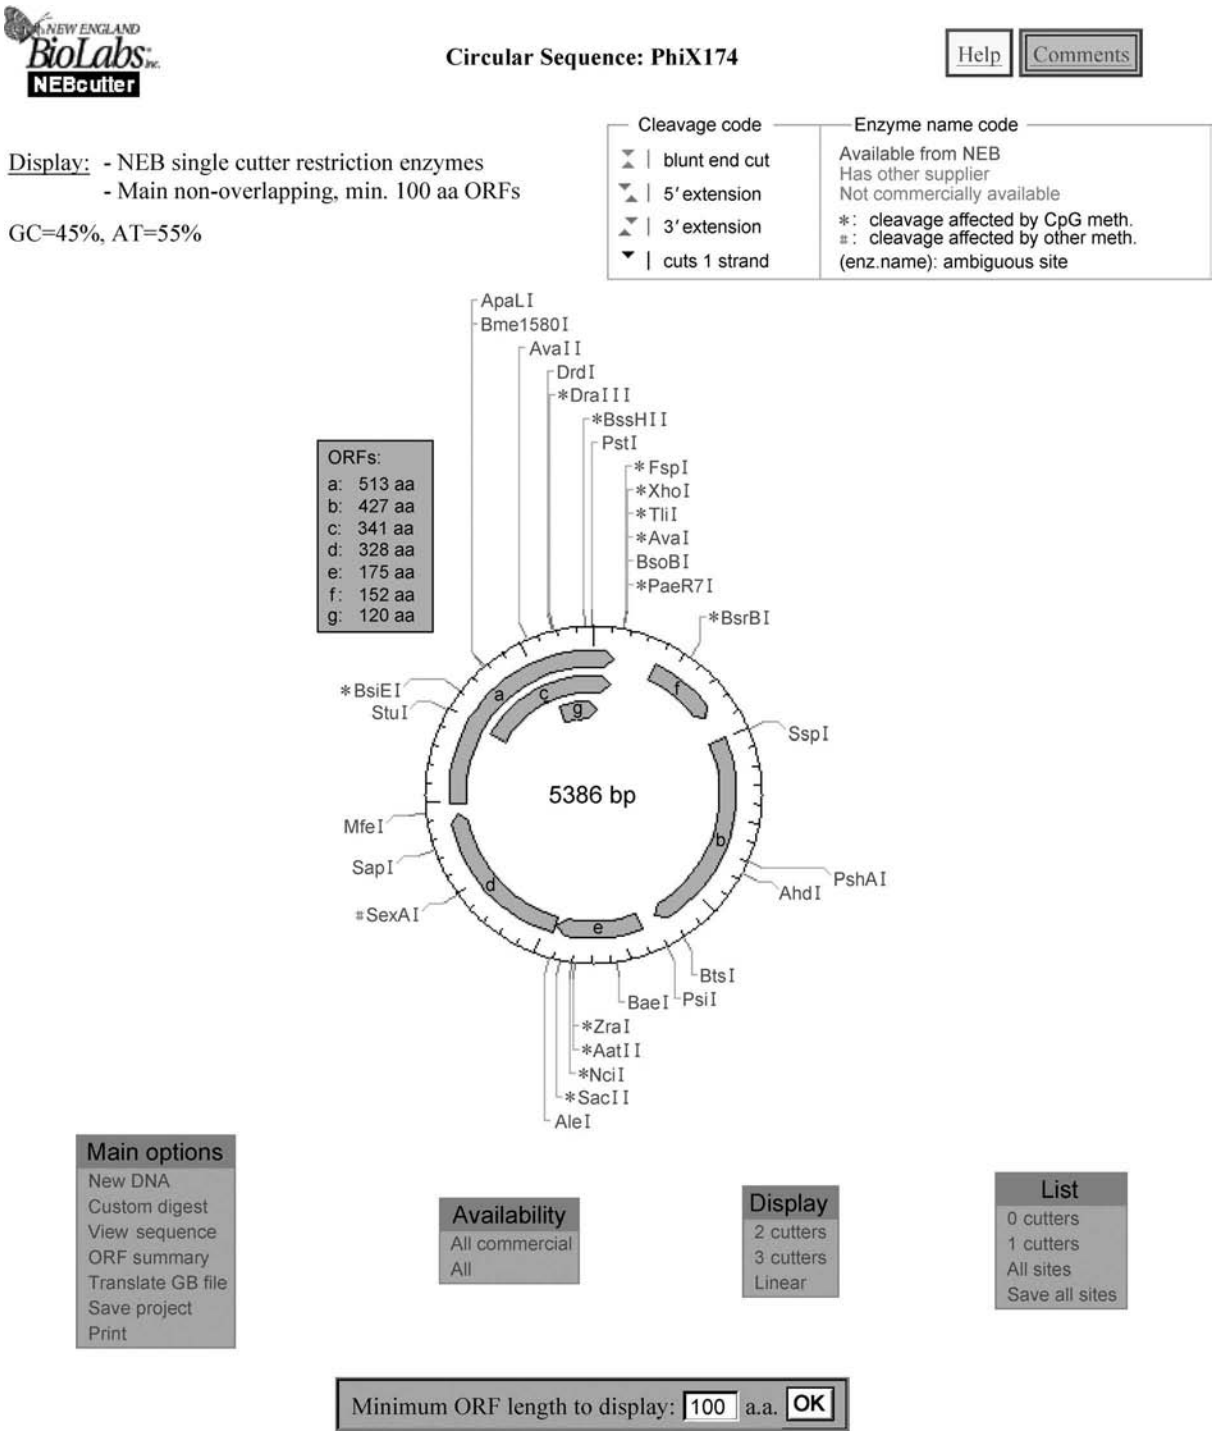

Fig. 1 Restriction digest analysis results for phage PhiX174. Sites for enzymes with single cuts in the circular 3.4-kb sequence are displayed. Methylation-sensitive sites are marked with symbols. Color coding distinguishes blunt end cuts from ones that create overhangs. Grey arrows indicate the genes. Menu options for further actions are available at the bottom of the web page. (*View this art in color at www.dekker.com.*)

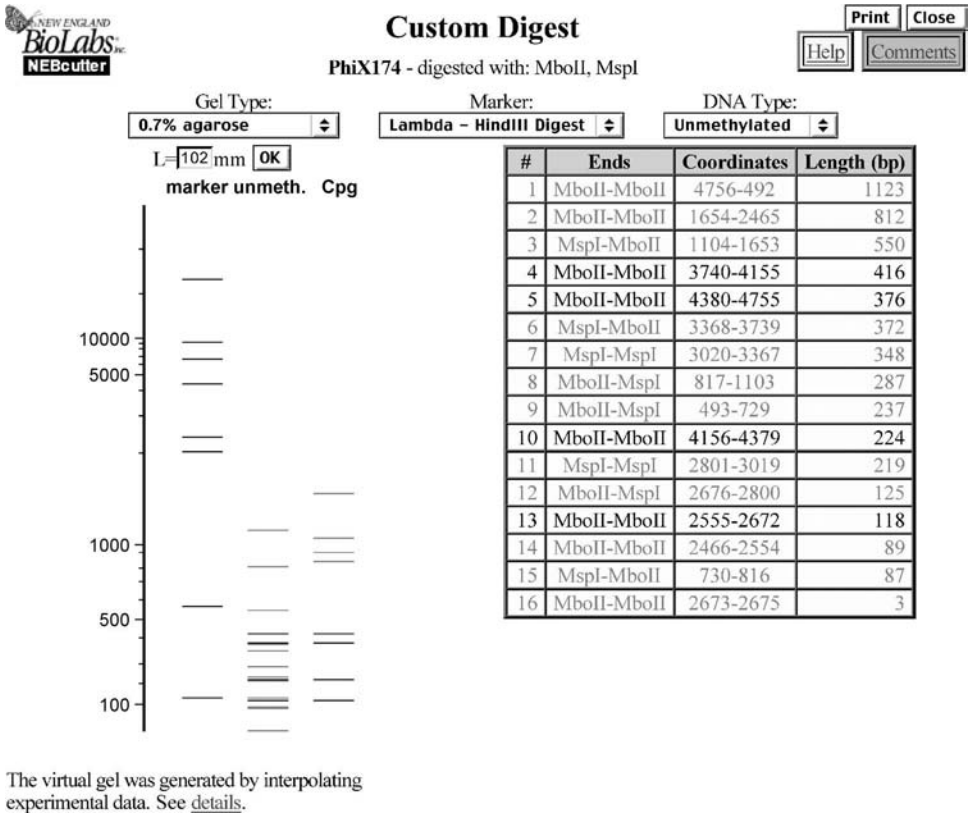
ORF finder routine, or to manually entered and edited data. Clicking on an arrow brings the represented ORF into focus. On this page, sites that flank the ORF are indicated. ORF-specific silent mutagenesis analysis can also be run. This module computes silent mutations that would turn previously noncutting enzymes into cutters.



#	Ends	Coordinates	Length (bp)
1	MboII-MboII	4756-492	1123
2	MboII-MboII	1654-2465	812
3	MspI-MboII	1104-1653	550
4	MboII-MboII	3740-4155	416
5	MboII-MboII	4380-4755	376
6	MspI-MboII	3368-3739	372
7	MspI-MspI	3020-3367	348
8	MboII-MspI	817-1103	287
9	MboII-MspI	493-729	237
10	MboII-MboII	4156-4379	224
11	MspI-MspI	2801-3019	219
12	MboII-MspI	2676-2800	125
13	MboII-MboII	2555-2672	118
14	MboII-MboII	2466-2554	89
15	MspI-MboII	730-816	87
16	MboII-MboII	2673-2675	3

Fig. 2 Virtual gel for the custom double digest of PhiX174 with the restriction enzymes *Mbo*II and *Msp*I. A lambda *Hin*dIII digest marker lane is included to scale the gel. Separate lanes simulate runs for unmethylated and CpG-methylated targets. Fragments are ordered in the table for the unmethylated DNA experiment. (*View this art in color at www.dekker.com.*)

From the results of calculated hypothetical digests, the program is able to simulate how the fragments would separate in various gel electrophoresis experiments (Fig. 2). A reference lane with selected marker fragments can be added to the view. Additional lanes will demonstrate the effects of possible DNA methylations.

With only a few clicks, NEBcutter will execute typical restriction digest analysis tasks. For more sophisticated tasks, sets of options are available. On-line context-specific help is accessible from every page. Pop-up windows show the basic information for every reported site. Direct links into REBASE are provided and detailed information about particular restriction enzymes is only a click away. Similarly, direct links connect to on-line enzyme ordering from New England Biolabs. Management tools enable users to save and later retrieve their own projects. User feedback is encouraged and facilitated via a built-in e-mail interface.

Software and Algorithms

The program runs on a Sun Ultraspark-II server, under SunOS 5.7 operating system. NEBcutter is a suite of cooperating routines, where program modules execute different tasks. Calculations and queue management are implemented in C (gcc version 2.96) modules. Calls to functions of the GD library perform the visualization tasks. User interfaces are HyperText Markup Language (HTML) pages, generated dynamically by PHP scripts and tested extensively for compatibility with Netscape and Microsoft Explorer browsers. Connections are open for these standard browsers via an Apache web server.

The program localizes all restriction sites in a single pass over the target sequence with a finite state automaton[12] algorithm. With this algorithm, execution time increases only in a linear fashion as the input sequence length increases. In the neighborhoods of sequence ambiguities, the program switches to a brute force algorithm.

When identifying ORFs, the program considers maximal length segments from start to stop, assuming standard codon assignment and bacterial (nonsplicing) DNA sequences. Overlapping ORFs are pruned by a heuristic algorithm, which favors longer ORFs over shorter ones.

Gel run simulations are based on mobility data from our own laboratory experiments, or from the gel manufacturer's manual (www.elchrom.com/technic/manuals/man007.asp).

Cubic spline curve interpolation[13,14] yields intervening data points.

Data Handling and Data Security

Suspended NEBcutter sessions can be resumed. Using the default settings, the program stores all project data (sequence, enzyme selection, display settings, and manual entry) on the server and deposits an associated session code on the user's computer. When the user later reconnects, these session codes are returned to the server, data from the user's earlier projects are retrieved, and results of those sessions are reconstructed. The identifier codes are randomly generated, unique numbers, and are stored in browser cookies. Each code is account-specific, so its use requires that the subsequent connection is made through the same log-in account. Another consequence is that people sharing an account also share each other's data. This data sharing can be avoided by using the ''delete project'' button on the main menu at the end of a session. Alternatively, users can block NEBcutter's save-and-resume feature by checking the appropriate menu option on the interface. Completely disabling a browser's use of cookies is another way of increasing data privacy.

The second method of saving and resuming NEBcutter sessions is activated through a menu option. With this option, project data are returned to the user and stored in a local data file, named by the user. To restart the project later, the user needs to upload this file. This second method is designed for reactivation of an analysis after an indefinite suspension of a session. The first method is intended for temporary interruption of a session. After 2 days of inactivity, server-stored session data files are deleted automatically.

By the time a session is reactivated, new restriction enzymes may have been added to the database, or the content of REBASE may have changed in other ways. Suspended sessions can still resume analysis with the original repertoire of enzymes, which makes the reconstruction of earlier results possible.

Concurrent users of NEBcutter do not notice each other, and they cannot access each other's data. For the purposes of troubleshooting, resource allocation, and optimization, NEBcutter administration routines monitor user activity, maintain log files, and compile usage statistics.

Graphics Output

NEBcutter gives users full access to the digest figures they create. The figures can be exported into graphic files in several standard formats. Resolution of the GIF raster format is selectable, and preview versions of vector graphics EPS format figures are adjustable. The graphic images are of high quality and are ready for inclusion in publications.

Supplementary Materials

Results from genomewide restriction enzyme digests have been precompiled and posted at http://www.neb.com/~posfai. For all prototype enzymes, site frequencies and densities, as well as average fragment lengths, appear here for mammalian, plant, and insect chromosomes, as well as for total genomic sequences. Site frequencies in one genome can be compared to site frequencies in other genomes, to frequencies predicted by first-order Markov models,[15] or to frequencies in randomized sequences. Both the Markov models and the randomized sequences are based on actual genome dinucleotide counts.

CONCLUSION

Restriction enzymes are invaluable tools of DNA engineering and analysis; they are used in many applications, both in research and in molecular diagnostic laboratories. The NEBcutter program provides tools for the design and interpretation of experiments that employ such enzymes. The software is freely available over the web, from the New England Biolabs web site. The program is aimed at the bench scientist, and has intuitive, easy-to-use interfaces. To assure that results are current, NEBcutter connects to REBASE directly, and updates its internal restriction enzyme data structures daily. An important and distinguishing feature of our software is its ability to consider the effects of base methylation—the potential interference with cleavage.

ACKNOWLEDGMENTS

Gel mobility data are from the experiments of Shawn Stickel at New England Biolabs.

Neisseria meningitidis

Martin J. Callaghan
Dominic F. Kelly
Andrew J. Pollard
University of Oxford, Oxford, U.K.

INTRODUCTION

Neisseria meningitidis is a gram-negative diplococcus and is a member of the family Neisseriaceae within the order Eubacteria. This family includes the genera *Neisseria*, *Moraxella*, *Kingella*, and *Acinetobacter*. The genus *Neisseria* includes two human pathogens, *Neisseria gonorrhoeae* and *Neisseria meningitidis* (the meningococcus). The meningococcus is enveloped by a polysaccharide capsule, which is essential for pathogenicity. Differences in the immunological reactivity of the capsule define 13 serogroups of which five (A, B, C, W135, and Y) are most commonly associated with invasive meningococcal disease.

EPIDEMIOLOGY

The epidemiology of *N. meningitidis* has been reviewed by Cartwright.[1] Humans are the sole natural host for the meningococcus, which is carried asymptomatically as part of the commensal nasopharyngeal microflora in approximately 10% of the general population. The meningococcus may occasionally cause invasive disease by traversing the nasopharyngeal mucosa into the bloodstream, where it multiplies rapidly. Although invasive behavior is poorly understood and unpredictable in the individual, it appears to be related to pathogen characteristics (e.g., serogroup, clonal lineage), host factors (e.g., age, smoking, immunological abnormalities, concurrent viral infections), and environmental factors (e.g., overcrowding, local climatic factors). The majority of disease occurs in the under 5 years age groups with a peak incidence in the 6–12 months age group. The United States and Europe experience an endemic rate of disease mainly caused by serogroup B, C, and Y meningococci (one to five cases per 100,000 yearly), punctuated by occasional hyperendemic or geographically localized outbreaks. In China and sub-Saharan Africa, epidemic and pandemic diseases caused by serogroup A, and, recently, serogroup W-135 meningococci, are common (up to 500 cases per 100,000) with major epidemics occurring every 5–10 years.

SPECTRUM OF DISEASE

The most characteristic presentations of meningococcal disease are septicemia and meningitis. Septicemic disease is usually accompanied by a hemorrhagic rash, and can be rapidly fatal with disseminated intravascular coagulation and multiorgan failure. More unusual presentations include low-grade septicemia with maculopapular rash, cellulitis, pneumonia, septic arthritis, and osteomyelitis.

DIAGNOSIS

In a patient with suspected meningococcal disease, diagnosis can be made by using microbiological culture of blood, cerebrospinal fluid, or aspirates from the hemorrhagic rash. Sensitivities of approximately 30% have been reported for diagnosis by blood culture.[4] These low levels of diagnostic sensitivity may be related to collection of blood and cerebrospinal fluid (CSF) after the first dose of antibiotics has been administered, as meningococci are rapidly killed following a single dose of intravenous penicillin. In the United Kingdom and some countries in Europe, antibiotics are given in primary care to reduce the potential for deterioration of the patient's condition during transport to the hospital.

Recently, diagnostic sensitivity has been improved by the introduction of polymerase chain reaction (PCR)-based molecular diagnostic methods into clinical practice. Blood or CSF can be taken from a suspected clinical case and meningococcal infection can be confirmed by identification of meningococcal gene sequences, which can persist in these fluids up to 4 days after the start of antibiotic treatment. Whereas molecular characterization utilizes genes with significant variation to distinguish different clones, clinical diagnosis requires the identification of genes conserved across all meningococci. In the United Kingdom, sensitive and specific assays have been developed using the *ctrA* gene, encoding a protein involved in capsular synthesis and transport.[2] This gene is specific to *N. meningitidis*, and common to all meningococcal serogroups. During recent clinical evaluation of

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020889

95 children with probable meningococcal disease, 82 (88%) had a positive PCR, whereas 32 (33%) were culture-positive.[3] No false negative PCR results were obtained with this protocol because all culture positive cases were confirmed by PCR. False negatives were observed in a previous *ctrA* PCR assay using different oligonucleotide PCR primers on serum or plasma samples.[4] Whereas false positive results have been observed in an assay based on the IS1106 insertion sequence,[5] which may be found in other microorganisms, no false positives have been observed to date with the *ctrA* PCR assay.

A further advance has been the development of a single-tube multiplex, real-time PCR assay for detection of all the organisms forming the major differential diagnosis of significant childhood sepsis and meningitis in Europe and North America.[6] This uses fluorescent dye-labeled sequence-specific probes for the simultaneous detection of the *N. meningitidis* capsular transport gene (*ctrA*), *Haemophilus influenzae* capsulation gene (*bexA*), and *Streptococcus pneumoniae* pneumolysin gene (*ply*). As soon as meningococcal infection is confirmed, the serogroup of the infecting organism can be determined. A PCR-based assay is used to detect the *siaD* gene, which encodes the serogroup-specific sialyltransferase enzyme, enabling differentiation of serogroup B, C, Y, and W135 organisms.[7,8] This assay is less sensitive in terms of detection of meningococci than the *ctrA* PCR assay. Serogroup A bacteria can be identified by PCR detection of the *mynA* gene, which encodes an enzyme involved in synthesis of the serogroup A capsular polysaccharide.[9]

MANAGEMENT

Prehospital treatment with intramuscular penicillin is recommended where disease is suspected, because deterioration of the patient's condition can be rapid. Although meningococci with intermediate resistance to penicillin have been described, they have not been associated with treatment failure. In practice, before a diagnosis is established, most patients will be treated with a third-generation cephalosporin such as ceftriaxone to give broad-spectrum antibiotic cover where the causative organism is not yet identified. There are no reports of resistant meningococci for this antibiotic.

The severe nature of meningococcal disease means that good supportive management of respiratory and cardiovascular function are essential. Admission to an intensive care unit is often required, and the focus on such supportive care has significantly improved mortality over the last 10 years.[10] A significant number of survivors are left with disabilities relating to limb amputation, skin damage, and neurological impairment.

PCR-based techniques have been of most importance in the fields of public health and epidemiology. The improved sensitivity of case ascertainment allows a more accurate measurement of the level of meningococcal disease in the human population, which is important for public health decision making.

CHARACTERIZATION OF MENINGOCOCCI

Effective public health countermeasures against meningococcal disease, such as vaccination programs, rely on the identification of meningococci, the ability to track temporal and geographical spread of meningococci, and the ability to relate locally and globally obtained isolates.[11] Furthermore, characterization of the genetic diversity of meningococcal isolate collections has provided insights into the structure of meningococcal populations, and the evolutionary mechanisms that shape them.[12] A range of techniques have been used to characterize meningococci, including differences in the electrophoretic mobility of cytosolic enzymes or the DNA sequence diversity of the meningococcal genome. However, methods relying on differences in the immunological reactivity of cell surface components are in most widespread use (Fig. 1).

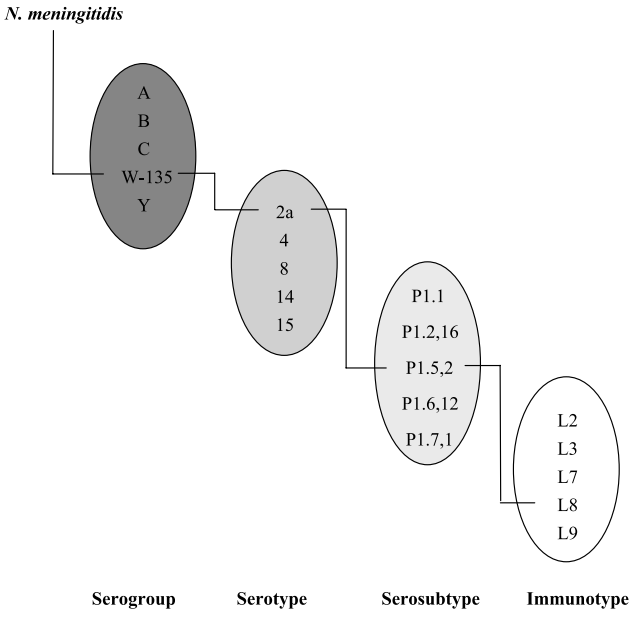

Fig. 1 Serological characterization of *N. meningitidis*. *N. meningitidis* can be further subdivided by the immunological reactivity of its capsular polysaccharide (serogroup), PorB protein (serotype), PorA protein (serosubtype), and LPS (immunotype). The figure describes the serological characterization of a meningococcal isolate with the classification: W-135:2a:P1.5,2:L8. (*View this art in color at www.dekker.com.*)

Immunological Characterization of the Meningococcus

In addition to determination of the meningococcal serogroup by the immunological reactivity of the capsular polysaccharide, more detailed characterization can be achieved by detection of antigenic variation of ''subcapsular'' components of the meningococcal outer membrane (Fig. 2).[13] Meningococci produce two porin proteins, PorA and PorB, which form trimeric pores in the meningococcal outer membrane. The antigenic variation in the PorB and PorA monomers is used to define the meningococcal serotype and serosubtype, respectively. The meningococcal surface is also coated in lipooligosaccharide (LPS), an amphipathic, phosphorylated glycolipid. This is composed of a membrane-anchoring lipid, a backbone to which core saccharides are attached, which are in turn linked to structurally variable oligosaccharide moieties. Variation in the oligosaccharide moiety of the surface LPS is used to define the meningococcal immunotype.

An inherent limitation of immunological characterization is the antigenically variable nature of the targeted surface components.[14] Such variation means that new reagents are continually required to identify previously uncharacterized variants.[15] A further problem is the dynamic nature within individual bacteria of expression of the structures to which serological typing reagents are targeted. Switching of antigenic types by horizontal genetic exchange of the genes encoding them, or involved in their synthesis, also poses problems for the reliability of immunological characterization techniques.[16] Some carried meningococci even lack the genes necessary for capsular synthesis and transport, thus precluding serogroup determination.[17]

Molecular Characterization of the Meningococcus

Molecular techniques offer improvements over immunological methods in both specificity and sensitivity. Techniques include ribotyping, pulsed-field gel electrophoresis (PFGE), analysis of repetitive elements, or DNA sequence determination of individual loci.[18] These techniques are particularly useful in detecting ''microevolution'' of rapidly evolving genes among related meningococci and for understanding their short-term epidemiology.[19] For example, DNA sequence-based analysis of *porB* gene polymorphisms has led to improvements in the discrimination between immunologically similar meningococci and in defining the relationships among them.[20]

For longer-term analysis of meningococcal epidemiology and population structure, ''multilocus'' characterization techniques are more useful. These techniques index neutral, slowly evolving variation at widely distributed genetic loci around the meningococcal chromosome, such as those encoding cytoplasmic ''housekeeping'' enzymes involved in central metabolic processes. As such, these methods are more representative of the genomic sequence

Table 1 Protein vaccine candidates that might offer protection against serogroup B disease

Vaccine candidate	Stage of development
Outer membrane vesicle	
Finlay Institute	Licensed in some South/ Central America countries
NIPH	Completed efficacy studies in teenagers
RIVM	Immunogenicity studies in various age groups
Purified outer membrane proteins	
Transferrin-binding protein B (TbpB)	Preliminary clinical studies in volunteers
Neisserial surface protein A (NspA)	Preclinical research
Transferrin binding protein A (TbpA)	Preclinical research
Ferric enterobactin receptor (FetA)	Preclinical research
Recombinant PorA	Preclinical research
Peptides from PorA	Preclinical research
T-cell-stimulatory protein A (TspA)	Preclinical research
Genome-derived antigens	Various stages

of individual isolates. Multilocus enzyme electrophoresis (MLEE)[21] exploits the differences in the electrophoretic mobilities caused by genetic variation of such enzymes. The resultant electrophoretic profile is used to assign an electrophoretic type (ET), and isolates with indistinguishable electrophoretic profiles are assigned to the same ET. Phylogenetic analysis of MLEE data has enabled the definition of meningococci into genetically related groups, commonly referred to as clonal lineages, known as subgroups (serogroup A), and clusters or complexes (serogroups B and C).

More recently, multilocus sequence typing (MLST)[11] has been introduced, which adopts a similar approach to MLEE except that determination of the sequence of seven gene fragments encoding housekeeping enzymes are used to collect genetic data directly, rather than by inference from the phenotypic differences of expressed proteins. This has allowed MLST to provide a much finer level of isolate characterization than MLEE. Unique combinations of the alleles at the seven loci are known as sequence types (STs), and related sequence types (those which have at least four identical loci to a known central genotype) are known as clonal complexes. Since its development in the late 1990s, MLST has become widely accepted as the standard method of meningococcal isolate characterization because of its discriminating power and the unambiguous nature of DNA sequence determination, which does not vary between different equipment, reagents, or operators involved in its preparation. Rapid electronic exchange and analysis of MLST data in conjunction with epidemiological information regarding the isolates from which the data were obtained can be achieved by internet connection to a central electronic database (http://neisseria.org/nm/typing/mlst). Multilocus analysis of meningococci isolated from asymptomatic carriage and also from cases of invasive disease has indicated that meningococcal populations are extremely diverse, being composed of many clonal lineages; however, most invasive disease can be attributed to a limited number of lineages, and these have been termed the hyperinvasive lineages.[12,22]

CONCLUSION: GENOMICS AND VACCINATION

Despite the advances associated with molecular techniques, meningococcal disease remains a globally significant health problem, and the prospect of comprehensive vaccination remains elusive. Whereas vaccines based on the capsular polysaccharide are either licensed or under development against meningococci associated with serogroups A, C, and Y, as well as W-135, attempts to develop a polysaccharide-based serogroup B vaccine have proven unsuccessful. This fact is especially relevant as much of the meningococcal disease in Europe and North America is caused by meningococci associated with the serogroup B capsule. A number of alternative approaches to the development of serogroup B meningococcal vaccines are currently in development,[14] and these are summarized in Table 1. The recent completion of three meningococcal genomes [(http://www.sanger.ac.uk/Projects/N_menigitidis/); Refs. [23,24]] has revolutionized the process of vaccine development and the application of genomic approaches such as reverse vaccinology to this resource has already led to the identification of novel vaccine candidates.[25]

Nested PCR and Multiplex Nested PCR

David Tarragó-Asensio
Ana Avellón-Calvo
National Center for Microbiology, Madrid, Spain

INTRODUCTION

Since the polymerase chain reaction (PCR) was described in 1985 many variations of the initial technique have been developed to improve the sensitivity, specificity, cost-effectiveness, and time consumed. The sensitivity rates are crucial in diagnostic PCR systems, especially those involving labile or not abundant microorganisms in clinical specimens. One of the methods currently employed to increase sensitivity and specificity is the nested PCR (nPCR). This technique consists in the utilization of two consecutive PCRs, each containing a different pair of oligonucleotides. Paradoxically, the high sensitivity of the method often results in a handicap when reagent or sample contamination is present. On the other hand, multiplex PCR approach has the potential to produce considerable savings of time and effort within the laboratory without compromising test utility. Although the technique has been shown to be a valuable method for the identification of viruses, bacteria, fungi, and/or parasites, it is really useful for the screening of clinical samples involved in syndromes and infections such as acute respiratory tract infections, genital infections, and meningitis and encephalitis. Multiplex and nested PCR have experienced a wide development overall in the field of infectious diseases caused by viruses.

NESTED POLYMERASE CHAIN REACTION

Principle

Nested PCR (nPCR) consists in the consecutive performance of two PCRs usually involving less than 45 cycles each. The larger fragment produced by the first reaction is used as template for the second PCR. The system is allowed if necessary to be preceded by a retro-transcription reaction (RT-nPCR). The performance of two individual reactions achieves a considerable improvement of the sensitivity and specificity (Fig. 1). Several reasons explain the fact that PCRs of 30 cycles each (first- and second-round PCR) improve the yield compared to a single reaction performing 60 cycles. It is known that DNA polymerases can reduce its activity after a number of high-temperature cycles.[1] Besides, the denaturalization step on amplicons from the first PCR is more effective than on the initial template because of their smaller size.[2] The specificity of the nPCR system is additionally improved, because the chance of unspecific primer hybridization is dramatically low.

nPCR Special Features

Primers

The first PCR contains external pairs of primers, whereas the second includes two primers that are internal to the first primer pair. The primers employed should be different in both reactions (Fig. 1); although there is a possibility of employing one of the first-round primers into the second reaction, designing a seminested PCR, however, sometimes results in unspecific amplifications. If during the primer design process it is not possible to choose four different conservative regions, the use of sense or antisense partially overlapping sequences is an allowed alternative. The hybridization temperatures of each pair of primers may be different, but it is convenient to be similar in order to make, if necessary, cross-primer reactions that permit to evaluate each individual primer function.

Biochemical conditions

The final biochemical conditions of both reactions should be experimentally determined individually as in one reaction PCR.

Template

Only a small amount of the first amplification fragment (1–3 μL) is necessary to serve as template for the nested reaction.

Avoiding nPCR Contamination

The extremely high sensitivity of the nPCR system often results in problems, due to contaminations coming from

Encyclopedia of Diagnostic Genomics and Proteomics
DOI: 10.1081/E-EDGP 120020676

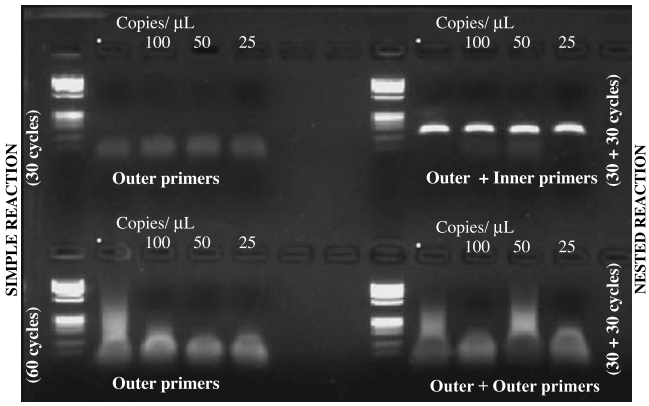

Fig. 1 The figure is based on a generic adenovirus-specific nPCR as described by Avellón et al.[4] On the left, simple PCR using the outer primers, with 30 (above) and 60 (down) cycles. On the right above, nPCR using outer and inner primers as the published method (sensitivity estimated of around 10 to 100 copies/mL). On the right down, nPCR employing outer primers in both reactions. The adenovirus amplification band (168 nt) is found only in the assay reproducing the published method.

previously amplified sequences. Those sequences can be carried on the skin surface of the operator or on laboratory materials, and can be found at the laboratory facilities. When a previously amplified sequence is included by chance into the reaction mixture, it results in a false-positive reaction. The use of negative controls can check the validity of the assay, but the possibility of individual contamination is almost impossible to be ruled out. Because of that, a wide routine precaution should be taken to avoid contaminations, including the following:

1. Sample aliquots: at least two different sample aliquots should be made and stored at a laboratory outside the PCR laboratory. A positive result should be always confirmed in a second aliquot.
2. Reagent preparation should be performed in a ''clean'' area separated from the rest of the laboratory, preferably in a flow laminar cabinet. First and nested PCR reactions should likewise be performed at separate laboratories, into distinct laminar flow cabinets and employing different supplies of pipettes, pipette tips, Eppendorf tubes, and any common reagent as distilled water or PCR buffer. Nucleic acid extraction procedures can be done in the same area and with the same materials as the first reaction activities. Finally, the detection process should be carried out in a specific laboratory. Summarizing, to perform nPCR we need four separate laboratories: a reagent laboratory, a nucleic acid extraction and first PCR laboratory, a nested laboratory, and an amplification detection laboratory.
3. Polymerase chain reaction operators should be meticulously trained before the initiation of their activity. They are encouraged to wear disposable gloves in each PCR area, changing them frequently, especially when leaving a laboratory to enter another. Equally, they should wear protective clothing in each area.
4. Positive control DNA plasmids should be carefully prepared at a limit of 1 or 2 logs higher than the expected limit of detection, to avoid being the origin of contamination.

MULTIPLEX PCR

Principle and Troubleshooting

The technical benefit of multiplex PCR over conventional PCR is that in multiplex PCR more than one target sequence can be simultaneously amplified by including more than one pair of primers in the PCR reaction. The optimization of multiplex PCRs may result in some difficulties and the main one is the preferential amplification of certain specific targets. The presence of more than one primer pair in the PCR reaction increases the chance of obtaining nondesirable amplification products, primarily because of the formation of primer dimers. Nonspecific products may be amplified more efficiently than the desired target producing impaired rates of annealing and extension. Trial-and-error approach may have to be used when testing several primer pairs, because there are no means to predict the performance features of a putative primer pair even among those that satisfy the general parameters of primer design. Special attention to the homology of primers with their respective target sequences, their GC content, and concentration, and obviously avoiding inter- and intraprimer homology have to be considered. All the primer pairs in a multiplex PCR should enable similar amplification efficiencies for their respective target. Polymerase chain reaction selection is defined as a mechanism that favors the amplification of certain templates due to the properties of the target or the target's flanking sequences. The choice of primers has been shown to be crucial to avoid PCR selection. A primer length of 18 bp or larger and a GC content around 40% and with identical or very close optimum annealing temperatures should not display any significant homology either internally or to one another could be assayed. Optimization of PCR components such as PCR buffer constituents, dNTPs, enzyme concentrations, and PCR additives, such as bovine serum albumin, dimethyl sulfoxide, glycerol, or betaine, has been reported to be useful in multiplex PCRs. These additives may act to avoid the stalling of DNA polymerization, which may occur through the formation of secondary structures within regions of

template DNA during the extension process. Such cosolvents may also act as destabilizing agents, reducing the melting temperature of GC-rich sequences, or as osmoprotectants, increasing the resistance of the polymerase to denaturation. The primer pairs must be inclusive for as many strains of the target microbe as possible, and depending on the amplicon detection method, their targets are easily resolvable. The latter may be achieved by using primer pairs that result in PCR products that can be separated and clearly visualized using gel electrophoresis or hybridization probes with maximum specificity.

Many multiplex PCRs developed before utilized a nested strategy. Nesting significantly increases the sensitivity of the assay but also increases the chance of false-positive results due to contamination and may also complicate automation.

CLINICAL APPLICATIONS OF NESTED AND MULTIPLEX PCR IN DIAGNOSTIC MICROBIOLOGY

Applications in Qualitative PCR

The nPCR systems are currently widely employed in both qualitative, simple[3,4] or multiplex,[5–13] and quantitative[14,15] diagnostic tests, as well as in PCR systems employed in the identification of viruses.[16–19] Regarding the above mentioned qualitative nPCRs, the primer design allows to detect from 10 to 100 genome copies per microliter of any adenovirus[4] or lyssavirus,[3] and can be performed from a variety of samples including cerebrospinal fluid (CSF), urine, stools, respiratory swabs, conjunctival swabs, or brain necropsies. These nPCRs can be included in multiplex systems, especially adenovirus nPCR,[12] as the range in hybridization temperatures and biochemical conditions is very high.

The first nested multiplex PCR for detection and typing of herpesviruses (HSV-1 and -2, VZV, CMV, HHV-6, and EBV) was applied to CSF from patients with meningitis, encephalitis, and other clinical syndromes.[5] This assay was further modified to include a reverse transcription step and primer pairs to detect enterovirus cDNA.[6,7] Utilizing equimolar concentrations of primers aligning the 3′ ends with one of two consensus regions within the herpesvirus DNA polymerase gene and the 5′ ends with the related or nonrelated sequences of each agent to be amplified, the first round of amplification yielded a 194-bp fragment indicating the presence of herpesvirus. The second round of amplification utilizing primer mixtures contained nonhomologous and type-specific primers selected from different regions of the aligned DNA polymerase genes of human herpesviruses producing a product with a different size for each related virus. These studies demonstrate the utility of this multiplex RT-nPCR for the detection of enteroviruses and herpesviruses in CSF samples from patients with various neurological manifestations and the usefulness of the technique in patient management and design of antiviral therapy. Additionally, a multiplex nPCR method was developed for the simultaneous detection and typing of all human lymphotropic herpesviruses described to date, including EBV, CMV, HHV-6, variants A and B, HHV7, and HHV8.[8]

A multiplex nPCR was also developed for differentiating simultaneously the DNA of polyomaviruses JC, BK, and SV40.[9] In the first amplification step the same set of primers were used to amplify a conserved DNA region of the large T antigen gene of JCV, BKV, and SV40. The second round of multiplex nPCR was carried out using a set of primers designed to render products of different sizes for each related virus. Cerebrospinal fluid was examined from AIDS patients with clinical and neuroradiological evidence of progressive multifocal leukoencephalopathy and from AIDS patients with other neurological alterations. Urine specimens from bone marrow transplant recipients affected by hemorrhagic cystitis were also tested. The results obtained suggest that the assay is a good tool for supporting the diagnosis of polyomavirus infection and could be used for epidemiological purposes and in other studies in order to define better the role of polyomaviruses in human disease. Other multiplex nPCR systems described allow the simultaneous detection of parainfluenza virus types 1 to 4,[10] measles virus, rubella virus, and parvovirus B19[11] or phlebovirus.[13]

Applications in Quantitative PCR

There are a wide variety of tests for the quantitative estimation of viruses. New methods to quantitate small amounts of DNA polyomavirus[14] and CMV[15] in clinical specimens were described based on nPCR. The method, a nested competitive polymerase chain reaction (ncPCR), is able to quantitate between 10 and 10^5–10^6 copies per tube of virus DNA and showed good reproducibility when clinical samples were analyzed. Throughout the whole procedure, an internal standard (mimic) competes for the primers with the target DNA. A solution containing 2×10^{10} DNA copies/ml is used as target sequence to generate a standard curve. Signals of both bands are analyzed by computerized densitometry. The original number of DNA copies present in clinical specimens is determined by interpolating the logarithmic signal ratio of amplified products into the standard curve.

Applications in Serotyping, Genotyping, and Subgrouping Viruses

Multiplex PCR has been shown to be a powerful and cost-effective tool for typing and subtyping virus strains in different epidemiological studies.

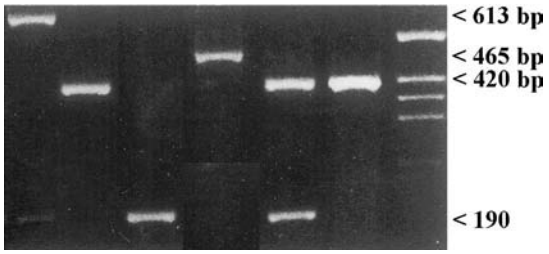

Fig. 2 gB Genotyping of clinical strains of CMV. From left to right lanes: gB2 (613 bp), gB 1 (420 bp), gB3 (190 bp), gB4 (465 bp), gB1 and gB3, gB1, molecular weights in base pairs. (*View this art in color at www.dekker.com.*)

For example, CMV gB was genotyped directly from clinical specimens by using multiplex nested PCR (M-nPCR) technology.[16] Specifically, a pair of primers to conserved regions of all gB genotypes within the gB gene (gB and gpUL55) was used for primary amplification. A mixture of nested primers to specific and conserved regions of each gB genotype was used for secondary PCR amplification, yielding amplicons of different sizes for each gB genotype that could easily be differentiated by agarose gel electrophoresis (Fig. 2). Using the above assay 40 serum specimens and 26 cerebrospinal fluid (CSF) samples, which had previously tested positive for CMV in 66 AIDS patients with different CMV disease conditions, were gB genotyped. Other nPCR systems are based on amplification and subsequent sequencing of the fragment for molecular analysis.[17–19] These systems allow genotyping and molecular analysis from small quantities of nucleic acid contained in clinical samples, without the need for cellular culture.

CONCLUSION

Nested and multiplex PCR have proven to be a valuable tool for the detection, quantification, and differentiation (subgrouping, subtyping, and genotyping) of viruses and other infectious agents.

Neuroblastoma—Clinical Implications of Real-Time PCR

Jörg Dötsch
Wolfgang Rascher
University of Erlangen, Nürnberg, Germany

Holger Christiansen
University of Erlangen, Marburg, Germany

INTRODUCTION

This review summarizes present knowledge on the clinical implications of real-time polymerase chain reaction (PCR), a novel fluorescence-based method for the quantitation of gene expression and gene copy number variations, as well as gene amplification and locus haploinsufficiencies in neuroblastomas. Particular emphasis is placed on precision and accuracy and the comparison of TaqMan® real-time PCR with other techniques and devices for quantitative real-time PCR, and more traditional methods for the quantitation of gene expression such as competitive quantitative PCR. Finally, applications with potential clinical implications, such as the detection of minimal residual disease (MRD) or the assessment of tumor malignancy, are discussed.

TECHNICAL DESCRIPTION

Principles of TaqMan PCR

The use of the TaqMan reaction has been described in a number of original and review articles.[1,2] This approach makes use of the 5′ exonuclease activity of the DNA polymerase (AmpliTaq Gold®). Briefly, within the amplicon defined by a gene-specific PCR primer pair, an oligonucleotide probe labeled with two fluorescent dyes is created, designated as TaqMan probe. As long as the probe is intact, the emission of the reporter dye (i.e., 6-carboxy-fluorescein, FAM) at the 5′ end is quenched by the second fluorescence dye (6-carboxy-tetramethyl-rhodamine, TAMRA) at the 3′ end. During the extension phase of PCR, the polymerase cleaves the TaqMan probe, resulting in a release of reporter dye. The increasing amount of reporter dye emission is detected by an automated sequence detector combined with a special software (ABI Prism 7700 Sequence Detection System; Perkin-Elmer, Foster City, CA). The algorithm normalizes the reporter signal (R_n) to a passive reference. Next, the algorithm multiplies the standard deviation of the background R_n in the first few cycles (in most PCR systems, cycles 3–15, respectively) by a default factor of 10 to determine a threshold. The cycle at which this baseline level is exceeded is defined as threshold cycle (C_t) (Fig. 1). C_t has a linear relation with the logarithm of the initial template copy number. Its absolute value additionally depends on the efficiency of both DNA amplification and cleavage of the TaqMan probe. The C_t values of the samples are interpolated to an external reference curve constructed by plotting the relative or absolute amounts of a serial dilution of a known template vs. the corresponding C_t values.

In most cases of mRNA quantitation, gene expression has to be related to housekeeping genes that are expressed relatively stable throughout the cells. One major general difficulty in the use of housekeeping genes for the determination of mRNA transcript ratios is the possibility that their expression might also be altered by coexpression of pseudogenes and environmental changes (e.g., by hypoxia in case of glyceraldehyde-3-phosphate dehydrogenase). Pseudogenes may be eliminated using primer combinations that are intron spanning. However, unidentified influences cannot be dealt with as easily. Therefore, we suggest the use of at least two housekeeping genes for quantitation of mRNA expression. However, this aspect clearly needs further evaluation.

A different approach to quantify gene expression is the use of an external standard with a known gene expression or gene amplification. Although these preconditions are difficult to meet for mRNA quantitation, a reliable external standard can easily be obtained for N-MYC amplification at the DNA level because healthy volunteers usually do not carry more than two copies of the genomic sequence per cell in their peripheral blood.

Alternative Real-Time PCR Methods

There are other methods for real-time PCR not relying on exonuclease cleavage of a specific probe to generate a fluorescence signal. One of them, the LightCycler® System (Roche Molecular), makes use of so-called

DOI: 10.1081/E-EDGP 120021989

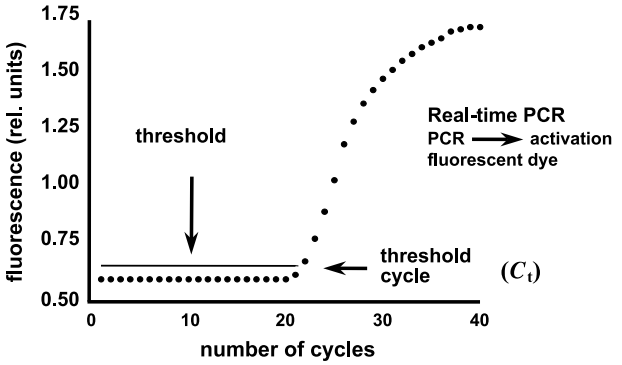

Fig. 1 Sketch of the principle of TaqMan PCR for the quantitation of gene expression. By measuring the amplicon concentration in the early exponential phase of the PCR reaction, the exhaustion of reagents is avoided. (From Ref. [3].)

''hybridization probes.''[4,5] Like exonuclease probes, hybridization probes are used in addition to PCR primers. But unlike the first, hybridization probes combine two different fluorescent labels to allow resonance energy transfer. One of them is activated by external light. When both probes bind very closely at the DNA molecules generated by the PCR amplification process, the emitted light from the first dye activates the fluorescent dye of the second probe. This second dye emits light with a longer wavelength, which is measured every cycle. Thus, the fluorescence intensity is directly correlated to the extent of probe hybridization and, subsequently, is directly related to the amount of PCR product. A major advantage of the LightCycler is the very short time of a PCR run. However, the TaqMan system allows to analyze a higher number of samples at one time and, at least theoretically, might be more accurate as there is an internal reference dye to monitor minor variations in sample preparation.

Apart from exonuclease and hybridization methods for real-time PCR, there are other options, including hairpin probes, hairpin primers, and intercalating fluorescent dyes. Hairpin probes, also known as molecular beacons, contain reverse complement sequences at both ends that bind together, whereas the rest of the strand remains single-stranded, creating a panhandle-like structure. In addition, there are fluorescent dyes at both ends of the molecule, a reporter and a quencher similar to the TaqMan probes. In the panhandle-like conformation, there is no fluorescence because the fluorescent reporter at one end and the quencher at the other end of the probe are very close to one another.[6] As the central part of a molecular beacon consists of a target-specific sequence, both ends are separated from each other when this part of the molecule is bound to the PCR product and a fluorescence signal can be emitted from the reporter dye. Hairpin primers, also named ''Amplifluor Primers®'' (Intergen), are similar to molecular beacons, but fluorescence is generated as they become incorporated into the double-stranded PCR product during amplification. Another very simple technique to monitor the generation of PCR product in a real-time fashion is the use of intercalating dyes, such as ethidium bromide and SYBR Green I®, which do not bind to single-stranded DNA but to the double-stranded PCR product.[5,7] However, hairpin primers and intercalating dyes do not offer the high specificity of the probe-based techniques and a positive signal might even be generated by primer dimers.

ROBUSTNESS, LIMITATIONS, AND PITFALLS IN THE USE OF REAL-TIME PCR

The use of TaqMan PCR may be particularly difficult if gene expression at a low level is to be quantified. One major pitfall in this context is the accidental determination of genomic DNA when RT-PCR is intended. There are various approaches to meet this problem: It is always useful to select primer combinations that are intron spanning.[8] If there is no possibility to select intron-spanning primers, RNA samples may be pretreated with DNAse. However, this measure should not be chosen routinely and may also be deleterious if only small amounts of RNA that are partially destroyed as well are present.[9]

One other difficulty is the high degree of technical expertise that is required to achieve as low a variation coefficient and as sensitive a measurement as possible. It could be shown that the degree of technical expertise may alter the gene level that is measured by up to 1000-fold.[9]

Because real-time PCR is highly sensitive, the risk of having interference with minor contamination is quite considerable. However, the risk of false-negative results must not be underestimated because post hoc PCR steps are not ''visible'' to the degree that is provided by the more traditional methods for gene quantification.[10]

RELIABILITY AND SPECIFICITY OF REAL-TIME PCR

The use of TaqMan real-time PCR for the quantification of gene expression in neuroblastoma tissues has been shown to be at least as reliable as the application of other quantitative PCR techniques such as competitive PCR.[11] Whereas the expression of highly expressed genes, such as the housekeeping gene glyceraldehyde-3-phosphate dehydrogenase, is well correlated between the two methods for the determination of genes with lower expression such as neuropeptide Y (NPY), TaqMan PCR is much more sensitive than competitive PCR in neuroblastoma tissues.[11] In addition, the spectrum of linear measurements for real-time PCR is in the range of 10^6, in contrast to 10^2 in competitive RT-PCR. Finally, a considerably

higher number of samples per day can be measured by real-time PCR (up to 400 measurements). In comparison to the Northern blot assessment, only a minimal fraction of mRNA is necessary to quantify gene expression by real-time PCR.[1]

CLINICAL APPLICATIONS OF REAL-TIME PCR APPLICATION IN NEUROBLASTOMAS

Quantitation of Prognostic Markers in Neuroblastoma Tissue

A number of biochemical markers have been investigated on the gene level as to their relevance in relation to patient prognosis. Among these are N-MYC, NPY, and somatostatin 2 gene expression.[12] The first two will be discussed in detail.

N-MYC

N-MYC amplification in neuroblastomas is of utmost interest with regards to the prognosis of disease. In fact, in clinical practice, N-MYC gene expression correlates with both advanced disease stage and rapid tumor progression.[13]

Several methods have been used for the detection of N-MYC detection mainly based on Southern or dot blot, quantitative PCR and fluorescent in situ hybridization techniques. However, the use of most PCR methods is restricted by the fact that end-point measurements are used for quantitation. Therefore, Raggi et al.[14] introduced a TaqMan real-time base method for the determination of N-MYC amplification in neuroblastomas. The authors demonstrate a precise assay with an interassay coefficient of variation of 13% and an intraassay coefficient of variation of 11%. The threshold cycle for the detection of N-MYC correlates in an inverse linear way with the logarithm of the input of genomic DNA molecules. There is a good linear relationship between the N-MYC amplification measured by TaqMan real-time PCR and competitive PCR. Using Kaplan–Meier survival curves, the authors showed that the amplification of N-MYC as assessed by TaqMan real-time PCR is closely linked to cumulative survival as this has already been demonstrated with several other techniques for the quantitation of N-MYC amplification.

Similar results were obtained by others using the LightCycler approach for the quantitation of N-MYC amplification.[15]

NPY

The detection of NPY mRNA expression in neuroblastomas has been of particular interest because NPY is known to correlate with the differentiation and malignancy of neuroblastomas. NPY is released into the circulation and may reflect the tumor burden of an individual neuroblastoma patient.

Consequently, NPY gene expression has been quantified by using a number of different techniques for quantitation such as Northern blot, competitive RT-PCR, and, lately, TaqMan real-time PCR.[11]

There is a good linear relationship between NPY mRNA expression as measured by quantitative competitive PCR and TaqMan real-time PCR. However, in the lower concentration range, only real-time PCR is able to discriminate different NPY mRNA levels. This finding suggests that the more traditional competitive PCR might not be able to detect differences in the expression of less abundant genes in neuroblastoma tissues. Definitely, with a limited amount of cells, real-time PCR would be the more desirable method to use.

MRD

Lately, the application of real-time PCR has focused on the detection of MRD of neuroblastoma. A number of groups used tyrosine hydroxylase—the key enzyme for the synthesis of catecholamines as a marker for the detection of neuroblastoma cells in the blood and bone marrow.

One group depicts that as few as 70 transcripts per milliliters can be measured. There were no false-negative samples in control samples.[16] Similar results with regards to the use of tyrosine hydroxylase for the detection of MRD were reported by another group, which described the sensitivity of the assay as $1{:}10^6$ white blood cells.[17] Again, real-time PCR was found to be more sensitive than qualitative PCR in the detection of MRD.[18] However, one pitfall in the use of tyrosine hydroxylase might be its association with a higher degree of differentiation of the neuroblastoma. Therefore, less differentiated tumors might be detected at higher threshold levels, or could even be missed.

A different surrogate parameter for the quantitation of MRD in neuroblastoma patients is GD2 synthase—the key enzyme for the synthesis of β1,4-*N*-acetylgalactosaminyltransferase. The measurements proved to have clinical relevance in evaluating adjuvant therapy with anti-GD2 antibodies for bone marrow purging in neuroblastoma by detecting a subclinical level of tumor cells in bone marrow aspirates and was predictive of long-term outcome.[19,20]

CONCLUSION

The recent studies that have used real-time PCR for the quantitation of target genes in neuroblastoma tissues

and for the detection of MRD provide encouraging data for the use of this technique introduced only 7 years ago. Apart from a high degree of precision, practical advantages of real-time PCR, such as easy handling, rapid measurements, and a broad linear range for the measurements, have to be highlighted.

From a diagnostic point of view, one interesting aspect for the future might be the use of semiautomated or automated real-time devices for the assessment of gene expression and amplification in neuroblastomas, putting into consideration the relatively easy and little time-consuming way of measurement. Real-time PCR might help to quantify more prognostic markers, expression of genes involved in multidrug resistance, and genes related to tumor invasion and metastasis. There are first reports on the use of multiplex real-time PCR, a development that might certainly facilitate diagnostic procedure in neuroblastoma diagnostics in the coming years.

Disease management as such might initially not be altered by a new method for the determination of genetic neuroblastoma markers. However, if this relatively novel method becomes available more widely (e.g., as a consequence of dropping costs for this still-very-expensive technique), the number of prognostic markers examined might help to improve therapeutic strategies in the long run.

Neurofibromatosis Type 1

Bruce R. Korf
University of Alabama at Birmingham, Birmingham, Alabama, U.S.A.

INTRODUCTION

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder that affects approximately 1 in 3500 individuals throughout the world. It displays a high rate of new mutation and complete penetrance. Diagnosis is based on clinical criteria, but molecular testing is now available on a clinical basis. Insights into pathophysiology based on understanding the *NF1* gene and the cellular pathway in which it participates are beginning to suggest possible avenues of therapy, with several clinical trials currently under way.

CLINICAL DESCRIPTION

NF1 is a progressive multisystem disorder, which includes some features that occur early in life and others that do not appear until later. It displays a wide range of variable expression, including differences within the same family. The hallmark feature is the neurofibroma, a benign tumor that arises from the nerve sheath.[1] There are two major types of neurofibromas: focal growths and plexiform neurofibromas. Focal neurofibromas arise as discrete nodules at some point along a nerve. They may occur at the nerve root, along the length of a nerve, or at a nerve ending. They may be visible as growths that protrude above the surface of the skin, or cause a swelling due to subcutaneous growth. Dermal neurofibromas often present with a purplish discoloration to the overlying skin. They are soft and painless, but may have significant cosmetic impact. Internal neurofibromas are usually asymptomatic, but some can cause symptoms of nerve compression such as pain or sensory loss, or may invade the spinal canal and cause cord compression. Focal neurofibromas are rarely present in young children, but gradually increase in number over the years. Tumors often first appear or grow during puberty, or in women, during pregnancy. The numbers of neurofibromas vary widely in individuals, from a few small tumors to uncountably many.

Plexiform neurofibromas consist of a diffuse enlargement of multiple fascicles of a nerve. Some extend over a considerable distance and include multiple nerve branches. Plexiform neurofibromas may be associated with overgrowth of soft tissues, causing significant cosmetic deformity and functional impairment. Most, if not all, occur congenitally. The tumors tend to grow during the early childhood years, and often remain static in size thereafter. Plexiform neurofibromas that occur near the surface of the body may invade the skin, causing thickening and palpable cords of tumor. Some are associated with irregular hyperpigmentation of the overlying skin.

NF1 usually presents with pigmentary features. Multiple café-au-lait macules begin in early childhood, and skin-fold freckles appear between 3 and 5 years of age.[2] Iris Lisch nodules are melanocytic hamartomas that are useful in diagnosis but are clinically silent.[3] Other common nontumor manifestations include skeletal dysplasia, macrocephaly, vascular dysplasia, and learning disabilities. Skeletal dysplasia most often affects long bones, particularly the tibia.[4] Tibial dysplasia presents in infancy and creates risk of fracture. Orbital dysplasia occurs in association with trigeminal plexiform neurofibroma. Children with NF1 tend to be short and have relative or absolute macrocephaly.[5] Vascular dysplasia consists of nodular proliferation within the arterial wall and may cause arterial stenosis or hemorrhage due to dissection.[6] Learning disabilities occur in at least 50% of affected individuals and include both verbal and nonverbal problems.[7] There may also be attention deficit disorder and neuromotor problems.

Individuals with NF1 are at increased risk for malignant neoplasms.[8] The most common is optic glioma, affecting approximately 15%.[9] Most of these tumors are asymptomatic, but progressive growths can impair vision or cause neuroendocrine disturbance. Gliomas can occur elsewhere in the brain, especially the brainstem. Malignant peripheral nerve sheath tumors are sarcoma-like lesions that arise from neurofibromas (usually plexiform neurofibromas), with a lifetime risk around 10%. Other malignancies that are associated with NF1 include juvenile myelomonocytic leukemia and rhabdomyosarcoma.

DIFFERENTIAL DIAGNOSIS

NF1 is one of a set of disorders subsumed under the term ''neurofibromatosis.'' The others are NF2 and schwannomatosis. The features of these disorders are compared in

DOI: 10.1081/E-EDGP 120025766

Table 1 Comparison of features of the three neurofibromatoses

	NF1	NF2	Schwannomatosis
Inheritance	Autosomal dominant Complete penetrance	Autosomal dominant Complete penetrance	Autosomal dominant Incomplete penetrance
Frequency	1:4000	1:40,000	Very rare
Features	Neurofibromas; café-au-lait macules; learning disabilities; skeletal dysplasia	Vestibular schwannomas; other schwannomas; meningiomas; ependymomas; cataract	Schwannomas
Gene/Protein	*NF1*—chromosome 17 Neurofibromin	*NF2*—chromosome 22 Merlin/schwannomin	Unknown
Function	GTPase-activating protein	Cytoskeletal protein	Unknown

Table 1. The clinical distinction between NF1 and the others is usually relatively easy to establish: only NF1 is associated with multiple café-au-lait macules, neurofibromas, optic glioma, etc. Both NF2 and schwannomatosis are characterized by multiple schwannomas, with the vestibular schwannoma being the hallmark of NF2. Clinical diagnostic criteria for NF1 are presented in Table 2.[10] Many of the features are age dependent, so the diagnosis is often not established at first evaluation of a young child. There are several variant forms of NF that need to be considered; these are also described in Table 2.

MANAGEMENT

There is no definitive medical treatment for NF1; management is currently limited to surveillance and symptomatic treatment of symptomatic manifestations. Life expectancy is decreased on average, with disease-related mortality due to malignancy and vascular accidents.[11] Affected individuals should be seen on a regular basis by a physician familiar with the disorder. Children should be followed by an ophthalmologist for evidence of optic glioma. Neurofibromas can be removed

Table 2 Diagnostic criteria for NF1 (top) and variant forms of NF1 (bottom)

- At least six café-au-lait macules
  5 mm prepuberty
  15 mm postpuberty
- Skin-fold freckles
- Two or more neurofibromas/one plexiform neurofibroma
- Two or more iris Lisch nodules
- Optic glioma
- Characteristic skeletal dysplasia
  Tibia
  Orbit
- Affected first-degree relative

Variant form	Features
Familial multiple café-au-lait spots	Autosomal dominant multiple cafe-au-lait spots with no other signs of NF1; some families allelic to NF1, others not
Spinal neurofibromatosis	Multiple spinal nerve root neurofibromas, but no other NF1 features; may be allelic to NF1 or NF2
Watson syndrome	Pulmonic stenosis, developmental delay, café-au-lait spots; allelic to NF1
Segmental NF	Features of NF1 confined to a restricted body region; most likely due to mosaicism for *NF1* mutation

An individual who fulfills any two criteria can be diagnosed as being affected.

Table 3 Major types of *NF1* gene mutation and applicable approaches to mutation detection

Type of mutation	Technique(s)
Whole gene deletion	FISH, microsatellite analysis for hemizygosity
Multiexon deletion or small insertion	RT-PCR analysis of RNA; Southern analysis; sequence analysis of cDNA
Splicing mutation	Analysis of cDNA for size, followed by sequencing; sequencing of intron–exon borders
Stop mutation/frameshift	Protein-truncation assay followed by sequencing, or direct sequencing of cDNA or genomic DNA
Missense mutation	Sequencing of cDNA or genomic DNA
Chromosome rearrangement	Chromosomal analysis

surgically, although regrowth of plexiform lesions is common. Optic gliomas that are asymptomatic do not need to be treated, but symptomatic lesions are treated with chemotherapy (vincristine/carboplatin). Children should be followed for the occurrence of learning disabilities and attention deficit disorder, both of which are managed by standard means. Affected individuals should be counseled regarding the warning signs of malignancy, particularly unexplained pain or sudden growth of a neurofibroma. Clinical trials are now underway toward development of nonsurgical treatments of neurofibromas, particularly plexiform neurofibromas. Clinical trials are tracked on the website http://www.nf.org/clinical_trials.

GENETIC COUNSELING

NF1 is inherited as an autosomal dominant, with complete penetrance but variable expressivity. An affected individual has a 50% chance of transmission of NF1 to any offspring, although severity cannot be predicted. Approximately 50% of cases occur sporadically due to apparent new mutation. Unaffected parents of a sporadically affected child face a risk of recurrence based on germline mosaicism, although this risk is low.

MOLECULAR GENETICS

The *NF1* gene is located on chromosome 17 and encompasses more than 300 kb of genomic DNA with 60 exons. The protein product is referred to as ''neurofibromin,'' a 2818 amino acid protein. Neurofibromin includes a GTPase-activating protein (GAP) domain, which regulates the conversion of Ras-GTP to Ras-GDP. Neurofibromin therefore appears to be a regulator of Ras-mediated intracellular signaling.[12] The *NF1* gene behaves as a classic tumor suppressor. Affected individuals are heterozygous for *NF1* mutations, but both alleles are mutated in tumor cells. The ''tumor cell'' of the neurofibroma is the Schwann cell, but much of the bulk of the lesion consists of other heterozygous cells, including fibroblasts and mast cells, recruited to the lesion by cytokines yet to be identified. Malignant growths are likely to arise from the acquisition of additional genetic changes, such as loss of function of p53. It is unclear whether some of the nontumor manifestations, such as learning disability, also arise from a tumor suppressor mechanism, or whether haploinsufficiency explains any of these lesions.

MOLECULAR GENETIC TESTING

Until recently, there was no reliable molecular diagnostic test for NF1, so diagnosis was limited to application of clinical criteria. Although it is usually easy to establish a clinical diagnosis of NF1, there are several situations in which molecular testing would be useful. The clinical diagnosis often is uncertain in young children with multiple café-au-lait spots or an affected parent, because other features such as skin-fold freckles or neurofibromas may not occur until a child is older. Individuals with atypical presentations, such as isolated plexiform neurofibromas, may also benefit from molecular testing. Finally, molecular diagnosis offers the possibility of prenatal testing by amniocentesis, chorionic villus sampling, or preimplantation testing.

The major challenges posed in molecular diagnosis are the large size of the gene and the fact that mutations can be distributed anywhere along the gene. There are no major ''hotspots'' or recurrent mutations. Mutation analysis requires use of a set of complementary techniques to detect the various types of mutations, including complete gene deletion, intragenic deletion or duplication, frameshift, stop mutation, splicing mutation, and the rare missense mutation[13] (Table 3). Genotype–phenotype correlations have been difficult to establish. The one clear correlation is that individuals with complete gene deletion tend to have a severe course, with developmental delay, dysmorphic features, and large numbers of neurofibromas.[14] The possibility of mosaicism must be considered in those with signs of the disorder in whom

no mutation is found; study of affected cells, such as Schwann cells from a neurofibroma, may be necessary to identify a mutation in individuals with mosaicism.

CONCLUSION

Neurofibromatosis type 1 is a relatively common single gene disorder with widely varied, progressive features. Management is currently focused on clinical diagnosis, surveillance, symptomatic treatment, anticipatory guidance, and genetic counseling. Since the identification of the *NF1* gene much has been learned about pathophysiology, indicating that the gene functions as a tumor suppressor. Genetic testing is now a clinical reality, and clinical trials have begun, raising hope of development of nonsurgical treatments in the near future.

Neuronal Ceroid Lipofuscinoses

Nanbert Zhong
New York State Institute for Basic Research in Developmental Disabilities, Staten Island, New York, U.S.A.

INTRODUCTION

Neuronal ceroid lipofuscinoses (NCLs), also known as Batten disease, comprise eight recessive and one dominant form, as well as several rare and atypical variants (Table 1) that are as yet unclassified. They are characterized by intralysosomal accumulations of ceroid lipopigments as the hallmark, which can be detected as granular osmiophilic deposits (GRODs), or curvilinear (CV), fingerprint (FP), or rectilinear (RL) profiles by electron microscopy (EM). In typical cases, GRODs are present in NCL_1, CV in NCL_2, and FP in NCL_3. However, the profiles can vary, and mixed profiles can occur.[1]

The incidence of NCLs has been estimated to be approximately 0.1–7 in 100,000 births in the general population, and as high as 1 in 12,500 births as a result of founder effects in genetically isolated populations such as the Finnish population.[1] With this number still growing, NCLs are becoming one of the most common neurodegenerative disorders of childhood.[2]

Although efforts at gene therapy, either in vivo or ex vivo, and protein replacement are making progress, presently, there is no effective treatment available for NCLs. The outcome of the disease is usually fatal within a few years after the onset of clinical symptoms.[3] Early definitive diagnosis of NCLs and characterization of genetic deficiency in the affected family are the primary intervention approaches. Carrier identification and prenatal diagnosis are the only ways currently available to prevent NCLs.

NCLs ARE GENETICALLY HETEROGENEOUS

Genetic studies have identified six genes—CLN_{1-3}, $CLN_{5,6}$, and CLN_8—underlying NCL_{1-3}, $NCL_{5,6}$, and NCL_8, respectively (Table 1). The function of each gene is yet unclear, although two lysosomal peptidases, palmitoyl-protein thioesterase 1 (PPT1) and tripeptidyl peptidase 1 (TPP1), have been characterized. The CLN_3-encoded protein, Battenin; the CLN_6-encoded protein, CLN6p; and the CLN_8-encoded protein, CLN8p are predicted to be transmembrane proteins. The CLN_5-encoded protein, CLN5p, was determined to be a lysosomal soluble protein, even if it contains hydrophobic segments. A total of 151 mutations have been identified, including 41 at locus CLN_1, 52 at CLN_2, 31 at CLN_3, 4 at CLN_5, 22 at CLN_6, and 1 at CLN_8 (http://www.ucl.ac.uk/ncl). Heterogeneity, both phenotypically and genotypically, has been demonstrated. CLN_1 mutations can result in clinical onset at infantile, late-infantile, or adult age; however, late-infantile onset can be caused by mutations of CLN_2, CLN_3, CLN_5, CLN_6, and CLN_8 genes.[2,4–6]

KEY PROCEDURES FOR DIAGNOSING NCLs

Clinical Assessment

Clinical features of NCLs include rapid progressive deterioration of vision, seizures, development of mental retardation, movement disorders, and behavioral changes.[7] Brain atrophy as documented by imaging studies, including magnetic resonance imaging (MRI), is most pronounced supratentorially and in the brainstem. Cerebellar atrophy, which results in enlargement of the fourth ventricle without concomitant cerebral atrophy, may be an early sign of NCLs.[8,9]

Practically, the progressive development of signs and symptoms is variable over time. Having a clear diagnostic algorithm (Fig. 1) will facilitate the clinical workup and characterization of the genetic deficiency. A good clinical evaluation, by which each individual examiner is capable of assigning an accurate Clinical Coding Score (CCS)[2] to any NCL patient, should be applied in the neurological assessment. The symptoms that should be evaluated include age at onset, first/initial symptoms at onset, and clinical course such as vision loss/blindness, learning and speaking disabilities, difficulty/inability to walk, involuntary movements/lack of coordination, rigidity/increased muscle tone, behavioral problems, and seizures/convulsions. A neuropsychological assessment for NCL patients may include WISC-IV,[10] WRAML,[11] and NEPSY,[12] in addition to the standard Mental Status Examination.[13]

Laboratory Diagnostic Strategies

Pathological studies using EM to identify ceroid lipopigmental inclusions were, and still are, the standard

DOI: 10.1081/E-EDGP 120025756

Table 1 NCLs comprise a group of neurodegenerative diseases characterized by ceroid lipopigments

[d]Progressive epilepsy with mental retardation.

procedure for making the initial differential diagnosis from other neurological disorders.[7] Whenever possible, EM should be carried out at the initial medical center for a patient believed to have an NCL. If the EM results are positive for lipopigment inclusions, further genetic characterization should be pursued. If the initial EM findings are negative, then the EM study should be repeated with different tissues every 3–6 months.

Deficiency of PPT1 or TPP1 has been determined in various tissues such as lymphocytes, lymphoblasts, fibroblasts, brain, and amniotic cells, and chorionic villi in NCL_1[14,15] or NCL_2.[16,17] Testing the activities of PPT1 or TPP1 may help to identify or exclude NCL_1 or NCL_2 patients. Testing of enzymatic activity is the choice method for carriers, for whom the information of familial DNA mutation is not available. However, if the familial mutations have been identified, molecular testing of the mutation(s) would be preferred to determine the carrier status.

Molecular testing of NCLs consists of two phases: clinically based testing for common mutations, and research-based testing for rare or novel mutations. Conducting molecular analyses of CLN_{1-3} genes will allow identification of the majority of NCL patients/families, which account for >85–90% of clinically recognized NCL cases in the general population with mixed ethnic backgrounds. Five common mutations in CLN_{1-3} genes, which are c.223A→G (Y109D) and c.451 C→T (R151X) in CLN_1, IVS5-1G→C (splicing error) and c.636 C→T (R280X) in CLN_2, and deletion of a 1.02-kb genomic fragment involving exons 7 and 8 in CLN_3, have been characterized.[18] Testing for these mutations may provide a sensitivity ranging from 66% for NCL_1, to 75% for NCL_2, to 78% for NCL_3, among clinically referred cases.[5,19] Mutation of the 2-bp deletion in exon 4 of the CLN_5 gene accounts for 90% of NCL_5 cases,[20] and the mutation c.70C→G (R24G) in CLN_8 was seen in all NCL_8 cases.[21] No single mutation in the CLN_6 gene could be characterized as common in the heterozygous population, but the mutation c.214G→T (E72X) in exon 3 has been found in 91% of NCL_6 families from Costa Rica.[22–24] A total of 144 ''private'' or ''familial'' mutations identified in CLN_{1-3}, $CLN_{5,6}$, and CLN_8 genes can be detected in research laboratories. NCL patients with a specific ethnic background (Fig. 1b) may present with one of the NCL variants encoded by the $CLN_{5,6}$ or CLN_8 gene. Therefore, mutation screening should be extended to these genes.

Molecular technology involved in the genetic analysis of common mutations (Table 2) for NCL_{1-3}, NCL_6, and NCL_8 includes the amplification refractory mutation system (ARMS) and allele-specific primer extension (ASPE).[18,25] DNA sequencing of polymerase chain reaction (PCR)-amplified genomic fragments (PCR

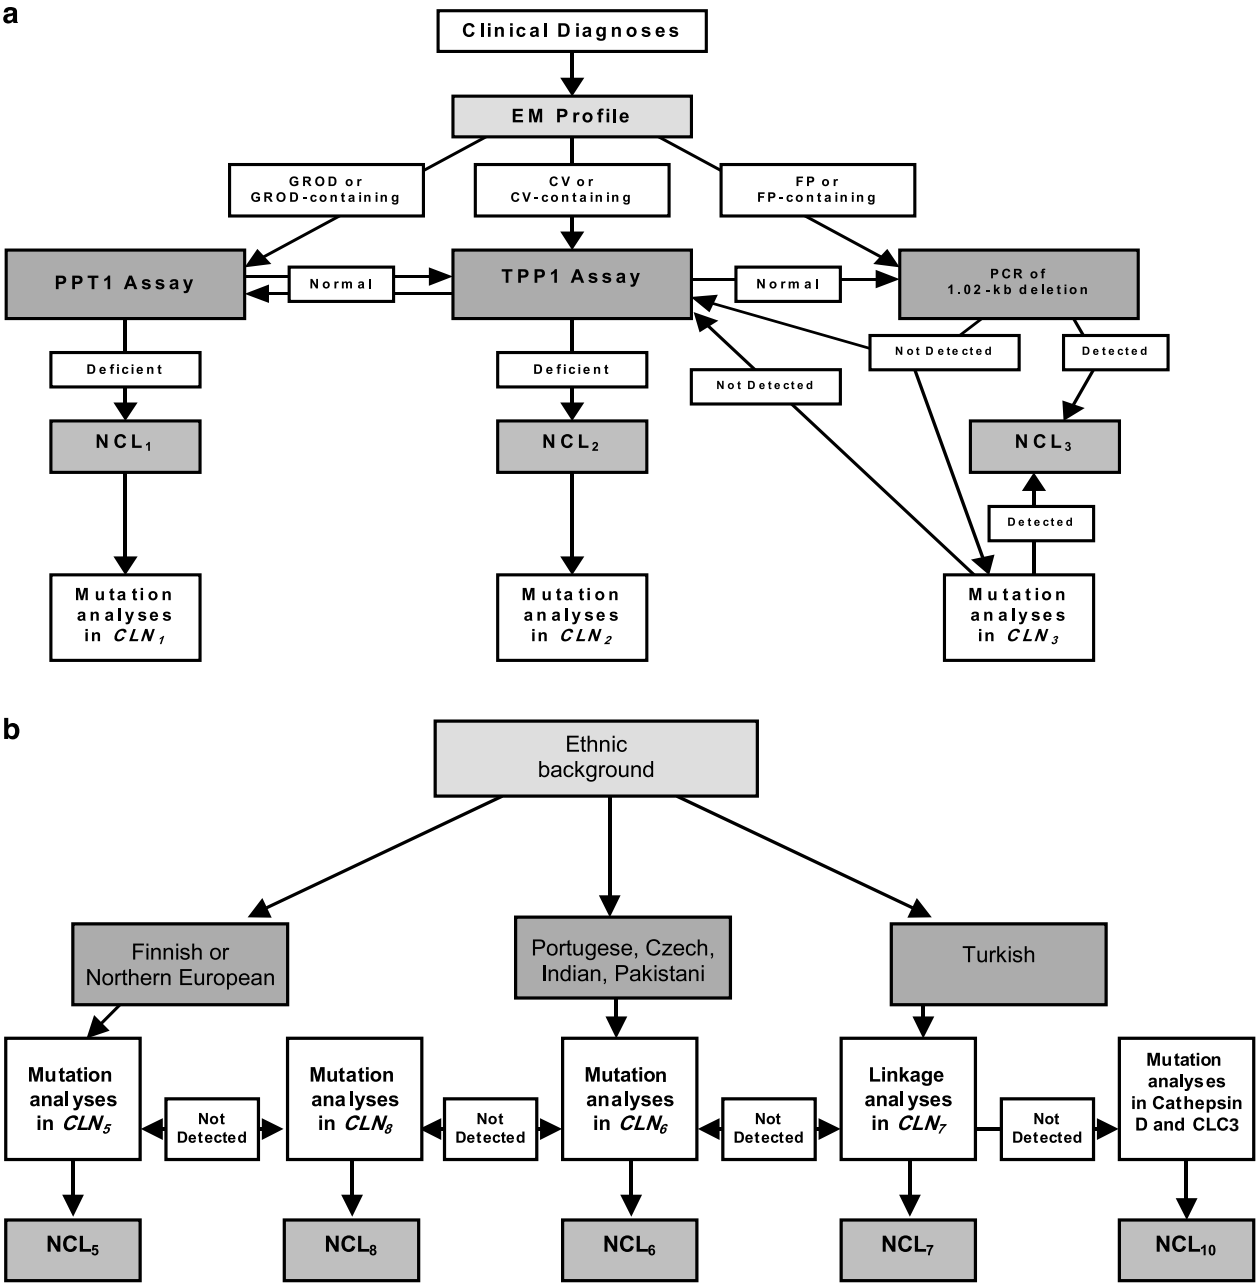

Fig. 1 (a) Diagnostic algorithm for $NCL_{1–3}$. Following clinical assessment, EM studies would provide ultrastructural information guiding the assays of either PPT1 or TPP1, and DNA deletion at the *CLN*$_3$ gene. If enzyme deficiency is demonstrated, mutation analyses will be followed at the *CLN*$_1$ or *CLN*$_2$ gene. (b) Diagnostic algorithm for $NCL_{5–10}$. Following molecular studies on *CLN*$_{1–3}$, the patient should be subjected to further analyses in genetic loci of *CLN*$_{5–10}$. NCL_9 is not included because of dominant inheritance, which can be recognized clinically. (*View this art in color at www.dekker.com.*)

sequencing), including six fragments for *CLN*$_1$, four for *CLN*$_2$, six for *CLN*$_3$, and five for *CLN*$_6$, is used as a golden standard procedure to screen rare or familial mutations for $NCL_{1–3}$ (Table 3). The PCR sequencing is also applied in NCL_6.[24] Although detailed information regarding primer sequences and PCR conditions is provided in this entry, the laboratory that performs the procedures should be aware that each individual protocol ought to be optimized, especially the annealing temperatures and the final concentration of Mg^{2+} in the PCR reactions. Validating the molecular protocols before genetic testing is offered because a clinical test is highly recommended.

CONCLUSION

Making a definitive diagnosis is a great challenge for health professionals dealing with NCLs. Accomplishment of the entire diagnostic procedure may require months, years, or decades before genetic approaches are applied, whereas enzymatic and molecular tests need only days or weeks. It is recommended that genetic tests be pursued when a patient shows progressive neurological symptoms, on account of not only time concerns, but also economic concerns. However, the molecular tests need to include more loci/mutations or to employ cutting-edge technology, such as microarray-based hybridization or capillary-based electrophoresis, to increase detection sensitivity.

Nipah Virus

Michael S. Bronze
Ronald A. Greenfield
University of Oklahoma, Oklahoma City, Oklahoma, U.S.A.

INTRODUCTION

Nipah virus (NiV) is a recently described zoonosis responsible for an epidemic of severe, febrile encephalitis in Malaysia and Singapore. Taxonomically, NiV is a member of the Paramyxoviridae family, Paramyxovirinae subfamily, and *Henipavirus* genus. There were 265 reported cases that resulted in 105 deaths. Ninety-two percent of the reported cases in Malaysia involved patients employed in pig-farming industries. The primary risk factors for infection were the presence of sick or dying pigs on farms and exposure to pigs displaying signs of NiV infection. Human to human transmission is thought to be uncommon. Affected patients presented with fever, headache, dizziness, and prominent neurological features, including changes in mentation and consciousness and signs of brainstem dysfunction. Pathologic examination of the brain revealed prominent vasculitis and thrombosis, neuronal degeneration, and nuclear and eosinophilic cytoplasmic inclusions. Treatment with ribavirin improved mortality in affected patients, and the epidemic was controlled after the culling of nearly 1 million pigs.

EPIDEMIOLOGY

The outbreak of NiV encephalitis began in September 1998 in Malaysia and subsequently spread to other regions of pig farming and then to Singapore. The outbreak was preceded by a respiratory illness in pigs and was originally thought related to Japanese encephalitis virus (JEV). However, the infection did not abate with mosquito control measures and JEV vaccination strategies, and all but a few persons were seronegative for anti-JEV IgM antibodies.[1] The 265 reported human cases likely represent an underestimate of the total number of human infections. The number of infected individuals who experienced asymptomatic seroconversion or became only mildly ill is not precisely known.[2] Asymptomatic infection was serologically identified in 6–17% of those tested in a case-control study evaluating risk factors for NiV infection.[3]

Epidemiological studies revealed that the primary risk for transmission to humans was exposure to sick pigs or fresh pig products. Only 8% of persons with NiV encephalitis had no reported contact with sick pigs, pig urine, or feces.[3] An additional risk factor included employment as an abattoir worker; however, employment as a pork seller or being part of the military effort responsible for culling pigs as part of an eradication campaign carried low risk for acquisition of infection. Human to human transmission was thought to be uncommon.[4]

Based on similarities to Hendra virus (HeV), a related *Henipavirus*, flying foxes (fruit bats) were evaluated as a natural reservoir of NiV. The presence of neutralizing antibodies against NiV was detected mainly in Island flying foxes (*Pteropus hypomelanus*) and Malayan flying foxes (*Pteropus vampyrus*), and NiV has been detected in the urine of Island flying foxes.[5] Neutralizing antibodies have not been routinely found in other animal species. These observations led to the hypothesis that pigs acquire the virus by consuming fruits partially eaten by bats that release the virus in their secretions.[2] Infection in humans is thought to be a dead-end infection.

VIROLOGY AND PATHOGENESIS

Viruses of the Paramyxoviridae family include a number of highly contagious human and animal pathogens, including measles and mumps viruses. NiV is a single-stranded, negative sense nonsegmented RNA virus that is protein encapsidated, helical in shape, and is 120–500 nm in diameter.[6] By electron microscopy, the virus is pleomorphic in appearance and the nucleocapsid has a ''herringbone appearance,'' as seen in Fig. 1.[7] The entire length of the NiV genome is 18,246 nucleotides, which is 12 nucleotides longer than HeV, and demonstrates 70% nucleotide homology in the open reading frames (ORFs) and 44–66% homology in the 5′ and 3′ noncoding regions with HeV.[2,6] It shows broad tropism for a number of cell lines, as is common for Paramyxoviruses. In culture, the virus infects cells through pH-independent membrane fusion mediated by its F and G glycoproteins, forms syncytia, and the cytopathic effect consists of multinucleated giant cells, vacuolation, and apoptosis.[7]

The NiV genome contains multiples of 6 nucleotides conforming to the ''rule of 6'' of other Paramyxovirinae,

DOI: 10.1081/E-EDGP 120028723

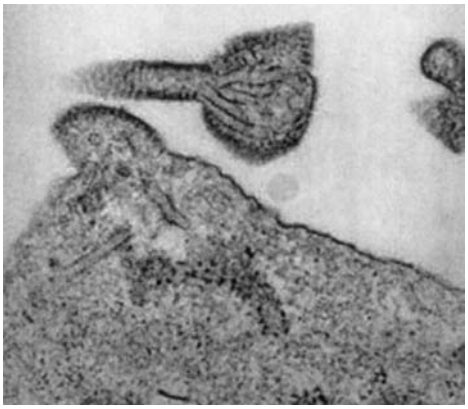

Fig. 1 Electron micrograph of Nipah virus. [From Commonwealth Scientific and Industrial Research Organisation (CSIRO), Australia.]

thereby allowing for greater efficiency of genome replication.[6,8] Additionally, the genome contains 6 major genes (in order from 3′ to 5′ end) as summarized in Table 1: N (nucleocapsid), P/V/C (phosphoprotein/V protein/C protein), M (matrix), F (fusion), G (attachment glycoprotein), and L (large polymerase).[9,10] The NiV 3′ leader sequence is 55 nucleotides long and is identical to other Paramyxovirinae, and there is a 33-nucleotide trailer at the 5′ end. Whereas the 3′ leader sequence is nearly identical to HeV, the NiV 5′ trailer is significantly longer and differs by 3 nucleotides.[6] The N gene of NiV is 2242 nucleotides long and contains two major predicted ORFs. The larger of the two (1599 nucleotides) encodes for a 532 amino acid protein, and the smaller ORF encodes for a 72 amino acid protein that is not found in the HeV N gene.[10] The ORF of the mRNA for the N gene of NiV shares 78% homology with that of HeV, whereas homology in the nontranslated 5′ and 3′ regions is 67% and 41%, respectively.[10] The N protein is the most abundant protein in the Nipah virion and has an apparent molecular mass of 58,000 Da.[9] Genomic RNA forms complexes with N to produce the nucleocapsid.

The mRNA for the P/V/C gene of NiV is predicted as 2702 nucleotides and contains ORFs that encode the P, V, and C proteins.[10] The extent of homology of the ORF between NiV and HeV is approximately 70% for the P gene, 88% for the V gene, and 85% for the C gene.[9,10] The P protein is the largest protein encoded by the P/V/C genes of NiV and has a calculated molecular mass of 78,301 Da.[9] C and V proteins may regulate transcription and replication. The V protein is thought to facilitate the evasion of host cell interferon by inactivating interferon signaling by direct inhibition of STAT1 and STAT2, which are interferon-responsive transcription factors.[11]

The mRNA for the M (matrix) gene is predicted at 1359 nucleotides in length and contains an ORF of 1059 nucleotides that encodes a 352 amino acid protein that has a molecular mass of 39,928 Da.[10] The HeV and NiV M proteins are 77.1% homologous and share significant sequence homology with M proteins of morbilliviruses. The ORF of the F gene is 1641 nucleotides in length, and the mRNA for the entire gene is predicted to be 2337 nucleotides. The F protein is thought to be a type I transmembrane protein whose membrane spanning domain occurs at amino acids 489–518 and is synthesized as an inactive precursor (F_0) that is cleaved by host proteases forming F_1 and F_2.[6] The ORF that encodes the putative attachment glycoprotein (G) of NiV is 2543 nucleotides in length and has 83.3% homology with that of HeV.[12] Both the F and G proteins are membrane glycoproteins that mediate viral fusion and attachment to host cells. Both the G and F proteins are targets for host neutralizing antibodies, suggesting a potential role for the F and G proteins as vaccine constructs.[12]

Nipah virus demonstrates significant tropism for endothelial and neuronal cells in humans and for neuronal and respiratory tract cells in pigs.[13] It is not fully known where initial replication occurs, but it is assumed that either lymphoid or respiratory sites are involved as with other Paramyxoviruses such as measles virus.[2] Viremia probably spreads the virus to other tissues. The endothelium may represent a secondary site of viral replication. Vasculitis is a key element in the pathogenesis of NiV infection, and the presence of viral antigens within endothelial and smooth cells supports the importance of vascular tropism in the pathogenesis of the infection.

Wong et al.[14] have recently reported an animal model of NiV infection that appears similar to acute infection in humans. In this study, golden hamsters (*Mesocricetus auratus*) were challenged either intraperitoneally or intranasally, and the investigators evaluated the clinical course, transmission of NiV to uninfected animals housed with challenged animals, and pathology in infected animals. Uninfected animals housed with challenged animals did not develop clinical signs or seroconversion.

Table 1 Molecular characterization of nipah virus

Gene	Length of gene[a]	Predicted protein size[b]	Molecular weight of protein (Da)
N	2242	532	57,993
P[c]	2704	709	78,301
M	1359	352	39,827
F	2337	546	60,233
G	2543	602	67,038

[a]Length in nucleotides as predicted from mRNA.
[b]Length in amino acids predicted from the ORFs.
[c]P gene includes ORFs for P, V, and C proteins. The predicted protein listed is the P protein only. The V protein of NiV is predicted to be 454 amino acids, while the C protein is 166 amino acids and has a M_r of 19,735 Da.
Source: Refs. [6,9,10].

Virus was identified or isolated by PCR or culture from urine, brain, lung, kidney, liver, and spleen, but not from blood. The authors speculated that the absence of detectable virus in the blood may be related to successful clearance of circulating virus by the immune system or by transport of virus particles out of the circulation by infected blood leukocytes. The role of endothelial cells in clearing virus from the circulation is not fully known. Pathological features resembled those of human infection, suggesting that this model may be beneficial in unraveling the pathogenesis of NiV in humans and as a tool to test antiviral and vaccine strategies designed to treat or prevent infection.[14]

CLINICAL FEATURES

The majority of patients reported contact with pigs. Following a short incubation period, most patients presented with fever, headache, dizziness, vomiting, and reduced level of consciousness.[15] Meningismus was not a common finding. In their series, Goh et al.[15] identified prominent neurological findings, especially in those with a reduced level of consciousness. Common neurological features included segmental myoclonus, cerebellar signs, seizures, and nystagmus, whereas bilateral ptosis, dysarthria, and dysphasia were less common features. The majority of patients were healthy prior to hospitalization with comorbid diseases present in approximately 12%.[15]

Laboratory features included thrombocytopenia and elevated hepatic transaminases in approximately one-third. The most common abnormalities of the cerebrospinal fluid were elevation of the white blood cell count and protein levels. Magnetic resonance imaging revealed multiple, discrete high signal intensity lesions disseminated throughout the brain with >10 lesions occurring in 70% of patients.[16]

The pathological findings of fatal human NiV encephalitis have been reviewed.[17] The major histopathologic findings included systemic vasculitis with extensive thrombosis and organ necrosis, especially in the central nervous system, lungs, and spleen, and endothelial cell necrosis and syncytial giant cell formation. Eosinophilic cytoplasmic and nuclear inclusions, resembling those in other *Paramyxovirus* infections, were seen. Viral antigens were particularly prominent by electron microscopy and immunohistochemistry in endothelial and smooth muscle cells and in neurons, linking vasculitis, and thrombosis to the pathogenesis of the infection.[17]

Diagnosis of NiV infection can be confirmed by detection of type-specific antibodies in cerebrospinal fluid or serum. Serum IgM capture enzyme-linked immunosorbent assay (ELISA) was positive in 65% within 4 days after onset of infection and in 100% by day 12, and IgG ELISA was positive in 100% by day 25.[2] Current ELISAs have 98.4% specificity but may have lower sensitivity.[18] Virus isolation requires biosafety level 4 laboratories, and virus has been isolated from cerebrospinal fluid, urine, and throat and nasal secretions.[17] NiV has tropism for a number of cell culture systems and grows well in Vero cells, forming syncytia. Demonstration of NiV can be accomplished using immunostaining, neutralization assays with specific antisera, polymerase chain reaction, electron or immunoelectron microscopy, or by ultrastructural in situ hybridization using positive or negative sense riboprobes.[7,18] Diagnostic reverse transcriptase-polymerase chain reaction (RT-PCR) assays are available through the Centers for Disease Control and Prevention (CDC) and can detect NiV sequences from tissues of CSF.[18] Diagnostic RT-PCR assays have been based on the sequences of the P and N gene coding regions.

Infection with NiV resulted in severe encephalitis with mortality reaching 40%.[1,2,15] The mean time from onset of illness until death was approximately 10 days, and death was usually related to severe brainstem involvement.[15] Factors associated with poorer prognosis included older age, lower Glasgow coma scores, the presence of segmental myoclonus, impaired brainstem function (manifested by abnormal doll's eyes and pupillary reflexes, vomiting, hypertension, and tachycardia), seizures, areflexia, and abnormal hepatic transaminases and platelet count at time of hospitalization.[15] Of those who survive, 15% of patients have residual neurologic deficits including persistent vegetative state, residual cognitive impairment, and cerebellar disabilities.[15] Interestingly, some patients with NiV infection presented with relapsing encephalitis and late-onset encephalitis.[19] Clinically, relapsing or late-onset encephalitis resembled the acute encephalitis and was thought to represent persistence of NiV.

Ribavirin, a broad-spectrum inosine monophosphate dehydrogenase inhibitor, was shown beneficial in treating patients with NiV encephalitis in an open label trial.[20] As compared with historical controls, treated patients had statistically lower mortality (32% versus 54%). By multivariate analysis, treated patients appeared to have less residual neurological deficits, although this did not reach statistical significance.[20]

Control of the epidemic was ultimately achieved by culling over 1 million pigs from 900 affected farms thought to represent the remaining reservoir of NiV. This posed a significant financial impact on the Malaysian and Indonesian economies and raises concern about the use of NiV as a bioterrorism agent to achieve economic disruption as well as cause disease. A surveillance program has been established to serologically monitor pig farms for evidence of NiV infection. Recently, Guillaume et al.[21] have reported preliminary data on a recombinant vaccinia virus expressing NiV G and F genes. These

vaccines protected hamsters against death following NiV challenge infection, but did not evoke sterile immunity, as evidenced by demonstration of increased levels of neutralizing antibodies after the challenge in all vaccinated animals.[21]

CONCLUSION

The outbreak of NiV infections in Malaysia is an excellent example of how a novel pathogen can significantly impact human and animal health and the economies of certain geographic regions. However, the recognition of the clinical illness, identification of NiV, and subsequent sequencing of its genome have revealed the impressive power of modern virology and clinical medicine to identify and define a pathogen and develop potential treatment and preventive strategies, thereby limiting its potential impact.

NIST Reference Materials for Medical Testing

Catherine D. O'Connell
John P. Jakupciak
National Institute of Standards and Technology, Gaithersburg, Maryland, U.S.A.

INTRODUCTION

Biomarker discovery and validation is in great demand by the pharmaceutical and healthcare industries. The translational component of the human genome information to clinical use is only now beginning to appear. This effort is largely being lead by the pharmacogenomics and toxicogenomics communities in the development of new drugs and in determining their safety and efficacy. Standardized controls or reference materials will be essential for the acceptance of data collected from these new technology platforms by regulatory agencies.

NIST REFERENCE MATERIALS PROGRAM

It is essential to have high-throughput[1] and global scanning[2] methods that are low-cost and reliable clinical platforms to analyze large cohort studies, which statistically validate potential DNA, RNA, and protein assays. The National Institutes of Standards and Technology has developed expertise in measuring genomic instability of DNA repeat elements, the measurement of mutations in nuclear-encoded genes, and the measurement of DNA sequence variations in the mitochondrial genome. This is due, in part, to the development of a measurement program for human identification in conjunction with the Department of Justice.[3,4] In addition to examining current practices and assessing specific causes of measurement error, NIST has developed standard reference materials (SRMs) for optimizing the reproducibility of measurements for restriction fragment-length polymorphism (RFLP) and short tandem repeat (STR) alleles, and mitochondrial DNA sequences used by forensic community. In total, five SRMs are currently available for this purpose, with two additional materials underway.

For the NIST measurement programs, we followed the ACMG guidelines including the recommendation that validation studies incorporate well-characterized samples and positive and negative controls, thus providing evidence of generic and specific sequence amplification.[5]

FRAGILE X SYNDROME

Genetic instability of triplet repeat sequences is an initial step in the etiology of hereditary neurodegenerative diseases and the cause of fragile X syndrome, the most common form of inherited mental retardation. This new paradigm of genetic disease, the transmission of expanded triplet repeat sequences, is associated with approximately 15 other human hereditary diseases.[6,7] Fragile X syndrome is caused by the progressive expansion of CGG repeats in the *FMR1* gene, and there is a direct correlation between the number of CGG repeats and the frequency of inheriting an expanded CGG tract. The *FMR1* gene in normal individuals harbors between 5 and 37 CGG repeats, and three other size categories are recognized that confer clinical information. Full mutations (>230 repeats) are associated with disease, whereas premutations (55–200 repeats) provide at-risk predictive information. The fourth category includes repeat lengths that provide inconclusive diagnostic and predictive information (45–54 repeats) and is generally referred to as the gray zone. Accurate measurements of the length of the CGG tract are critical to the clinical diagnostics community.

The National Institute of Standards and Technology (NIST) has established a quantitative measurement program for trinucleotide repeats[8] through the development of accurate protocols and reference materials for the analysis of the *FMR1* gene after polymerase chain reaction (PCR) amplification of the CGG repeats. Amplification is a commonly used technique for *FMR1* gene analysis and is faster than the traditionally used Southern blot. However, interlaboratory comparisons on the accuracy of amplifying CGG repeats have shown tremendous variation. This is because, in part, of the secondary structure properties of triplet repeats and the lack of standardized protocols. We have determined the metrics in need of standardization for fragile X repeat measurements and have reported the specific measurement variability associated with slab-PAGE and capillary electrophoresis (CE) separations, interlane variability, intercapillary variability, and the variability associated with the amplification of CGG repeat elements.

DOI: 10.1081/E-EDGP 120030814

As reported,[8] the measurement errors associated with slab gels ranged from 0.05 to 0.35 standard deviation (SD). There was also little variation between gels and amplification reactions. The CE measurements were more precise with SD between 0.02 and 0.29. This measurement error is equivalent to one nucleotide of a single triplet repeat. The accuracy in determining the number of CGG repeats was in agreement for the normal and gray-zone length alleles using both slab-PAGE and CE. However, accuracy decreased for the measurement of larger alleles, where repeat size varied ±3 repeats for measuring 85–95 repeats and ±4 repeats for measuring 105–110 repeats, our largest amplified allele. The size of the CGG repeat element in each sample was confirmed by automated fluorescent DNA sequencing.

Summary

The complexity of the various CGG-containing alleles, the variable severity of disease manifestations, and the marked heterogeneity of clinical presentation in carriers are hallmarks of fragile X syndrome. As the risk of reoccurrence is high in the family and carrier relatives, accurate diagnosis of at-risk individuals, even before classic signs of disease manifest, is important. Accurate methods to measure CGG repeat length, and reference materials to distinguish alleles within the different size categories, are important for diagnosis and counseling of affected families. Although CE measurements had better precision than slab-gel measurements, anomalous rapid electrophoretic mobility of repeats occurs in proprietary gels. Hence NIST has developed a control material consisting of an allelic DNA ladder to enable accurate size determinations across platforms. This material, SRM 2399, will be released in late 2004.

TP53

The TP53 tumor suppressor gene is associated with numerous pathways that maintain genetic stability and control cell life and death. Normally, p53 protein levels are very low; however, the levels of p53 change over time. P53 levels fluctuate as cells adapt to pathway-initiated stimuli and p53 feedback systems.[9] Activation of p53 occurs when cells are stressed or damaged. For example, DNA single-strand breaks caused by ionizing radiation are sufficient to trigger up-regulation of p53. Damaged cells have a greater risk of becoming cancerous, thus p53 protein inhibits the cell cycle resulting in programmed cell death. The normal p53 protein does not function in human cancers when the gene is inactivated as a result of mutations. Hence p53 appears to be a critical element in the protection against tumorigenesis.[10]

Almost all mutations in the p53 gene reduce the p53 protein's capability to activate transcription. The majority of p53 mutations that occur in human tumors are located in the sequence-specific DNA binding domain.[11] Hence mutations in the *p53* gene disrupt basic cellular function. PCR-based cancer diagnosis of the status of the *p53* gene requires detection of both common and rare mutation(s) that occur throughout the gene. Moreover, amplification efficiencies of mutant and wild-type sequences are unequal and associated with the distance from the primer to the point mutation.[12] For sensitive detection of TP53 mutations, reliable detection technologies and reference materials for PCR mutation detection systems are needed to monitor both the accuracy of detection and the possible introduction of errors during PCR. Renewable reference materials, such as the NIST TP53 mutation panel,[2] serve to normalize the data collected in different laboratories using different primers and analytical platforms.

The renewable reference panel contains the single-base substitutions most commonly found in human cancers, as well as three that proved difficult to detect by scanning technologies.[2] The panel consists of 12 plasmid clones derived from human genomic DNA containing a wild-type *TP53* gene, 11 of which contain a specific mutation in exons 5–9; the 12th is wild type. This panel accounts for 30% of reported TP53 cancer-associated mutations.[13] We evaluated the panel using single strand conformation polymorphism (SSCP), denaturing gradient gel electrophoresis (DGGE), denaturing high performance liquid chromatography (DHPLC), and exon sequencing, four of the most commonly used methods for mutation detection. Following exon-specific amplification, the amplicons of all 12 clones were analyzed by SSCP, DGGE, DHPLC, and sequencing. SSCP detected 75% of the mutations in the reference panel, as expected. The heteroduplex technologies, DGGE and DHPLC, as well as fluorescent sequencing, positively identified 100% of the reference mutations.

Summary

The reference panel for the detection of TP53 mutations was created from site-directed mutagenesis and cloned into a renewable plasmid vector. Validation of the panel was performed by direct DNA sequencing and with common mutation scanning technologies.

Our results demonstrate that these reference materials and methods can be used in the clinical diagnosis of TP53 mutations in heritable and somatic disease. They may also be useful in the validation of other mutation detection technologies. The panel provides internal quality control and lowers the inherent error of measurements by ensuring that protocol optimization can always detect the mutations contained in the panel. Hence each diagnostic laboratory

can adjust its ''in-house'' protocols to obtain expected and normalized results that can be readily shared and easily compared between different diagnostic laboratories using different analytical techniques.

MITOCHONDRIA

A major focus to improve health-care outcomes for patients with solid tumors is the early detection of disease.[14] This includes identification of early cancer biomarkers and the validation of both detection technologies and clinical utility. As one of three Biomarker Validation Laboratories of the Early Detection Research Network (EDRN), NIST evaluates analytical methods for the identification of biomarkers associated with the early detection of cancer, and develops high-throughput assays/technologies for clinical applications. Validated biomarkers can be reliably used by laboratories to detect cancer in asymptomatic patients at risk for a specific cancer, make a diagnosis once symptoms appear, or monitor cancer patients for recurrence.

Mitochondrial dysfunction has been demonstrated by progressive decline of oxidative phosphorylation capacity of muscles, liver, heart, and brain.[15] The impaired bioenergetic function of the mitochondria has been associated with carcinogenesis in human tissues.[16] Mutations have been detected in both coding and noncoding regions of the mitochondrial genome in cancer and thus may correlate with disease status and serve as a biomarker.[14] Little data exist to explain the mechanism of how mitochondrial mutations and dysfunction predispose individuals to cancer(s). It is likely that energy depletion and free radical generation triggered by alterations in mitochondrial genotype underlie the basis of tumorigenesis.

Recently, we developed a high-throughput DNA sequencing protocol for the detection of mitochondrial DNA mutations (sequence variants) in cancer.[17] The protocol was compared with currently available protocols and technology platforms to assess their utility in identifying mitochondrial sequence variants associated with lung cancer. Primary lung tumors and patient controls (blood) were used to isolate mtDNA, which was analyzed by slab gel and capillary electrophoresis and DNA resequencing microarrays.

Mitochondrial DNA was fully sequenced from both blood and tumor obtained from 12 individuals with lung cancer. Using a nested protocol and M13 primers for sequencing, the CE protocol developed was able to obtain 97–100% sequence coverage for the forward strand and 90–100% sequence coverage for the reverse strand. Tumor-specific sequence variants were identified in 6 of 12 clinical samples from lung cancer patients.

Although many nucleotide changes were detected, our study demonstrates that 45% of mutations do not alter the amino acid sequence. In this limited study, individuals with lung cancer that were of the same age had strikingly different mitochondrial genome signatures, suggesting that these variants are cancer-associated changes. Although the sample set is small, we note that no correlation could be made with respect to presence or number of sequence variants and either tumor type or patient age from which the tumor sample was derived. For example, one individual, age 82, contained 4–7 sequence variants, while two others, age 78 and 84, contained no or one sequence variation between somatic and germ line.

Two SRMs have been developed for validation of mitochondrial sequence changes.[18,19] SRM 2392 is used to confirm homoplasmic mitochondrial DNA sequence of the entire mitochondrial genome. SRM 2394 is used to detect and quantify unique heteroplasmy within the mitochondria present in a population of cells.

Summary

These results demonstrate the advantages of fluorescent sequencing for the identification of both heteroplasmic and homoplasmic sequence variants in small quantities of human tissues and bodily fluids. In addition, cost analysis revealed that automated CE is cheaper than microarray resequencing in its currently available format. CE high-throughput analysis of the entire mitochondrial genome from lung cancer patients detected sequence variants in Stage I, Stage III, and Stage IV tumors, suggesting that mitochondrial instability could serve as a biomarker for early detection. Because mitochondrial mutations, unlike nuclear genes, are not restricted by cancer type, the identification of mtDNA sequence variants may serve as a universal fingerprint for other cancers and mitochondrial-linked diseases.

CONCLUSION

The National Institute of Standards and Technology (NIST) compares, evaluates, and validates DNA (and other biologic) markers for clinical diagnostics. Where applicable, we develop high-throughput techniques for both solid tumor and noninvasively (i.e., serum) collected sample analysis. We incorporate broad-based consensus via interdisciplinary NIST-sponsored workshops into the development of reference material(s). In general, NIST activities in fragile X, TP53, and mitochondrial variants provide specialized technical and scientific expertise for measurement needs, thus fostering economic and clinical development.

ACKNOWLEDGMENTS

This study was funded in part by the National Cancer Institute, Early Detection Research Network. We thank Kristy Richie (kristy.richie@nist.gov) for providing an update on the development of SRM 2399, fragile X syndrome standard reference material.

Certain commercial equipment, instruments, materials, or companies are identified in this paper to specify adequately the experimental procedure. Such identification does not imply recommendation nor endorsement by the National Institute of Standards and Technology, nor does it imply that the materials or equipment identified are the best available for the purpose.

Nucleic Acid Sequence-Based Amplification (NASBA) and Transcription-Mediated Amplification (TMA)

N

Margareta Ieven
University Hospital of Antwerp, Edegem, Belgium

Katherine Loens
University of Antwerp, Wilrijk, Belgium

INTRODUCTION

The qualitative and quantitative detection of RNA is clinically important. Reverse transcription of RNA followed by polymerase chain reaction (PCR) is a two-step reaction, which can be inconvenient; furthermore, it may be difficult to differentiate mRNA from contaminating genomic or proviral DNA. This review presents alternative RNA amplification strategies and describes the data published in studies that have used this methodological approach. Nucleic acid sequence-based amplification (NASBA) (bioMérieux, Boxtel, The Netherlands) and transcription-mediated amplification (TMA) (Gen-Probe Inc., San Diego, CA; Bayer Diagnostics Division, Tarrytown, NY; Chugai Diagnostics Science, Tokyo, Japan) amplify RNA under isothermal conditions. The constant temperature maintained throughout the amplification reaction allows each step of the reaction to proceed as soon as an amplification intermediate becomes available. Products of TMA and NASBA are single-stranded and thus can be applied to detection formats by using probe hybridization without any denaturation step.

TECHNICAL ASPECTS

Using an RNA template, NASBA and TMA amplify RNA via the simultaneous action of three enzymatic activities: an RNA polymerase activity, a reverse transcriptase (RT) activity, and RNase H activity. The synthesis of cDNA is primed by specifically designed primers, one end of which is a target-specific sequence, while the other end contains a promoter for the RNA polymerase. The RT synthesizes an RNA–DNA hybrid, the RNase H digests the RNA component, and the RT synthesizes double-stranded DNA; finally, the RNA polymerase produces numerous RNA copies (Fig. 1). An excellent overview of the NASBA amplification principle and primer and probe design rules is given by Deiman et al.[1]

NASBA and TMA were originally applied for specific RNA amplification, but the protocol is adaptable for DNA amplification as well, by changing template denaturation, primer design, and sample extraction.

Because the amplification product is single-stranded RNA, it can easily be detected by hybridization with sequence-specific probes. Different techniques can be used: enzyme-linked gel assay,[2] electrochemiluminescence (ECL),[3] and real-time detection by molecular beacons.[4–7]

MULTIPLEX NASBA AND TMA

Greijer et al.[5] designed a multiplex real-time NASBA using molecular beacon probes labeled with three different fluorophores to quantify human cytomegalovirus (CMV) IE1 mRNA by competitive coamplification of wild-type and calibrator RNA. A simultaneous detection of late pp67mRNA in whole-blood samples of CMV-infected lung transplant patients was also obtained. Despite the somewhat lower sensitivity of the real-time NASBA compared with the conventional NASBA, the simultaneous quantification of IE1 and detection of pp67 RNA was reproducible and accurate. Loens et al.[6] also developed a multiplex real-time NASBA for the simultaneous detection of *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella pneumophila* RNA in respiratory specimens by using three fluorophores. They also found a slightly lower sensitivity of the multiplex real-time assay compared to the conventional ECL detection on spiked respiratory samples.

The Procleix human immunodeficiency virus-1/hepatitis C virus (HIV-1/HCV) assay (Gen-Probe Inc.) detects both HIV- and HCV RNA in 1 tube.[8] The source of the reactivity can be determined by discriminatory assays using virus-specific probes. The HIV-1/HCV assay and the discriminatory assays are able to detect 10–13 copies of HIV-1/mL with 95% detection rates, and can detect 30 copies/mL of HCV with 95% sensitivity. Furthermore,

DOI: 10.1081/E-EDGP 120024072

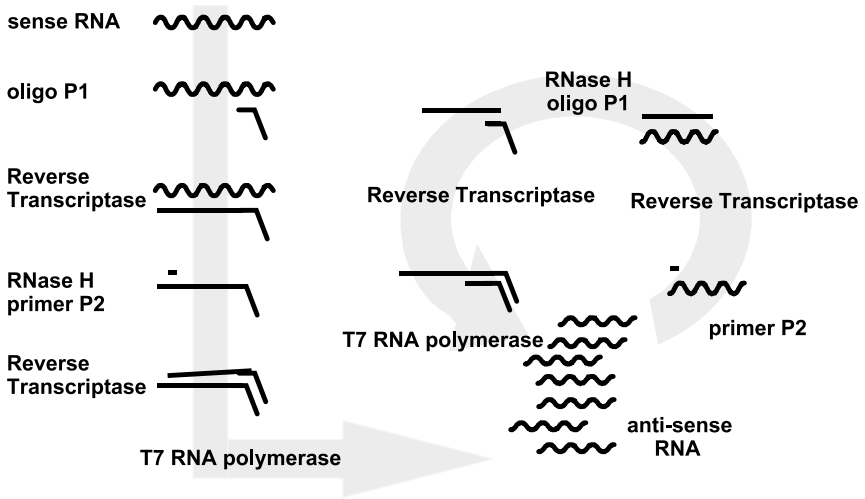

Fig. 1 NASBA amplification.

the assay can be used with high sensitivity and specificity for the screening of donor blood.[9]

Gaydos et al.[10] evaluated the performance of the APTIMA Combo 2 assay (Gen-Probe Inc.) for the simultaneous detection of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* in endocervical swabs and first-catch urine specimens (FCU) from females, and compared the results with patient infected status, available by using other commercial nucleic acid amplification techniques. Sensitivity and specificity rates for *C. trachomatis* in swabs were 94.2% and 97.6%, respectively, and 94.7% and 98.9%, respectively, in FCU. Sensitivity and specificity for *N. gonorrhoeae* in swabs were 99.2% and 98.7%, respectively, and in FCU, 91.3% and 99.3%, respectively.

ADVANTAGES AND DISADVANTAGES

One advantage of NASBA and TMA compared to PCR is that they are continuous, isothermal processes that do not require a thermocycler. The constant temperature maintained throughout the amplification reaction allows each step of the reaction to proceed as soon as an amplification intermediate becomes available. Thus, the exponential kinetic of the amplification process, which is caused by multiple transcription of RNA copies from a given DNA product, is intrinsically more efficient than DNA amplification methods, which are limited to binary increases per cycle.[11]

RNA is the genomic material of numerous viruses. The application of an RNA-based amplification technique offers advantages compared to a DNA-based amplification technique: no additional RT step is required, thus saving time and reducing the risk of contamination.

NASBA and TMA can be targeted at ribosomal RNA; thus they offer a diagnostic advantage because bacterial rRNA is present in multiple copies/cell and it also implies biological activity, whereas DNA is present at a much lower number of copies. Therefore the likelihood of initiating amplification is greater when rRNA is targeted instead of DNA. Furthermore, the assays could be used in viability studies.

There are also a number of disadvantages. The specificity of the reactions might be lower because the enzymes used are not thermostable, and so that the reaction temperature may not exceed 42°C without compromising the reaction. However, the specificity rate is increased by additional hybridization with target-specific probes. Finally, the length of the amplified RNA target sequence should be in the range of 120–250 nucleotides. Shorter and longer sequences are amplified less efficiently.

Furthermore, RNA integrity and amplification inhibitors are also the main causes of concern for NASBA, TMA, RT-PCR, and other RNA amplification procedures. Stability of RNA may be affected during collection, processing, and storage of specimens prior to its isolation. The addition of RNase inhibitors to the clinical specimens, such as guanidine thiocyanate, is required to preserve RNA integrity. Some studies suggest that quality control of buffers for storage of clinical material is critical when RNA is to be analyzed.[2]

To overcome part of this problem and to improve the reproducibility of the in-house developed NASBA standardized reagents, the ''NucliSens Basic Kit'' (bioMérieux) is now commercially available. It contains all the necessary reagents for 1) nucleic acid release and inactivation of RNases and DNAses; 2) silica-based extraction of nucleic acids; 3) NASBA reagents; and 4) reagents for electrochemiluminescent detection including the ECL probe, and

paramagnetic particles to link the capture probe for detection. The primers and the target-specific biotinylated capture probe are to be synthesized for each target.[12]

QUANTITATIVE NASBA AND TMA APPLICATIONS

Quantitative nucleic acid amplification tests are gradually introduced into the laboratory. These assays are used for determination of the viral load of patients infected with blood-borne viruses such as human immunodeficiency virus type 1 (HIV-1) and hepatitis C virus (HCV).

HIV-1 RNA: Using the NucliSens HIV-1 QT (bioMérieux),[13,14] between 25 and $>5\times10^6$ copies/mL of HIV-1 RNA can be detected with a 95% detection rate of 176 copies/mL, by using 1 mL of EDTA, citrate, or heparin plasma as a sample. Murphy et al.[13] compared the Roche COBAS AMPLICOR MONITOR version 1.5 (Roche Molecular Systems), the NucliSens HIV-1 QT with extractor, and the Bayer Quantiplex Version 3.0 (Bayer) for quantification of HIV-1 RNA in 460 plasma specimens from HIV-1 infected patients. They observed that NucliSens showed 100% specificity and the best sensitivity with an input of 2 mL. In another recent study, the same specificity was displayed by the NucliSens HIV-1 QT assay.[14] In a comparison with the ultrasensitive AMPLICOR HIV-1 Monitor version 1.0 assay (Roche Molecular Systems), the NucliSens and the AMPLICOR assays were equivalent in detecting HIV-1 RNA (concentrations of 10^3–10^5 copies/mL), although at lower RNA concentrations, the NucliSens assay was more sensitive.

Recently, a real-time NASBA was described for the quantification of HIV-1 isolates.[7] All HIV-1 groups and subtypes could be detected and quantitated with equal efficiency. The throughput of the assay was high, with 96 samples amplified and detected within 60 min.

The performance of the Gen-Probe HIV-1 viral load assay was compared to that of widely used commercial HIV-1 RNA assays by using a panel of primary isolates from Kenya.[15] The Gen-Probe HIV-1 viral load assay and the Roche AMPLICOR HIV-1 MONITOR test version 1.5 were both sensitive for the quantitation of the Kenyan isolates, which represent subtypes A, C, and D. For the majority of viruses, the Gen-Probe HIV-1 viral load assay was more sensitive than the Roche AMPLICOR HIV-1 MONITOR version 1.0, the Bayer Quantiplex HIV RNA 3.0 assay, and an in-house RT-PCR method.

The conserved 5′NCR of HCV has been used as a target for the development of qualitative and quantitative ECL-based NASBA assays for genotypes 1a, 1b, 2, 3, 4, and 5.[16] When different assays were compared, the HCV NASBA-QT assay was over 10 times more sensitive than the bDNA assay, while the quantitative results of both assays were highly concordant. The HCV NASBA-QT assay was comparable in sensitivity with the HCV MONITOR assay (Roche Molecular Systems), but the latter yielded consistently lower values.[16]

The qualitative COBAS AMPLICOR HCV version 2.0 PCR assay (Roche Molecular Systems) and the VERSANT HCV RNA qualitative assay (Bayer) were compared for analytical sensitivity and clinical performance.[17] The calculated limit of detection for HCV TMA was 6 IU/mL. To compare clinical performance, 300 specimens were evaluated [112 samples indeterminate in an anti-HCV enzyme immunoassay (EIA) and HCV PCR negative, 79 EIA positive and HCV PCR negative samples, and 105 EIA and HCV PCR positive samples]. For these groups, the interassay accordance ranged from 96.2% to 100%. HCV TMA demonstrated an excellent concordance with HCV PCR on clinical samples.

Quantitative assays for determination of the viral load of cytomegalovirus (CMV) might be important, but are still under development and have to be further evaluated in clinical studies.

NASBA and TMA may have an increased sensitivity compared to PCR-based methods.[15,18] In patients chronically infected with HCV who are undergoing antiviral therapy, sustained virologic response is suggested by viral clearance by end of treatment. However, some individuals relapse after achieving apparent viral clearance by end of treatment. Residual serum HCV RNA was detected by TMA in end of treatment samples from 34.6% of patients who had achieved apparent viral clearance by PCR.[18] Such new sensitive assays could help redefine end-of-treatment response and assist in the antiviral management of HCV infection.

OTHER NASBA AND TMA APPLICATIONS

CMV mRNA: Although it is not the most sensitive tool available, NucliSens CMV pp67 test (bioMérieux) specifically detects only the clinically relevant stages of infection, and was shown to have the best specificity and positive predictive value for disease development.[19]

Recently, quantitative NASBA assays have been described for the detection of IE1 and pp67 mRNA expression in lung transplant recipients, and for the quantitative detection of IE1, pp67, and immune evasion genes US3, US6, and US11 in CMV-infected cells.[20] Greijer et al. concluded that effective antiviral treatment was reflected by a rapid disappearance of pp67 mRNA, confirming the clinical utility of the assay.

The BDProbeTec ET *Mycobacterium tuberculosis* Complex Direct Detection Assay (DTB) (Beckton Dickinson Biosciences, Sparks, MD) was compared with the enhanced *M. tuberculosis*-amplified Direct Test (AMTDII) (Gen-Probe Inc.), acid-fast staining and culture, with the combination of culture and clinical diagnosis as the

gold standard.[21] After resolution of the discrepant results, the sensitivity and specificity rates, as well as positive and negative likely ratios for AMTDII were 88%, 99.2%, 110, and 0.11 for respiratory specimens and 74.3%, 100%, 740, and 0.26 for extrapulmonary specimens, respectively. The corresponding values for DBT were 94.5%, 99.6%, 235, and 0.05 for respiratory specimens and 92.3%, 100%, 920, and 0.07 for extrapulmonary specimens, respectively. Differences between both assays were associated with the presence of inhibitors.

A sensitive and specific NASBA assay was developed for the amplification and detection of *M. pneumoniae* 16S rRNA in respiratory specimens.[2] The sensitivity of this NASBA was comparable to that of a PCR targeted at the P1 adhesin gene. A commercially available NASBA NucliSens Basic Kit® assay[12] and a real-time NASBA assay for the detection of *M. pneumoniae* 16S rRNA in respiratory specimens were developed by the same group.[4] The intrarun variability coefficients for the real-time detection of specimens spiked with 50, 500, and 5000 color changing units (CCU) of *M. pneumoniae* were 26.4, 8.1, and 4.6 respectively; the interrun variation coefficients for the same inputs were 34.8, 10.7, and 13.9, respectively. The intrarun variation coefficients for the electrochemiluminescence detection of 50, 500, and 5000 CCU were 61.8, 45.3, and 28.2, respectively; the interrun variation coefficients for the same inputs were 57.7, 78.2, and 42.6 respectively. Loens et al. concluded that real-time NASBA, in comparison with ECL detection, shows high concordance in sensitivity and specificity with a clear advantage for the real-time technology regarding handling, speed, and number of samples that can easily be tested in a single run. Furthermore, the real-time NASBA assay requiring less manipulations and producing results without postamplification processing reduces the potential risk for product carryover.

Goessens et al.[22] compared the Gen-Probe transcription-mediated amplification assay (AMP CT), the LCx assay (Abbott Laboratories, Chicago, IL), and the Roche COBAS AMPLICOR assay for the detection of *C. trachomatis* in urine samples. Sensitivities and specificities were calculated by using the following gold standard: true positive if two or more techniques yielded a positive result. The sensitivities of LCx, COBAS AMPLICOR, and AMP CT were 84%, 93%, and 85%, respectively. Specificity exceeded 99% for all three assays.

CONCLUSION

An increasing number of NASBA- and TMA-based assays—such as those for HIV-1 and HCV genomic RNA, CMV mRNA assays, as well as *C. trachomatis* and *M. tuberculosis* rRNA assays—containing all the necessary components required for isolation, amplification, and detection have become commercially available. They are user-friendly and easy to use in clinical settings.

For various other applications, specific primers and probes have been designed that can be used in combination with the NucliSens Basic Kit, which contains all the components except for the specific primers and probes. These assays need further evaluation in clinical settings.

At present, ECL is the most sensitive method for the detection of the NASBA amplicon. An increasing number of real-time applications are being evaluated, even in multiplex formats. A major advantage of the use of molecular beacons is the ability to carry out real-time detection during amplification, which shortens the overall time of the assay, reduces the risk of contamination, and also provides information about the kinetics of the reaction.

Quantitative assays will become increasingly important, especially for the follow-up of patients, infected with blood-borne viruses such as HIV and HCV, who are under antiviral treatment.

Because NASBA and TMA have been shown to be unaffected by sensitivity and specificity problems associated with other isothermal techniques, it seems likely that their unique features will make this a technology that will be widely used in research and diagnosis. As the processes become more refined and standardized, both assays may displace or supplement current methods for rapid clinical laboratory diagnosis.

INTRODUCTION

Hybridization between molecules of single-stranded DNA, including short sequences (i.e., oligonucleotides), is a key step in many molecular biology technologies including polymerase chain reaction (PCR) and DNA microarrays. The design of the oligonucleotides for these two applications is the subject of this article. Many of the design considerations are overlapping between the two applications.

OVERVIEW

DNA hybridization methods exploit the base-pairing properties that enable one strand of DNA to recognize its specific complementary strand to form the double-stranded DNA molecule. Thus on a microarray chip, a single strand of DNA tethered to a surface (a probe) can readily hybridize with its single-stranded complement even in a complex mixture of many other DNA molecules. When the target molecules are fluorescently labeled, the resulting signal at a particular location on the array establishes the existence of the complimentary sequence in the target.

Polymerase chain reaction (PCR) is another technology where DNA hybridization plays a central role. In PCR, the initial hybridization is between the oligonucleotide primers and the target DNA to be amplified. The PCR reaction produces large numbers of copies of a defined DNA fragment. The primers bind to a complementary sequence and initiate extension of the adjacent DNA regions using DNA polymerase. Primer design is one of the key determinants for the specificity and the yield of the reaction. Robust PCR primer design requires that the melting temperatures of the two primers must be closely matched.

Thus the melting temperature is one of the primary design variables in both of these technologies. The melting temperature, T_m, of a DNA duplex is defined as the temperature where one-half of the nucleotides are paired with their complement and one-half are unpaired. T_m is typically measured as the midpoint of the spectroscopic hyperchromic absorbance shift during DNA melting. T_m depends mainly on the DNA GC base content, cation concentration of the buffer, and DNA double-strand length. Currently, the most accurate prediction of T_m for oligonucleotide DNA uses the thermodynamic nearest-neighbor (NN) model. The NN model for nucleic acids assumes that the stability of a given base pair depends on the identity and orientation of neighboring base pairs. The NN model basic assumption is that probe free energy can be calculated from the enthalpy and entropy of all NN pairs. NN calculations for T_m prediction are useful for microarray design and for the selection of PCR primers and hybridization probes.

MELTING TEMPERATURE PREDICTION

The nearest-neighbor melting temperature thermodynamic model[1] is represented by

$$T_m = \frac{\Delta H}{\Delta S + R \ln C_t} + 16.6 \log_{10}[x_{salt}]$$

where

$$\Delta H = \sum_i n_i \Delta H_i + \Delta H_{\substack{\text{init} \\ \text{GC}}} + \Delta H_{\substack{\text{init} \\ \text{AT}}} + \Delta H_{sym}$$

$$\Delta S = \sum_i n_i \Delta S_i + \Delta S_{\substack{\text{init} \\ \text{GC}}} + \Delta S_{\substack{\text{init} \\ \text{AT}}} + \Delta S_{sym}$$

and where ΔH_i and ΔS_i are the enthalpy and entropy terms associated with the $n-1$ pairs of neighboring nucleotides contained in the sequence of interest. R is the universal gas constant (1.987 cal/mol K). C_t is the total molar concentration of single strands when oligonucleotides are self-complementary or it is equal to 1/4 of this concentration in the case of non-self-complementary

DOI: 10.1081/E-EDGP 120030820

sequences. The model assumes an equal concentration of the complementary strands.

POLYMERASE CHAIN REACTION PRIMER DESIGN

The task of designing PCR primers[2] starts from the identification of the target sequence (amplicon) of interest. It is assumed here that the target sequence is known from previous work. The region near each end of the target is then analyzed for promising primer sequences. Variables at this stage include the starting location and primer length. The base composition and particular sequence of each potential primer impact the ability of the primer to perform well through their influence on secondary variables including melting temperature and nonspecific annealing.

The melting/annealing temperature of a primer can be predicted from the nearest-neighbor model described above. The first requirement is that the primer pair must have closely similar annealing temperatures because extension of both strands occurs simultaneously under the same reaction conditions. The primers, being small and mobile, outcompete the complementary target strands and anneal forming a short double-stranded section with a long 5′ single-strand overhang. The annealing temperature chosen for the PCR reaction is usually 5–10°C less than the melting temperature of the primer pair to promote stable hybridization between the primers (which typically exist in excess numbers) and the amplicon to obtain high yield in each cycle.

The choice of a very low annealing temperature often leads to nonspecific annealing where the primers hybridize with mismatches at the wrong location on the single-stranded target. Nonspecific hybridization can lead to unexpected amplicons and competition with the desired target for reaction constituents. This provides a design incentive to use longer primers that have a higher annealing temperature. However, the requirement of longer primers often complicates primer design because of increased opportunities for primer hybridization to other primers (primer dimers) or hybridization between sections of a primer (secondary structure such as hairpins).

To avoid primer dimers, complementarity can be detected at design time by aligning the primers which is a simple task for short sequences. The stability of a primer dimer can be predicted by calculating its melting temperature. In most cases, it is best to simply choose a primer set that does not have such complementarity, although short complementary regions have such a low melting temperature that they usually do not present a problem.

Hairpins, where a single-stranded molecule loops back and anneals with itself (because of an inverted repeat), can form in single-stranded DNA and interfere with primer annealing. Such structures can be more stable than similar length annealing between separate molecules because the loop stabilizes one of the ends. Hairpins formed with highly stable ends can sometimes exhibit slow melting kinetics which implies that they may exist in a hairpin state even after a typical PCR denaturing protocol at 94°C. If a fraction of the primers are bound up as hairpins, the yield of the PCR reaction will be reduced. Hairpin potential can be predicted based on sequence analysis.

Nonspecific annealing of primers to the target at locations other than the exact match can cause reductions in yield of the PCR reaction. Potential annealing sites can be predicted and ranked by alignment of the primers to the target sequence. Because primer extension will only occur when the 3′-end is hybridized, 3′-end stability at mismatched locations is the most important consideration. For mismatch sites where the 3′-end is matched, the primer sequence must exhibit sufficient mismatches in the rest of the sequence to destabilize the hybridization. A related issue is that the preferred 3′-end sequence is CTA or CAT and the worst choice is CGG. This is based on the fact that mismatch stability increases $G:T \leq G:A < T:T \leq G:G < A:A < C:C < C:T < C:A$.[3] Thus a 3′-end structure such as CGG provides relatively stable hybridization with a wide range of mismatch conditions and can thus promote nonspecific amplification.

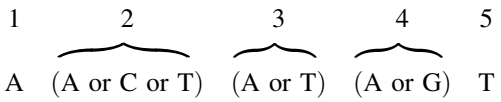
DESIGN OF DEGENERATE SEQUENCE OLIGONUCLEOTIDES

In some DNA microarray-based applications, ‘‘universal’’ primers, which enable amplification of several related amplicons simultaneously, can significantly reduce the number of reactions needed and thus save cost and time. The design of universal PCR primers relies on multiple sequence alignment (alignment of multiple sequences that inserts gaps into the individual sequences to align conserved sequences in the same column) which is used to identify sequences of highly conserved regions. Instead of developing individual primer sets for each of a group of paralogous genes or alleles of a single gene, universal primers can be designed to amplify several such genes simultaneously. Identification of the resulting amplicons by DNA microarrays allows discrimination of a range of genes using a single PCR reaction, as demonstrated for amplification and identification of 16 Staphylococcal enterotoxins simultaneously.[4]

As a rule, these universal primers are designed from conserved regions of related genes. In many cases, there

are several positions within these conserved regions that exhibit variation. Universal primers can be designed, based on such regions, as a mixture of all the sequence permutations represented by the variation at each location. Such primers are termed degenerate and are described using the International Union of Pure and Applied Chemistry (IUPAC) base nomenclature.

For example, the sequence AHWRT represents a degenerate primer 5 bases long with degeneracy at positions 2–4 where H represents A, C, or T, W represents A or T, and R represents A or G.



During synthesis of this degenerate primer, a mixture of the indicated phosphoamidites is added into the reaction at the variable positions; for example, the second base in the example sequence can be A, C, or T. The synthesis results in a mixture of 5-nt-long primers instead of a single sequence. The degeneracy of the final primer mixture is the product of the degeneracy at each base position (degeneracy = 12 for the 5-nt example).

Degenerate primers have a range of melting temperature which can be calculated using the nearest-neighbor model. The lower limit of the range typically corresponds to the sequences formed by low melting bases (A–T) and can be recommended as the annealing temperature in initial experiments. A second concern regarding degenerate primers is concentration of the primers in a PCR reaction. The concentration of each individual sequence in a degenerate primer mixture is the total concentration divided by the degeneracy. Thus the primer concentration must be increased by a factor equal to the degeneracy to achieve the proper primer concentration for each individual primer in the mixture.

High values of degeneracy are impractical because of issues associated with primer concentration and the increased potential for primer dimers. Several rules can be applied to decrease the degeneracy of a primer designed for a particular set of conserved sequences. First, a few weakly destabilizing mismatches such as G:T can be ignored because they do not disrupt the duplex stability greatly. Second, universal nucleotide analogs can be used, such as inosine, which pairs stably with any of the four nucleotides. Because degenerate primers are actually mixtures of oligonucleotides, the experimental conditions (annealing temperature, buffer, magnesium chloride, primer concentration) should be optimized experimentally, similar to the procedure for multiplex PCR (PCR reaction which multiple DNA regions amplified simultaneously using multiple primers).

MICROARRAY PROBE DESIGN

From a probe design perspective, there are two types of oligonucleotide microarrays utilizing short (up to 25 nt) or long (up to 60 nt) probes. Long probes are major successors of cDNA-s and PCR amplicons utilized for expression profiling and whole genome comparisons, whereas short probes are good for single nucleotide polymorphism analysis genotyping and identification of microbial pathogens.

Selection of proper probes is one of the key steps for obtaining consistent and reliable data from microarray hybridization experiments. The main goals in probe design are common for all platforms and can be summarized as high specificity (complementary to the unique region of the sequence of interest) and uniform hybridization properties for all of the probes in the array. Attainment of these design goals provides accurate detection and quantification of the target over a large dynamic scale.

To satisfy these design goals, the typical range of GC content should be between 40% and 60% to avoid the presence of long GC clusters that could cause unspecific binding. Repetitive motifs or regions consisting of the same consecutive bases may result in slippage along the target resulting in unspecific hybridization. Self-annealing sites allowing hairpin formation have the potential to reduce the number of available probes for hybridization. Common practice is to eliminate secondary structure concerns by using denaturing solutions during the spotting step (50% DMSO) and/or high stringency conditions for the hybridization step (20–50% formamide or 55–65°C).

Whereas these rules of probe design are reasonable and straightforward, still, there is no simple model for a priori prediction of hybridization intensities that produces consistent estimates of hybridization behavior. Several parameters such as probe GC content, length, base order, and even kind of terminal nucleotides, as well as size, type (DNA or RNA), and secondary structure of the target could influence both the thermodynamics and kinetics of probe-target duplex formation. Additionally, hybridization conditions (temperature, time, ionic strength, concentration of the probe and the target, the presence of denaturing agents or detergents) and washing conditions (temperature and ionic strength) contribute to final signal intensity on microarrays.

One of the most promising approaches for probe design is based on the nearest-neighbor model described above. This model postulates that the stability of DNA–DNA duplexes mainly depends on the composition and orientation of neighboring base pairs. The duplex stability is correlated with a value of target-probe hybridization free energy (ΔG), which can be calculated from entropy and enthalpy of each possible matched nearest-neighbor

pair. Despite the fact that values used in the nearest-neighbor model were obtained for hybridization in solution, calculated free energies of duplexes demonstrate a clear correlation with the hybridization intensities on microarrays. Probes with similar ΔG values of duplex formation are found to bind their corresponding targets with equal intensity.

Methods for probe synthesis and immobilization on a chip surface must be taken into account when discussing quantitative reliability of DNA-microarray data. Recent advances in technology allow synthesis of high-density arrays of probes (up to 10^6 probes/cm^2) directly on a chip surface using photolithography. However, the chemistry of the in situ synthesis has a finite yield such that in a 25-step reaction with 99% yield at each step, the resulting yield of probes with the correct sequence is only 78% ($0.99^{25}=0.78$). Alternative array manufacturing approaches such as ink-jet printing and robotic spotting each produce microarrays with different hybridization properties.

Microarrays of probes attached to a chip surface by either their 3′- or 5′-ends appear to have nearly identical sensitivity, specificity, dynamic range, and reproducibility. At the same time, probes synthesized on a chip surface in $3' \rightarrow 5'$ direction or attached to a glass slide through 3′-ends cannot be utilized in many common types of enzymatic modifications such as primer extension, ligation, and flap cleavage.

Selection of proper length of probes is dictated by the experiment objective. In general, long probes (50–60 nt) produce more intense hybridization signal than shorter ones but possess lower specificity. Intensity of the hybridization signal rises rapidly for probe lengths in the range of 17–50 nt and then reaches a plateau. The presence of a linker (typically 6–9 carbon atoms) between the chip surface and probe sequence facilitates hybridization for short probes that increases hybridization signal and results to higher sensitivity.

Single nucleotide polymorphisms (SNP) have increasing importance in both clinical and diagnostic roles. When designing a probe, some additional design rules should be applied for the best resolution of perfect match (PM) and single base pair mismatch (SBM) situations. In general, mismatch stability (T_m or ΔG of the duplex) is dependent on the length of probe, nature of the mismatch, mismatch position along the probe, and nearest neighbors of the mismatch. For shorter probes, the destabilizing effect of a mismatch is more dramatic. A reasonable compromise between specificity and sensitivity of SBM analysis can be achieved by using shorter probes (18–20 nt). The type of a mismatch is even more important than its location along the probe.

For example, in case of a G:A mismatch, reliability of the assay can be increased by switching to the antisense strand. The resulting C:T mismatch has a higher destabilizing effect, and the decrease in fluorescence intensity is more readily detected. Mismatch location is also an important concern in designing probes for SNP detection. In general, mismatches located near the ends of a probe have smaller destabilizing effect on the duplex. As a rule, ultimate and penultimate mismatches cannot be reliably detected even after optimization of hybridization and washing conditions.

POLYMERASE CHAIN REACTION PRIMERS AND PROBES FOR ANALYSIS OF CONSERVED SEQUENCES

Gene families are groups of closely related genes having similar DNA sequences which evolved from a single ancestral gene and may code for similar products. For example, Staphylococcal enterotoxins (SEs) are a family of 17 major serological types of heat-stable enterotoxins that are one of the leading causes of gastroenteritis resulting from consumption of contaminated food. These toxins share similar DNA sequence and similar biological activities. Analysis of gene families using multiple sequence alignment is important for both phylogenetic research as well as such practical applications as detection and identification of clinically relevant genes.

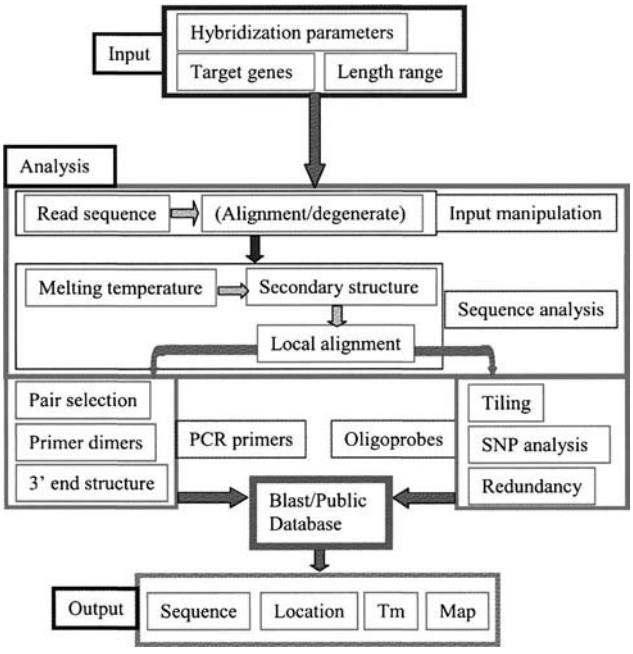


Fig. 1 Outline of computer program for oligonucleotide design. The algorithm includes three modules: input, sequence analysis, and output. (*View this art in color at www.dekker.com.*)

For the design of universal PCR primers and gene-specific microarray probes for analysis of gene families and conserved sequences, there is a need to identify conserved regions flanking variable regions among all sequences. The conserved regions may be used to design universal primers for simultaneous amplification of the variable regions from multiple target organisms. These genetically divergent regions may be used to design gene-specific oligonucleotide probes to discriminate among the target sequences.

The selection of these sequences follows the same basic rules as the selection of oligonucleotides for simple PCR and microarray applications with the additional constraints that the conserved regions between divergent sequences are frequently limited regions of the genes and the use of universal primers implies that the primers have a range of melting temperatures.

ALGORITHM FOR OLIGONUCLEOTIDE DESIGN

Software for oligonucleotide design is commonly available[5,6] and generally has input, sequence analysis, and output modules. An outline of such an algorithm for oligonucleotide design is shown in Fig. 1.

In the input module, the user specifies the target sequence and various parameters for the desired oligonucleotides including melting temperature range, salt concentration, and the length range. Other input parameters (not shown) may include weighting factors for the various design constraints under consideration. The analysis module first carries out input manipulation, reading the target sequences and performing multiple alignment of sequences if the genes analyzed are part of a gene family or include conserved domain. The alignment allows design of PCR primers for amplification of multiple conserved sequences and the development of oligonucleotides that can either detect all conserved sequences or distinguish among conserved sequences.

A first element of the sequence analysis is the T_m calculation for each candidate oligo using the nearest-neighbor model. Each sequence is then scored for potential secondary structures, such as hairpins and self-complementary regions, to limit self-annealing. Alignment between the candidate oligo and the target (local alignment) is performed to look for and avoid other hybridization sites.

The sequence analysis module may perform additional analysis steps for oligonucleotides to be used as PCR primers, including pair selection of forward and reverse primers using all of the permutations of the candidates. Amplicon length is calculated for each primer pair along with the melting temperature of each primer. Additional rules for primer selection such as 3′-end requirements can be applied at this point to find preferred primer pairs. For oligonucleotides to be used as probes, SNP analysis and selection of overlapping primers (tiling) may be performed.

Finally, the output module produces a list of oligonucleotides with their sequences, location on the target sequence, and melting temperature, and may include a map of the target sequence indicating the position of the oligonucleotides.

CONCLUSION

Applications of oligonucleotides as PCR primers and microarray probes have expanded dramatically in recent years. The design of oligonucleotides for these applications involves a large number of considerations starting with the melting temperature and including a number of competing criteria. Each application has unique aspects making it impossible to cover the subject of oligonucleotide design in full generality. The key design issues are summarized in this article and discussed in terms of simple applications with reference to a software-based design approach that allows the user to balance the competing design criteria. This design approach has proven very successful but the final test of a well-designed oligonucleotide must be performed using the molecules themselves because biological systems exhibit more complex behavior than can be fully captured in software.

Onchocerca volvulus

Thomas R. Unnasch
University of Alabama at Birmingham, Birmingham, Alabama, U.S.A.

INTRODUCTION

Onchocerciasis, or river blindness, has historically been one of the most important causes of infectious blindness. It is endemic to sub-Saharan Africa and six countries of Central and South America. The disease, although not fatal, results in severe socioeconomic disruption of affected communities. Onchocerciasis is caused by infection with the nematode *Onchocerca volvulus*. *O. volvulus* is an obligate parasite of humans, which is notable because most *Onchocerca* are parasites of ungulates. The sexual stages of the parasite exist in the human host. The adult females produce large numbers of larvae (known as microfilaria), which distribute themselves throughout the dermis of an infected individual, although they are also capable of invading other organs, such as the eye. The parasite is transmitted between infected humans by vector black flies of the genus *Simulium*. When a black fly takes a blood meal from an infected individual, microfilaria are ingested along with the blood. The microfilaria undergo two molts to form infective larvae, or L3, which migrate to the head capsule of the fly. When an L3-infected fly feeds, the L3 are introduced. The L3 then undergo two more molts to produce adult parasites, completing the life cycle. The prepatent period, or the time between the introduction of the L3 into a human host and the final development of a fertile female, is 18–24 months.

Three internationally supported programs to eliminate onchocerciasis as a public health problem have been initiated in the past 30 years. These included the Onchocerciasis Control Programme in West Africa (OCP), which was instrumental in eliminating blinding onchocerciasis as a public health problem in 11 countries of West Africa. The OCP conducted active operations in the period of 1975–2002. The OCP primarily relied on a strategy of vector control supplemented in later years by ivermectin distribution, the single drug known to be safe and effective for the treatment of onchocerciasis. Two programs, the African Program for Onchocerciasis Control (APOC) and the Onchocerciasis Elimination Program in the Americas (OEPA), are currently active. Both solely rely on ivermectin distribution. The goal of this article is to review the development of DNA-based diagnostics for *O. volvulus* and their application both to onchocerciasis control and to biogeographical studies.

DEVELOPMENT OF DNA-BASED DIAGNOSTIC TESTS FOR *O. VOLVULUS*

Development of DNA-based detection methods for *O. volvulus* began in the 1980s before the development of the polymerase chain reaction (PCR). Using conventional screening approaches, several DNA probes were identified that exhibited varying specificities.[1] Some were specific for parasites of the genus *Onchocerca*,[2] while others were specific for *O. volvulus*.[3,4] One probe (pFS-1) was developed that was specific for parasites endemic to the rain forests of West Africa.[5] DNA sequence analysis revealed that all of these probes were related, having been derived from a tandemly repeated DNA sequence family specific to the genus *Onchocerca*,[6] designated the O-150 repeat family. Further analysis of the O-150 repeat family revealed that its variation was constrained, and that the members could be grouped into subfamilies in which the members were nearly identical. Some subfamilies were found in all members of the genus *Onchocerca*. Others were specific for *O. volvulus* or other *Onchocerca* species, and some were found only in certain isolates of *O. volvulus*.[6] These results explained the observed specificity of the previously isolated DNA probes and permitted the rational design of new oligonucleotide probes.[6]

The repeated nature of the O-150 repeat made it particularly amenable to the development of a PCR assay.[7] In the initial PCR assays, degenerate primers were used to amplify all of the subfamilies of the O-150 repeat and the products distinguished on the basis of hybridization to oligonucleotide probes.[7] Subsequently, primer pairs were developed that specifically targeted a subfamily of the O-150 repeat that was found only in *O. volvulus*, resulting in an *O. volvulus*-specific PCR.[8]

Before the development of the O-150 PCR, the gold standard for the diagnosis of *O. volvulus* was microscopic detection of microfilaria in small skin biopsies (skin snips) collected from infected individuals. The sensitivity

DOI: 10.1081/E-EDGP 120020890

of the O-150 PCR ranged from 90% to 100% when compared to the microscopic skin-snip assay.[9–11] The specificity of the O-150 PCR was 100% when tested on individuals never exposed to *O. volvulus*. In one study, amplification was also obtained from 13/34 skin-snip-negative individuals residing in an *O. volvulus* endemic area, suggesting that the O-150 PCR of skin-snip-derived DNA might be more sensitive for the detection of *O. volvulus* than microscopic examination.[9] However, a similar study found the O-150 PCR to be no more sensitive than microscopy when care was taken to thoroughly examine the snip.[10] Taken together, these results suggested that the O-150 PCR assay was 100% specific for the detection of *O. volvulus* and at least as sensitive and perhaps more sensitive than the skin-snip assay.

The original O-150 PCR assays involved the detection of products following amplification and Southern blotting followed by oligonucleotide hybridization.[7] Subsequently, enzyme-linked immunosorbent assay (ELISA)-based[12] and chromatographic (test strip) methods were also developed.[13,14] Both methods were found to have comparable sensitivities and both were at least as sensitive as gel electrophoresis.[12–14] The ELISA-based method allows the investigator to define a rational cutoff for defining positive samples. The test strip methods, although not permitting the assignment of a quantitative cutoff, do not require the use of any sophisticated equipment, bringing the O-150 PCR one step closer to field applicability.

One of the disadvantages of the skin snip is that collection of skin biopsies requires the use of a sclerodermal punch. These instruments are expensive and must be sterilized between uses. The painful nature of the test also limits its acceptance among affected communities. Thus attempts have been made to use the O-150 PCR to detect parasite DNA in samples that can be collected by less invasive means. Toé et al.[15] demonstrated that parasite DNA could be detected in superficial skin scrapings using the O-150 PCR. The sensitivity of this assay was high when compared to microscopy (92%) but lower when compared to O-150 PCR amplification of skin-snip DNA. The O-150 PCR has also been used to detect *O. volvulus* DNA in the urine of infected individuals.[11] Although successful, the sensitivity of the urine-based PCR was quite low (14%).

Perhaps the most important application of the O-150 PCR has been for the identification of *O. volvulus* L3 in black flies. The overall goal of both the OCP and OEPA is to eliminate transmission of *O. volvulus.* In the pursuit of this goal, it was necessary to determine the level of transmission. The most efficient way to accomplish this was by examining vector black flies for L3 rather than monitoring for new infections. This is because it is difficult to monitor infection incidence in underdeveloped areas where populations are mobile and medical records are incomplete. In addition, the long prepatent period (18–24 months) means that new human cases provide a snapshot of transmission that is at least 18 months old.

Traditionally, transmission monitoring has been accomplished through dissection of individual black flies. However, there are two drawbacks to dissection. The first is that throughout much of West Africa, *O. volvulus* is sympatric with *Onchocerca ochengi*. Both *O. volvulus* and *O. ochengi* are transmitted by the same black flies, and their L3 are morphologically indistinguishable. This means that it is difficult to obtain an accurate estimation of the level of transmission for *O. volvulus* using dissection in areas where both parasites are found. This difficulty was overcome through the development of the O-150 PCR and of species-specific oligonucleotides capable of distinguishing *O. volvulus* and *O. ochengi*. A second disadvantage to dissection is that it becomes increasingly inefficient as the prevalence of infected flies declines, as occurs in the face of an effective control program. The high sensitivity of the O-150 PCR for the detection of *O. volvulus* DNA opened the possibility that this assay might be used to screen pools of black flies, permitting the efficient simultaneous screening of large numbers of flies. Therefore, the O-150 PCR was adapted to permit its use on pools of flies, and a method was developed to predict the prevalence of infection in the vector population based on the proportion of negative pools found and the number of flies contained in each pool.[16] This method was evaluated in field studies in Africa[17] and the Americas[18] that compared infection rates estimated by dissection and pool screen PCR. In all cases, the PCR results were indistinguishable from the prevalence of infection as estimated by dissection.

Recently, the pool screen PCR technique has been used in a countrywide study in Ecuador to estimate the effect of long-term ivermectin distribution on *O. volvulus* transmission.[19] The data from this study documented a dramatic reduction in *O. volvulus* transmission as a result of long-term ivermectin distribution, and demonstrated that in one focus transmission had been completely suppressed. This demonstrated that the O-150 PCR could be used to assist control programs in monitoring transmission in areas where the intensity of transmission was low, and also provided evidence that under certain circumstances, *O. volvulus* transmission could be eliminated through ivermectin distribution alone.

THE O-150 REPEAT FAMILY AS A TOOL TO STUDY RELATIONSHIPS AMONG *O. VOLVULUS* POPULATIONS

Since the 20th century, it had been known that onchocerciasis exhibited two distinct clinical presentations in West Africa. In the rainforest bioclime, a nonblinding

form of the disease existed where onchocercal blindness was rare, even in hyperendemic areas. In the savanna bioclime, a blinding form of the disease was endemic, where onchocercal blindness was common. Epidemiological, entomological, pathological, biochemical, and immunological studies all supported the hypothesis that this difference was linked to the fact that two distinct strains of the parasite were endemic to the rainforest and savanna bioclimes of West Africa. Before the development of the O-150 PCR, a DNA probe derived from the O-150 repeat sequence family (pFS-1) was identified that hybridized only to parasite isolates collected from the forested regions.[5] Following the development of the O-150 PCR, this probe was used to classify PCR products from villages from West Africa that exhibited blinding or nonblinding epidemiological disease patterns. The results demonstrated an almost perfect correspondence of the probe classification and disease pattern.[20] This suggested that the differences in disease pattern were due to genetic differences in the parasite populations and that the O-150 PCR, when used in conjunction with strain-specific probes, was capable of distinguishing the two strains.

The discovery that the O-150 repeat family was variable enough to differentiate the forest and savanna strains of *O. volvulus* in West Africa suggested that it might also be used as a tool to study the relationships among other populations of *O. volvulus.* For example, strain-specific probes developed to classify West African parasites have been used in studies of *O. volvulus* from Uganda,[21] which suggested that Ugandan parasites might form a population that was distinct from those found in West Africa. Similarly, extensive analyses were carried out on the O-150 families from West African parasites and those from Sudan and the Americas.[22,23] The results demonstrated that, as expected, parasites from the savanna and forest bioclimes of West Africa were statistically different from one another. Parasites from Southern Sudan were statistically indistinguishable from those in the West African savanna in keeping with the fact that onchocerciasis is endemic throughout the wide savanna zone spanning the entire continent of Africa from east to west. In contrast, parasites from the Abu Hamad focus of onchocerciasis in Northern Sudan were distinct from both West African strains.[23] The Abu Hamad focus is isolated from all other foci of *O. volvulus* by the desert, and the vector there is a distinct species of *Simulium damnosum* s.l. Parasites from Guatemala and Brazil were found to be distinguishable from the forest strain of West African *O. volvulus* but were indistinguishable from savanna strain parasites.[22] This finding supported the hypothesis that *O. volvulus* was introduced into the Americas as a result of the trade in African slaves, as the majority of the slaves imported into both Guatemala and Brazil originated from the savanna areas of West Africa.

CONCLUSION

As the sections above demonstrate, the O-150 PCR has been established as a sensitive and specific tool for the detection of *O. volvulus*. The assay has been adapted to detect infections both in humans and vector black flies, and it has been exploited by onchocerciasis control programs in both Africa and the Americas. The variable nature of the O-150 repeat also makes it a useful tool for differentiating parasite populations and for conducting biogeographical studies.

Several improvements could still be made to increase the utility of the O-150 PCR. For example, automated and microtiterplate-based DNA purification techniques may improve the throughput of the assay and may increase the number of flies that may be tested in a given pool, decreasing the marginal cost of the assay. Furthermore, previous studies have demonstrated that the O-150 PCR may be used to measure the filaricidal effects of various experimental drugs.[24] However, ivermectin, the only drug currently approved for treatment of onchocerciasis, kills *O. volvulus* microfilaria but has less of an effect on the adult form of the parasite. Thus, it is difficult to measure adult viability in the face of ivermectin treatment, something that is necessary to determine when an *O. volvulus*-infected individual has become infection free and treatment may be stopped. It is possible that use of the O-150 PCR to detect *O. volvulus* DNA in tissues other than skin might be used for this purpose.

Orthopoxviruses—Monkeypox, Cowpox, *Vaccinia*, Camelpox, Mousepox

O

M. Sofi Ibrahim
James D. Mellott
The United States Army Medical Research Institute of Infectious Diseases, Fort Detrick, Maryland, U.S.A.

INTRODUCTION

One of the most remarkable achievements in medical history is the eradication of smallpox, a once devastating disease that plagued mankind for millennia. Although the *Variola* virus, the causative agent of smallpox, is the only *Orthopoxvirus* specific for humans, other zoonotic *Orthopoxvirus* species, e.g., buffalopox, cowpox, monkeypox, and *Vaccinia* viruses, can cause disease in humans. Concerns have been raised that *Variola* may reemerge or other orthopox viruses may be rendered more pathogenic by genetic engineering. Reemergence of *Variola* or genetically altered chimeras would pose serious public health threats of global proportions. The recent occurrence of the first monkeypox infection in the Western Hemisphere clearly demonstrates the ease with which zoonotic *Orthopoxvirus* infections can cross geographic boundaries and species barriers. Evidence exists that altering *Orthopoxvirus* genome can enhance host susceptibility to infection. For example, it has recently been demonstrated that engineering interleukin-4 gene into the mousepox (ectromelia) virus genome induced lethal infection in genetically resistant and vaccinated mice.

MORPHOLOGY, TAXONOMY, AND GENOMIC ORGANIZATION
